If untreated, trichomonal infection in women can last for months and even 3–5 years. Symptoms and signs of chronic infection do not vary much from those of acute infection.[134] Trichomoniasis can be rarely complicated by vaginitis emphysematosa in which gas filled blebs occur in the vaginal wall. The condition will resolve when infection is eradicated.[135] Women with trichomoniasis are more likely to develop vaginal cuff cellulitis after abdominal hysterectomy.[136] This complication, like the obstetrical ones, probably results from the changes in the bacterial flora that accompany the protozoan infection.

Laboratory diagnosis

The accurate diagnosis of trichomoniasis cannot relay on clinical findings and depends on demonstrating the pathogen in the vaginal discharge.[133]

Microscopic examination

Trichomonads can be identified in vaginal secretions using the wet mount technique. A sample of vaginal fluid is mixed with a drop of saline on a slide. The preparation is covered with a cover slip and viewed under a phase contrast microscope at medium magnification. *T. vaginalis* is easily recognized by its characteristic movements. This technique detects 60–80% of cases and is less sensitive in asymptomatic patients.[108] In the majority of cases (50–75%) large numbers of white blood cells (> 1 per epithelial cell) are also seen. The epithelial cells appear normal; in florid infection epithelial cell turnover may be rapid and increased numbers of parabasal cells (small and ovid) can be observed. The bacterial flora consists of either rods or coccobacilli.[118]

The Gram, Giemsa and acridine orange stains and Papanicolaou smear are less useful than the wet mount. Direct fluorescent antibody staining, latex agglutination, enzyme linked immunosorbent assay and oligonucleotide probe techniques are more sensitive than the wet mount (80–90%) but less so than culture.[119,137,138] The PCR techniques show high sensitivity (~95%) and specificity (~98%) when performed on vaginal specimens,[139] although results may vary, especially in women and with urine samples.[120] As of 2005 these tests are not yet approved for diagnostic purposes.

Culture

This remains the most sensitive (≥ 95%) technique for the diagnosis of trichomoniasis. Culture should preferably be inoculated anaerobically; most isolates show growth within 48 h. The modified Diamond's

medium is considered the 'gold standard'[122]; however, a modified thioglycolate medium was recently found to be as reliable and readily available.[140] The combination of culture and wet mount examination will give a sensitivity close to 100% and remains the standard approach for detecting *T. vaginalis* in patient samples.

Treatment

CDC-recommended treatment regimen is 2 g of metronidazole as a single oral dose for both females and males.[23] Cure rates range from 82–88%, with concurrent treatment of partners improving efficacy to more than 95%.[122] Alternative regimens consist of metronidazole 500 mg orally twice daily or 250 mg orally three times daily for 7 days. The advantage of the extended course therapy over the single dose treatment, is its higher efficacy in men and its improved tolerance.[122] On the other hand, the prolonged administration may decrease compliance. Because of the gastrointestinal side effects of systemic metronidazole (nausea, bad taste, Antabuse-like effects), one is tempted to use the drug intravaginally; however, only systemic therapy is capable of eradicating trichomonads from extravaginal sites. The major concern with metronidazole administration is its potential carcinogenicity and teratogenicity. Although the available literature[141,142] does not support the association between the drug and these risks, metronidazole remains relatively contraindicated during the first trimester of pregnancy. Symptomatic pregnant women may initially be treated with clotrimazole, 100 mg vaginal tablet at bedtime for 1–2 weeks, which will cure the infection in some and relieve symptoms in most cases. After the first trimester, the CDC recommends the single 2 g regimen for infected pregnant women.[23]

In case of metronidazole treatment failure, one should consider: (a) reinfection from an untreated sexual partner; (b) noncompliance; (c) increased hepatic inactivation of the drug (e.g., when coadministered with phenobarbital); and (d) true drug resistance. Metronidazole resistance remains rare and can be overcome with higher and more prolonged regimens: 2 g daily for 3–14 days, with or without intravaginal metronidazole tablets, 500 mg twice daily. Some resistant cases have been cured with intravenous metronidazole, up to 2 g every 6–8 h for 3 days or more.[119] Successful therapy with tinidazole (another 5-nitromidazole derivative) 2 g daily for 2 days or more, has been reported in a number of metronidazole resistant cases.[134]

Prevention

Asymptomatic infected women should be treated because they represent an important reservoir of the pathogen; moreover, about one-third of these women will become symptomatic during the following few months. Sex partners should be treated. Infected male sex partners are usually asymptomatic. Patients should be instructed to avoid sex until patient and partner are cured. Screening for *T. vaginalis* of high-risk pregnant women on entry into prenatal care and of those undergoing high risk obstetrical or gynecological procedures has been advised.[122]

Genital warts (human papillomavirus infection)

Human papillomavirus (HPV) attacks the squamous epithelium and causes lesions ranging from benign genital warts (condyloma acuminatum) to dysplasia and invasive squamous carcinoma of the lower genital tract. In pregnant women, genital warts may rapidly enlarge with advancing gestation and mechanically obstruct labor. Perinatal exposure may result in the development of laryngeal papillomatosis in the infant. Only the clinical aspects of genital warts will be discussed herein, the carcinogenic effects of HPV being beyond the scope of this chapter.

The pathogen and pathogenesis

Human papillomaviruses are highly species-specific, and cross-species infections do not occur. The virus, which is non-enveloped, has an icosahedral capsid containing a double-stranded circular DNA genome. Over 70 types of HPV have been identified based on DNA homology, approximately one-third of which infect the genital tract.[143] Each type is associated with a distinct histopathologic process: benign exophytic and flat genital warts are most commonly caused by HPV types 6 and 11 and less often by types 42–45.[144,145] The types that are strongly associated with dysplasia and carcinoma (e.g., 16, 18, 31, 33 and 35) usually cause subclinical infection, although occasionally are found in exophytic warts.

It is assumed that the virus replicative cycle begins with the entry of particles into the basal epithelial cells. Some infected cells undergo the characteristic transformation of koilocytosis consisting of large, polygonal squamous cells with a shrunken nucleus lodged inside a large cytoplasmic vacuole.[144] It is speculated that HPV infection may persist throughout life in a dormant state and become infectious intermittently. Exophytic genital warts may rarely transform into squamous cell carcinoma.[144] Women with a history of anogenital warts have a 30-fold increased risk of anal cancer.[146]

Anti-HPV antibodies, which tend to disappear with disease resolution, probably contribute to virus neutralization.[144] The importance of the cellular immune system in the resolution of HPV disease is suggested by the observation that the regression of one wart is frequently followed by disappearance of others.[144] The decrease of HPV prevalence in older women may suggest an increase in immunity to HPV with age.[147] HPV infection occurs frequently and is often more severe in patients with both primary and secondary

immune deficiencies. Genital warts are particularly persistent in patients with diabetes mellitus, organ transplantation, corticosteroid therapy, lymphoma or HIV infection.[144]

The suppressed cellular immunity may probably explain the increased incidence and severity of HPV disease in pregnancy.[144] It has been suggested that hormonal changes during pregnancy may also play a role in the enhancement of viral infection or expression.[143,148] Transmission during delivery can result in the development of juvenile laryngeal papillomatosis which is most commonly associated with types 6 and 11. Rarely the disease can spread to the trachea and bronchi.[145]

Epidemiology

About two-thirds of sexual contacts of patients with anogenital warts subsequently develop the disease.[144] The risk of acquiring condyloma acuminatum is strongly associated with increased number of sexual partners and younger age.[147,149,150] Whether patients with subclinical HPV infection are as contagious as patients with warts is unknown. In children, anogenital warts should raise the suspicion of sexual abuse; however, about one-fifth of prepubertal children with condyloma acuminatum have 'non-genital' types of HPV.[144] Infants can acquire the virus during passage through an infected birth canal.[151] Many children with respiratory papillomatosis are first-born infants who were delivered vaginally to young mothers.[151] Acquisition of the virus *in utero* is also possible, probably by ascending infection from the mother's genital tract, as suggested by cases in which the disease was documented at birth even after cesarean delivery.[144,152,153] The role of fomites in the transmission of HPV if not clear, although theoretically possible since HPV is resistant to heat.

It is estimated that genital HPV causes approximately 30 million new infections annually.[149] Anogenital warts are the most common viral sexually transmitted in the United States and United Kingdom.[149] Several studies conducted in these countries have shown that the incidence of the disease has continued to increase rapidly in the 1980s.[144,149] A comparative analysis of women attending a STD clinic and college women showed that 11% of the patients with an STD but only 2% of the college students presented with visible genital warts. However, when cervical specimens from women without visible lesions were analyzed, 10% of the patients with an STD and 11% of the students were positive for HPV DNA or antigen.[154] In a recent investigation among an ethnically diverse group of urban adolescent females, genital HPV infection was documented in 24%, while genital warts were observed in 3.5% of women. There was a strong association with number of lifetime sexual partners; no ethnic difference in prevalence was noted.[150] A similar prevalence of genital HPV DNA (29%) was documented among women attending a STD clinic in Jamaica.[147] In Sweden, one-third of women 25 years of age and younger who visited a contraception clinic reported a history of condyloma.[149]

Clinically apparent HPV infection of the female genital tract seems to occur more frequently during pregnancy and regresses rapidly after delivery.[155,156] Schneider *et al.*[157] reported detection of HPV DNA in exfoliated cervical cells of 28% of pregnant women compared with 12.5% in non-pregnant women control women. In their longitudinal study, Rando *et al.*[148] have observed a dramatic increase in the percentage of pregnant women harboring HPV DNA in exfoliated cervical cells from the first (21%) to the third trimester (46%), with a sharp decrease in the postpartum examination (17.5%). This association between pregnancy and increased prevalence of HPV infection was not reconfirmed in a recent cross-sectional study.[158] Transmission of HPV from infected mothers to their newborns is rare and does not appear to be associated with persistent infection. Transmission rates are similar for newborns born vaginally and those delivered by cesarean section.[159]

Laryngeal papillomatosis has a bimodal age distribution with peaks in children 2–5 years of age and young adults. It is estimated that the incidence of juvenile respiratory papillomatosis is similar to that of neonatal HSV infection: 1/2500 to 1/10,000 cases per year.[143]

Clinical manifestations

Wives of American soldiers returning from the Korean war with penile warts developed genital warts after an incubation period of 4–6 weeks after exposure.[144] The majority of lesions are located in the posterior introitus and to a lesser degree in the labia majora and minora and the clitoris. Other sites that may be involved are the perineum, vagina, anus and urethra.[144] Only rarely do condylomata develop in the cervix.[143] The warts appear as flesh- to gray-colored exophytic papules, either sessile or, more frequently, attached by a short, broad peduncle. Their size ranges from less than a millimeter in diameter to several square centimeters when they merge into plaques. Flat condyloma can be demonstrated on the uterus cervix by colposcopy after soaking with 3% acetic acid. Typically these lesions are shiny, white patches with poorly defined borders and an irregular surface containing characteristic capillary loops.[144] In the vagina, in addition to the flat condylomas, small white nodosities, called spiked condylomas, have been described.[144]

About one-fourth of patients with anogenital warts are symptomatic.[144] Itching, burning, tenderness and pain are common complaints. Not less important are the psychological consequences of the disease that may be severe.[144] Spontaneous remission of lesions may occur: this has been noted in 10–20% of untreated patients over a few months' period.[144]

During pregnancy condylomas may become so large as to impair normal delivery mechanically.[144] The lesions often regress spontaneously after delivery.

Patients with laryngeal warts present with hoarseness or, in infants, with an altered cry; respiratory distress may follow. Rapid growth of lesions in young children often threatens the patency of the upper respiratory tract and may require repeat surgical excision to prevent suffocation. If spread to the lower respiratory tract occurs, lesions can lead to obstruction, infection and respiratory failure.[144]

Diagnosis

Because of their distinctive appearance genital warts are usually diagnosed by physical examination. Condyloma acuminatum should rarely be confused with other STDs, although it may be difficult to distinguish from molluscum contagiosum, particularly in its more atypical form. Molluscum contagiosum is a benign human disease caused by a pox virus. Of worldwide occurrence, it spreads by close contact, including sexual intercourse. The typical lesions are in the form of small firm umbilicated papules which resolve spontaneously. In contrast to condyloma acuminatum, the lesions of malluscum contagiosum tend to predominate over the pubis and are rarely pedunculated, but rather appear to be very smooth sessile domes from which cheesy material can be expressed.[160]

The use of colposcope with prior application of an acetic acid solution is an important diagnostic tool for HPV infection. To confirm diagnosis, careful colposcopic examination of the genital area should be done after application for 3–5 min of a 3% acetic acid solution; the white epithelium should be noted and biopsied. Koilocytes on histology or cytologic smear are the hallmark of HPV infection. Depending on the patient's age, the location and the nature of the HPV infection, the sensitivity of Pap's smear in detecting the infection ranges from 30% to 90%.[144] Dysplasia and malignant changes should be ruled out.

Diagnosis of HPV infection by DNA detection is currently possible, but no consensus exists as to the indication for such testing in clinical practice. No clear management strategy has been established for patients who test positive for HPV DNA but who have no detectable high-grade dysplasia.

Treatment

With the currently available therapeutic arsenal, the only clear indication for treatment of HPV infection is alleviation of symptoms and restoration of normal anatomy when large lesions obstruct the birth canal.[23] Most therapeutic means consist of physical and chemical destruction of macroscopic lesions; no therapy has been shown to eradicate HPV and recurrence rates are high with all modalities.[143] No studies have assessed whether treatment of warts reduces transmission of HPV.

Treatment of genital warts should be guided by the preference of the patient, while taking care to avoid expensive, toxic and scar-forming modalities. For women with cervical warts, dysplasia must be excluded before therapy is started.

For the treatment of extensive warts, carbon dioxide laser and surgery are most useful. Laser is expensive and requires general anesthesia; its efficacy is 43%, with recurrence rate of 5–50%. Surgical excision is effective in 35–70% of cases with 29% recurrence rate[23]; scarring is common.

Interferon therapy is not recommended by the CDC because of its cost, frequency of side effects and an efficacy that is not greater than that of other methods.[23]

Imiquimod 5% cream is a topical cell-mediated immune response modifier. The efficacy of imiquimod ranges between 30% and 50%, with a relatively low recurrence rate of 15%. Local inflammatory reactions are common (70%). Imiquimod can weaken condoms and diaphragms, and sexual contact is not recommended while the cream is on the skin.

5-Fluorouracil cream frequently causes local irritation. Controlled experience with this method is limited, and it is not recommended by the CDC for treatment of genital warts. The use of 5-fluorouracil in pregnancy is contraindicated.[23]

Cryotherapy with liquid nitrogen or cryoprobe is relatively inexpensive, does not require anesthesia and can be used in all localizations. It does not result in scarring if performed properly and is safe in pregnancy. The efficacy of cryotherapy ranges between 63% and 88%, with a relatively low recurrence rate of 21–39%.[23]

Podophyllin is a resin extract of the mayapple plant. It is simple to use: a 10–25% solution is applied directly on the wart once weekly and should thoroughly be washed-off in 1–4 h. Efficacy rate: 32–79%, recurrences are seen in 5–30% of cases. Local irritation or pain can occur after treatment. Severe systemic complications can develop if the solution is applied on a large area (application should be limited to a volume not exceeding 1 ml/day). Use of podophyllin is contraindicated in pregnancy. Podofilox (0.5% solution) is a purified derivative of podophyllin. It is less toxic than podophyllin and can be self-applied by the patient at home. Efficacy is 45–88%; recurrence, 33–60%. It is contraindicated during pregnancy.

Trichloroacetic acid, 80–90%, has a limited controlled experience. It should be applied only on warts, and unreacted acid should be removed with talcum powder. Application is painful and can cause ulcers. Trichloroacetic acid can be useful for vaginal lesions. Efficacy is 81% and recurrence rate is 36%. It is safe in pregnancy.

Few data are available on efficacy of electrodesiccation or electrocautery. In a single randomized trial, electrodessiccation was effective in 94% of cases, with a recurrence rate of 22%. Local anesthesia is required, and it can cause moderate discomfort and leave scarring.

Removal of genital warts is recommended prior to delivery. The preferred modalities in pregnancy include electrocautery, electrodiseccation and cryotherapy. Podophyllin, podofilox and 5-fluorouracil are contraindicated.[144]

Prevention

After warts have been removed, follow-up is not necessary. However, annual cytologic screening is recommended for women with or without warts. Examination of sex partners is not necessary for management because the role of reinfection is probably minimal. The use of condom may reduce transmission to uninfected sex partners. Cesarean delivery is not justified solely to prevent transmission of HPV to the newborn. However, cesarean section may be indicated in rare cases in which warts may be so extensive as to cause pelvic outlet obstruction, or if vaginal delivery would result in excessive bleeding.[23] Anti-HPV vaccines against oncogenic strains are currently under development.

Chancroid

While considered a rare disease in industrialized countries, chancroid is the most common cause of genital ulcer disease in many parts of the world, particularly in the developing countries of Africa and Asia. The disease is characterized by necrotizing genital ulceration which may be accompanied by inguinal lymphadenitis and bubo formation. The most important public health problem associated with *Haemophilus ducreyi* infection is its role as cofactor in transmission of HIV.

The pathogen and pathogenesis

Haemophilus ducreyi is a small pleomorphic gram-negative coccobacillus with fastidious growth requirements.[161] It is believed that *H. ducreyi* initiates an infective process within the genital skin after the formation of epidermal microabrasions during sexual intercourse. The pathogenesis of *H. ducreyi* infection is still poorly understood. Most wild-type isolates express pilli. The role of *H. ducreyi* surface lipooligosaccharide and cytotoxin in producing chancroid lesions is being investigated. Recent data have linked genital ulcer disease, especially chancroid, to an increase in heterosexual transmission of HIV infection.[161] No adverse effects of chancroid or pregnancy outcome or on the fetus have been reported.

Epidemiology

Transmission of the infection from an infected individual to a sex partner has been well documented. A study in Kenya has revealed that 59% of secondary female contacts of males with chancroid have also developed *H. ducreyi* ulcers; only one contact (3%) carried the organism in the cervix without evidence of ulcer formation.[162] The infection is associated with low socioeconomic status and poor hygienic conditions.[163] Chancroid is most often seen in non-White, uncircumcised men.[163] In North America, only 10% of the reported cases are in women, an observation that might be due to clinically unapparent carrier state and/or infected prostitutes with large numbers of male contacts.[164,165]

Chancroid is worldwide in distribution. The infection is endemic in the tropics, where it is the most common cause of genital ulcer disease. In sub-Saharan Africa and Southeast Asia, *H. ducreyi* can be isolated from 20–60% of patients with genital ulcerations.[166]

Although long considered of rare occurrence in developed countries, the incidence of chancroid began to rise in 1986 in the United States and peaked in 1989 when 5191 cases were reported.[164,167] Major outbreaks of chancroid have recently occurred in Canada and the United States,[164,165] related to prostitution and other forms of promiscuous sexual behavior associated with the use of crack cocaine.[167] A high rate of HIV infection among patients with chancroid has been reported in the tropics as well as in the United States. HIV seropositive patients have increased numbers of genital ulcers which may heal at lower rates.[168] As many as 10% of patients with chancroid may be coinfected with *T. pallidum* or HSV.[23]

Clinical manifestations

The incubation period of chancroid is usually between 3 and 10 days, although it can extend to several weeks. The lesion begins as a tender papule surrounded with erythema. The papule ulcerates within 1–2 days to form the typical chancroid ulcer which is painful, minimally indurated and has undermined ragged edges. The base is covered with a purulent exudate and bleeds easily during swabbing. Individual ulcers vary from 1 to 20 mm in diameter. Adjacent lesions may merge and form confluent giant or serpiginous ulcerations. Multiple ulcers (up to 10 or more have been reported) are seen more often in women; they are frequently due to auto-inoculation ('kissing ulcers'). Superinfeciton of ulcers may occur and lead to rapid and extensive destruction of external genitalia (phagedenic chancroid). In women, lesions are most often located at the entrance of the vagina, particularly on the fourchette, and can also be found on the labia, clitoris, cervix and anus.[161] In approximately half of the cases painful inguinal lymphadenopathy appears within a week after the initial lesion. It is usually unilateral and may become fluctuant (bubo). Therapeutically undrained buboes may rupture spontaneously to form chronic draining sinuses or extensive ulceration of surrounding tissue. Extragenital cases of chancroid with lesions on inner thighs, breasts, and fingers have been reported but are rarely seen in clinical practice.[168] Untreated, the mean duration of lesions is approximately 60 days.[161,166]

Diagnosis

Clinical diagnosis of chancroid is inaccurate because genital ulcers of other etiologies may appear similar and may occur concomitantly. A gram-stained smear of material from the ulcer may be difficult to interpret because of the possible presence of various other bacteria. Smears of bubo aspirate are more specific when typical gram-negative coccobacilli are demonstrated, although the diagnostic sensitivity of the procedure is low. Diagnosis of chancroid should be confirmed by isolation of *H. ducreyi* from a lesion.[161] However, *H. ducreyi* is an extremely difficult organism to culture from clinical specimens in the hands of inexperienced laboratory staff, and conventional culture facilities are often not available. Even if culture facilities are available, it often takes several days for the organism to grow. The sensitivity of culture relative to the multiplex PCR is approximately 75%.[168]

The multiplex PCR technique offers a highly sensitive and specific way to detect *H. ducreyi*. However, this is an expensive tool which is mostly used in research and outbreak investigation.[168] Other diagnostic techniques, such as detection of *H. ducreyi* in ulcer material by immunofluorescence, oligonucleotide probes and serologic assays, have been reported.[161] Their usefulness in the diagnosis of chancroid remains to be established.

Because similarity in presentation and possible coexistence, it is important to exclude syphilis and HIV infection in every case of suspected chancroid. Patients should be tested for HIV and syphilis at the time of diagnosis and 3 months later if initial results are negative.

Treatment

The classical drugs used to treat chancroid, i.e., tetracycline and sulfamethoxazole-trimethoprim, are no longer appropriate because of high rates of resistance to these agents.[161] In addition, most isolates of *H. ducreyi* in recent years have been shown to produce β-lactamases.[167]

The therapeutic regimens proposed by the CDC[23] are shown in Table 158.6. Of the recommended regimens, azithromycin and ceftriaxone offer the advantage of single dose therapy,[170,171] which is an important factor in controlling STDs.

In addition to antibiotic therapy, drainage of buboes by needle aspiration through normal skin, or incision and drainage, is required to avoid spontaneous rupture which may result in chronic draining sinuses or extensive ulcerations.

Patients with HIV coinfection may need longer courses of therapy; healing in these patient may be slower and treatment failures do occur.

If treatment is effective, improvement occurs within seven days of its initiation. If no improvement is observed, the following possibilities should be considered: incorrect diagnosis; coinfection with another STDs agent; HIV coinfection; lack of compliance; or isolate is resistant to the administered agent.

Table 158.6 Regimen proposed by the Centers for Disease Control and Prevention for the treatment of chanroid[23]

Recommended regimens
Azithromycin,* 1 g orally in a single dose
or
Ceftrioxone, 250 mg intramuscularly in a single dose
or
Erythromycin, 500 mg orally 4 times a day for 7 days
Alternative regimens
Amoxicillin, 500 mg, plus clavulanic acid, 125 mg orally 3 times a day for 7 days
or
Ciprofloxacin,** 500 mg orally 2 times a day for 3 days†

*Safety for pregnant and lactating women has not been established
**Contraindicated in pregnant and lactating women and in individuals < 17 years of age
†A single dose appears to be as effective (recommended by WHO)[168]

Prevention

Symptoms in individuals who had sexual contact with a patient within the 10 days preceding onset should be examined and treated. Eradication of infection in human reservoirs of *H. ducreyi*, such as prostitutes, is imperative in controlling outbreaks of chancroid[161,164] and may have contributed to the decrease in the incidence of the disease in the United States since 1989. As for any STD, properly used condom may be useful in preventing transmission of chancroid.

Donovanosis

Donovanosis (formerly called granuloma inguinale) is characterized by slowly progressive hypertrophic ulceration with tissue destruction of the lower genital tract.

The pathogen and pathogenesis

Calymmatobacterium granulomatis, the causative organism of donovanosis was discovered by Donovan in 1905. The encapsulated, pleomorphic gram-negative bacilli with bipolar densities ('Donovan bodies') can be found in the cytoplasma of large mononuclear cells. After intracellular multiplication, the organisms are released from the ruptured intracytoplasmic vacuoles to infect other cells. *C. granulomatis* shares antigenic and morphologic characteristics with *Klebsiella*

species. The organism is otherwise poorly characterized because it is difficult to culture *in vitro* or to propagate in laboratory animals.[166,172]

Epidemiology

Several arguments such as the age distribution of patients, the frequent coexistence of other STDs and the predominance of the genital involvement, advocate for the sexual transmission of the infection. However, the possibility of additional mechanisms of spread is suggested by the existence of extragenital lesions and by the occurrence in young children. The infection affects predominantly the lower socioeconomic classes and is characterized by low infectivity.[172]

Donovanosis is endemic in parts of Africa, Southeast Asia, southern India, South America, the Caribbean Islands and among the indigenous populations of Australia. The disease is rare in Europe and North America, with less than 100 cases reported annually in the United States.[172]

Donovanosis is frequently diagnosed during pregnancy, and it has been suggested that pregnancy may exacerbate the disease.[173] However, it is also possible that the routine examination during pregnancy is associated with increased detection rate of asymptomatic lesions.[172]

Clinical manifestations

The incubation period of donovanosis is 8–80 days, but may extend up to 6 months.[172] The initial small painless papule ulcerates and progresses over a course of days to weeks into an exuberant beefy-red granulomatous ulcer that bleeds easily. New lesions may form by auto-inoculation, and multiple lesions may coalesce into large destructive ulcers. Spontaneous healing results in scar formation and secondary deformities. When the scar tissue blocks the lymphatics, lymphedema develops that may lead to elephantiasis of external genitalia. In women, the labia and the fourchette are most often involved, but lesions can also be seen in the vagina and cervix. The infection can spread to the inguinal region causing groin swelling that involves the soft tissues, but not the lymph nodes ('pseudobuboes').[172]

Systemic spread is rare but can occur more often in women with cervical lesions. Hematogenous spread can result in pelvic granulomas and bone and joint lesions, while lymphatic spread can lead to lymphadenitis in rare cases.[172] Constitutional symptoms should suggest secondary bacterial infection or another concomitant STD.

Diagnosis

The clinical diagnosis of donovanosis, based on the identification of characteristic lesions, should be confirmed by the demonstration of intracytoplasmic encapsulated Donovan bodies in macrophages. A specimen of tissue is obtained by curettage or punch biopsy from the edge of an active lesion and crushed between two glass slides to prepare an impression smear which is stained with Giemsa, Wright or Leishman stain.[174] Under the microscope the organisms appear in clusters of blue or black with the characteristic safety-pin configuration. In cases where malignancy has to be ruled out, biopsy specimens are mandatory. If the diagnosis of donovanosis cannot be confirmed by microscopy, the genital ulcer should be cultured for *H. ducreyi*.[166]

Treatment

Most information on therapeutic efficacy of various antibiotic regimens derives from open, non-comparative trials. Tetracyclines, in a standard dosage, are considered the drug of choice. Trimethoprin-sulfamethoxazole, administered for at least 2 weeks, has also been reported to be effective. Comparable results were obtained with erythromycin, 500 mg four times daily, which has been used mainly in pregnant women.[173] Other useful antibiotics are the quinolones, chloramphenicol and aminoglycosides.[172] With successful therapy lesions begin to heal from the edges toward the center. Treatment should be continued until complete epithelialization occurs.[172]

159 Human immunodeficiency virus/AIDS in pregnancy and delivery

K. Olshtain-Pops and S. Maayan

Epidemiology

In the latter part of the 1990s, human immunodeficiency virus (HIV) infection spread to all continents, infecting some 30,000,000 individuals.[1] The greatest burden of the infection was felt in the developing world, where an estimated 90% of infected individuals resided. The World Health Organization has estimated that by the year 2000 a total of 40,000,000 individuals will have been infected by the AIDS virus since the start of the epidemic in 1981.[2] Four different patterns of spread of HIV have been described.[3] Pattern 1 is seen mainly in the developing world; HIV infection spreads mainly as a sexually transmitted disease (STD), about 50% of those affected being women. Pattern 2 is seen mainly in the developed world; the virus spreads mainly among homosexuals, drug abusers and persons receiving contaminated blood transfusions. Heterosexual spread is the exception rather than the rule and thus only 20% of HIV seropositives are women, and most are intravenous drug abusers. Although the rate of heterosexually acquired HIV infection among females in pattern 2 countries has been increasing steadily, it is not expected to reach the rates in the developing world.[4] Pattern 3 spread has been described in Southeast Asia and India,[5,6] and is characterized by a late introduction of HIV infection (in the early 1990s) and a rapid spread among heterosexuals. Male-to-female ratios reach African proportions of roughly 1:1. Pattern 4 spread has been seen in the Middle East, with a slow spread of the epidemic, mainly among established groups with risky behavior.[7,8]

The AIDS virus, target cells for the virus and molecular epidemiology of HIV1

The AIDS virus, human immunodeficiency virus 1 (HIV1), is a member of the retrovirus family to which three other human viruses [HIV2, human T-cell lymphoma virus 1 (HTLV1) and HTLV2] and several other primate viruses (SIV in monkeys, FELV in cats) belong. Only HIV1 and HIV2 cause immunodeficiency, but HIV2, a less pathogenic virus than HIV1, is endemic only in West Africa.[9] HIV1 has spread worldwide. Like other retroviruses, HIV1 is characterized by the retroversion of its genetic material, from RNA to DNA, upon penetration to target cells. This retroversion is done by the viral enzyme, reverse transcriptase, in the cytoplasm of target cells. The AIDS virus uses two major receptors on target cells for anchoring and penetration: CD4 and CCR5/CXCR2.[10–12] Research on CD4 receptors detected their abundance on T-helper cells, macrophages, Langerhans and glia cells. All these cells are thus targets for HIV1. Although no CD4 receptors were detected on spermatozoites, HIV1 was detected,[13] the idea being that CD4 receptor is present but not expressed on spermatozoites.[9] The CCR5/CXCR2 receptors were shown in 1996 to be second and indispensable receptors for HIV to penetrate target cells.[10] It was also shown that macrophages and Langerhans tropical strains of HIV uses the CCR5 receptor, while lymphocyte tropical strains use the CXCR2 receptor.[12] As was recently shown, the lack of this second receptor confers natural resistance to HIV infection.[11]

HIV subtypes and their importance

HIV1 is constantly mutagenic in its component (envelope, core and enzymes). The rate of mutations, however, is not constant.[12] Mutations in the envelope region tend to cluster in several patterns, giving rise to different viral clades (quasispecies, subtypes). Eight HIV subtypes (A–F) were thus described. All were found to circulate in equatorial Africa. Only the B subtype is endemic in North America, Europe and Australia, while in Southeast Asia, the B, C and E subtypes predominate.[15,16] Some studies have recently

suggested that different viral strains have different tropism to target cells in the immune system: E and C HIV subtypes replicate better in Langerhans cells, which are abundant in the sexual organs, while B subtypes replicate better in peripheral blood lymphocytes derived from the circulation.[17,18] The suggestion was made that this different pattern of replication may account in part for the difference in the prevailing mode of transmission of HIV in the different continents. Thus, in areas where non-B subtypes prevail (Africa and Asia), heterosexual transmissions of the virus prevail. In areas where the B subtype prevails, contact with contaminated blood plays a significant role in HIV transmission. Recently, a preferential expression of the CCR5 receptor on Langerhans cells was proposed as accounting for the preferential heterosexual transmission of macrophage tropical HIV strains.[18,19]

Diagnosis of HIV1 infection

The mainstay of diagnosis of HIV1 is antibody tests (AIDS tests).[19] Two types of tests are being used: ELISA tests for screening and western blot tests for confirmation. Screening tests, very sensitive and somewhat less specific, employ selected recombinant HIV proteins as antigens. Confirmatory (western blot) tests employ all HIV proteins as antigens. Since confirmatory tests are more specific than the screening tests, all positive screening tests need to be confirmed. Diagnostic pitfalls of HIV infection arise mainly in two situations:

(1) The initial 3 months following seroconversion ('window period'). In this period antibody levels are too low to be detected with the current HIV screening tests, giving false-negative results.
(2) During the perinatal period and up to 18 months of age in infants born to HIV seropositive mothers. Due to passive transfer of HIV antibodies through the placenta, HIV antibody tests in these infants will invariably be positive even if perinatal transmission of HIV did not occur. Since the current rate of HIV transmission in zidovudine-treated women is about 8%, most perinatal HIV antibody tests give false-positive results[21] (discussed elsewhere in this book). All infants seropositive due to passive transfer will serorevert by 18 months.[22]

To overcome the diagnostic difficulties during these periods, HIV(P24) antigen tests can be used. The presence of HIV antigen in the serum points to active replication of HIV (established infection). A positive test in the window period or during the perinatal period confirms the presence of true HIV infection. Clinical data suggest, however, that the sensitivity of the antigen test may not be higher than the current antibody tests.[23]

Other potentially useful tests in this category employ virologic tests: the polymerase chain reaction technique for detection of HIV DNA sequences in lymphocytes and for measuring HIV viral load. Negative tests by 6 months of age exclude perinatal HIV transmission.[22]

Natural history of HIV infection: viral dynamics

During the initial 2–10 weeks following seroconversion, acute HIV syndrome, with a pattern resembling infectious mononucleosis, may appear in 50–80% of individuals.[24] The main symptoms of fever, maculopapular rash and lymphadenopathy are at times accompanied by meningoencephalitic features. Viral load during this phase is very high, with millions of copies of HIV RNA/ml. The syndrome usually resolves spontaneously, viral load decreases to lower levels and the infected person enters the asymptomatic clinical phase, lasting an average of 2–8 years. During this period, massive viral replication and destruction of target cells continues relentlessly, mainly in the lymph glands. On average, some 2 billion CD4+ cells are eliminated by the virus every 24 h with partial replenishment from preexisting pools.[24–26] This gradual elimination of CD4+ cells leads to the gradual loss of almost all cell-mediated immunity, which, in turn, results in the development of full-blown AIDS (the reactivation of opportunistic infections) and death, usually by 8–10 years following infection.

Drug therapy for HIV infection

The late 1990s have witnessed significant breakthroughs in the field of antiretroviral treatment.[27] The combination of two, three or four drugs highly active antiretroviral (HAART) of the reverse transcriptase and protease inhibitors has shown promise in arresting HIV replication over long periods and lowering HIV load in plasma to undetectable levels. In addition, these 'cocktail' HAART combinations prevented the emergence of resistant HIV mutants over periods of over 2 years.[28,29] The clinical effectiveness of these combinations was soon to be manifested in the form of lowering hospitalization and death rates of AIDS patients.[30] The 'cocktail' combinations are available only in the West. Their cost prohibits their present and future usage in the developing world, where most HIV infections occur. Although very effective, the long-term side effects and effectiveness of these combinations are still unknown.

Three types of antiretroviral agents form the current 'cocktail' combinations:

(1) *Reverse transcriptase inhibitors*: These drugs, nucleic acid analogs, cause chain termination in the process of transcribing HIV RNA to DNA by the viral enzyme reverse transcriptase in the cytoplasm.

The currently approved drugs are zidovudine, zalcitabine, didanosine, 3TC and D4T. When given as monotherapy, these drugs lose their effectiveness after a few months due to the rapid emergence of resistant mutations of the reverse transcriptase enzyme. The drug should be administered in combination with other drugs, non-reverse-transcriptase inhibitors, in order to lower the rate of emergence of resistant viral mutants.

(2) *Non-nucleoside reverse transcriptase inhibitors*: These block reverse transcription by mechanisms other than being nucleoside analogs. These drugs should always be given in combination with other drugs. The available drugs are nevirapine, atevridine and delavridine.

(3) *Protease inhibitors*: These drugs block HIV protease activity during proteolitic cleavage of viral proteins following transcription. Despite their great *in vitro* effectiveness, rapid emergence of resistance follows their use as monotherapy. The available drugs are indinavir, ritonavir, saquinavir and nelfimaviz.

Natural history of HIV infection in women and during pregnancy

In controlled studies, no appreciable gender differences in the rate of acceleration of established HIV infection were observed.[31,32] Detection of HIV infection among women was sometimes delayed due to a lack of awareness of the importance of vaginal candidiasis as a presenting sign of HIV infection. An increased incidence of cervical dysplasia was found among HIV seropositive women[33,34] and cervical neoplasia has been clearly associated with human papilloma virus infection.[35] Pregnancy does not seem to affect the natural course of HIV infection.[36] Congenital anomalies due to HIV infection in the first trimester were described, although their occurrence is rare.[36]

HIV transmission through the female genital tract

The presence of concomitant STD and bacterial vaginosis was found to play a critical role in easing HIV transmission.[37–39] Treatment of STD, as seen in the African setting, was shown to reduce HIV transmission rates. An association between HIV load in vaginal secretions and the presence of vaginal inflammation was also demonstrated. Other biochemical and physical factors, e.g. the use of contraceptive pills, the lack of male circumcision, vitamin A deficiency, the presence of bacterial vaginosis and trichomonas vaginalis, were also associated with increased rates of acquisition of HIV in the African setting.[38–45]

Perinatal transmission of HIV

Multiple factors probably play a role in aiding perinatal HIV transmission. Detailed studies recently demonstrated a direct correlation between high HIV viral load in the plasma of pregnant women and the increased rate of HIV transmission to the newborn.[42,43] However, in the landmark placebo-controlled zidovudine intervention study of over 800 pregnant women followed to term in the USA, Europe and Australia, HIV transmission occurred at all levels of HIV viral load.[46] A low CD4 level during pregnancy was also associated with increased rates of HIV transmission, as well as low vitamin A levels (in African women).[44] The most important obstetrical factor associated with increased HIV transmission was found in a large prospective US study to be the premature rupture of membranes of over 4 h in HIV seropositive women.[47]

Timing of HIV transmission

Despite the findings of placentitis in placentas of seropositive mothers,[38] studies have indicated that most HIV transmission to the newborn occurs during delivery and the perinatal period, rather than in the first trimester of pregnancy.[48,49] Supporting evidence for this comes from the rarity of congenital HIV syndrome and from analysis of twins born to HIV seropositive mothers: statistically, more first- than second-borns are found to be infected by HIV, suggesting transmission during passage in the birth canal.[50,51]

The importance of breast feeding in HIV transmission during the perinatal period has been demonstrated since early on in the epidemic in studies carried out in Australia and Africa.[52,53] It is estimated that 15–20% of perinatal HIV transmission in Africa occurs as a result of breast feeding. However, since the alternative, bottle feeding, carries a far greater danger to infant health in the form of gastroenteritis and dehydration, UNESCO has ruled that breast feeding should continue to be the practice of choice in infant nutrition during the AIDS era in underdeveloped countries.[54,55]

Drug therapy with zidovudine to reduce perinatal transmission of HIV

A pivotal study, completed in 1994 and updated in 1996, has demonstrated conclusively that zidovudine, given in the second and third trimesters as well as during delivery and for 6 weeks to the newborn infant, reduces HIV transmission to the newborn by approximately 66% (from 22.6% to 7.6%).[46,48] This cornerstone, placebo-controlled study, has changed the practice of obstetrics in pregnant HIV seropositive women in the West. The exact factors that determine

the lowering of HIV transmission in zidovudine-treated women are still poorly understood. In many of the study participants receiving zidovudine, HIV transmission did not occur despite a meager degree of reduction in plasma viral HIV load. Other factors, such as the zidovudine level in the newborn tissues, may account for the apparent protection. The success of this intervention study has prompted modifications aimed at making zidovudine treatment accessible to pregnant women in the developing world. Newer protocols such as a single dose of zidovudine given during delivery or parenteral zidovudine given only during active delivery are being studied in Africa and Thailand. Other protocols with combination antiretrovirals aimed at lowering perinatal transmission of HIV even further.[56–58]

Other interventions

No conclusive evidence for the protective role of cesarean section has yet surfaced, although two meta-analyses addressing this issue have demonstrated the existence of clear benefit of this procedure in reducing HIV transmission to the newborn compared to vaginal delivery.[59,60] The analyses were carried out prior to the introduction of zidovudine to the routine care of pregnant women. Other procedures, such as cleansing of the vaginal canal with chlorhexidine prior to delivery were not shown to reduce the rate of HIV transmission.[61]

Recommended zidovudine protocol for the prevention of HIV transmission during delivery

To the expectant mother, zidovudine 500 mg is given daily in the second and third trimesters. During delivery, a loading dose of intravenous zidovudine 2 mg/kg is given over 1 h. Maintenance intravenous zidovudine is administered, 1 mg/kg/h until half an hour after termination of delivery. Within 8–12 h following delivery, administration of zidovudine syrup to the newborn is started, 2 mg/kg/dose every 6 h for 6 weeks.[54]

Additional recommendations

Cesarean section should be considered if the delivering women are at advanced stages of HIV infection, will not receive intravenous zidovudine and have had over 4 h of premature rupture of membranes.[47]

Breast feeding should be discouraged for all infants born to HIV seropositive mothers in developed countries.[54] All killed vaccines (e.g. pneumococcal, hepatitis B) as well as Hib and influenza virus should be given to the pregnant woman. They should also receive the same prophylactic regimens as non-pregnant women. Trimethoprim sulfamethoxazole appears safe as prophylaxis against pneumocystic pneumonia during pregnancy. Dapsone is also safe and should be used in cases of allergy to trimethoprim sulfamethoxazole.

Conclusion

HIV among women continues to spread unabated worldwide, especially in sub-Saharan Africa and Southeast Asia. In recent years, important biological factors have been defined as cofactors in HIV transmission to women and during delivery. The lack of access to medical care in many parts of the world delays effective therapy. However, no biological differences in disease progression or response to antiretroviral drugs, when available, can be detected among women.

160 Pneumonia in pregnancy

D. Miron and R. Raz

Introduction

The prevalence of antepartum pneumonia is 1 in 350 to 2300 deliveries. Maternal conditions associated with increased risk for the infection are immunodeficiency state (e.g. HIV/AIDS, malignancy and chemotherapy), chronic cardiopulmonary disease, diabetes mellitus, poor nutrition, cocaine use, smoking and anemia. Such risk factors were found in up to 45% of pregnant women who presented with pneumonia.[1–5]

Etiology

The agents associated with pneumonia in a pregnant woman are those that most commonly cause pneumonia in non-pregnant women. Currently, in 40–60% of patients, no agents can be found despite improved laboratory diagnosis (see below).[1,5]

The most frequent organism causing community-acquired pneumonia is *Streptococcus pneumoniae*. Other less common agents are *Haemophilus influenzae* and β-hemolytic streptococcus. A large section of pregnant women with pneumonia is made up of those with atypical pneumonia. Common etiologic agents include *Mycoplasma pneumonia*, *Legionella pneumophilia*, *Chlamydia pneumonia* and viruses.[1,2,6,7] Infection with *Coxiella burneti* (Q-fever) can occur in endemic areas (including Israel) with frequent contact with domestic animals or unpasteurized milk.[7] The bacteria can infect the placenta, resulting in prematurity, low birth weight or fetal death. Chicken pox during pregnancy is associated with pneumonitis in 10–20% of patients, which may be life-threatening. In endemic areas, yeast infections such as *Coccidioides immitis* or *Histoplasma capsultum* may be life-threatening. Nosocomial pneumonia is usually caused by gram-negative bacteria (e.g. *Klebsiella pneumonia*, *Pseudomonas* spp.) or anaerobic bacteria.[1,2,5]

More women with primary or secondary immunodeficiency are now surviving through their reproductive years and attempting pregnancy. In these women, unusual agents have been associated with pneumonia, including *Pneumocystis carinii*, *Mycobacterium avium* complex (mostly in women with AIDS) and *Mycobacterium tuberculosis* (MTB). In areas endemic for tuberculosis, infection of pregnant women with MTB can be associated with either congenital tuberculosis or infection of young infants by untreated mothers.[2,4,5]

Diagnosis

In about 40–60% of women with pneumonia a specific agent can be found. The most helpful tests are sputum for gram stain and culture, sputum and urine for antigen detection, blood culture and serology. Specific diagnostic measures for the main causes of pneumonia are presented in Table 160.1.

An adequate sputum test is defined as > 25 neutrophils and < 10 epithelial cells per low-powered microscopic field. Sputum can be obtained either by induction or by bronchoalveolar lavage (BAL). Gram stain of the sputum remains the commonest way for rapid identification of causative agents. For example, predominance of gram-positive diplococci is highly suggestive of pneumococcal pneumonia.[1,2]

Several rapid, highly sensitive and specific diagnostic methods have recently been developed using sputum. Direct fluorescent assays for *Legionella* and *Pneumocystis carinii* antigens have 50–80% sensitivity and > 95% specificity. DNA hybridization tests for ribosomal RNA and polymerase chain reaction (PCR) amplification are also highly sensitive, specific and rapid tests that are commercially available for identification of *Legionella* and MTB. These tests can profoundly shorten the time of identification of the agent and initiation of effective therapy. In 5–20% of patients with bacterial pneumonia, blood cultures are positive. Most of the available serology tests are of enzyme-linked immunosorbent assay (ELISA). These tests are highly sensitive and specific. A radioimmunoassay test for identifying *Legionella pneumophilia* serogroup I antigen in the urine is a new method with comparable sensitivity to other methodologies, and is much easier to perform.[1,2,5]

Clinical manifestations

Signs and symptoms of pneumonia vary, depending on the agent causing the disease and the patient's

Table 160.1 Laboratory diagnosis of pneumonia

Agent	Sputum	Blood culture	Serology	Others
Bacterial pneumonia	Gram stain, culture of pleural	Positive		Fluid
S. pneumoniae				
H. influenzae				
Group A streptococci				
β-hemolytic streptococcus				
Atypical pneumonia				
L. pneumophilia	Direct fluorescent assay,	Positive		Urine antigen
	DNA tests			
M. pneumonia	Probe, culture		Positive	
C. pneumonia			Positive

PCR, polymerase chain reaction

underlying immune status. Generally, most pneumonia occurs during fall and winter. Pneumococcal pneumonia presents with high fever, productive cough, chills and pleuritic chest pains. These patients may develop a stormy disease with sepsis syndrome, hypoxemia and adult respiratory distress syndrome (ARDS). The chest x-ray shows involvement of one or more lobes, or bronchopneumonia. In patients with involvement of the pleural membranes, fluid collection within the pleural cavity can be demonstrated. In such patients the disease may have a range from pleural effusion to emphysema, necessitating invasive drainage procedures and prolonged antibiotic therapy. Chest ultrasound and/or computed tomography are helpful for evaluation of the fluid volume viscosity, for the development of intrapleural cavity septa and for drainage procedures. Atypical pneumonia is more insidious in onset, with moderate fever, non-productive and sometimes prolonged cough, headache and myalgias. The disease may occasionally progress to a more advanced level. In many patients, history of a similar infection can be elicited in other family members. Chest x-ray usually demonstrates broncho- or interstitial pneumonia. Patients with *Legionella* pneumonia may present with abdominal pains (10–20%), diarrhea (25–50%), hepatitis and neuralgic symptoms ranging from lethargy to encephalopathy.[1–3,6] Contact with domestic animals (such as goats or sheep), or unpasteurized milk, could raise the possibility of Q-fever in an endemic area.[7] In patients with tuberculosis there is usually a history of exposure to an infected person. The typical presentation is of prolonged fever and cough with persistent pulmonary infiltrate (with or without pleural effusion), or cavity on the chest x-ray. These women, if not aggressively diagnosed and treated, may be highly infectious to the fetus and close contacts. In every HIV/AIDS patient with a history of prolonged cough and dyspnea, with or without fever, *Pneumocystis carinii* pneumonia must be considered. Chest x-ray shows an interstitial pattern of pneumonia, although rarely lobar involvement and abscess-like formation have been reported. Involvement of the lungs in *Mycobacterium avium* complex infection is part of multiorgan involvement in a patient with advanced AIDS or other immunocompromised conditions. *Varicella zoster* pneumonia should be suspected in every woman with chicken pox who develops dyspnea. Chest x-ray demonstrates interstitial pneumonitis. These women may deteriorate rapidly to ARDS. Chicken pox during the first

half of pregnancy may be associated with a congenital varicella syndrome in 3–5% of fetuses.[2,4,5]

Prognosis

The prognosis for pregnant women with pneumonia has improved markedly since the introduction of antibiotics. Important added factors include the availability of ventilatory aids and more precise technology to monitor fluid requirements and vital signs. These advances have resulted in a reduction of maternal death from about one-third of cases to 4%. Clinical features that are associated with significant morbidity include: (1) more than one lobe involved; (2) respiratory rate greater than 30 breaths/min; (3) severe hypoxemia, hypoalbuminemia and septicemia; (4) chronic underlying disease such as immunodeficiency syndrome, diabetes mellitus or chronic pulmonary disease and poor nutrition and (5) maternal smoking.[2,3]

However, obstetric complications have not been altered, with a rate of preterm delivery of 15–43%, and perinatal death rate of 4–11%. Several factors are associated with poor outcome of the fetus. In pregnancy there is a mild increase in the alveolar–capillary difference because of an increased oxygen consumption and peripheral extraction by mother and fetus. As early as 4 weeks' gestation, progesterone effects occur, resulting in maternal hyperventilation and respiratory alkalosis.[3,4,8]

This hyperventilation of pregnancy decreases fetal oxygen tension, so that any disease such as pneumonia that causes hypoxia and dyspnea will increase the respiratory rate and have adverse effects. These include a decrease in uterine blood flow with vasoconstriction, a decrease in maternal venous return and a decrease in umbilical blood flow. Hyperventilation and hypocapnia shift the oxygen–hemoglobin dissociation curve to the left for both mother and fetus, resulting in increased hemoglobin affinity for oxygen. A dangerous situation exists if the blood pH exceeds 7.6 or the PaO_2 falls below 55 mmHg. In addition to the above effects, the increased effort from the work of breathing may result in further extraction of oxygen from the fetus and organs such as the placenta, uterus and kidneys. The uteroplacental circulation is a low-pressure, highly vascularized system, well developed by the 12th gestational week. Its blood flow is 20% of the cardiac output by the 26th gestational week. Any maternal oxygen debt will harm the fetus.[3,4,8]

It is apparent that oxygen consumed for the work of breathing has a proportionately small and smooth increase during gestation. If the mother has dyspnea and hypoxia from pulmonary disease, the oxygen required for the work of breathing may be taken from the fetus and organs such as the placenta, uterus or kidneys.[3,6,8]

Immunologic changes in the mother and fetus may contribute to the adverse outcome of pneumonia in pregnancy. The fetus has a decreased immunologic defense since only immunoglobulin G can cross the placenta, so any infection of the mother can be disastrous for the fetus. There is an increase in the normal number of T-suppressive cells formed to protect against the rejection of the fetus as a foreign body, and this may explain the reduced immune response to infections.[3]

The precise reasons for the high rate of preterm labor despite effective antimicrobial therapy are not fully explained. One postulated mechanism is a production of prostaglandins, either locally in the cervicovaginal area, or as part of the inflammation in the lungs. These agents could circulate to the uterus and produce preterm labor.

Perinatal death associated with pneumonia in pregnancy could be due to either maternal hypoxemia or premature delivery.[5,6,8]

Therapy

The key to the care of a pregnant woman with pneumonia is early diagnosis. Patients with respiratory symptoms should immediately be evaluated for the possibility of lower respiratory infection, including chest x-ray when needed. In such women with pneumonia, the etiology must be elicited by using blood cultures, sputum Gram stain and culture and other diagnostic tests as necessary. In addition, careful monitoring of arterial PO_2 and appropriate oxygenation should be performed. A healthy fetus depends on the mother keeping oxygen debt to a minimum, and supplementing oxygen is vital whenever hypoxia is manifested. A warning sign of dyspnea in pregnancy is a respiratory rate > 18 breaths/min. Premature labor can present difficulties, necessitating adequate hydration and close monitoring of uterine activity.[1,2]

Antimicrobial therapy is limited because of known or possible adverse effects on the fetus (Table 160.2). Most patients with community-acquired pneumonia can be treated as outpatients unless they are dehydrated, clinically ill or immunocompromised. For patients with typical pneumococcal pneumonia penicillin should be started, either orally or intravenously. For patients allergic to penicillin, erythromycin is the drug of choice.[1,2,5]

Recently, pneumococci that are either partially or completely resistant to penicillin have been reported from different areas in the world to cause pneumonia and other invasive diseases. In areas with a high frequency of such pneumococci, either second- or third-generation cephalosporins should be empirically initiated until sensitivity studies are available. The drug of choice for atypical pneumonia is erythromycin. Recently, new second-generation macrolides and azoles derivatives (e.g. azithromycin) have been approved for use for such infections. They have equal activity, but less adverse effects on the mother. In many cases of pneumonia, the exact causative agent cannot be

Table 160.2 Antimicrobial agents for pneumonia

Agent	Indication route	FDA pregnancy categories*

Ethambutol	Tuberculosis PO	–
Acyclovir	Varicella pneumonia IV, PO	C

FDA, Food and Drug Administration; BLI, β-lactamase inhibitors; PCP, *Pneumocystis carinii* pneumonia; PO, oral; IV, intravenous; IM, intramuscular
*FDA pregnancy categories: A, adequate studies in pregnant women, no risk; B, animal studies show no risk but human studies not adequate, or animal toxicity but human studies show no risk; C, animal studies show toxicity, and human studies inadequate, but benefit of use may exceed risk; D, evidence of human risk, but benefits may outweigh risk; **for ampicillin sulbactan no oral drug is available; ***only third-generation cephalosporins should be used by intravenous route

determined. In these patients, therapy should be directed against the most likely organisms, which are pneumococci, *Mycoplasma* and *Legionella*. Erythromycin or second-generation macrolides have been found to be active against all and should be given empirically.[1,5]

Varicella zoster pneumonia requires special attention in pregnant women. In general, patients who are not immunocompromised are at high risk for ARDS when infected with varicella viruses, and in these cases acyclovir should be started. If a patient complains of dyspnea or tachypnea, then admission should be considered and acyclovir should be given intravenously. While in hospital, appropriate isolation measures should be taken.[2,5]

161 Prevention of infection in cesarean section

A. Dražančić

Introduction

The rate of cesarean sections has increased to more than 10% of all deliveries, predominantly because of fetal indications. Without an elevated incidence of cesarean section rate it is impossible to achieve low perinatal mortality and to avoid the early and late neonatal sequelae. Numerous complications are possible during and after the operation. Immediate complications, anesthesiologic and surgical, are not frequent. Early postoperative complications are more frequent, predominantly due to infection: puerperal fever, endomyometritis and suppuration of the abdominal wall, paralytic ileus, pelveoperitonitis and diffuse peritonitis and/or sepsis.

The frequency of infectious complications is variously quoted in the literature.[1–5] This is because of the difference of interpretation of the symptoms, the variety of surgical aseptic approaches and the differences in pharmacological prophylaxis and treatment. By analysis of 15 publications[2] the range of complications was established: the average for puerperal fever was 19%, endomyometritis 4.4%, pelveoperitonitis 1.2% and wound infection 1.5% (Table 161.1).

Maternal infections follow cesarean section in spite of the usual surgical aseptic measures, which include washing and cleaning of the lower abdominal wall skin and the use of sterile instruments and other operative materials. In fact, during operation the uterine cavity has to be opened, in which the aerobic and anaerobic gram-positive and -negative bacteria can be found.[6,7]

Bacteria are always present in the uterine-amniotic cavity when more than 6 h has elapsed since the rupture of the membranes.[7,8] Even when the amniotic membranes persist during labor, pathogenic bacteria have been established by amniocentesis in the amniotic fluid in 8 out of 78[9] and in 18 out of 31[10] deliveries. Among the isolated bacteria the most frequent are the gram-negative aerobes and anaerobes; among the aerobes the most frequent are *Escherichia coli* and *Enterococcus*, and among the anaerobes, *Peptostreptococcus.*[6–12] The same bacteria have been isolated from the surgeon's gloves and thereafter from the wound suppuration[6] and from the peritoneal cavity, amniotic fluid and wound suppuration.[8] There is a relationship between the colonization of the amniotic fluid and the time elapsed from membrane rupture.[13] The bacteria detected during postcesarean infection may be regularly isolated from the vagina.[14] The clinical manifestation of infection is related to the number of vaginal examinations and to the invasive monitoring during delivery,[15] to the time elapsed since the rupture of the membranes and to the existence of the signs of infection before the operative procedure. In our analysis in 1981, the relationship of puerperal fever and wound infection to the duration of time since membrane rupture was established (Table 161.2).

The presence of bacterial agents in the amniotic fluid and uterine cavity, and the possibility of propagation of the infection during cesarean section to the endometrium, myometrium, peritoneum and even the blood circulation,[16] has stimulated clinicians to start antibiotic prophylaxis of infection during and following cesarean section. The various antibiotics are given alone or in combination, during the operative procedure or following it, in a single or repeated dose.

The first report was published by Miller and Crichton in 1968.[17] By the application of penicillin during the 5 days following cesarean section, puerperal morbidity has been reduced by 50%. In Table 161.3 the type of antibiotic prophylaxis, i.e. the antibiotic used, the time and duration of application and their effect upon the puerperal postcesarean endometritis and wound infection are presented. From the table, the favorable effect of antibiotic prophylaxis can be seen. Until 1980, the penicillins, and thereafter the cephalosporins, have been used predominantly. The cephalosporins have an advantage in relation to the penicillins due to their broader spectrum of activity, especially on the gram-negative agents (*E. coli*).

Table 161.1 Reported rates of puerperal fever, endomyometritis, pelveoperitonitis and wound infection in women following cesarean section (data from Dražančić and Orešković[2])

	Mean incidence (%)	Range (%)
Puerperal fever	19.0	7.3–48.0
Endomyometritis	4.4	1.0–7.3
Pelveoperitonitis	1.2	0.2–4.7
Wound infection	5.4	1.6–7.5

Table 161.2 Puerperal fever and wound infection in relation to the duration of membrane rupture in 263 cesarean sections without pharmacological prophylaxis performed by Zagreb in 1981

Time from membrane rupture	Puerperal fever	Wound infection
Existing membranes ($n=106$)	12 (11.3%)	1 (0.9%)
1–6 h ($n=58$)	13 (22.4%)	2 (3.5%)
7–12 h ($n=42$)	14 (33.3%)	6 (14.3%)
> 13 h ($n=57$)	18 (31.6%)	12 (21.0%)
Total ($n=263$)	57 (21.7%)	21 (8.0%)

Since there is no difference between the effect of a single intraoperative dose and a multiple postoperative application (Table 161.4), the trend today is to apply a single intraoperative dose immediately after cord clamping.

Nevertheless, pharmacological prophylaxis does not seem to be sufficient. We would like to present our results of 13 years' follow-up of cesarean section deliveries, grouped into five periods, according to the pharmacological and surgical proceedings.

Materials and methods

Our approach to the prevention of infection in cesarean deliveries has changed during the past 13 years; we can distinguish five periods, which followed one after another. For each period the results with regard to puerperal morbidity, i.e. fever and the wound infection, will be presented.

First period, 1981–1982

Antibiotic prophylaxis was not performed. The antibiotics were applied after operation, depending on the clinical behavior of the patient, the temperature, bowel function and leukocyte count. The surgical procedure was 'usual': the laparotomy was by transverse incision; after the opening of the abdomen the uterus was wrapped in gauze; following extraction of the child and the placenta, and the removal of the gauze, the uterus was sutured by two rows of single catgut sutures, or one row of single and another of continued catgut sutures.

Second period, 1983–1986

Antibiotic prophylaxis was by cefuroxim for 3–5 days, 3×1.5 g daily starting after the operation. The surgical procedure was as before.

Third period, 1987–1989

Antibiotic prophylaxis was as before. After opening of the uterus, suction of the amniotic fluid and blood was carried out. After removing the gauze, wiping and washing out of the peritoneal cavity was performed with isotonic solution.

Fourth period, 1990–1992

Pharmacological prophylaxis was administered only in cases with membrane rupture over 6 h, and after cord clamping cefuroxim 1.5 g was given intravenously. The surgical procedure was as before, with suture of the uterus incision by one row of interrupted single Dexon sutures; before closing the abdominal wall there was a change of sheets, instruments and surgical gloves.

Fifth period, 1993–1994

Pharmacological prophylaxis was administered in all cases after cord clamping, with cefuroxim 1.5 g intravenously. The surgical procedure was as before.

In all cases puerperal fever and wound infection were evaluated. For puerperal fever, all cases with temperature more than 38°C, starting from the second day of puerperium were registered. For wound infection, all cases of suppuration, irrespective of the involved layer of the abdominal wall, were declared.

The first 12 months of each period were included in the analysis, except the fourth period, for which two complete years were analyzed.

In the first period, 263 cases were analyzed, 99 (37.6%) of them with a rupture of membranes (ROM) of more than 6 h; in the second period 237 cases, 105 (44.3%) of them with ROM > 6 h; in the third period 428 cases, 180 (42.1%) of them with ROM > 6 h; in the fourth period 1153 cases, 332 (28.8%) of them with ROM > 6 h and in the fifth period 333 cases were analyzed, 74 (22.2%) of them with ROM > 6 h.

Results and discussion

The results are presented in Table 161.5. In the first period, without pharmacologic or extended surgical

Table 161.3 Review of the antibiotic prophylaxis of infection following cesarean section

		Effect	
	Antibiotic	**Endometritis***	**Wound infection (%)**
Miller and Crichton[17]	Ampicillin 5 days postoperatively	Reduction for 50%	
Weissberg *et al.*[18] (*n*=40)	Penicillin + kanamycin 5 days	Reduction from 35 to 10% postoperatively	
Gibbs *et al.*[19] (*n*=67)	Ampicillin + kanamycin	45–19%	16–0
D'Angelo and Sokol[20] (*n*=49)	Cefalexin 1 day, 4 × 1.0 g	65–29%	
	Cefalexin 5 days, 4 × 0.5 g	65–20%	
Dillon *et al.*[21] (*n*=31)	Cefoxitin 5 days, 4 × 1.0 g	Infection reduced	
Harger and English[22] (*n*=196)	Cefoxitin 1 day, 3 × 2.0 g	20–10%	7.4–1.0
Gonik[23] (*n*=50)	Cefoxitin 1 day, 3 × 1.0 g	14%	
Von Mandach *et al.*[24]

McGregor *et al.*[25]			
(*n*=195)	Cefamycin intraoperatively, 1 × 2.0 g	4.1%	2.5
(*n*=91)	Cefoxitin 1 day, 3 × 2.0 g	9.9%	3.3
Kristensen *et al.*[26] (*n*=102)	Cefuroxim intraoperatively, 1.5 g	10–1%	1.0–0
Neuman *et al.*[27]			
(*n*=87)	Penicillin 10 million + 1 day tetracycline 2 × 250 mg	7.3%	5.2
(*n*=96)	Penicillin 10 million + 3 days ampicillin 3 × 2.0 g and tetracycline 3 × 0.5 g	4.8%	6.9
Ehrenkranz *et al.*[28] (*n*=906)	Intraoperatively**	2.1 to 0.7%	2.0–0.2
Faro *et al.*[29]			
(*n*=161)	Cefazolin 1 day, 3 × 1.0 g	22.5%	
(*n*=148)	Cefazolin intraoperatively, 2.0 g	10.6%	
(*n*=141)	Ampicillin intraoperatively, 2.0 g	12.8%	
Carlson and Duff[30]			
(*n*=192)	Cefazolin intraoperatively, 2.0 g	19.3%	1.6
(*n*=185)	Cefamycin intraoperatively, 2.0 g	21.1%	1.6
Watts *et al.*[31]			
(*n*=50)	Cefamycin intraoperatively, 2.0 g	18.0%	4.0
(*n*=52)	Cefoxitin 1 day, 3 × 2.0 g	13.5%	3.9

*Endometritis and/or puerperal fever; **type of antibiotic not specified

prophylaxis, there is an evident increase of puerperal fever after ROM, especially after 6 h. Wound infection increased continuously from 0.9% to 21.0% (see Table 161.1).

In the second period the pharmacologic postoperative prophylaxis does not reduce the incidence of puerperal fever (44.3%) and wound infection (10.5%).

In the third period, with the same pharmacologic prophylaxis and with surgical prophylaxis, there is a slight decrease of febrile puerperiums (10.2%) and wound infection (6.1%).

In the fourth period, with intraoperative single-dose antibiotic prophylaxis only in cases of ROM more than 6 h, and with systematically performed

Table 161.4 The intraoperative and postoperative antibiotic prophylaxis of wound infection

	Antibiotic	Incidence of wound infection (%)	
		Postoperative prophylaxis	Intraoperative prophylaxis
McGregor *et al.*[25]	Cefamycin or cefoxitin	3.3	2.5
Neuman *et al.*[27]	Penicillin + tetracyclin	6.9	5.2
Watts *et al.*[31]	Cefoxitin or cefuroxim	3.9	4.0
Dražančić and Orešković[2]	Cefuroxim	6.1	1.6

Table 161.5 Puerperal fever and wound infection in relation to the type of pharmacologic and surgical prophylaxis

Type of prophylaxis	*N*	Puerperal fever	Wound infection
Antibiotics postoperatively and selectively (1981)	263	57 (21.6%)	21 (8.0%)
Cefuroxim postoperatively 3–5 days (1983)	237	105 (44.3%)	25 (10.5%)
Cefuroxim 3–5 days, surgical prophylaxis partial (1987–1988)	428	44 (10.2%)	26 (6.1%)
Cefuroxim intraoperatively when membrane rupture > 6 h, surgical prophylaxis extended (1990–1991)	1153	129 (11.2%)	18 (1.6%)
Cefuroxim intraoperatively in all cases, surgical prophylaxis extended (1993–94)	333	13 (3.9%)	2 (0.6%)

surgical prophylaxis, there is no change in the rate of febrile puerperium (11.2%), and there is a decrease in wound infection to 1.6%.

Only in the fifth period with extended surgical prophylaxis and pharmacological prophylaxis in all cases, irrespective of ROM, is the evident decrease of puerperal fever (3.9%) and wound infection (0.6%) established.

The more detailed analysis of 1153 cases during the fourth period (Table 161.6), with systematically extended surgical prophylaxis, revealed the importance of combined pharmacological and surgical prophylaxis. There are no significant differences between the cases with and without antibiotic application within the separate groups. Puerperal fever was established by persistent membranes in 10.2% vs. 7.9%, by ROM 0–3 h in 7.7% vs. 10.3% and by ROM 4–6 h in 12.9% vs. 11.5% of the cases, respectively. Among 81 cases without ROM or with ROM less than 6 h, which manifested puerperal fever, 45 (55.6%) were without membrane rupture and without antibiotic prophylaxis. Wound infection, which is more specific and indicative of puerperal infection, appeared in 10 cases with persistent membranes without antibiotic prophylaxis, that is, 55.6% of the 18 cases with wound infection. The above data influenced us to introduce the regime of extended surgical plus pharmacological prophylaxis in all cases, irrespective of membrane rupture. In this way, out of 333 cases of cesarean section during the period July 1993 to March 1994 only 13 cases (3.9%) of febrile puerperium and only two cases (0.6%) of wound infection were registered (Table 161. 5). The causes of febrility over 38°C were two cases of wound infection, three cases of endomyometritis, one case of pelveoperitonitis (cured conservatively), one case with pyelonephritis and six cases without established origin of febrility.

Since 1993 we have introduced general pharmacological and surgical prophylaxis in all cases of cesarean section. The pharmacological prophylaxis includes all cases, irrespective of rupture of the membranes. As a routine, 1.5 g of cefuroxim is administered intravenously immediately after the cord clamping. The surgical prophylaxis comprises the wrapping of the uterus with gauze, suction of the blood and amniotic fluid that flows out from the uterine incision, one row of interrupted suture of the uterine incision, wiping and washing of the peritoneal cavity and – at the end – a change of the sheets, surgical gloves and instruments before the suturing of the abdominal wall.

The surgical prophylaxis seems to be of special importance. After 6 h following ROM, all the uterine cavities are infected[7,8] and even with persisting membranes the amniotic fluid may be infected.[9,10] The suction of the blood and amniotic fluid during uterotomy and the wiping and washing of the peritoneal cavity hinders the dissemination of (infected) uterine contents

Table 161.6 Peurperal fever and wound infection in relation to the rupture of membranes and to antibiotic prophylaxis (Zagreb 1990–1991)

		n	Fever >38°C	Wound infection
Membranes persistent	A	443	45 (10.2%)	10 (2.3%)
	B	89	7 (7.9%)	0
Membranes ruptured 0–3 h	A	91	7 (7.7%)	3 (3.3%)
	B	58	6 (10.3%)	0
Membranes ruptured 4–6 h	A	62	8 (12.9%)	4 (6.4%)
	B	78	8 (11.5%)	0
Membranes ruptured >6 h	B	332	47 (14.2%)	1 (0.3%)
Total		1153	129 (11.2%)	18 (1.6%)

A, without antibiotic prophylaxis; B, antibiotic prophylaxis, one dose intraoperatively

to the peritoneum. The exchange of sheets, instruments and gloves prevents the implantation of infectious material to the abdominal wall. The one-row uterine suture should prevent myometritis, because it hinders the formation of uterine wall pockets with retention of the potentially infected material; during the one-row suturing the possibility of a hematoma forming at the edges of the uterine incision is reduced.

The selective antibiotic prophylaxis in the cases with membrane rupture of more than 6-h duration is, without doubt, beneficial. However, with this type of antibiotic prophylaxis about 20% of infected cases are missed in the deliveries with persistent membranes or with membrane rupture of less than 3-h duration.

The one-dose antibiotic application intraoperatively is not less effective than several days' postoperative treatment,[23–27,29] but it is less expensive.[32] We used cefuroxim, but other cephalosporins of the third generation resistant to β-lactamase and first-generation cephalosporins are also efficient. The single-dose application is efficient as a prophylactic measure. It does not suffice when the cesarean section is performed during delivery with evident intrauterine infection: fever during delivery, tachycardia, uterine tenderness, pus discharge from the uterus and excessive leukocytosis with a shift to the left. In such cases, intensive antibiotic treatment with a combination of penicillins, aminoglycosides and metranidazol, or cephalosporins and clindamycin, before operation and for some days after operation are necessary.

The prophylaxis of infection after cesarean section has to start during pregnancy and continue during labor and after delivery. During pregnancy the treatment of vaginitis and bacterial vaginosis will be beneficial. During labor all procedures that propagate ascending infection should be avoided: superfluous vaginal examinations, invasive fetal monitoring and prolonged labor.

Pharmacological prophylaxis should be selective or total. If it is selective, it is administered in cases with a higher risk of infection: membrane rupture over 6 h, maternal age over 35 years, obesity, diabetes or persistent or previous uroinfection. We incline to total prophylaxis, i.e. for all women undergoing cesarean section. Pharmacologic prophylaxis has to be in parallel with extended surgical prophylaxis.

Conclusion

Careful and extended surgical prophylaxis combined with pharmacological antibiotic prophylaxis decreases the incidence of infectious complications after cesarean section to the minimum: less than 5% for puerperal fever (endomyometritis) and less than 1% for wound infection.

Cefuroxim or other cephalosporins in a single intraoperative intravenous dose successfully reduce the rate of endomyometritis and wound infection and several days of postoperative prophylaxis is not more effective.

162 Septicemia and septic shock

S. J. Fasouliotis and J. G. Schenker

Definition

Septicemia and septic shock are dramatic clinical syndromes that result from acute invasion of the bloodstream by certain microorganisms or their toxic products. Fever, chills, tachycardia, tachypnea and altered mentation are common acute manifestations of septicemia. When hypotension and signs of inadequate organ perfusion develop, the condition is termed septic shock. The circulatory insufficiency is characterized by a lowered systemic vascular resistance, decreased myocardial contractile function and pooling and altered distribution of blood in the microcirculation. Diffuse cell and tissue injury and, ultimately, widespread organ failure develop. Even with appropriate antimicrobial and supportive care many patients die of septic shock, making strategies for prevention and more effective treatment of critical importance.

Etiology

Septicemia can be caused by all classes of organisms; however, septic shock is most commonly caused by gram-negative bacteria (60–70% of cases).[1] Gram-positive organisms and especially staphylococci, pneumococci and streptococci are less frequent causes (20–40% of cases), as are opportunistic fungi (2–3%) and, rarely, mycobacteria or certain viruses or protozoans. *Escherichia coli*, *Klebsiella, Enterobacter*, *Proteus*, *Pseudomonas* and *Serratia* are the most frequent blood culture isolates in septic shock, followed by *Staphylococci* and *Pneumococci*. Gram-negative bacteremia is complicated by shock in about 40% of patients; shock is seen in 5–15% of patients with acute bacteremias caused by pneumococci or staphylococci. The incidence of suppurative complications (metastatic seeding to bones, joints and viscera), on the other hand, is much higher with gram-positive microorganisms. Gram-positive bacteria have the capability of adhering to endothelial cells and subendothelial matrix substances (such as fibronectin, laminin, fibrinogen and endothelial cell proteins) to a much greater degree than do gram-negative organisms, so that seeding to heart valves, to other organs and especially to foci of trauma and/or preexisting inflammation is much more common.

Epidemiology

Infections most commonly occur in the hospital setting. Many infected patients become bacteremic. It is estimated that of 100 randomly chosen patients who appear to be infected (septic) in a hospital setting, approximately 90% are actually infected. Of these, about 20% develop some evidence of hemodynamic instability and appear, at least temporarily, to have shock. About half of shock patients (or about 10% of all septic-appearing patients) go on to real septic shock and/or manifest serious end-organ malfunction related to the septic episode, such as adult respiratory distress syndrome (ARDS), renal failure or disseminated intravascular coagulation (DIC). Since about 5% of all hospital patients are either admitted with or develop an infection during hospitalization, the number of patients at risk of developing septic shock is large. Despite the introduction of new antimicrobial agents, the overall mortality from gram-negative bacteremia has averaged about 25% over the past two decades, and is highest in patients who have major associated diseases or shock. Predisposing factors include diabetes mellitus, cirrhosis, alcoholism, leukemia, lymphoma or disseminated carcinoma, cytotoxic chemotherapy and immunosuppressive drugs that cause neutropenia, total parenteral nutrition, a variety of surgical procedures, and infections arising from the urinary, biliary or gastrointestinal tracts. Gram-positive bacteremias are more often community acquired, except staphylococcal sepsis from indwelling intravenous catheters. Opportunistic fungal sepsis is most often seen in immunosuppressed patients with severe neutropenia, or in postoperative patients with intravenous catheters, and usually follows prolonged antibiotic therapy.

Pathogenesis and pathology

Most of the bacteria causing gram-negative sepsis are normal commensals in the gastrointestinal tract. From

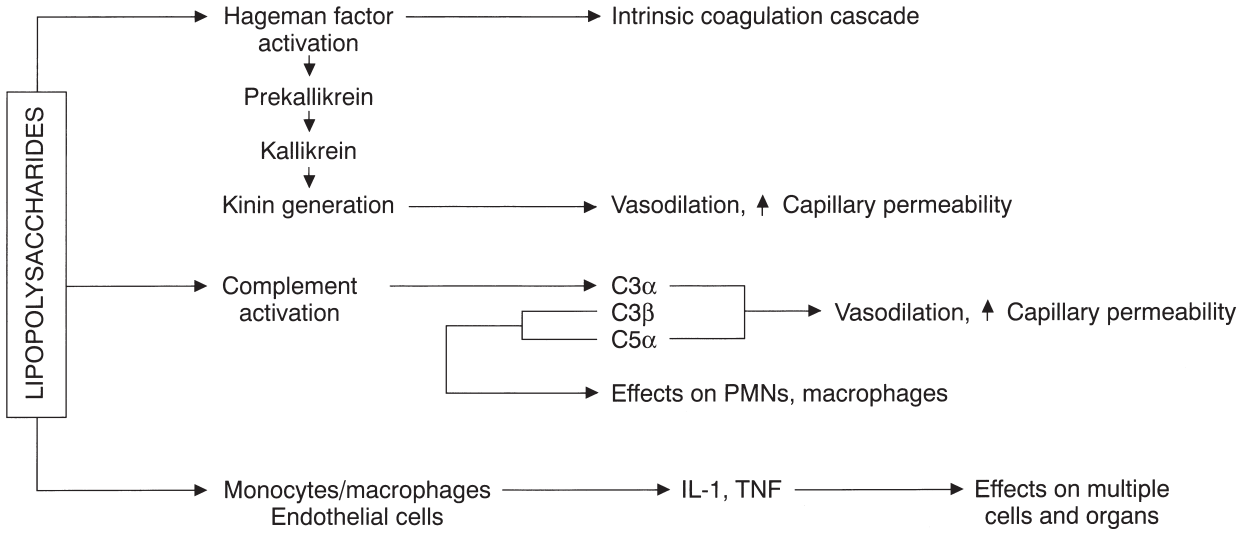

Figure 162.1 Schematized interactions between gram-negative lipopolysaccharides (LPS) and host humoral and cellular mediator systems in sepsis. PMNs, polymorphonuclear leukocytes; IL-1, interleukin 1; TNF, tumor necrosis factor-α.

there they may spread to contiguous structures, as in peritonitis after appendiceal perforation, or they may migrate from the perineum into the urethra or bladder. The genitourinary, gastrointestinal and biliary tracts or the lungs, are usually the primary sites from where gram-negative bacteremia starts, and less commonly from the skin, bones and joints. On the other hand, gram-positive bacteremias usually arise from the skin or respiratory tract. Bacteremia, mainly caused by gram-positive or anaerobic organisms, may be complicated by the formation of metastatic abscess.[2]

Pathophysiology

The classic clinical picture of septicemia and septic shock is a result of the interactions between microbial substances and host mediator systems. A vicious circle is established regarding vascular perfusion and organ function, which result in altered blood flow in the microcirculation and progressive injury to the capillary endothelium and tissues. Unless this circle is interrupted by control of the infection and correction of the hemodynamic and metabolic alterations, death usually results.

Microbial factors that are most important include gram-negative lipopolysaccharides (LPS), especially the lipid A component, peptidoglycans from gram-positive organisms, or mannan from fungal cell walls, certain polysaccharides and extracellular enzymes (e.g. streptokinase) or toxins (e.g. toxic shock enterotoxins of staphylococci). LPS, which has been studied thoroughly, seems to activate directly humoral or cellular systems, which in turn promote the development of the septicemic and shock syndromes, whereas other microbial products, although not as well defined, seem to affect the same systems in varying degrees.

Host mediators that have been associated with the pathogenesis of septic shock include active metabolites of the complement kinin, and coagulation systems as well as factors released from stimulated cells, in particular the cytokines, tumor necrosis factor-a (TNF) and interleukin-1, enzymes and oxidants from polymorphonuclear leukocytes (PMN), vasoactive peptides and products of the metabolism of arachidonic acid. In addition, the secretion and action of counterregulatory vasoactive catecholamines, angiotensin, pituitary hormones, insulin and glucagon all contribute to the clinical laboratory events in sepsis.

One of the proposed mechanisms involves the direct activation of both the coagulation and kinin systems by LPS through its effect on Hageman factor (Figure 162.1). The intrinsic coagulation cascade is activated, and increased amounts of factors XII, VIII and V, and fibrinogen are found. Plasmin is also generated by activated Hageman factor. Cleavage of prekallikrein to kallikrein by the activated Hageman factor leads to the production of bradykinin and related kinins, which are potent vasodilators, increase capillary permeability, and increase gastrointestinal motility. The complement system can also be activated by LPS and other microbial products and the generation of the anaphylatoxins C3α and C5α contributes to the vasodilation and increased capillary permeability. A reduction of C3 levels in septic shock has been associated with a fatal outcome. Effects on PMN include aggregation, increased adhesion to endothelial cells, promotion of lysosomal enzyme release and activation of the superoxide generating system. The activated PMN has enhanced bactericidal capabilities, and also the capability of damaging host tissues. The activated PMN possesses increased amounts of lysosomal enzymes and a variety of toxic metabolites of molecular oxygen, all of

which are both bactericidal and cytocidal. Also, the activated PMN produces both inflammatory prostaglandins and several products of the lipoxygenase system, many of which enhance inflammation by also producing vasodilation, capillary leakage and chemotaxis and PMN activation. The activated PMN adhere to each other (the leukopenic phase of sepsis during which PMN aggregates in capillaries) and to endothelial cells to cause severe damage and capillary leakage.

The production of TNF and interleukin-1 by macrophages, endothelial cells and perhaps other cells plays a central role in the multiple actions of LPS and other microbial products in sepsis.[3] Large doses of TNF in experimental animals produce all the systemic and pathologic features of LPS- or bacteria-induced septic shock, including hypotension, pulmonary injury with platelet and leukocyte thrombi and hemorrhagic necrosis of the intestine, acute renal failure, severe metabolic acidosis and death. Classic symptoms appearing in sepsis, such as fever, myalgia and somnolence follow administration of small amounts of recombinant TNF or interleukin-1 to human beings. Experimental studies have shown that these two cytokines act synergistically, contributing to many of the characteristic hormonal and metabolic changes seen in sepsis in human beings [hypoalbuminemia, hyperlipidemia and elevations in plasma adrenocorticotropic hormone, arginine vasopressin (AVP), growth hormone, cortisol, catecholamines, glucagons and insulin].[4]

Arachidonate metabolites also seem to participate in this complex process. Thromboxanes produced by activated platelets and PMN are platelet aggregating agents and induce pulmonary arterioral constriction. On the other hand, prostacyclins, which are formed by endothelial cells, are potent vasodilators and increase capillary permeability. Interleukin-1, TNF and LPS induce the production of these factors as well as of the classic prostaglandins. LPS can also cause the production, by various cells, of leukotrienes (which can induce asthma and pulmonary edema) and of the platelet activating factor, which is a vasodilator, increases capillary permeability and also has effects on PMN that duplicate those of the leukotrienes.[5]

After the initiation of this cascade process, the interactions between these varying contributing mediators become very complex. Endothelial cells and the microcirculation are major sites of reaction. There is evidence of cytotoxicity, precapillary shunting, the plugging of postcapillary venules, with PMN and platelet thrombi, and fibrin deposition. A generalized capillary leak syndrome appearing as pulmonary edema is a common event. Kinins, C3a, C5a, histamine released by mast cells, arachidonate metabolites, proteases and oxygen products released by activated neutrophils, monocytes and macrophages can all contribute to the vasomotor alterations characteristic of sepsis, and can participate in capillary damage. Tissue hypoxia and eventual cell death result from the disordered microcirculation.

Severe sepsis produces hemodynamic changes in two phases. Septic patients initially have hemodynamic changes primarily reflecting vasodilatation. Systemic vascular resistance is decreased, the pulse rate increases to compensate and cardiac output is dramatically increased. A state of cardiodepression exists during severe sepsis, and a circulating myocardial depressant factor (MDF) has recently been discovered. This MDF seems to be TNF. Septic patients develop a fall in cardiac ejection fractions to 20–25%, despite the markedly increased cardiac output. As this hyperdynamic state develops, complement-mediated leukoagglutination combines with other inflammatory mediators to cause a severe capillary leak, the intravascular volume decreases, the blood pressure falls and the cardiac output now further declines. Several additional factors contribute to the decline in cardiac output. Peripheral resistance increases in late septic shock, and other cardiodepressants participate, such as vasopressin and encephalin. Hyperventilation is a characteristic early response to sepsis, leading to varying degrees of respiratory alkalosis. Blood lactate concentrations rise early in sepsis, and in the late stages marked metabolic acidosis usually predominates.[6]

Individual organs may be damaged independently of the hypotensive events. Sepsis is the leading cause of ARDS. A progressively widening alveolar–arterial oxygen gradient and the appearance of diffuse pulmonary infiltrates on chest x-ray are characteristic features. ARDS develops in 20–45% of patients with severe sepsis, and it is associated with an 80–90% mortality rate, with complicating secondary pneumonias responsible for many of the deaths that occur late in the course.

Evidence of renal hypoperfusion or renal injury including oliguria, azotemia, proteinuria and the appearance of tubular and epithelial cells and coarse granular casts in the urine will be detected in the majority of patients. Late complications include acute tubular necrosis or, rarely, renal cortical necrosis as part of a generalized Shwartzman reaction.

The direct action of LPS as well as activation of platelet aggregation by multiple mechanisms seem to be responsible for the thrombocytopenia that is seen in up to 70% of patients with septicemia. Platelet counts below 50,000 μl are usually associated with evidence of DIC. Activation of Hageman factor and release of plasminogen activator from macrophages and endothelial cells also contribute to the appearance of this syndrome.

The syndrome of multiple organ failure has a central role in evaluating the damage that occurs during sepsis. Septicemia is the most important of a number of precipitating causes. Other causes include severe trauma, burns, pancreatitis and all other causes of shock. Once the syndrome is initiated, the patient

becomes febrile and hypermetabolic, exhibits hyperactive hemodynamic measurements and develops progressive failure of one or more organs. Mortality approaches 90% despite all modern therapeutic measures.

Clinical manifestations

Early phase

The abrupt onset of sepsis is characterized by fever and chills. However, up to 13% of patients may be hypothermic, with rectal temperature < 36.5°C at the onset of sepsis, and an additional 5% of patients who are not initially hypothermic may fail to mount a febrile response above 37.5°C. The absence of fever is seen primarily in the elderly and in those with underlying diseases such as alcoholism and uremia, and has been associated with a poor prognosis. The skin is warm and dry and a redness of the facial skin is usually observed. In the initial stages of sepsis, alterations in mental status may be subtle, with disorientation or personality change as the only manifestation. During this phase, which is called 'hyperdynamic' or 'warm', increased cardiac output and decreased peripheral resistance are observed due to the peripheral vasodilatation that afterward leads to hypotension and in general to a hyperdynamic circulation. Tachypnea follows, which results in respiratory alkalosis. The duration of this phase varies from 30 min to 16 h and the response to treatment may be satisfactory.

Late phase

A hypodynamic circulation ('hypodynamic' or 'cold' phase) characterizes this phase as a result of the hypotension and the hypovolemia due to the capillary leakage of fluids. Peripheral vasoconstriction follows, whereas the skin becomes cold, dry and cyanotic. Respiratory alkalosis is followed by metabolic acidosis. While increased lactate production by poorly perfused tissues may be a factor, reduced removal of lactate by the liver and kidneys appears to play a major role. In the late stages of septic shock, generalized hypoperfusion and the use of vasoconstricting pressors also aggravate the acidosis. Gastrointestinal manifestations are seen in approximately one-third of patients. They include nausea, vomiting, diarrhea or ileus. Upper gastrointestinal bleeding may occur, and rarely hemorrhagic necrosis of the bowel, which may be exacerbated by preexisting atherosclerotic disease. Mild to moderate jaundice may be present related to a sepsis-induced defect in bile secretion. Less frequently, shock-induced hepatic necrosis occurs. Also, later in the disease, more obvious changes of obtundation and coma may be present. Death is associated with refractory hypotension and persistently low systemic vascular resistance, progressive lactic acidosis and evidence of multiple organ failure (ARDS, DIC, acute renal failure and hepatic failure) despite administration of fluids, pressors and antibiotics.[7]

Laboratory findings

Several laboratory tests are often helpful in the evaluation of a potentially septic patient. There is usually leukocytosis with a left shift, but normal white blood cell counts and even leukopenia can occur. As white cells aggregate, platelets become caught up in the process. Thrombocytopenia is common, and when severe it is usually a sign of concomitant DIC, and is associated with a prolonged thrombin time, decreased fibrinogen level and elevated fibrin degradation products. Abnormalities in serum electrolytes can include an elevated anion gap with reduction of the bicarbonate concentration and metabolic acidosis. Liver function test abnormalities include modest hyperbilirubinemia and elevations of the transaminases that may be pronounced in severe shock. Hypoalbuminemia, mild at first, may progress as sepsis continues and malnutrition supervenes. Serum lipids are often elevated. Rarely, changes in serum calcium and phosphorus levels are seen. On urinalysis, mild abnormalities are seen, such as proteinuria, whereas with shock, acute tubular necrosis may develop with oliguria, azotemia and cellular or granular casts. In the initial stages of sepsis there is respiratory alkalosis and arterial blood gases reveal an elevated pH and decreased pCO_2. Serum lactate elevation is highly predictive of deterioration, leading to septic shock, and the blood may show hypoxemia and a metabolic acidosis. Chest x-ray abnormalities may include an underlying pneumonia as the source of sepsis, congestive heart failure as a result of myocardial depression and volume resuscitation or the diffuse infiltrates of ARDS. The electrocardiogram often shows non-specific ST–T wave abnormalities.

Diagnosis

The presumptive diagnosis of sepsis must be made when the setting and attendant clinical signs are suggestive. In general, patients with fever should be considered septic until proven otherwise. Therapy should always be initiated for high-risk febrile patients in advance before microbiologic confirmation of sepsis. The setting in which the episode is occurring should be evaluated promptly. Crucial to appropriate initial decision-making are the background history, which may help to define the type of host–defense defect present, and prior culture data, which might predict the infecting organism. The physical examination should be directed at quickly but thoroughly searching for the septic source as well as signs of end-organ failure that might indicate

progression to shock, such as altered mental status, progressive edema and hypotension. All potentially infected foci should be appropriately sampled, and the material obtained should be gram-stained and cultured. The diagnosis and etiology of sepsis is confirmed by finding pathogenic organisms in the blood or at other sites of infection. Other entities often confused with septic shock include myocardial infarction, pulmonary embolus, drug overdose, occult hemorrhage, cardiac tamponade, rupture of aortic aneurysm and aortic dissection.

Treatment

Management of the septic patient involves several stages. Determination and withdrawal of the source of bacteremia is essential, as removal or drainage of the source can turn a potentially fatal disease into an easily treatable one. Intravenous, Foley and drainage catheters should be checked and replaced if necessary.

The severity of the underlying disease influences the outcome of sepsis. Measures, according to the disease, should be undertaken in order to improve this outcome. For example, patients who are immunosuppressed by virtue of drugs or a disease will have an improved outcome if the immunosuppressive medication can be decreased or discontinued, or if the underlying disease can be effectively treated.

Support of respiration is necessary. Arterial oxygen should be monitored by pulse oximetry or by direct measurement. Oxygen should be provided nasally or by mask, sufficient to maintain arterial oxygen saturations in excess of 95%. If respiratory failure develops, intubation with mechanical ventilation should be employed.

Hemodynamic support should also be provided. Fluids should be administered as a measure against hypotension. It is not clear whether colloids or crystalloids are superior. Blood transfusions may be needed in cases of severe anemia. The pulmonary capillary wedge pressure should be maintained between 15 and 20 mmHg or the central venous pressure between 10 and 12 cm H_2O. Urine output should be kept above 20 ml/h. Mean arterial pressures > 60 mmHg are considered satisfactory in previously normotensive patients. About a third of patients will respond to fluid administration alone, with reversal of the hypotension; if volume resuscitation fails to increase blood pressure, pressor drugs should be given. Dopamine, dobutamine and norepinephrine are the agents most frequently used.[8]

Therapy of acidosis and DIC is required. Acidosis often resolves with therapy of the underlying infection and correction of hypoperfusion. If the pH falls below 7.20, sodium bicarbonate should be given. Treatment of the underlying infection is of critical importance in the management of DIC. Asymptomatic DIC (laboratory abnormalities only) or mild manifestations, such as ecchymoses or oozing at venipuncture sites, do not require specific therapy. If major bleeding is detected, replacement of clotting factors and platelets is essential.

Broad antibiotic coverage is required in patients with severe sepsis. Prior to the institution of antibiotics, blood cultures as well as cultures of relevant body fluids and exudates should be obtained. Identification of a portal of entry or localized site of infection can guide initial antibiotic therapy. When considering the choice of antibiotics prior to the availability of culture results, an antibiotic or combination of antibiotics should be chosen with activity against both gram-positive and gram-negative organisms. Once the results of the culture are known, therapy can be more specific.

Recently, two multicenter studies prospectively compared high doses of methylprednisolone sodium succinate (MPSS) with placebo in a blinded protocol in over 600 severely septic patients. Glucocorticoids were administered within 4 h of recognition of the septic event. Both studies showed no efficacy of MPSS and one study showed increased mortality in patients who had mild degrees of renal malfunction or who developed ARDS. Thus, glucocorticoid therapy has no proven role in the treatment of human sepsis.[9,10]

The use of anti-inflammatory drugs such as the antiprostaglandins is under active investigation. These agents may selectively suppress inflammatory damage caused by the activated PMN, without interfering with the antibacterial capabilities of these important host defense cells.

Naloxone, an opiate antagonist, has been used by several clinicians in the treatment of septic shock on the basis of the contribution of the endorphin system to hemodynamic instability. However, in primate models naloxone appears to increase blood pressure without leading to improved tissue perfusion. Also, data from small controlled trials in human sepsis have not documented any long-term benefits from naloxone administration.[11]

Administration of polyclonal antibodies directed at common core LPS antigens of the J5 mutants of *E. coli* has been shown to decrease mortality in patients with gram-negative bacteremia and septic shock and to prevent the development of shock when given prophylactically to high-risk patients. Immunotherapy for gram-negative sepsis is under investigation using monoclonal antibodies to core components of LPS and to TNF. Results are not yet available, but both techniques hold promise as a possible novel approach to therapy.[12]

Prognosis

Most febrile patients lacking other signs of severe sepsis will usually do well even when bacteremic. Such patients usually respond quickly to fluid administration, antibacterial therapy and drainage of

the primary focus of infection. However, the presence of shock and/or progressive dysfunction in any organ system significantly increases morbidity and mortality. Even when the inciting infection is localized, shock is associated with a 30–50% mortality rate. Full-blown bacteremia-associated septic shock has a greater than 50% mortality rate. Early diagnosis and treatment of severely septic patients decrease morbidity and mortality.

Prevention

Prevention of infection, especially in the hospital, is the key to reducing morbidity and mortality associated with septic shock. This fact emphasizes the need to limit invasive procedures, limit the use of intravenous lines, avoid Foley catheterization and practice good infection control at all times in an attempt to prevent the occurrence of these infections. The use of active and passive immunization against cell wall components of gram-negative organisms holds promise as a preventive measure in the future.

Bacteremia and septic shock in obstetric and gynecological patients

Infections that most commonly cause bacteremia and septic shock in obstetric patients are septic abortion, antepartum pyelonephritis and puerperal sepsis. Septic abortion most commonly refers to an infected, incomplete abortion, although some patients present prior to the passage of any products of conception. Therefore, any threatened, inevitable, or incomplete abortion associated with elevated temperature should be considered a septic abortion. Incomplete passage of the products of conception may follow spontaneous abortion, legal abortion or illegal abortion. The pathophysiology includes the ascending spread of microorganisms that are normally found in the upper vagina and cervix. Retained products of conception act as a nidus for the development of local infection, which can then lead to a more generalized sepsis. Bacteria migrating through the uterine wall via venous and lymphatic channels may produce cellulitis and abscesses in the broad ligaments and retroperitoneal space of the pelvic floor. Tubo-ovarian abscesses may occur as direct extensions of intrauterine infection. In severe cases, septic pelvic thrombophlebitis may result in multiple, small septic pulmonary emboli, bacteremia and metastatic infection to other organs.

The most common microorganisms isolated from both the blood and the uterine cavity are anaerobes and microaerophilic bacteria. Anaerobic gram-positive cocci are the most common isolates, but *Bacteroides* species and *Clostrodium* species can also play a major role in the pathogenesis of septic abortion. The most common aerobic isolates include *E. coli* and group B streptococci. Treatment involves the use of broad-spectrum antibiotics, uterine curettage and supportive therapy in severe cases. Hysterectomy is seldom indicated unless the uterus has been lacerated or is obviously intensely infected.

Acute pyelonephritis is the most common serious medical complication of pregnancy, occurring in 1–2% of pregnant women. In most women, renal parenchymal infection is caused by bacteria that ascend from the lower tract. Between 75% and 90% of renal infections are caused by bacteria that have P-fimbrial adhesions. The most common isolates include *E. coli*, *Klebsiella pneumoniae* and *Enterobacter* or *Proteus*. About 15% of women with acute pyelonephritis also have bacteremia. For women with pyelonephritis, continuing sepsis is usually from urinary obstruction caused by calculi or a perinephric abscess or phlegmon. Ureteral catheterization or percutaneous nephrotomy may be life-saving, and if this fails, surgical exploration may be indicated. In some cases end-stage pyelonephritis is found as a source of continuing sepsis and nephrectomy must be performed.

Puerperal sepsis may be caused by infection in the genital tract, by infection of the respiratory tract, pyelonephritis, thrombophlebitis and in cases of laparotomy by incisional wound abscess. Postpartum uterine infection, also called endometritis, is relatively common following uncomplicated vaginal delivery, but still continues to be a major problem in women delivered by cesarean section. In the majority of cases, bacteria responsible for pelvic infection are those that normally reside in the bowel and also colonize the perineum, vagina and cervix. Complications of uterine infections include wound infections, necrotizing fasciitis, peritonitis and septic pelvic thrombophlebitis. Treatment includes broad-spectrum antibiotics, and in cases where it is indicated, surgical intervention should be applied.

Among infections that most commonly cause bacteremia and septic shock in gynecological patients are pelvic inflammatory disease and postoperative infections. Pelvic inflammatory disease affects thousands of women every year. Microorganisms most commonly causally related to inflammatory disease include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Hemophilus influenzae*, *E. coli*, group B streptococci, anaerobes (*Peptostreptococcus* species, *Peptococcus*, *Bacteroides* species), *Mycoplasma hominis*, *Ureoplasma urealyticum* and *Actinomyces israelii*. Most cases are caused by an ascending infection. Usually, an endocervical infection exists and the microorganisms gain entrance to the endometrial cavity when the cervical mucus barrier to infection alters, either in conjunction with menstruation or through changes in the hormonal milieu. In the endometrium, the microorganism stimulates an inflammatory response. With continued canilicular spread, with help from a vehicle such as a sperm or by reflux of menstrual

blood into the fallopian tubes, the gonococcus reaches the tubes and peritoneal surface, stimulating inflammatory reactions. Pelvic inflammatory disease comprises cervicitis–endometritis–salpingitis–peritonitis and, in some cases, oophoritis with abscess formation occurs. Ambulatory management with antibiotics is applied in mild cases, and in-patient intravenous antibiotic treatment in severe cases.

Postoperative infections that may lead to sepsis include incisional infection, pelvic cellulitis, vaginal cuff abscess, pneumonia, pelvic abscess, septic thrombophlebitis, urinary tract infection and catheter sepsis. In wound infections the most common isolates include *Staphylococcus*, *E. coli*, *Proteus*, *Pseudomonas*, nonhemolytic *Streptococcus* and *Klebsiella*. Management includes opening of the incision, removal of all necrotic tissue and debris and frequent dressing drainages. Antibiotics are indicated when there is evidence of significant cellulitis, systemic signs suggesting bacteremia or signs suggestive of a necrotizing infection, or in high-risk patients (diabetes, patients under steroid treatment). Necrotizing wound infections are uncommon, but of life-threatening potential, demand prompt recognition and accurate therapy and do not resolve without surgical intervention. The incidence of soft tissue pelvic infections has decreased over recent years with the advent of prophylactic antibiotics; however, pelvic cellulitis remains a significant problem in gynecological surgery. Treatment includes antibiotics, and in cases where abdominal or pelvic abscess is suspected, drainage of the abscess, either percutaneously or through open laparotomy, is mandatory.

163 Gastrointestinal infections in pregnancy and neonates

I. Krause and S. Ashkenazi

Infectious gastrointestinal disease may have an impact on the course of pregnancy and its outcome. Several pathogens such as *Salmonella* and *Campylobacter* may cause bacteremia with secondary infection of the placenta and the fetus. Other microorganisms cause severe circulatory compromise due to dehydration and electrolyte imbalance, and may bring about fetal hypoxia.

Some infections in mothers can be transmitted during delivery, and later on by the fecal–oral route, to the neonate. Neonatal infections often have atypical presentation, with a more serious course. Breast feeding is of great importance as a preventive measure against many gastrointestinal infections. Special considerations should be made regarding antimicrobial therapy during pregnancy.

This chapter deals with several aspects of gastrointestinal infections during pregnancy and the neonatal period.

Salmonella species

Salmonellae are motile, gram-negative, non-capsulated, non-sporulating rods that belong to the family Enterobacteriaceae. The large number of different serotypes makes the classification of salmonellae somewhat confusing; therefore different systems have been suggested. There are three main groups of salmonellae, named by the species *Salmonella enteritidis*, *S. typhi*, and *S. cholerasuis*. These species are further divided into serogroups and serotypes according to principal antigens: flagellae (H) antigens, the cell wall (O) lipopolysaccharide antigen, and the envelope virulence (Vi) heat-labile antigens.[1]

Salmonellae are resistant to many physical agents, but can be killed by heating to 54.4°C for 1 h or 60°C for 15 min. They may remain viable for days and even weeks in sewage, dried food and fecal material.

The precise mechanisms of salmonellae virulence are not completely understood. Two-thirds of *Salmonella* strains produce enterotoxin immunologically related to cholera toxin, and this may explain the watery diarrhea often seen in *Salmonella* gastroenteritis. Salmonellae secrete several protein synthesis-inhibiting cytotoxines that are not immunologically related to the cytoxines produced by *Shigella dysenteriae* or *Escherichia coli* (mainly serotype O157:H7). The pathogenic role of these cytotoxins is unclear. The ability of salmonellae to survive inside the phagolyposomes of phagocytic cells due to the properties of their lipopolysaccharides has major clinical significance. It may explain treatment failure with antibiotics, which do not penetrate the phagolyposomes, prolonged fever even with adequate therapy, and relapses of the disease after apparent recovery.

Both humoral immunity and cell-mediated immunity are activated during *Salmonella* infection; it is thought that cellular immunity plays a more important role in eradication of the microorganism, because macrophages activated by T cells have the ability to kill intracellular bacteria.

Non-typhoid salmonellosis

Epidemiology

Salmonellosis is one of the most common gastrointestinal infections in humans worldwide. Salmonellae cause disease in animals as well, although most of the infections are asymptomatic. More than 500,000 culture-proven cases of salmonellosis are reported annually in the United States, and the actual estimated number is up to 4,000,000. The highest isolation rate is reported among infants less than 1 year of age. The incidence of *Salmonella* infection during the first year of life is about 75 cases per 100,000 infants. Meat, milk, poultry, and eggs are the main sources of *Salmonella*. Up to 50% of poultry, 5% of beef, 16% of pork, and 40% of frozen egg products contain *Salmonella*. Reptiles, particularly pet turtles, may serve as a source of the infection. In hospitals, *Salmonella* infection may be transmitted by contaminated food, personnel, inadequately sterilized equipment, and administration of animal extracts (pituitary, liver, pancreas, etc.). The occurrence of nursery outbreaks and intrafamilial infection suggests person-to-person spread.

Salmonella is rarely acquired by the neonate from the mother during delivery, but it can easily be transmitted to the neonate by infected mothers after delivery. The mother may be symptomatic or asymptomatic. Contaminated human milk, raw milk, formula, fomites such as delivery room resuscitators, rectal thermometers, oropharyngeal suction devices, and air condition filters may serve as reservoirs of *Salmonella*.[2] Once having entered a nursery, *Salmonella* is difficult to eradicate. Epidemics lasting for up to 30 months have been reported. The risk of the newborn becoming infected once *Salmonella* is introduced into a nursery may be as high as 20–27%.[2] The incubation period varies from 6 h to several days.

Outbreaks of salmonellosis may be widespread, and it is important to find the source of the infection. Outbreak tracing has improved with the development of molecular epidemiology techniques such as plasmid analysis and endonuclease digestion of chromosomal genes. After infection, non-typhoidal *Salmonella* are excreted in feces for a median of 5 weeks. Chronic carrier state is rare in non-typhoidal salmonellosis (< 1%) in healthy individuals, but occurs with higher frequency in young children and in patients with biliary disease or immune deficiency.

Pathogenesis

Ingested salmonellae enter the stomach. Gastric acidity provides the first protective barrier, as most organisms are killed at a pH of 2.0. Several factors may interfere with this protective effect: achlorhydria, buffering medications, and rapid gastric emptying. Neonates and infants have hypochlorhydria and rapid gastric emptying, and are therefore more susceptible to symptomatic salmonellosis.[3] Premature and low birth weight infants appear to be at higher risk of acquiring *Salmonella* infection than full-term infants.[4] Bacterial flora of the small and large intestines, which may be affected by antibiotic therapy, serve as an additional barrier to *Salmonella*. Decreased intestinal motility due to anatomic causes or medications prolongs the contact time of salmonellae with the mucosa and increases its pathogenicity.[1]

The organisms multiply within the lumen and then penetrate the mucosa, usually at the distal part of the ileum and the proximal part of the colon. Afterward, salmonellae enter the Peyer patches. Most non-typhoidal salmonellae remain within the lamina propriae and the local lymph nodes. *S. dublin* and *S. choleraesuis* may rapidly invade the blood stream with little intestinal damage. The ability to cause bacteremia is related to specific virulent genes, which are found in strains of *S. typhimurium*, although any *Salmonella* strain may produce bacteremia. Patients with impaired reticuloendothelial or cellular immune response such as chronic granulomatous disease and acquired immune deficiency syndrome (AIDS) are prone to *Salmonella* infections. Sickle cell anemia predisposes to *Salmonella* septicemia and osteomyelitis, probably due to multiple infarcts in the gastrointestinal tract, bones, and reticuloendothelial system. Chronic infections are more common in the presence of cholelithiasis and hepatosplenic disease caused by *Schistosoma mansoni*.

Pathology

Pathologic findings are consistent with enterocolitis and include diffuse mucosal inflammation, edema, erosions, and microabscesses. Penetration of mucosa by salmonellae does not usually cause destruction of epithelial cells, hence mucosal ulcers are not found. Polymorphonuclear cells and macrophages infiltrate the lamina propria. Enlargement of intestinal lymphoid tissue is seen; the reticuloendothelial system in the liver and spleen may undergo hyperplasia.

Clinical manifestations

Several clinical syndromes occur with non-typhoidal *Salmonella* infection.

Acute gastroenteritis

This is the most common presentation of non-typhoidal salmonellosis. In neonates and young infants there is an abrupt onset of nausea, vomiting, and crampy abdominal pain, followed by diarrhea, which may be watery or dysenteric – green, mucous- and sometimes blood-containing stools. Fever of 38.5–39°C is found in about 70% of patients. Abdominal examination may reveal tenderness, and mild leukocytosis can be detected. There are some differences in presentation of the disease depending on the *Salmonella* serotype. A few infants with *Salmonella* gastroenteritis develop necrotizing enterocolitis, although it is not clear whether *Salmonella* is the causative agent.[5]

The duration of symptoms is 2–7 days in healthy individuals. In neonates, young infants, and patients with immune deficiency, the disease may last for several weeks. In patients with AIDS, the infection may cause multisystem involvement, septic shock, and death.

Gastrointestinal complications of *Salmonella* infection include protracted diarrhea due to secondary carbohydrate intolerance, and non-specific chronic diarrhea associated with prolonged excretion of *Salmonella*.

Bacteremia

The precise incidence of bacteremia is unknown, and differs according to the age of the patient and the presence of risk factors. Prospective studies of infants in the first year of life suggest a risk of bacteremia of 1.8–6%.[6] Several retrospective studies have reported the risk to be as high as 30–50% during the first month of life.

Extraintestinal spread may occur in infants who initially present with diarrhea and in those without

gastrointestinal tract symptoms. Some serotypes of *Salmonella* are more invasive in the first 2 months of life than in older patients, for example, *S. newport*, *S. enteritidis*, *S. infantis* and *S. typhimurium*, but virtually any *Salmonella* serotype can cause bacteremia in neonates.

The spectrum of clinical signs and symptoms in patients with *Salmonella* bacteremia ranges from toxic appearance with high-grade fever and chills to good general condition and absence of fever;[7] enlarged liver and spleen are common. Certain underlying conditions put the patient in a high-risk group for bacteremia: neonates and infants (aged less than 3 months), AIDS and other immune deficiency states, malignancies, immunosuppressive or steroid therapy, hemolytic anemias, including malaria and bartonellosis, collagent vascular disease, inflammatory bowel disease, gastrectomy, achlorhydria or antacid medications, schistosomiasis, and malnutrition. Although infants with bacteremia may have spontaneous resolution without therapy, a sufficient number develop complications. The complications are most common during the first month of life.

In pregnancy, *Salmonella* septicemia may cause sepsis and fetal loss.[8] Two cases of *Salmonella* urinary tract infection during pregnancy have been reported.[9]

Extraintestinal focal infection

Salmonella may cause suppurative infection of almost any organ. The most common focal infections involve the skeletal system, meninges, and the endocardium. Endophthalmitis, hepatic abscesses, intra-abdominal abscesses, mastitis, pericarditis, peritonitis, pleuropneumonia, soft tissue abscesses, splenic abscesses and genitourinary tract infection, otitis media, cholecystitis, and infected cephalhemotoma have all been reported to be caused by *Salmonella*.[10] Endocarditis has rarely been reported in neonates. Meningitis is the most frightening complication. Of all cases of non-typhoidal *Salmonella* meningitis, 50–75% occur during the first 4 months of life.[11] The serotypes associated with neonatal meningitis are *S. typhimurium*, *S. heidelberg*, *S. enteritidis*, *S. sant-paul*, *S. Newport*, and *S. panama*. The presenting symptoms are vague: little or no fever, bulging fontanelle, and decreased appetite. Rapid deterioration and a high mortality rate (30–60%) occur despite appropriate antibiotic therapy. Relapse has been reported in up to 64% of cases. The survivors suffer from early and late neurologic sequelae including hydrocephalus, seizures, ventriculitis, abscess formation, subdural empyema, mental retardation, hemiparesis, visual impairment, and athetosis.

Asymptomatic infection

After clinical recovery from *Salmonella* gastroenteritis, asymptomatic fecal excretion of the organism occurs for several weeks. A chronic carrier state is defined as asymptomatic excretion of *Salmonella* species for more than 1 year. The precise incidence is not known, but the condition seems to be rare. Patients with biliary tract disease are prone to become carriers.

Diagnosis

Diagnosis is based on culturing the organism from stools, blood, cerebrospinal fluid, or aspirated specimens from sites of local suppuration. Selective media such as MacConkey, xylose-lysine decarboxylase (XLD), bismuth sulfite, or Salmonella–Shigella agar should be used for specimens normally containing bacterial flora. Two tests, based on latex agglutination and fluorescence, are commercially available for the rapid diagnosis of *Salmonella* colonies growing in stool culture.[1] Clinical experience is limited. An experimental method for rapid detection of *Salmonella* using chromosomal fragments, which are unique to the genus, as DNA probes, is under evaluation.[1] Serologic assays for detecting antibodies against *S. typhimurium* and *S. enteritidis* are available, although their clinical relevance is unclear. Because of the potential complications of *Salmonella* infection during pregnancy, bacteremia, fetal loss, and urinary tract infection, diarrheal disease during pregnancy should be evaluated for a possibility of *Salmonella* infection.

Prevention

Adequate food hygiene practices, chlorination of water, and hand washing are important for preventing salmonellosis. Hospitalized patients should be isolated. Proper sterilization of medical equipment should be performed.

Individuals with symptomatic or asymptomatic excretion of *Salmonella* need to be excluded from handling food and taking care of children until repeated stool cultures are negative. Control of the spread of *Salmonella* in humans requires control of the infection in animal reservoirs and use of appropriate food processing.

Breast feeding may prevent *Salmonella* infection by reducing the risk of contamination relative to other foods, especially in developing countries, and by class-specific antibodies against *Salmonella*.[12]

Treatment

The most important aspect of treating *Salmonella* gastroenteritis is supportive care, i.e. correction of dehydration and electrolyte and acid–base imbalances. Antimotility agents should be avoided because they prolong intestinal transit time and may increase the risk of invasion. Antimicrobial therapy is not routinely recommended in patients with uncomplicated *Salmonella* gastroenteritis, because it does not shorten the clinical course, or eliminate fecal excretion of *Salmonella*.

Antibiotics may suppress normal intestinal flora, prolong the excretion of *Salmonella*, and increase the

risk for chronic carrier state. Antibiotic therapy is indicated in infants of less than 3 months because of a high rate of extraintestinal complications, in patients with underlying conditions that increase the risk of a disseminated disease, and in those with a severe or protracted course of the disease. Patients with bacteremia or extraintestinal focal *Salmonella* infections should always receive antimicrobial therapy.

The choice of the antibiotic drug depends on the epidemiologic data, because antibiotic susceptibility of *Salmonella* differs significantly from region to region. In areas where *Salmonella* is susceptible to ampicillin, it is an effective agent (200 mg/kg/24 h in four divided doses, adults 2–12 g/24 h). Trimethoprim–sulfamethoxazole (TMP–SMX) is not recommended for use in neonates and pregnant women because of the risk of kernicterus. If chloramphenicol is used, serum levels must be closely monitored to avoid toxicity.

Increasing resistance of *Salmonella* to these three agents is reported from all over the world. For this reason, third-generation cephalosporins are used with increasing frequency. Cefotaxime 100–200 mg/kg/24 h in three to four divided doses (in adults 2–12 g/24 h) or ceftriaxone 50–100 mg/kg (in adults 1–4 g/24 h) in one or two divided doses are effective.

Quinolones, although effective, are not approved for use in children and in pregnant women because of the potential damage to growing cartilage. The dosage, route of application, and duration of therapy depend on the site and severity of the infection.

Acute gastroenteritis may be treated for 3–5 days by antibiotics given orally. Ceftriaxone may be given intramuscularly on an ambulatory basis. Patients with bacteremia are treated for 10–14 days intravenously, acute osteomyelitis warrants 4–6 weeks of therapy, and meningitis should be treated for 4 weeks intravenously with the highest recommended dosage.

Enteric fever

Enteric fever is a clinical syndrome produced by *S. typhi* (typhoid fever) and occasionally by other serotypes of *Salmonella*.

Epidemiology

The incidence of enteric fever has decreased in developed countries. In the United States, 400 cases of enteric fever are reported each year (incidence of less than 0.2:100,000). The incidence is similar in Western Europe and Japan. In southern Europe, the annual incidence is estimated to be 4.3–14.5 per 100,000. In developing countries, the incidence may be as high as 500:100,000. Every year 12.5 million cases occur worldwide according to the estimation of the World Health Organization. The disease is not common in neonates. Humans are the only natural reservoir of *S. typhi*. The most common mode of transmission is ingestion of food or water contaminated with human feces. Congenital transmission of the disease can occur by transplacental infection from a bacteremic mother to the fetus, while intrapartum transmission may occur by the fecal–oral route.[2]

Pathogenesis

The inoculum size required to cause disease is 10^5–10^9 for *S. typhi* organisms. Ingested organisms adhere to the microvilli of the ileal brush border, invade the epithelial cells, enter the intestinal lymph node follicles, and reach the mesenteric lymph nodes. Organisms enter the blood stream through the thoracic duct. Reticuloendothelial cells in the liver, spleen, and bone marrow are infected with circulating bacteria. Following proliferation in the reticuloendothelial system, the bacteremia recurs. The gallbladder is especially prone to infection.

Clinical manifestations

The incubation period is usually 7–14 days, but may be as short as 3 days and as long as 30 days.

Neonatal infection

Neonatal disease may begin within 3 days of delivery, with vomiting, diarrhea, and abdominal distension. Fever as high as 40.5°C may be present. Seizures, jaundice, anorexia, and weight loss may be seen. Hepatosplenomegaly can be found. Laboratory findings include low blood leukocyte counts, thrombocytopenia, disturbed liver function test results, and proteinuria. Fecal leukocytes or blood are common.

Complications include intestinal perforation and hemorrhage, myocarditis, central nervous system manifestations, hepatitis, cholecystitis, osteomyelitis, and arthritis. Pneumonia or bronchitis may occur.[13]

Infection during pregnancy

Enteric fever during pregnancy puts women at risk of aborting the fetus. In 1930, 64 pregnant women with typhoid fever were reported.[14] Fetal and maternal mortality rates of 26% and 60%, respectively, were noted. The rate of premature delivery was 25%. With prompt diagnosis and appropriate antibiotic therapy, pregnancy does not appear to put the woman at increased risk of death from enteric fever.[15] Premature labor and fetal death are reported occasionally, despite adequate antimicrobial therapy.[16,17] In one case of spontaneous abortion due to typhoid fever, extensive fetal necrosis was found.[15] Typhoid fever must be considered in the differential diagnosis of pelvic pain, urinary symptoms, and fever in pregnant patients. One case of typhoid cholecystitis, which required surgical intervention, has been reported.[18]

Diagnosis

Diagnosis is based on culturing. Blood cultures are positive in 40–60% of patients early in the course of the

disease.[1] Repeated blood cultures are recommended. Stool and urine cultures may become positive after the first week. Late in the course of the disease, when blood cultures are sterile, *Salmonella* may be found in bone marrow. Bone marrow culture is the most sensitive test (positive in 85–90%). *Salmonella* may be cultured in amniotic fluid, cervical swabs, and placenta in cases of premature labor due to enteric fever.[16,17]

New methods for rapid diagnosis include direct detection of *S. typhi*-specific antigens in the serum or urine by monoclonal antibodies and polymerase chain reaction (PCR).[1] Serologic tests are of little clinical value. The Widal test, which measures antibody titer against O- and H-antigens of *S. typhi*, is not sensitive or specific.

Prevention

Appropriate sanitation, hand washing, control of food production, and eradication of *S. typhi* from carriers are needed. Several vaccines (parenteral and oral) against *S. typhi* are available.[19] Parenteral heat-phenol-inactivated vaccine provides only limited protection (51–70%) and is associated with a high rate of adverse effects such as fever, headache, and local reactions. The most effective vaccine that is currently in use is an oral live-attenuated preparation of the Ty21a strain of *S. typhi*. The efficacy is 67–82%, and no significant adverse effects have been reported. This vaccine should not be used in immunocompromised patients, and is not recommended for children under 6 years because of limited experience. Infants do not seem to develop immune response with this preparation.

Treatment

Antibiotic therapy should be given to all patients with suspected enteric fever. Prompt antimicrobial treatment is of great importance during pregnancy, since it may prevent fetal loss and maternal morbidity. High resistance rates to many antibiotic drugs, including ampicillin, chloramphenicol, and TMP–SMX, are currently common worldwide. Resistant strains are usually susceptible to third-generation cephalosporins. Cefotaxime 200mg/kg/24 h (maximal dose 12g/24 h) intravenously, divided in three to four doses, and ceftriaxone (100 mg/kg/24 h, maximal dose 4 g/24 h) intravenously in one or two doses are effective in treating enteric fever. Ceftriaxone is used in pregnancy, although its safety has not been established. Fluoroquinolones are efficacious but currently not approved for use in children and pregnant women, although several authors recommend ciprofloxacin as a drug of choice for treatment of ampicillin-resistant typhoid fever during pregnancy.[20] Given orally, ciprofloxacin produces more rapid resolution of fever than parenteral ceftriaxone. A short course of dexamethasone, 3 mg/kg for the initial dose, followed by 1 mg/kg every 6 h for 48 h, has been shown to improve the survival rate of patients with shock. Supportive treatment is needed to correct fluid and electrolyte imbalance. Attempts to eradicate chronic carriage of *S. typhi* are recommended. A course of 4–6 weeks of high-dose ampicillin or amoxycillin with probenecid results in an 80% cure rate. In the presence of biliary disease, the eradication is difficult and sometimes cholecystectomy is recommended.

Shigella species

Shigellosis is the clinical illness caused by bacteria of the genus *Shigella*, which belong to the family Enterobacteriaceae.[21] Shigellae are gram-negative rods that are non-motile and do not ferment lactose or do so slowly. They are divided into four species or serogroups: *Shigella dysenteriae*, serogroup A; *Shigella flexneri*, serogroup B; *Shigella boydii*, serogroup C; and *Shigella sonnei*, serogroup D. The species differ in their geographic distribution. *S. sonnei* is the most common species in developed countries, where its relative prevalence is increasing.[21] In developing countries, *S. flexneri* is most frequent, with outbreaks that are often caused by *S. dysenteriae.*

Shigellosis has worldwide distribution, and the organisms spread through the fecal–oral route. Because of the low infectious dose – 10–200 organisms can transmit the disease – person-to-person transmission of shigellosis is common. However, transmission by contaminated food, drinking water, swimming pools, and flies has been documented.[21] Seasonality in the incidence of *Shigella* infections is well documented. In temperate climates, including the United States, the peak incidence of shigellosis is during summer and early fall; in the tropics the disease peaks in the rainy season.

The major virulence trait of shigellae is their ability to invade mammalian cells. This ability depends on a 120–140-MDa plasmid, which encodes the synthesis of several polypeptides that are necessary for invasion.[21] Several chromosomal loci are needed to regulate the invasion polypeptides and for complementary virulence traits. Of particular importance are loci encoding the synthesis of bacterial lipopolysaccharide, which is mandatory for full virulence and determines the serotype of *Shigella*.

Shigella strains excrete several toxins. Best known is Shiga toxin, which is produced mainly by *S. dysenteriae* serotype 1 and plays a major role in the complications of shigellosis.[22] Shiga toxin is capable of damaging mammalian cells by inhibiting protein synthesis. Two *Shigella* enterotoxins have recently been identified, cloned, and sequenced; additional toxins are probably produced.

Clinical manifestations

Shigellosis is characterized by acute diarrhea, which develops after an incubation period of 1–2 days. The illness often starts as watery diarrhea and in about

half of the patients then progresses to bloody or mucous stools. Diarrhea is usually accompanied by high fever, generalized toxicity, anorexia, and vomiting. Defecation is painful, with urgency. When untreated, diarrhea usually lasts about 1 week. More prolonged diarrhea and even chronicity have been described in immunocompromised patients, especially those with AIDS and malnourished infants. The disease caused by *S. dysenteriae* type 1 is usually more severe. Physical examination during the acute disease may show abdominal distention, tenderness, and hyperactive bowel sounds.

Although usually self-limited, several complications of shigellosis may develop. Intra-abdominal complications include ileus, toxic megacolon, pseudomembranous colitis, perforation with local abscesses, and cholestatic hepatitis.

Neurologic symptoms are among the most frequent extraintestinal manifestations of shigellosis, mainly in children. Of these, convulsions are the best documented, developing in 12–45% of hospitalized children with culture-proven shigellosis.[21] Seizures are usually benign, self-limited, and have no neurologic sequelae. Other neurologic symptoms include lethargy, confusion, severe headache, and hallucinations, and are often referred to as encephalopathy. Fatal outcome can occur. The pathogenesis of *Shigella*-associated neurologic symptoms is not clear.

Septicemia is occasionally seen in patients with shigellosis. A study in Bangladesh found *Shigella* bacteremia in 4% of patients. Septicemia with other enteric bacteria is also found during shigellosis, probably secondary to the damaged gut and loss of the intestinal barrier function. Focal extraintestinal infections of *Shigella* include vaginitis, cystitis, conjunctivitis, iritis, arthritis, and pneumonia. Reactive arthritis and Reiter syndrome may develop.

Especially with *S. dysenteriae* type 1 infection, hemolysis, hemolytic uremic syndrome, and thrombotic thrombocytopenic purpura may develop. It is thought that damage to endothelial cells by Shiga toxin is the initial event in pathogenesis.[22]

Shigellosis in pregnancy and neonates

Shigellosis is relatively rare in neonates and young infants. This is related, at least in part, to protecting maternal antibodies that are transferred through the placenta and by breast feeding.[21] According to published series, less than 4% of *Shigella* cases occur during the first 3 months of life and less than 2% in the neonatal period.[23,24] Of the neonatal *Shigella* cases, more than half occur within 3 days of birth, suggesting fecal–oral transmission during parturition. Haltalin found that in 11 of 16 neonates with shigellosis, the mothers or other family members had clinical diarrhea, sometimes with isolation of *Shigella* species from their stools.[24] Infection from asymptomatic mothers can sometimes occur. Intrauterine infection with *Shigella* is rare; Armor described chorioamnionitis caused by *S. sonnei*, with transmission of the infection to the neonate as pneumonia.[25]

Shigellosis in the neonatal period has distinct clinical characteristics. As compared to older children and adults, neonates with shigellosis usually have low-grade (< 39°C) fever or are afebrile, a lower rate of typical bloody diarrhea, and often abdominal distention.[23,24,26] Lethargy, general toxicity, and feeding difficulties are more frequent in neonates.[24]

Complications are relatively frequent in neonatal shigellosis. Hypothermia, electrolyte imbalance, especially hypernatremia, acidemia, and dehydration are seen.[23] Toxic megacolon, necrotizing enterocolitis, and perforation may develop.[26–28] Chronic diarrhea leading to malnutrition may be seen.[27]

Development of septicemia is of particular importance. *Shigella* bacteremia has been reported to occur in 12% of infants younger than 3 months who had shigellosis,[23] with the rate in neonates even higher.[24,29] Bloodstream invasion with *Shigella* has been reported in an asymptomatic newborn infant.[29] Two neonates have been reported with *Shigella* meningitis.[23,30]

Data on age-related mortality during *Shigella* infections show a particularly high fatality rate during the neonatal period. In the series of Huskins and colleagues, five of 24 (21%) neonates with shigellosis died, and in infants younger than 3 months the mortality rate was over 16%.[23] It has been estimated that in developing countries the mortality rate of neonatal shigellosis is over 50%.[24]

Diagnosis

Culturing is the cornerstone in the diagnosis of neonatal shigellosis, particularly because of the atypical presentation of the disease in this age group. Shigellosis should be suspected not only in neonates with diarrhea, but also in those who look septic and in those presenting with shock and abdominal symptoms suggesting necrotizing enterocolitis, midgut volvulus, and intussusception. A history of diarrhea in the mother or other family members is important.

Stool, but also blood and when relevant cerebrospinal fluid, specimens should be obtained for culture. Culture media should include MacConkey agar as well as selective media such as xylose-lysine decarboxylase (XLD) and Salmonella–Shigella agars. After growth, the species (serogroups) are identified by agglutination. Identification of *Shigella* by culture takes at least 2–3 days, and the yield of stool specimens is relatively low. New techniques for more rapid and possibly more sensitive diagnosis include DNA probes, PCR, and antigen detection methods. These, however, are still being developed.

Treatment

Correction of fluid and electrolyte disturbances is always the mainstay in treating patients with diarrhea. Particular attention should be given to neonates with

shigellosis who are more likely to develop dehydration, hypernatremia, hypoglycemia, and acidemia.

Appropriate antibiotic therapy has been shown to be efficacious in shigellosis. Clinically, it shortens the duration of fever, diarrhea, and general toxicity; bacteriologically, fecal excretion of shigellae is stopped in a few days. Complications are probably decreased by antibiotics.

The major problem is the increasing antimicrobial resistance of *Shigella* species worldwide. Oral TMP–SMX, in daily doses of 10 mg/kg of trimethoprim and 50 mg/kg of sulfamethoxazole, divided into two doses, is the usual recommended therapy.[21] TMP-SMX is not recommended in young infants because of the potential risk of kernicterus, nor is it recommended during pregnancy. In addition, in certain geographic locations, high rates of TMP–SMX resistance of shigellae have been reported.

When epidemiologic or laboratory data suggest susceptibility to ampicillin, it can be used orally or parenterally, according to the condition of the patient. The daily dose is 100 mg/kg divided into four doses. Chloramphenicol treatment, with careful monitoring of blood levels, may be considered. Third-generation cephalosporins, and especially ceftriaxone (50 mg/kg/day in a single dose), are adequate alternatives, especially for the more severe cases. Although efficacious, quinolones are not approved for use in children (< 17 years) because of potential damage to the growing cartilage.

Antimotility agents, such as diphenoxylate and atropine, can prolong the duration of fever, diarrhea, and fecal excretion of the pathogen in patients with shigellosis, and should therefore not be used when shigellosis is suspected. Intestinal motility with constant fluid flow may actually be an important host defense mechanism for rapid clearance of the infection.

Prevention

Breast feeding can reduce the risk of *Shigella* infection in early infancy or lessen its severity. It should be especially recommended in developing countries, where *Shigella* infections are more frequent and have a significant impact on nutrition and growth.[21] Because person-to-person transmission of shigellosis is common, strict personal hygiene, and especially hand washing after defecation or diaper changing, and before food preparation and consumption, is mandatory. In developing countries, running water and closed sewage systems are important. Several approaches to the development of *Shigella* vaccines are currently under investigation.

Yersinia enterocolitica

Yersinia are gram-negative bacilli of the family Enterobacteriaceae. Adherence to the intestinal epithelial cells and production of heat-stable enterotoxin produce watery diarrhea. Cytotoxin secreted by *Yersinia* causes ulcerative ileocolitis with mesenteric adenitis. Pathogenic strains require iron and survive only in red-blood-cell-containing products. Patients with hemochromatosis or after accidental overdose of iron are susceptible to septicemia with *Yersinia*.[31]

Epidemiology

Animals, food, and water are the major reservoirs of *Yersinia enterocolitica*. Swine, cattle, goats, dogs, and cats are the most common carriers of this organism. Transfusion-transmitted *Y. enterocolitica* infection has been reported. The risk of transfusion-associated disease increases with blood stored for over 2 weeks. Person-to-person transmission may occur by the oral–fecal route. Infection occurs primarily in children and young adults.

Clinical manifestations

Infection with *Y. enterocolitica* has not been reported in association with complications during pregnancy. Neonatal infection with *Y. enterocolitica* is rare.[32] Infants present either with watery diarrhea or with stools containing mucus and blood. Bacteremia and sepsis are common (20–30%) in infants younger than 3 months,[33] and meningitis is rare. Complications include erythema nodosum, hemolytic anemia, thrombocytopenia, and reactive arthritis.

Diagnosis

Diagnosis is based on culturing the organism. *Y. enterocolitica* can be recovered from stool, throat swabs, peritoneal fluid, blood, and mesenteric lymph nodes. Stool culture should be performed on *Yersinia*-selective agar and incubated at reduced temperatures. It is worthwhile to keep the culture for longer periods. Isolation from body fluids that do not normally contain bacteria (blood, cerebrospinal fluid) may be made on routine media.

Distinction between pathogenic stool strains and nonpathogenic ones may be made by Congo red–magnesium oxalate agar and certain biochemical tests. Antibody titers against *Y. enterocolitica* can be measured but are useful for epidemiologic purposes only.

Prevention

Appropriate means of preparing food, especially meat, pasteurization of milk, and hand washing, may prevent transmission of *Y. enterocolitica*. Human milk might inhibit adhesion of *Y. enterocolitica*.[34]

Treatment

Antibiotic therapy is indicated in culture-proven septicemia, in patients less than 3 months with gastroenteritis, who have a high rate of septicemia. Otherwise, uncomplicated enterocolitis due to *Y. enterocolitica* in previously healthy patients is a self-limited disease and the benefit of antimicrobial treatment has not

been established. Aminoglycosides in combination with third-generation cephalosporins, or TMP–SMX, are effective against *Y. enterocolitica* infections.

Vibrio cholerae

Vibrio cholerae are gram-negative, non-spore-forming, curved, motile rods with a polar flagellum. There are many serotypes of *V. cholerae*, but only *V. cholerae* 01 and 0139 (Bengal) cause epidemics. *V. cholerae* 01 is divided into two serotypes, Inaba and Ogawa, and two biotypes, classical and E1 Tor.[35]

Epidemiology

V. cholerae is found in warm, salty water, roots of plants, and shellfish. Person-to-person transmission is rare. Epidemics of cholera still occur worldwide. In 1991, epidemic of cholera appeared in South and Central America. In 1992, strains of a new serotype 0139 caused an outbreak in Madras (now called Chennai), India.

Pathophysiology

In order to cause disease, vibrios, which are acid-sensitive, must overcome the stomach barrier and reach the small bowel. Vibrios adhere to the mucous layer and produce proteolytic enzymes. Virulence of *V. cholerae* is mainly due to production of enterotoxins. The most important of these toxins is cholera toxin, a large heat-labile protein containing a single A subunit and five B subunits. B subunits are responsible for toxin binding to the enterocyte membrane ganglioside GM1, and the A subunit is an adenosine diphosphate (ADP)-ribosyltransferase, which causes elevation of cyclic adenosine monophosphate (cAMP) levels. cAMP decreases the active absorption of sodium and chloride by villous cells and increases active secretion of chloride by crypt cells. Another toxin produced by *V. cholerae* alters the intracellular tight junctions and increases the permeability of intestinal mucosa to water and electrolytes. A third enterotoxin is an ion-transporting ATPase. These three enterotoxins are coded by chromosomal genes.

Clinical manifestations

The most common clinical presentation is watery diarrhea and vomiting. The incubation period varies from 6 h to 5 days. Fever may be present. In severe cases, there is profuse diarrhea with 'rice water' consistency and fishy odor. Dehydration may cause circulatory collapse, acidosis, impaired consciousness, electrolyte imbalance, and renal failure.

Pregnancy

Cholera during pregnancy, especially in the third trimester, is associated with a high incidence of fetal death.[36] Bacteremia is unusual with cholera, and it has not been found in cultures of placenta and aborted fetuses. Miscarriage is probably attributed to fetal acidosis and hypoxemia resulting from the marked metabolic and circulatory changes in the sick mother. Risk of stillbirth is correlated with the severity of maternal disease.[2]

Neonatal cholera

Neonatal cholera is rare. Even infants born to mothers with active diarrheal disease may not be infected.[37] Several factors may contribute to the low rate of infection in newborn infants. Breast feeding provides effective protection due to the existence of specific antibodies against *V. cholerae*,[38] receptor-like glycoprotein that inhibits adherence of the bacteria,[39] and gangliosides that bind cholera toxin.[40] The limited exposure to contaminated food and water further reduces the neonatal risk of acquiring cholera.

Diagnosis

Two selective media are used to culture *V. cholerae*: thiosulfate–citrate–bile–sucrose (TCBS) and tellwrite–taurocholate–gelatin agar (TTGA). Specific antibody tests and DNA probe methods for direct detection in stool samples are available. Vibriocidal, agglutinating, and toxin-neutralizing antibodies may be found 7–14 days after the onset of illness, though providing only retrospective diagnosis.

Prevention

Breast feeding is the most practical method of prevention in infants. Proper handling of food and water are needed to prevent epidemics. A vaccine composed of killed bacteriae given parenterally is currently available.[1] The efficacy of this vaccine is about 50% by 3–6 months after vaccination. It has a high frequency of adverse reactions (pain, erythema, local induration, fever, headaches). The vaccine is not recommended for children under 6 months of age. New vaccines using combinations of killed whole cells with cholera toxin B subunit, live recombinant organisms, or synthetic peptides are under investigation.

Treatment

The most important purpose in treating cholera is correction of fluid and electrolyte imbalance. Oral rehydration solution (ORS), recommended by the World Health Organization and containing 90 mmol/l Na^+, 20 mmol/l K^+, 80 mmol/l ClV^-, 111 mmol/l glucose, and 30 mmol/l bicarbonate, has been shown to be highly effective. When fluids cannot be given orally, parenteral fluid and electrolyte replacement should be provided.

Antibiotics, although of secondary importance in treating cholera, shorten the duration of the illness. TMP–SMX and tetracycline are effective, but these agents are not recommended for use in pregnancy and

the neonatal period. Alternative therapy may consist of ampicillin.

Campylobacter species

Etiology

Campylobacter is a curved gram-negative rod. The genus *Campylobacter* includes 15 species, and 8 of them are considered pathogenic for humans: *C. jejuni*, *C. fetus*, *C. coli*, *C. hypointestinalis*, *C. laridis*, *C. cinaedi*, *C. fennelliae*, and *C. upsaliensis*. *Campylobacter* organisms are microaerophilic, with optimal growth at 5–6% oxygen. The growth in blood culture may take as long as 5–14 days after the initial inoculation.[41]

Epidemiology

Campylobacter is one of the most common causes of bacterial gastroenteritis worldwide. In the United States, isolation rates of this organism range from 28 to 71 per 100,000 annually. The most common pathogen of gastroenteritis is *C. jejuni*. *C. coli* and *C. laridis* cause gastrointestinal infections as well. Extraintestinal and systemic infections are associated with *C. fetus*. *Campylobacter* gastroenteritis is more common in children under 17 years of age, with the highest incidence in the first year of life. The second peak occurs in adolescents and young adults. Infection may be asymptomatic. The mode of transmission is zoonosis. The gastrointestinal tract of many domestic and wild animals such as chickens, turkeys, young dogs and cats, and waterfowl serve as the main resevoir of infection. *Campylobacter* is transmitted from animals to persons by the fecal–oral route, by ingestion of contaminated meat, milk, or water. The inoculum needed to cause disease is between 2×10^2 and 10^4 organisms.

Perinatal and person-to-person transmission may occur, although it is much less common. Communicability is greatest during the acute phase of the illness, and may last as long as 2–3 weeks. Chronic carriage is uncommon. Homosexual men are at increased risk for *C. cinaedi* and *C. fennelliae* infections.[2]

The organism is often carried asymptomatically in the intestinal or biliary tract of sheep and cattle. It has a high affinity for placental tissue, and during bacteremia in pregnancy it may invade the uterus and multiply in the fetus. The infected fetuses are usually aborted. It is not clear whether humans acquire *C. fetus* only from animals or from asymptomatic human carriers who transmit it venereally. *C. fetus* infections predominantly occur in older men with a history of animal exposure, and in pregnant women during the third trimester.[42]

Pathogenesis

Mucosal invasion is mediated by bacterial surface proteins. *Campylobacter* produces cytotoxins, and some strains of *C. jejuni* secrete cholera-like enterotoxin. *C. fetus* contains a surface protein capsule that inhibits opsonophagocytosis and enables the pathogen to reach the reticuloendothelial system and bloodstream.

Clinical manifestations

Pregnancy

Infection with *Campylobacter* is an uncommon cause of abortion and premature labor.[42] Although *C. fetus* is most frequently implicated as a pathogen in cases of septic abortion,[43] invasion of the amniotic cavity causing abortion by other strains of *Campylobacter*, such as *C. coli*, *C. upsaliensis*, and *C. jejuni*, has also been reported.[44–47]

Infection with *C. fetus* is usually associated with mild or no symptoms during pregnancy, but often leads to premature labor[43] and may cause recurrent abortions. Cervical cultures remain positive in women who have recurrent abortions and whose husbands have a high titer of antibodies to *C. fetus*.[48] Prolonged febrile illness with bacteremia and pneumonitis in the third trimester of pregnancy has been reported.[2] Unless appropriately treated, symptoms usually resolve only after abortion or delivery of an infected fetus.[42]

Campylobacter infection should be actively sought for in pregnant women with suspected infectious diarrhea, because it may lead to stillbirth and perinatal infection.[47,49] Diarrhea caused by *C. jejuni* consists of loose, watery stools or blood and mucus-containing stools. Fever, vomiting, abdominal pain, malaise, and myalgia are common. The incubation period is 1–7 days. Most patients recover in less than 1 week, but illness may last longer in immunocompromised hosts. Fecal excretion of the organisms in untreated patients usually lasts for 2–3 weeks, but may last as long as several months. Young children tend to shed the organisms for longer periods.

Perinatal infection

Maternal *C. fetus* and *C. jejuni* infections may cause neonatal sepsis and meningitis.[50] The infected neonates, who are often premature, develop signs suggesting sepsis, including fever, cough, respiratory distress, vomiting, diarrhea, cyanosis, convulsions, and jaundice. Newborn infection with *C. jejuni* is associated with diarrhea that may be bloody.[51] Focal infections caused by *C. jejuni*, such as pancreatitis, cholecystitis, urinary tract infection, arthritis, and peritonitis, may occur in neonates.

Late complications

Guillain–Barré syndrome has been reported 1–3 weeks after culture-proven *C. jejuni* gastroenteritis. Serologic studies suggest that 20–40% of patients with Guillain–Barré syndrome have evidence of recent infection with *C. jejuni*.[41] Other late immunoreactive complications

include arthritis, erythema nodosum, hemolytic anemia, and immune complex glomerulonephritis.

Diagnosis

The diagnosis is based on identification of *Campylobacter* in cultures. Selective media such as Skorrow's or Batzler's media are used. Rapid diagnosis of *Campylobacter* enteritis may be made by direct carbolfuchsin stain of fecal smear, indirect fluorescence antibody test, dark field microscopy, or latex agglutination. Diagnosis with species-specific DNA probes and gene amplification by PCR have been described.

Prevention

Proper food handling and hand washing after contact with animals decrease the risk of infection with *Campylobacter*.

Breast feeding protects against infectious diarrhea caused by *C. jejuni*. Specific immunoglobulin A antibodies have been found in human milk.[52]

Treatment

Erythromycin (50 mg/kg/24 h, maximal dose 500 mg × 4/day for 5 days) is the drug of choice for treatment of *C. jejuni* and *C. coli* infections. Antibiotic therapy significantly shortens fecal excretion of *Campylobacter*. Erythromycin resistance has been reported. Antibiotic treatment should be given to patients with the dysenteric form of the disease, high-grade fever, pregnant women and immunocompromised hosts. Infections with *C. fetus* require parenteral antibiotic therapy for 3–4 weeks. Gentamicin is the recommended drug until antibiotic susceptibility is proven.

Parasitic infections: *Entamoeba histolytica*

Etiology

Infection is caused by ingestion of parasite cysts that exist in the small intestine to form trophozoites. Trophozoites colonize the lumen of the large intestine and may invade the mucosa.

Epidemiology

Humans are the major reservoir. It is estimated that 12% of the population worldwide is infected with *E. histolytica;* symptomatic disease occurs in 1–17% of infected subjects. Chronically institutionalized persons, homosexual men, and lower socioeconomic groups are at increased risk of acquiring *E. histolytica*. The most common modes of transmission are consumption of food or water contaminated with cysts, and direct fecal–oral contact.

Clinical manifestations

Intestinal amebiasis is the most common form of the disease. The presentation may be with gradual onset of bloody mucous diarrhea and abdominal pain. Fever is found in one-third of patients and constitutional symptoms are usually absent. Complications include extraintestinal spread, local perforation, and peritonitis.

Hepatic amebiasis occurs in 1% of infected individuals, usually in patients with amebic colitis, although it may appear in patients with no clear history of intestinal disease. Hepatic amebiasis presents with fever, abdominal pain, and enlarged, tender liver. Elevation of the diaphragm may be seen on chest x-ray examination. Leukocytosis, anemia, and elevation of liver enzymes may be present.

Pregnancy

Amebiasis is known to be more severe and even fatal in pregnant women.[53] This is thought to be due to several factors, including high progesterone levels[54] and failure of immunoglobulin levels to rise during infection.[55] Pregnant women are more susceptible to hepatic amebiasis as well. Several cases of rupture of amebic liver abscesses and peritonitis during pregnancy and puerperium have been reported.[56] Hepatic amebiasis may cause premature delivery,[56] but early diagnosis and adequate treatment results in successful outcome of the pregnancy. Vertical transmission of *E. histolytica* has not been reported. Infection in neonates probably results from ingestion of fecal material at birth, from oral fluids given as a supplement to breast feeding, or from close contact with infected mothers. The disease in newborns may be severe.[57]

Diagnosis

This is based on detecting the organisms in stool samples, tissue biopsy samples, and aspirates of a liver abscess. At least three stool samples should be examined, within 30 min of passage. In patients with hepatic amebiasis, stool cultures are negative in 50% of the cases. Indirect hemagglutination test is used to detect antibody titer.

Treatment

Intestinal amebiasis may be treated with iodoquinol, which is a luminal amebicide and has been used in pregnancy, apparently without causing fetal harm.[58] Invasive amebiasis of the intestine, liver, or other organs should be treated with metronidazole, a tissue-amebicidal drug. The use of metronidazole in the first trimester of pregnancy is controversial, although several studies have described the safe use of metronidazole in pregnancy.[58] Since invasive amebiasis is a

life-threatening disease, particularly in pregnancy, and metronidazole is the drug of choice for this condition, the benefit of use outweighs the risk.

Small hepatic abscesses may be treated with metronidazole alone, but larger abscesses should be treated with transabdominal aspiration. If rupture is suspected, laparotomy is essential and life-saving.

Other parasitic infections

Infections with several protozoa including *Giardia lamblia*, *Cryptosporidium* and *Isospora belli* may cause diarrheal disease in neonates. Adverse effects in pregnancy have not been reported. Breast feeding is believed to protect against symptomatic infection.[2]

164 Central nervous system infections in pregnancy

E. Rubinstein and B. Rubinovitch

Introduction

Central nervous system (CNS) infection in a pregnant woman is the result of the same expected epidemiological and predisposing factors that operate in CNS infections in non-pregnant adults. Chances for CNS invasion and disease are generally very low, even for a pathogenic microorganism that is more likely to colonize and infect women during pregnancy and/or the puerperium (e.g. *Listeria monocytogenes*, streptococcus group B).

Infections of the CNS are divided into different clinical syndromes according to the principal site of the infection within the CNS (meningitis, encephalitis and myelitis) and with regard to the time course of the disease (acute or chronic). The distinction between syndromes is clinically useful in guiding management, but is artificial in terms of etiology and pathology.

In this chapter are discussed the principal CNS infectious syndromes, with emphasis on aspects unique to pregnancy, mainly the impact of infection, disease and therapy on the fetus and the newborn.

Meningitis

Meningitis is an inflammation of the subarachnoid space and is identified by an abnormal number of white blood cells in the cerebrospinal fluid (CSF). The acute meningitis syndrome is characterized clinically by the sudden onset of symptoms (high fever, headache, photophobia, stiff neck and altered mental status) over a course of hours or days. It may be caused by a wide variety of infectious agents: bacteria (including rickettsiae, spirochetes and mycobacteria), viruses, fungi and protozoa, and may also be a manifestation of non-infectious diseases. Most commonly, it is caused by viruses (aseptic meningitis) or bacteria. Chronic meningitis typically has a gradual onset of symptoms and signs (over weeks to months) and the patient is more likely to present a picture of chronic general debility, as well as having symptoms referable to the CNS.[1]

Acute bacterial meningitis

Epidemiology and microbiology

Bacterial meningitis remains an important disease worldwide. Despite the development of new and more effective antimicrobial agents, the overall case fatality rate remains about 25%. Nowadays, the three most common meningeal pathogens in adults with community-acquired meningitis are *Streptococcus pneumoniae, Neisseria meningitidis* and *L. monocytogenes*, with pneumococci and meningococci accounting for half of the cases. Uncommon pathogens are *Staphylococcus aureus*, streptococci (groups A, B, D), *Haemophilus influenzae* and gram-negative bacilli.[1,2]

Pathogenesis

Nasopharyngeal colonization of a typical meningeal pathogen *(S. pneumoniae, N. meningitidis, H. influenzae)*, which is asymptomatic, usually precedes meningitis. Mucosal invasion and bacteremia follow colonization, depending on the interplay between specific virulence factors and host defense mechanisms. Meningeal invasion occurs due to unknown mechanism(s). Bacterial replication in the subarachnoid space and release of bacterial components initiate subarachnoid space inflammation (i.e. meningitis).[1]

Clinical presentation

Two-thirds of the patients have the classical triad of fever, nuchal rigidity and change in mental status, ranging from confusion to lethargy and coma. Ninety percent have headache. Seizures (occurring in 30% of patients), and focal cerebral signs (10–20%) are the result of inflammation and thrombosis of subarachnoid blood vessels, causing cortical and subcortical ischemia. Cranial nerve palsies, especially those involving cranial nerves III, IV, VI and VII (10–20%), develop as the nerve becomes enveloped by exudate in the arachnoid sheath surrounding it. Isolated palsy of cranial nerve VI may be a sign of increased intracranial pressure. Other signs of elevated intracranial

Table 164.1 Normal CSF composition, and composition with bacterial meningitis

CSF parameter	Normal value	Typical value in bacterial meningitis
Opening pressure (mmH_2O)	50–180	> 180
White blood cell count	< 4/mm^3	1000–5000/mm^3
Neutrophilic percentage	1%	> 80%
Protein level (mg/dl)	20–45	100–500
Glucose level (mg/dl)	40–70	< 40
Lactate level (mg/dl)	10–20	> 35

CSF, cerebrospinal fluid

pressure are coma, hypertension and bradycardia. Papiledema is seen in 1% of cases. Unilateral pupil dilatation, due to involvement of the parasympathetic fibers of cranial nerve III, heralds transtentorial brain herniation.

Accompanying signs and symptoms may suggest a specific etiologic diagnosis. Rash is noted on admission in 10% of patients, of whom two-thirds have meningococcal meningitis.

An obvious primary focus of bacteremia is found in more than half of the adults with community-acquired meningitis, and the most common are pneumonia, acute otitis media and sinusitis.[1]

Characteristics of CSF

Diagnosis of bacterial meningitis rests on examination of the CSF by lumbar puncture. Typical findings are elevated opening pressure, neutrophilic pleocytosis, elevated protein level, hypoglychorrachia and elevated lactate level.[1] Pregnancy by itself does not alter normal CSF composition and pressure. Typical CSF findings are presented in Table 164.1.

Many patients with bacterial meningitis have atypical CSF findings (e.g. lymphocytic predominance, normal glucose value, slightly elevated protein level, very low CSF white blood cell count), therefore a Gram stain and cultures should be performed on all spinal fluid specimens regardless of the composition.

Microbiological evaluation

Gram stain examination of CSF identifies accurately the causative microorganism in 60–90% of all cases. It is less sensitive for meningitis caused by gram-negative bacilli or *L. monocytogenes*. In addition, sensitivities of Gram stain and culture are reduced by prior antibiotic use. Latex agglutination assays for detection of bacterial antigens in CSF currently detect the antigens of *S. pnuemoniae, H. influenzae, N. meningitidis*, streptococcus group B and *Escherichia coli* K1. Sensitivity ranges from 50–90%, depending on the kit used.[1]

Initial management of a patient suspected to have bacterial meningitis

Bacterial meningitis should be considered in the differential diagnosis of a febrile patient with any of the following: meningeal signs, change in mental status, headache, photophobia, convulsions and/or focal neurological signs, petechial rash or close contact with patients with meningitis. In suspected bacterial meningitis, performance of lumbar puncture is mandatory.

The timing of performance of lumbar puncture, head and brain computed tomography scan and initiation of antibiotic therapy depend on the following factors:

Pattern of onset: In approximately 20% of cases, patients become critically ill within hours. Others develop meningeal symptoms over several days. In critically ill patients, and whenever results of lumbar puncture cannot be obtained in 30 min, empirical antimicrobial therapy may precede lumbar puncture and should be given immediately after obtaining blood cultures. Whenever possible, consultation with an infectious diseases expert, an internist or an intensivist should be sought.

Presence of papilledema or other signs of elevated intracranial pressure: A simple method to reduce intracranial pressure is elevation of the head of the bed to 30°, to maximize venous drainage with minimal compromise to cerebral perfusion. Hyperventilation and use of manitol should be performed by experienced personnel.

Presence of focal neurologic signs or seizures: More than 50% of patients with focal findings (excluding ophthal-moplegia) or seizures have evidence on computed tomography scan of an intracranial abnormality (i.e. cerebral edema, hydrocephalus, subdural effusion or empyema, cavernous sinus thrombosis, abscesses). Because of the potential risk of brain herniation, computed tomography scan of the head should be performed prior to lumbar puncture if the above signs are present.[1,3]

Table 164.2 Specific antimicrobial therapy of bacterial meningitis in adults

Microorganism	Standard therapy	Dosage per 24 h
Streptococcus pneumoniae		
Penicillin MIC < 0.1 mg/ml	Penicillin G	4×10^6 U × 6
Penicillin MIC 0.1–1.0 mg/ml	Ceftriaxone or	2 g × 2
	Cefotaxime	2 g × 4–6
Penicillin MIC ≥ 2.0 mg/ml	Vancomycin plus	1 g × 2–3
	ceftriaxone or cefotaxime	As above
	±rifampicin	600 mg × 1
Neisseria meningitidis	Penicillin G	4×10^6 U × 6
Haemophilus influenzae		
β-Lactamase negative	Ampicillin	2 g × 6
β-L actamase positive	Ceftriaxone or cefotaxime	As above
Listeria monocytogenes	Ampicillin or penicillin G	As above
	±gentamicin	3–5 mg/kg
Streptococcus agalactiae	Ampicillin or penicillin G	As above
	±gentamicin	3–5 mg/kg

MIC, minimal inhibitory concentration

Recommended empirical therapy is aimed against the most common pathogens (i.e. *S. pneumoniae, N. meningitidis*). Currently, the drug of choice is a parenteral third-generation cephalosporin.[1,3] Penicillin should be added whenever certain risk factors for *L. monocytogenes* meningitis exist. Specific recommendations are given in relevant sections and are summarized in Table 164.2.

Adjunctive corticosteroid therapy

As described earlier, subarachnoid space inflammatory response is a major factor contributing to morbidity and mortality. Recent evidence has indicated that antibacterial agents initially potentiate cerebral inflammation, by causing bacterial lysis and discharging bacterial components that accelerate release of cytokines. This has renewed interest in adjunctive therapies such as corticosteroids. Ample data support the routine use of dexamethasone in infants and children with bacterial meningitis. In adults, the benefits of steroids are currently less certain. However, adults with severely impaired mental status, documented cerebral edema or markedly elevated intracranial pressure, as well as patients with a high CSF bacterial concentration, may benefit from adjunctive dexamethasone. For optimal effect, the first dose of dexamethasone should be administered shortly before or concomitantly with the first dose of antibiotics. Recommended dosage is 0.15 mg/kg intravenously every 6 h for 4 days or 0.4 mg/kg every 12 h for 2 days.[1,3]

S. pneumoniae meningitis

Pneumococci are encapsulated gram-positive, lancet-shaped diplococci. This is a major respiratory pathogen, frequently colonizing the nasopharynx of normal adults and healthy children. *S. pneumoniae* is the most common etiologic agent of bacterial meningitis in adults, accounting for a third of cases.[1] Specific immunodeficiencies and chronic diseases predispose to severe pneumococcal infections. The most relevant for women of childbearing age are absent or hypofunctioning spleen and acquired immunodeficiency syndrome (AIDS). In addition, patients with previous head trauma, CSF leak, or a break in the integrity of the dura, have a unique predisposition to recurrent meningitis caused by pneumococci.[1,2] Africans seem to have a peculiar susceptibility to severe pneumococcal infections, including pneumococcal meningitis. An unexplained association of pneumococcal meningitis with pregnancy and the puerperium was recorded in Nigeria in the early 1960s.[4]

Clinical manifestations

Pneumococcal meningitis in pregnancy has no distinctive clinical or laboratory features. Fever, headache, nuchal rigidity and altered mental status are common. One-third of patients have seizures. Most cases occur in late pregnancy and the first week of the puerperium. Apparent sources of infection are pneumonia and purulent otitis media or sinusitis as expected, but a high percentage have primary bacteremia. Although *S. pneumoniae* is only occasionally isolated in puerperal or postabortal sepsis,[5] ascending infection of the female genital tract may be relevant as a source of bacteremia and meningitis in some cases of puerperal and postabortal meningitis. The fatality rate for maternal pneumococcal meningitis is 27%, and is correlated with obtunded mental status. In Nigeria, hyperthermia (body temperature above 41°C) was found to be a bad prognostic sign. About half of the survivors have neurologic sequelae (i.e. deafness, hemiparesis and cranial nerve palsies and cognitive

impairment).[4] Rates of mortality and neurological morbidity in adults with pneumococcal meningitis have not decreased much in the last 30 years,[1,2] reflecting the severe damage caused by the subarachnoid inflammatory process. In severe maternal pneumococcal disease, overall fetal loss is 45% (abortion, stillbirth and early neonatal death).[4,5] Whenever pregnancy continues to term, newborns survive. Neonates of mothers with puerperal pneumococcal meningitis may also develop pneumococcal meningitis, pneumonia and/or sepsis.[6] Mode of transmission is either transplacental (hematogenous spread) or through a colonized birth canal. Neonatal pneumoccocal disease has an early onset and carries a grave prognosis.[5] The mortality rate is 48% and of the survivors 13% are left with neurologic sequelae. Fatal maternal meningitis may spare the newborn, as seen in a rare case of successful postmortem cesarean section in fulminant pneumococcal meningitis.[7]

Diagnosis

Examination of a gram-stained specimen of CSF provides the correct diagnosis unless antibiotic has already been administered. In the latter case latex agglutination assay for detection of pneumococcal capsular antigen is useful. Cultures of CSF specimens, blood and any other relevant material (e.g. from the genital tract) should always be performed.

Treatment

Penicillin can no longer be recommended as empirical therapy in suspected pneumococcal meningitis due to an increasing frequency of penicillin resistance in pneumococci. A parenteral third-generation cephalosporin is recommended pending results of susceptibility tests (see Table 164.2). Optimal therapy for meningitis caused by pneumococci highly resistant to penicillin [i.e. minimal inhibitory concentration (MIC) greater than 1 mg/ml] is a subject of debate. Currently, vancomycin and a third-generation cephalosporin are recommended. Some authorities advise the addition of rifampicin (RMP).[1,3] Penicillin G and the cephalosporins (first, second and third generation) are considered safe in pregnancy. Data on the use of vancomycin in pregnancy are limited; however, no toxicity was demonstrated in a small controlled study of infants exposed in the second and third trimesters. RMP has caused teratogenic effects in rodents treated with high doses, and is probably best avoided during pregnancy.[1,8] The duration of antimicrobial therapy is 10–14 days.[1,9]

N. meningitidis meningitis

Meningococci are gram-negative encapsulated diplococci. Strain serogrouping is based on capsular polysaccharides. Serogroups A, B and C are the most important clinically, while current commercial vaccines contain polysaccharides of groups A, C, Y, and W-135, and are effective in 90% of recipients 2 years of age or older. *N. meningitidis* is the second most common cause of community-acquired bacterial meningitis, accounting for 13–20% of cases. In epidemics, meningococci are more likely to be implicated than pneumoccoci as a cause of meningitis. Patients with deficiencies in the terminal complement components have a markedly increased incidence of meningococcal diseases. However, the vast majority of patients with meningococcemia and/or meningitis have an intact complement system.[1]

Clinical manifestations

Meningococcal infections are capable of diverse presentations, which range from transient fever and bacteremia to fulminant disease with circulatory collapse and death ensuing within hours of the onset of clinical symptoms. Meningeal or neurological signs do not distinguish meningitis caused by meningococci from meningitis caused by other etiologies. The most important clinical finding is the rash, which is typically petechial, but can be purpuric or sometimes maculopapular. The presence of petechiae in conjugation with purulent meningitis has a very high sensitivity and specificity rate for *N. meningitidis* meningitis. Lesions are found on the trunk, lower portions of the body, the face and mucous membranes, and new petechiae may appear during the physical examination.

Shock, heart failure and disseminated intravascular coagulation are complications of overwhelming meningococcemia and are associated with poor prognosis.[1]

Meningococcal meningitis in pregnancy is apparently uncommon.[10] In one study, meningitis occurred in late pregnancy, and the newborns were delivered while the mothers were acutely ill. One newborn died immediately, although there was no evidence of infection; the mothers survived.

Diagnosis

CSF examination provides the diagnosis in 50–90% of cases. Blood cultures are positive in 50% of cases. Latex agglutination assays are useful when prior antibiotic has been administered. Bacterial antigens can be detected longer in the urine than in other body fluids, and concentrated urine specimens, in addition to CSF, should be studied for antigen in such patients.[1]

Treatment

Penicillin G is the treatment of choice for meningococcal meningitis.[1,3] Strains of meningococci that are relatively resistant to penicillin have emerged, but their clinical significance is unclear. For penicillin-allergic patients a third-generation cephalosporin is an alternative. Duration of therapy is 7 days.[9]

Antibacterial prophylaxis

Therapy to eliminate asymptomatic nasopharyngeal colonization is recommended for all intimate contacts

of the index case (household and nursery-school contacts). The index case should also receive therapy to eradicate nasopharyngeal carriage (after completion of therapy for meningitis), unless treated with a cephalosporin.[1] RMP, 600 mg for adults or 10 mg/kg for children, 12 hourly for 2 days, is used as prophylaxis. An alternative for pregnant women is a single dose of intramuscular ceftriaxone 250 mg.

Vaccination

Vaccination with the quadrivalent meningococcal vaccine is recommended during outbreaks of disease caused by the serogroups represented in the vaccine preparation. Vaccination is not contraindicated in pregnancy.[1]

L. monocytogenes meningitis

L. monocytogenes is a gram-positive bacillus that is widespread in nature. Outbreaks are associated with consumption of contaminated food, but most cases are sporadic. *L. monocytogenes* is the third most common cause of community-acquired bacterial meningitis in adults, accounting for 10% of cases.[1,2] Patients susceptible to listeriosis are those with suppressed T-cell-mediated immunity, serious underlying diseases, the elderly, and pregnant women and their offspring.[1,11]

Clinical manifestations

Listeria infection of the CNS manifests either as fulminant bacterial meningitis or as subacute meningoencephalitis. Meningitis in pregnancy occurs rarely, although listeriosis associated with pregnancy accounts for a third of all cases. It is not known why CNS invasion occurs very rarely in pregnant women, but does occur in half of the cases not associated with pregnancy.[1,11–13] *Listeria* meningitis in immunocompromised hosts has a mortality rate of 20–40%; in previously healthy adults the risk of mortality is very low. All pregnant women reported with *Listeria* meningitis have survived. While serious illness in the mother is rare, transmission to the fetus and neonate causes serious diseases with high mortality rates. Fetal loss is high with early intrauterine infection, and perinatal mortality rates are 20–50% for the 'late' form. The devastating illness granulomatosis infantisepticum is almost always fatal.[1,11,13]

Diagnosis

CSF findings do not distinguish between *Listeria* and other bacterial etiologies of meningitis. CSF Gram stain for detection of *L. monocytogenes* has a low sensitivity, but the organism will usually grow on appropriate culture media.[1]

Treatment

The treatment of choice for *Listeria* meningitis is either penicillin or ampicillin in sufficient dosages[1] (see Table 164.2). The addition of gentamicin is based on laboratory data only. Duration of therapy should be 14–21 days.[9] For penicillin-allergic patients, trimetoprim–sulfamethoxazole is an alternative. Sulfonamides should not be administered during the last month of pregnancy due to increased risk of kernicterus in the newborn. The teratogenicity of trimetoprim is not clearly defined.[1,8]

Standard empirical therapy for bacterial meningitis in the adult would be a third-generation cephalosporin (see above), an antimicrobial agent to which *Listeria* is inherently resistant. Taking into account the rarity of *Listeria* meningitis in pregnancy, it is suggested that penicillin need not be added routinely to the standard empirical treatment of bacterial meningitis in the otherwise healthy young pregnant woman.

Streptococcus agalactiae meningitis

S. agalactiae [group B streptococcus (GBS)] is a gram-positive coccus, which frequently colonizes the genitourinary tract and lower gastrointestinal tract of pregnant women. GBS is an important cause of maternal postpartum infections, as well as bacteremia and meningitis, in the neonate.[1] It is a rare cause of meningitis in adults, representing < 1% of etiologic agents, with most affected patients having severe underlying diseases.[14]

Clinical manifestations

The presentation is similar to that of other types of acute bacterial meningitis, with a high incidence of neurological dysfunction. Cases of postpartum GBS meningitis are reported rarely,[14] occurring during the first 2 days postpartum. In contrast with an overall mortality rate of 27% for GBS meningitis in adults, all parturient women recovered. Mortality rates of neonatal GBS infections have decreased to 2–8% in term infants, but a significant number of the neonates surviving GBS meningitis will suffer neurologic sequelae.[1,14]

Diagnosis

CSF Gram stain and culture provide the diagnosis in 90% of cases. Concomitant bacteremia is frequent.

Treatment

High-dose penicillin G is the drug of choice for GBS meningitis in adults; addition of gentamicin is based on *in vitro* synergy. Duration of therapy is 14–21 days.[1,14]

Acute viral meningitis

Enteroviruses (echoviruses and coxackieviruses)

Echoviruses and coxackieviruses group B are currently the leading recognizable causes of the acute aseptic meningitis syndrome.[1] These are RNA viruses, members of the Picornaviridae family, with a worldwide distribution.

Epidemiology

Most cases occur in children and young adults. There is a marked summer/fall seasonality, but infection may occur at any time.

Clinical manifestations

Fever, headache, meningismus, nausea, vomiting and photophobia are common. There may be accompanying non-specific signs and symptoms such as rash, diarrhea, upper respiratory findings and myalgia. Illness is sometimes biphasic, with fever and myalgia present for a few days, followed by defervescence and absence of symptoms for 2–10 days before the sudden reappearance of fever and headache signaling the onset of meningitis. Duration of illness is usually less than 1 week, and most children and adults recover uneventfully without sequelae. Seizures, lethargy and coma or full-blown encephalitis occur in less than 5% of cases. A more severe meningoencephalitis may be seen in neonates (and in individuals with deficient humoral immunity that impairs clearance of enteroviruses). In such cases morbidity and mortality are considerable.[1]

Enteroviral meningitis complicating pregnancy is a rare occurrence.[15] Specific echovirus and coxackievirus serotypes are usually responsible for severe, frequently fatal disease in the perinatally infected neonate.[1] Ample experimental evidence indicates that the fetus is relatively protected during maternal infection by the placenta, but the newborn has the highest risk of infection. Thus, the most critical factor determining the outcome of neonatal enterovirus infection is the timing of maternal infection in relation to the development of maternal virus-specific immunoglobulin G antibodies and delivery of the infant.

Diagnosis

CSF parameters are aseptic meningitis with lymphocytic pleocytosis (10–1000 cells/mm^3), mildly elevated CSF protein and usually normal glucose level. Early in the course there may be polymorphonuclear neutrophil predominance and it may be difficult to exclude bacterial meningitis on the basis of CSF analysis alone. Diagnosis is based on enterovirus isolation from stools, nasopharyngeal swabs and CSF. Serology is useful only to confirm diagnosis for specific type.

Treatment

No specific antiviral therapy exists. In cases of severe neonatal disease (as in the rare cases of chronic enterovirus meningoencephalitis in agammaglobulinemic patients), high doses of intravenous immunoglobulin have been reported to improve outcome.[1]

Human immunodeficiency virus

Human immunodeficiency virus (HIV) causes acute aseptic meningitis syndrome associated with the acute retroviral syndrome in 5–10% of cases. Onset of illness ranges from 1 to 6 weeks after exposure to the virus. Clinical manifestations are non-specific, with fever, headache, photophobia and meningismus. Typical CSF findings show mild lymphocytic pleocytosis (20–300/mm^3), mildly elevated protein and normal or slightly decreased glucose.

Diagnosis is based on detection of HIV p24 core antigen in serum and CSF, since the enzyme-linked immunosorbent assay (ELISA) for HIV antibodies remains negative for an average of 2–3 months.[1]

For management strategies regarding HIV-infected pregnant women, the reader should consult HIV authorities.

Acute viral encephalitis

Enecephalitis is an inflammation of the brain. Acute encephalitis associated with viral infections includes two distinct clinico-pathological diseases: acute viral encephalitis of which the most important etiologies are herpes simplex virus type 1 (HSV-1), and the arthropod-borne viruses (arboviruses), and postinfectious encephalomyelitis, with the number of cases decreasing greatly since the institution of immunization against measles, mumps and rubella.[16] Important issues in the differential diagnosis of encephalitis are to rule out non-viral diseases (which may require urgent treatment) and to properly identify cases due to HSV-1, where morbidity and mortality can be greatly reduced with specific antiviral therapy.

Herpes simplex encephalitis

HSV-1, a member of the Herpesviridae family, is the commonest cause of localized sporadic encephalitis in otherwise healthy adults and children.

Clinical manifestations

The distinctive pathology, localization of inflammation and necrosis to the temporal and frontal lobes, determines the clinical manifestations. Signs that suggest a localized lesion in one or both temporal lobes are present in 90% of patients.[16] This may manifest itself as personality changes, bizarre behavior and hallucinations, which can dominate the clinical picture for a few days before other signs evolve. Onset may be abrupt or insidious. Fever, headache and altered consciousness are very common. Other focal findings (seizures, dysphasia, hemiparesis, autonomic dysfunction, ataxia and cranial nerve palsies) occur in 30–80% of the cases The course in untreated patients is usually one of rapid deterioration, over several days, to coma and death. Therapy reduces the mortality rate from 70% to 19%, but patients may suffer severe neurological sequelae, even with early specific treatment.[1,16]

HSV encephalitis in pregnancy is rare, but carries significant morbidity and mortality for the mother

and fetus. Only a few cases that were treated with acyclovir have been reported, and most had a favorable outcome, for both the mother and the fetus.[17]

Diagnosis

CSF findings are abnormal in more than 95% of patients. Typical findings are mildly elevated protein level, lymphocytic pleocytosis and normal glucose level. Red blood cells are found in 20–50% of cases.[16] Computed tomography scan may show a low-density abnormality in one or both temporal lobes, but is less sensitive than magnetic resonance imaging (MRI) for detecting focal findings, especially early in the course of the disease. The electroencephalogram is always abnormal but its specificity is low.

The 'gold standard' for diagnosis is brain biopsy, with appropriate histologic and cultural techniques. Non-invasive diagnostic tests such as viral culture of CSF, and CSF and serum serology have unacceptably low sensitivity and/or specificity regarding therapeutic decisions. Newer diagnostic tests [e.g. ELISA for CSF antigen detection and polymerase chain reaction (PCR) assay of CSF] appear to be highly sensitive and specific but are not widely available.[16]

It is generally accepted that even with extensive clinical experience, the accuracy of the diagnosis of HSV encephalitis is only 50% by using clinical judgment, spinal fluid examination and imaging. Should all patients with suspected HSV encephalitis be biopsied? In view of the disastrous nature of the disease, the effectiveness of the available treatment and its low toxicity (see below), empirical acyclovir treatment is justified in most cases of acute sporadic encephalitis in the normal host.[1,16]

Treatment

Acyclovir is currently the drug of choice for HSV encephalitis.[1] Dosage is 10 mg/kg intravenously every 8 h for 14 days. Dosage should be modified with renal function impairment. Use of acyclovir during pregnancy was not found to be teratogenic in animal studies.[1] Human experience with high intravenous dosages during the first trimester is lacking. No adverse reactions for the fetus have been reported when the drug has been used during the third trimester.[17]

Arbovirus encephalitis

The term arbovirus refers to viral pathogens transmitted by arthropod vectors (mosquito or tick). More than 20 arboviruses cause human encephalitis. Each has a specific geographic distribution, is associated with a different ratio of inapparent to clinical infections and causes encephalitis of variable severity.[16]

Japanese encephalitis virus is the causative agent of the most important arbovirus encephalitis worldwide. The virus is a member of the Flaviviridae family and is widely distributed in Asia. Most human infections are asymptomatic, with only 1 in 300 infections resulting in typical encephalitis.[16]

Clinical manifestations

Illness begins with non-specific febrile prodrome lasting several days, followed by abrupt onset of encephalitis with focal spastic paralysis, most commonly of the upper extremities, cranial nerve palsies and extrapyramidal signs. After 2–4 days, patients begin to improve or deteriorate rapidly. The case-fatality rate is 25% and neurological sequelae occur in up to 70% of the survivors.[1,16] In pregnant women infected during the first or second trimester, spontaneous abortion and fetal death have been documented, and the virus has been isolated from the conceptus. The risk of transmission during the third trimester is not known.[1,18]

Diagnosis

Typical CSF findings are lymphocytic pleocytosis, mildly elevated protein level and normal glucose level. Imaging studies of the brain (MRI and to a lesser degree computed tomography) may show abnormalities in basal ganglia and the brain stem. Specific diagnosis is serologic, by means of virus-specific immunoglobulin M ELISA, performed on CSF or on paired (acute and convalescent) sera.

Treatment and vaccination

No specific antiviral treatment exists. However, an inactivated whole virus vaccine is available and is indicated for travelers to endemic or epidemic areas. The vaccine is 90% effective and is not contraindicated in pregnancy.[1]

Tuberculous meningitis

Tuberculosis is caused by *Mycobacterium tuberculosis*, an acid-fast bacillus, for which humans are the only reservoir. In developed countries tuberculosis has emerged as an important problem since 1985, due to a combination of interrelated factors, namely illicit drug abuse, urban homelessness and the AIDS epidemic.[1] Tuberculosis in pregnancy has been a topic of concern and controversy for many decades.[1,19] Currently, it seems that the impact of pregnancy on tuberculosis is minimal, except for potentially obscuring the diagnosis and possibly increasing the risk of disease activation during the postpartum period. Tuberculous meningitis in adults is usually caused by rupture of a quiescent subependimal tubercle into the subarachnoid space. Less often, it is a complication of milliary tuberculosis (i.e. hematogenous spread).

Clinical manifestations

Usually, illness is subacute in presentation, and begins with a prodrome of malaise, intermittent headache and low-grade fever, followed within 2–3 weeks by protracted headache, vomiting, confusion, meningismus and focal neurologic signs.

The clinical spectrum is broad, ranging from chronic headache or subtle mental status alteration to sudden

and severe meningitis progressing to coma.[1] Tuberculous meningitis in pregnancy tends to occur during the postpartum period or late pregnancy. The clinical presentation is often of chronic meningitis. Mortality and neurological morbidity are correlated with delay in diagnosis and initiation of appropriate therapy.[20] There is no evidence that tuberculosis affects the course of pregnancy. Intrauterine transmission of tuberculosis is very rare.[19] The neonate is at risk of acquiring tuberculosis postpartum if born to a mother with open pulmonary tuberculosis.[1,19]

Diagnosis

Findings on physical examination, chest x-ray films and extraneural cultures are often not helpful. The initial tuberculin skin test is negative in more than half of the patients.

The cornerstone of diagnosis is examination of the CSF. Characteristic findings are lymphocytic pleocytosis (occurring in three-quarters of patients), hypoglycorrhachia (with initially normal glucose value in many patients) and elevated protein level. CSF smears are positive for acid-fast bacilli in a minority of cases on initial examination, but when four consecutive smears from lumbar punctures are examined, the sensitivity approaches 90%. Cultures are positive in the majority of cases, but growth takes 10–21 days. Newer rapid diagnostic tests include various antibody and antigen detection assays, but these are currently not widely available. The PCR to detect mycobacterial DNA in CSF has limitations due to the high rates of false-positive results.[1]

Treatment

Modern therapy for tuberculous meningitis consists of isoniazide (INH, oral 300 mg daily), RMP (oral 600 mg daily) and pyrazinamide (PZA, oral 20–35 mg/kg daily) plus initially either ethanbutol (EMB, oral 15–25 mg/kg) or streptomycin (STM, intramuscularly 0.5–1 g daily), if drug resistance is suspected. Duration of therapy is 6–12 months, depending on the protocol used. The adjunctive use of corticosteroid (prednisone 60–80 mg daily for 1–2 weeks, with gradual decrease) is advised in patients with altered mental status or other neurologic findings.[1] In a large epidemiologic study of antituberculous drugs in pregnancy, RMP was associated with fetal abnormalities in 3% of exposed fetuses, compared to 2% for EMB and 1% for INH. STM should not be used during pregnancy due to the risk of nerve toxicity in the fetus. The risk of teratogenicity for PZA has not been determined.[8]

Neurosyphilis

Syphilis is a complex systemic disease with protean clinical manifestations, caused by the spirochete *Treponema pallidum*. The pathogen cannot be cultivated *in vitro*.

Clinical manifestations

There are numerous presentations of neurosyphilis. Syphilitic meningitis as a complication of secondary syphilis is often asymptomatic, and its diagnosis is based on CSF abnormalities (lymphocytic pleocytosis, elevated protein level, decreased glucose concentration) and/or positive Venereal Disease Research Laboratory test response. Symptomatic secondary syphilitic meningitis usually presents similarly as other forms of aseptic meningitis with headache, nausea and vomiting. Meningeal signs occur in 60% of patients and fever in less than half. Cranial nerve palsies are relatively common (45%). Other focal abnormalities or mental status changes are not common. Late (tertiary) symptomatic neurosyphilis is divided into two major clinical categories that are correlated with pathologic findings: meningovascular neurosyphilis, usually starting 5 years after acquisition of syphilis, and parenchymatous neurosyphilis (general paresis and tabes dorsais), appearing 10–25 years after primary syphilis.[1] Although syphilis occurs in a relatively small percentage of the population, data support the widespread screening of obstetric patients for syphilis. Among pregnant women found to have latent syphilis, a fifth of patients have evidence of asymptomatic neurosyphilis following examination of spinal fluid.[21] Despite maternal therapy, 11% of the infants born to mothers with syphilis have reactive serum and CSF involvement.

Diagnosis

Whenever a positive serum treponemal test (fluorescent treponemal absorption test or *T. pallidum* hemagglutination assay) is detected, the clinical staging of syphilis must be accomplished by examination of the CSF. Abnormal CSF findings (even a few cells), a positive CSF non-treponemal test and/or a positive treponemal test establish the diagnosis of neurosyphilis.

Treatment

Only penicillin reliably treats the infant, therefore the treatment of choice for pregnant women with neurosyphilis is penicillin G 2–4 million units intravenously every 4 h for 10 days. An alternative for the penicillin-allergic patient is ceftriaxone 1 g intravenously or intramuscularly for 2 weeks.[1]

CNS toxoplasmosis

Toxoplasmosis is a worldwide zoonosis, caused by *Toxoplasma gondii*, an intracellular protozoan parasite. In humans, toxoplasma infection is acquired either orally (through the ingestion of undercooked meat containing tissue cysts or water and food contaminated by oocysts) or congenitally. Acute toxoplasma infection in an immunocompetent host, including pregnant women, goes unrecognized in ~90% of cases, but may result in a tragic outcome for the offspring

(discussed elsewhere in this book). Chronic (latent) infection ensues in all infected patients, due to persistence of *T. gondii* in the cyst form. Reactivation, with resultant life-threatening (mostly CNS) toxoplasmosis, occurs exclusively in patients who are severely immunocompromised.[1] In women receiving chronic immunosuppression after organ transplantation, not a single case of CNS toxoplasmosis was observed during pregnancy.[22] In pregnant women who are infected with HIV, the incidence of CNS toxoplasmosis is very low,[1,22,23] is correlated with HIV immunosuppression (CD4 cell count < 100 mm^3) and is not influenced by pregnancy. At present, data are insufficient to define the risk of congenital transmission of *T. gondii* by HIV-infected mothers who have chronic toxoplasma infection.[1]

Clinical manifestations

A wide range of clinical signs and symptoms are seen with CNS toxoplasmosis. Characteristically, there is a subacute onset of encephalitis with focal neurologic signs. CSF is normal or may show a non-specific mild 'viral' inflammatory response.

Diagnosis

Brain biopsy with appropriate cultural and histologic techniques is the gold standard for diagnosis of CNS toxoplasmosis. Serological tests (serum and CSF) are not helpful. Brain imaging studies (MRI and to a lesser degree computed tomography scan) show characteristic multiple lesions, which tend to occur at the corticomedullary junction and involve the basal ganglia. In AIDS patients, such focal CNS lesions suggest the diagnosis.[1]

Treatment

For the immunodeficient patient with CNS toxoplasmosis, standard therapy is a combination of pyrimethamine (oral 200 mg loading dose, then 50–75 mg daily) and sulfadiazine (oral 1–1.5 g every 6 h) or clindamycin (oral or intravenously 600–1200 mg every 6 h). Addition of folinic acid (oral, intravenously or intramuscularly 10–20 mg daily) minimizes pyrimethamine-associated myelotoxicity.

Duration of treatment is 4–6 weeks, followed by lifelong maintenance treatment.[1] For the HIV-infected woman the reader is advised to consult HIV authorities.

165 Anaerobic infections in pregnancy

Y. Schlesinger

Introduction

The role of anaerobic organisms as a cause of infections of the female genital tract is well established. Anaerobic bacteria, among others, can be cultured from virtually all specimens from women with clinically important gynecological infections. Anaerobic infections in pregnancy are particularly important due to the impact of the infection on both the pregnant mother and the developing fetus. There is increasing evidence that ascending infection from the lower genital tract is an important cause of preterm delivery and low birth weight infants. Similarly, bacterial vaginosis has been linked to a number of complications of pregnancy, including preterm labor and delivery, chorioamnionitis, postcesarean amnionitis, and postabortion septic thrombophlebitis. This chapter will attempt to summarize the impact of and the approach to anaerobic infections in the pregnant woman.

The pathogens

The classification of anaerobic bacteria has changed dramatically over the last decade, due to the introduction of molecular biology techniques in this field. A detailed description of the new nomenclature of anaerobic bacteria is beyond the scope of this chapter, and the interested reader is referred to recent comprehensive reviews.[1–3]

The normal flora of the vagina has been the subject of several studies in both healthy women and those with pathologic conditions.[4–6] The microbial environment of the vagina is very delicately balanced and can be altered by many factors. These include hormonal changes from aging, pregnancy and oral contraceptives. Also, in certain conditions such as antibiotic therapy and uncontrolled diabetes mellitus, the normal vaginal flora is altered. Local factors such as malformation and anatomic deformities after surgery, vaginal douching and foreign material such as contraceptives (intrauterine device, diaphragm and spermicides) and tampons also play an important role. In the healthy woman, the vaginal flora is dominated by lactobacilli. In contrast, in the vaginal flora of women with bacterial vaginosis, the predominance of lactobacilli is replaced by a combination of aerobic, facultatively anaerobic and strictly anaerobic bacteria. The most important pathogens include *Gardnerella vaginalis* (the 'clue' cell organism), *Bacteroides* species, *Prevotella (Bacteroides) melaninogenicus*, *Mycoplasma hominis* and *Mobiluncus* species. The importance of bacterial vaginosis in pregnancy will be discussed later in detail.

Numerous anaerobic bacteria are encountered in obstetric and gynecological infections. Most of these infections are of polymicrobial nature and include both aerobic and anaerobic bacteria. In a large-scale survey by Brook and colleagues,[5] anaerobic pathogens were recovered from 714 out of a total of 736 patients sampled. These specimens included 53 from infected Fallopian tubes, 470 from infected endometrium, 94 from infected amniotic fluid, 57 aspirates of cul-de-sacs in instances of pelvic inflammatory disease, 14 labial and vaginal abscesses and 26 of Bartholin's cyst abscess. A total of 2052 isolates were recovered, out of which 1139 were anaerobes (1.6 per specimen). The most commonly isolated anaerobic bacteria were *Bacteroides* species (566 isolates), anaerobic gram-positive cocci (391), *Clostridium* species (48) and *Fusobacterium* species (36).

The most important anaerobic infection of the genital tract during pregnancy is bacterial vaginosis, due to the possible effect on the outcome of pregnancy. Therefore, most of the rest of this chapter will be devoted to the diagnosis and treatment of bacterial vaginosis. Other forms of anaerobic infections in pregnancy are clinically less significant and will be mentioned only briefly.

Bacterial vaginosis

Bacterial vaginosis is not an infection in the ordinary sense. In contrast to vaginitis, in which there is an inflammatory response of the vaginal wall, bacterial vaginosis is not associated with such inflammation.

The manifestations of bacterial vaginosis are an increased homogenous vaginal discharge that has an elevated pH, a characteristic odor after addition of potassium hydroxide and a microscopical appearance characterized by epithelial cells with adherence of bacteria (mostly *G. vaginalis*) to the cell margins (the so-called 'clue cell'). In bacterial vaginosis the normal lactobacillus-dominated vaginal flora is replaced with anaerobic bacteria, *Mobiluncus* species, *G. vaginalis* and *M. hominis*. A standard method for the diagnosis of bacterial vaginosis has been described by Spiegel and colleagues[7] and Nugent and associates.[8]

The normal vaginal flora of 171 pregnant women in labor at term was studied by Hillier and colleagues.[6] A score of 0–10 was assigned in light of the relative proportions of large gram-positive rods (lactobacilli), small gram-negative or gram-variable rods (*Bacteroides* or *Gardnerella*) and curved gram-variable rods (*Mobiluncus).* The flora was categorized as normal (a score of 0–3, *Lactobacillus*-predominant), intermediate (a score of 4–6) or representative of bacterial vaginosis (a score of 7–10). Bacterial vaginosis was diagnosed in 39 women (23%); the vaginal flora was diagnosed as normal in 50% of cases and as intermediate in 27%. The microorganisms most frequently recovered from women with bacterial vaginosis were *G. vaginalis*, anaerobic bacteria (*Prevotella* species, *Bacteroides* species, *Fusobacterium, Peptostreptococcus*), *Mobiluncus* species, viridance streptococci, *Ureaplasma urealiticum*, and *M. hominis*. The presence of H_2O_2-producing lactobacilli was inversely associated with the presence of bacterial vaginosis.

The effect of bacterial vaginosis on the outcome of pregnancy has been the subject of several studies in the last decade.[9–18] Most investigators agree that there is an association between bacterial vaginosis and premature delivery, premature rupture of membranes (PROM), infection of the chorion and amnion,[15,16] histologic chorio-amnionitis,[16] and infection of amniotic fluid. In a recent multicenter comprehensive study by Hillier and colleagues,[13] a cohort of 10,397 pregnant women was followed. The study end point was a preterm (< 37 weeks) or a low birth weight (< 2500 g) delivery. In 16% of all the women, bacterial vaginosis was detected at 23–26 weeks of gestation, based on vaginal pH and Gram stain. In a multivariant analysis, bacterial vaginosis was found to be associated with preterm delivery or low birth weight (odds ratio 1.4, 95% confidence interval 1.1–1.8). Among women with bacterial vaginosis, the highest risk of preterm delivery or a low birth weight infant was found among those with both vaginal *Bacteroides* and *M. hominis* (odds ratio 2.1, 95% confidence interval 1.5–3.0). In contrast to these and other findings, Hillu and associates[14] found no evidence that bacterial vaginosis is associated with prematurity or adverse pregnancy outcome. The authors suggest that the characteristics of their study population, i.e. differences in normal vaginal flora due to different antibiotic usage habits, may account for the conflicting results. Kurki and colleagues also found conflicting results[11] in an assessment of the association between bacterial vaginosis early in pregnancy and adverse pregnancy outcome. Bacterial vaginosis in this particular study was diagnosed by Gram stain, bacterial culture and Papanicolaou stain, performed between 8 and 17 weeks of gestation. Bacterial vaginosis was diagnosed in 169 of 790 women (21.4%), and associated with a 2.6-fold risk (95% confidence interval 1.3–4.9) for preterm labor (premature contractions), a 6.9-fold risk (2.5–18.8) for preterm birth, and a 7.3-fold risk (1.8–29.4) for PROM. However, the authors indicate that due to the high rate of false-positive findings, the positive predictive value of bacterial vaginosis for pregnancy outcome is only 4–11%. Hence, the role of treatment of bacterial vaginosis in the prevention of adverse pregnancy outcome remains unclear.

The mechanism by which bacterial vaginosis causes premature delivery is not completely clear. It may involve prostaglandins, endotoxins, mucinase, salicidase, interleukin-1 and other mediators derived from fetal membranes or decidua, as well as these and other agents released from the bacteria themselves. The role of chorioamniotic infection and histologic chorioamnionitis in prematurity was the subject of a study by Hillier and colleagues.[16] Microorganisms were recovered from the chorioamnion in 23 of 38 placentas (61%) from women with premature labor (< 37 weeks of gestation) and in 12 of 56 placentas (21%) from women who delivered at term (odds ratio 5.6, 95% confidence interval 2.1–15.6). The most frequent isolates from the placentas of those whose infants were delivered prematurely were *U. urealiticum* and *G. vaginalis.* The recovery of any organism from the chorioamnion was strongly associated with histologic chorioamnionitis and bacterial vaginosis. Silver and colleagues[15] also found that bacterial vaginosis organisms (*M. hominis*, anaerobes and *G. vaginalis)* were associated with each other in 408 cases of intra-amniotic infection, and that women with bacterial vaginosis were most likely to have *M. hominis* and *G. vaginalis* in their amniotic fluids. These and other studies suggest that the mechanism of premature labor in patients with bacterial vaginosis, especially early in pregnancy, is amniotic fluid infection and chorioamnionitis.

The timing of bacterial vaginosis in relation to prematurity has also been investigated. Riduan and colleagues[17] examined the association between preterm delivery and bacterial vaginosis in early and late pregnancy. A total of 490 pregnant women were evaluated for the presence of bacterial vaginosis at 16–20 weeks and 28–32 weeks of gestation, and subsequently followed to delivery. A significant association was found between preterm delivery (< 37 weeks of gestation) and bacterial vaginosis diagnosed at 16–20 weeks of gestation (odds ratio 2.0, 95% confidence interval 1.0–3.9). In contrast, no significant correlation was

found with bacterial vaginosis diagnosed at 28–32 weeks of gestation. The authors suggest that these findings are in accordance with the assumption that bacterial vaginosis causes an ascending infection resulting in chorioamnionitis, which in turn is the cause of prematurity, since chorioamnionitis is likely to occur at an earlier stage. Russel[19] found that the incidence of chorioamnionitis declined as gestational age increased, from 94.4% for women who delivered at a gestational age of 21–24 weeks, to 39.6% at 25–28 weeks, 35.4% at 29–32 weeks and 10.7% at 33–36 weeks. A reasonable conclusion from these findings is that early detection and treatment of bacterial vaginosis may reduce the rate of prematurity and low-birthweight deliveries. In contrast, other studies do not confirm these results.[14] Four hundred women from the north of Israel were followed up to delivery. The presence of bacterial vaginosis was evaluated twice: at 15–20 weeks and 27–32 weeks of gestation. Bacterial vaginosis was found in 15% of the women at 15–20 weeks and in 12.5% of the women at 27–32 weeks of gestation. However, no association was found between bacterial vaginosis in either stage of pregnancy and premature delivery. As mentioned before, these conflicting results may be explained in part by differences in normal vaginal flora due to different antibiotic usage habits between the study populations.

Given this information, should bacterial vaginosis be screened for and treated during pregnancy with the aim of reducing premature delivery, low birth weight infants and PROM? This issue is still debated, due to the marginal efficacy and the microbiological and financial cost of unnecessary mass antimicrobial usage. In a randomized, double-blinded controlled study, Hauth and colleagues[20] found that compared to placebo, treatment of women with bacterial vaginosis with metronidazole and erythromycin lowered the rate of prematurity (31% vs. 49%, $P=0.006$). This effect was not found in women at high risk for premature delivery who did not have bacterial vaginosis.[20] These findings are in accordance with those of McGregor and associates,[21] who found in a prospective study that screening for bacterial vaginosis in pregnancy and treatment with oral clindamycin 300 mg twice daily for 7 days resulted in approximately 50% reduction in preterm birth and/or rupture of membranes. Similarly, Morales and coworkers[22] compared treatment of asymptomatic women with both a history of preterm birth and findings of bacterial vaginosis with oral metronidazole or placebo. They obtained nearly 70% reduction in prematurity, low-birthweight and PROM in the clindamycin-treated women.[22] In contrast, based on data derived from several studies, Joesoef and Schmid concluded that treatment of bacterial vaginosis should be reserved only for symptomatic patients.[23] In their review, the authors suggest that treatment of asymptomatic patients with the rationale of preventing adverse pregnancy outcome should be deferred until further data are available. Hence, no firm recommendations about the routine screening for and treatment of bacterial vaginosis in pregnancy can be given at the current time. However, due to substantial evidence that bacterial vaginosis, at least in the second trimester, is associated with adverse pregnancy outcome, and the relative low cost and simplicity of oral or topical antibiotics for the treatment of bacterial vaginosis, it is probably reasonable to offer such therapy in this subset of patients.[18,24]

Other forms of anaerobic infections in pregnancy

All the anaerobic bacteria mentioned previously can contribute to virtually every type of obstetric infection,[5] varying in severity from minor to life-threatening infections. These infections commonly include abscess of the perianal soft tissue or glands, endometritis, salpingitis, tubo-ovarian abscess, septic abortions and postoperative infections. Clues to the presence of anaerobes in these infections include a foul-smelling discharge, presence of gas in tissue, abscess formation and pelvic thrombophlebitis.

Clostridia species are isolated from 5–10% of normal vaginal flora, and up to 19–29% of women in the postabortion period. Hence, their presence does not necessarily indicate the presence of infection. An important exception in which *Clostridia* clearly play a major role is uterine gas gangrene, now a rare complication that was previously seen in the setting of septic abortion. Rarely, uterine gas gangrene has followed amniocentesis,[25] or a cesarean section. It is debatable whether or not hysterectomy should always be performed in cases of uterine gas gangrene.

Treatment

The treatment of anaerobic infections in pregnancy follows the usual rules of antimicrobial treatment of anaerobic infections. The primary agents that are effective against most anaerobic bacteria include metronidazole, clindamycin, some penicillins, chloramphenicol and imipenem–cilistatin. Among the penicillins, those that are combined with beta-lactamase inhibitors, i.e. amoxicillin–clavulanate, piperacillin–tazobactam, ticarcillin–clavulanate and others, are particularly effective. Various treatment regimens can be offered. The decisions regarding the specific agent, the dose, the route of administration (parenteral, oral or topical) and the length of therapy are dictated by the type and severity of the particular infection being treated. Antibiograms, derived from *in vitro* susceptibility testing, are very difficult to perform and interpret for anaerobic bacteria and should not be used routinely in the selection of the antimicrobial agent. Bacterial vaginosis can be treated with

oral metronidazole 500 mg twice daily for 1 week, or just as effectively by metronidazole or clindamycin gel.[24,26] Treatment of the male sex partner is controversial, but may be recommended in cases of recurrent bacterial vaginosis.[23,24] Treatment of bacterial vaginosis prior to surgical abortion with the aim of preventing postabortion pelvic inflammatory disease is recommended by some authors.[23] The use of metronidazole in pregnancy has traditionally been avoided due to a fear of teratogenicity. However, in a meta-analysis by Burtin and colleagues[27] it was shown that metronidazole is safe for use in pregnancy and lactation and therefore need not be avoided. Other forms of therapy include surgical debridement and hyperbaric oxygen, but these are reserved for invasive infections in severe cases.

166 Malaria in pregnancy

I. Kassis, M. Giladi and M. Efrat

Introduction

Malaria, the most important of the human parasitic protozoa, is endemic in many parts of the world, mainly in the tropical and subtropical areas. An annual incidence of > 300 million new cases and 2–3 million deaths is almost undoubtedly an underestimation. Mortality and morbidity are greatest in children and pregnant women, especially in sub-Saharan Africa, as well as in non-immune travelers. In the latter, disease may develop months to years after leaving an endemic area, and thus the diagnosis can be easily delayed and possibly missed. Delay in diagnosis can lead to significant morbidity and even death.

Globally, *Plasmodium vivax* accounts for 80% of cases, and *Plasmodium falciparum* for 10–15%. The remaining cases are caused by *Plasmodium ovale* or *Plasmodium malariae*. Occasionally, mixed infections can occur. The epidemiology of human malaria varies, and different species may predominate in different areas. Severe complications and mortality are almost always due to falciparum malaria.

The parasite and life cycle

Malaria is acquired when the female anopheline mosquito bites for a blood meal. Sporozoites travel via the blood stream to the liver. They invade hepatocytes and develop into mature tissue schizonts. Within 1–2 weeks, infected hepatocytes rupture and thousands of merozoites are released from each tissue schizont into the bloodstream. Each merozoite may invade a human erythrocyte. Each parasite replicates asexually every 48–72 h and releases 8–32 merozoites during rupture of infected erythrocytes. Some erythrocytic parasites develop into sexual forms (gametocytes). These forms are ingested by the feeding *Anopheles*. After completing the stages of sexual reproduction in the mosquito, sporozoites develop and migrate to the mosquito's salivary gland. They will be injected into, and will potentially infect, the next human bitten. Alternatively, erythrocytic forms may infect humans by blood or by maternal–fetal transfusion.

In the liver, *P. vivax* and *P. ovale* may exist as dormant forms (hypnozoites). These forms may cause relapse (in almost a third of cases), even years after the primary infection. *P. falciparum* has no dormant form and there is no true relapse. Deterioration after a period of clinical improvement may occur, but not due to liver hypnozoites, and is termed recrudescence.

P. malariae is the rarest cause of human disease. It may exist in peripheral blood for years, causing low-grade parasitemia, often asymptomatic.

Clinical manifestations

The clinical picture is highly variable. Some infected people may have few symptoms and others may develop a rapidly fatal course. The pattern of fever and other symptoms in primary infection is not typical and may imitate many other febrile diseases. Furthermore, the state of host immunity plays a major role, thus a high level of suspicion is required. Malaria should be suspected in every patient in the proper epidemiological setting.

During the initial period of symptomatic malaria, patients may not exhibit the typical cyclical fever classically attributed to malaria. They may have low-grade fever with random peaks. After several days, synchronous febrile peaks may occur. One to 2 h of feeling cold with rigors are followed by 4–6 h of high fever, which is then followed by an often massive diaphoresis and a concomitant reduction of temperature, and exhaustion. These paroxysms are coincident with the rupture of erythrocytes and release of parasites into the circulation. This pattern occurs roughly every 72 h in *P. malariae* infection and every 48 h in the others (*P. falciparum*, *P. vivax* and *P. ovale*). Other symptoms may occur including lethargy, anorexia, nausea, vomiting, diarrhea, headache and low back pain. Malaria may mimic many other febrile illnesses prevalent in both endemic and non-endemic regions.

Untreated patients with malaria due to *P. vivax* and *P. ovale* may have attacks for weeks. Spontaneous recovery after several attacks is the rule. Clinical symptoms due to *P. falciparum* may begin as early as 8–12 days after infection. If untreated, paroxysms may continue for 3 weeks. Recrudescence may occur. In some instances, the clinical course of disease may progress with severity and rapidity and lead to complications

and death. This is determined, in part, due to factors, such as age (children are more susceptible), general medical and nutritional status, degree of immunity to malaria, virulence of the parasite, pregnancy and time of onset of effective treatment. Life-threatening severe and complicated malaria develops almost exclusively with *P. falciparum* infection, although the majority of falciparum infections do not progress to this extreme form, even if not treated. In those who develop complications, the variable spectrum of manifestations may include anemia with or without hyperparasitemia, pulmonary edema, renal failure, acidosis, shock, cerebral involvement, disseminated intravascular coagulation and death.

Central nervous system (CNS) involvement (cerebral malaria) with confusion, obtundation, seizures, coma and death may occur. It is of supreme importance to note that patients with malaria and CNS symptoms may have other reasons for these symptoms. Bacterial meningitis should be excluded by lumbar puncture. Encephalitis and various causes of encephalopathy should be considered. Hypoglycemia, another potential cause of CNS symptomatology, may complicate malaria, especially during pregnancy and childhood, and is further augmented by treatment with quinine or quinidine.

Hypovolemia, renal microvascular sequestration of erythrocytes and hemoglobinuria may act together to cause renal failure, which is more common in non-immune patients and is usually non-oliguric. Hemodialysis or hemofiltration may be required. Pulmonary edema is uncommon in developing countries. It may be precipitated by iatrogenic fluid overload. This complication occurs mainly in adults and is usually associated with high-grade parasitemia ($> 250{,}000$/ml, $> 5\%$).

Patients with specific organ complications usually die if not appropriately treated with both antimalarials and supportive therapy. Patients who survive cerebral malaria may be left with varying degrees of neurological sequelae.

Pathogenesis

P. falciparum is the most severe form of disease. This species invades erythrocytes of all ages. Parasitized red blood cells adhere to endothelial cells in capillaries and postcapillary venules of the brain, kidneys, lungs and other organs. Mature asexual forms of the parasite disappear from peripheral blood and sequester in the microcirculation. The adherence of parasitized erythrocytes to endothelial cells in the postcapillary venules is considered the main mechanism of pathogenesis. Uninfected circulating erythrocytes bind to infected erythrocytes with mature parasites (rosetting). Microvascular obstruction facilitates tissue hypoxia, hypoglycemia and the production of lactate. In addition, tumor necrosis factor-α (TNF-α) and other cytokines, nitrous oxide and free oxygen radicals, contribute to the pathogenetic sequence of events at the tissue level. The resultant severe metabolic dysfunction is manifested by specific organ complications. With the institution of appropriate therapy, most of these effects are abolished, largely without permanent damage. The absence of neurological sequelae in the majority of cases (but not all) implies that reversible metabolic mechanisms, e.g. synaptic dysregulation by tissue mediators, are responsible for cerebral malfunction. Anemia occurs frequently in malaria. Its etiology is multifactorial. Infected erythrocytes rupture with the release of parasites. This is associated with the release of cytokines, such as TNF-α, which has a suppressive effect on erythropoiesis (dyserythropoiesis). Activated reticuloendothelial cells, mainly in the spleen, destroy defective erythrocytes as well as uninfected erythrocytes that are coated with malaria antigens. In developing countries, underlying anemia is common (malnutrition, intestinal parasites, physiological effects of pregnancy, etc.).

P. vivax and *P. ovale* infect mainly reticulocytes and young erythrocytes (1–2% of erythrocytes) and microvascular sequestration does not occur. Tissue involvement is not present and hemolysis is usually mild.

P. malariae invades primarily senescent erythrocytes. Low-grade parasitemia may continue even asymptomatically for years. Immune complex glomerulonephritis and hypersplenism may develop.

Diagnosis

Malaria is a life-threatening disease. It should always be suspected in the appropriate epidemiological setting. Clinical symptoms and signs may be misleading, therefore clues, such as living in or traveling to endemic areas even years before, a history of previous malaria, previous prophylaxis for malaria or blood transfusions, may help. Blood smear is still the cornerstone of diagnosis. Trained personnel should prepare thick and thin peripheral blood smears, which are best stained with Giemsa. Smears should be examined at length before they are declared negative. In order to confirm or exclude the diagnosis of malaria by classical methods, smears should be examined every 6–8 h for up to 3 days. The degree of parasitemia should be assessed. To exclude the possibility of drug resistance, follow-up smears are required after the institution of therapy.

Falciparum malaria must be differentiated from the other forms. When initial speciation cannot be determined, treatment must be for *P. falciparum*. When chloroquine-resistant *P. falciparum* is a possibility, initial treatment must reflect this possibility. Other diagnostic methods such as serology are available, but have limited value in practice. Sensitive staining techniques (acridine orange) and antigen detection (by specific antibodies) are being increasingly used, especially in non-endemic countries. In the future, field-adapted molecular diagnostic tests may become

available for diagnosis and for the identification of drug-resistant parasites.

Malaria in pregnancy

Malaria has a special impact on pregnant women, the placenta, the fetus and the newborn infant. In endemic areas, the frequency and severity of falciparum malaria and its complications are greater during pregnancy. The impact of non-falciparum malaria on the materal–fetal unit has yet to be accurately defined. Almost 500 million women live in endemic areas; in some regions more than 50% of the pregnant women may be parasitemic and have clinical manifestations of variable severity, or may be asymptomatic.

Parasitemia and malaria attacks are 4–12 times more common during pregnancy. The susceptibility to infection and severity of disease are determined in part by the prepregnancy immune status. In areas where transmission of malaria is low or seasonal, acquired antimalarial immunity is poor. Pregnancy alone downregulates immune responses, thus pregnant women may suffer more from malaria and its complications. In endemic areas where the transmission of malaria occurs year-round, protective immunity may develop and disease tends to be less severe, albeit more prevalent. In non-immune women, the susceptibility to infection with malaria is similar in all parities. In endemic areas with intense transmission, primigravidara are more often infected, and the severity of the disease is greater. In areas with seasonal or low-level transmission, the effects of malaria are felt in subsequent pregnancies as well. Interestingly, for grand multipara, the effect of protective immunity wanes. Some specific features and complications of malaria during pregnancy deserve special mention. Other than anemia, the following complications occur uniquely with *P. falciparum.*

Anemia

Anemia is very common in pregnancy, especially in developing countries. It usually develops during the second trimester. Anemia is usually normochromic and normocytic, and hemoglobin levels of < 7 g/dl are not uncommon. In the anemia associated with malaria, factors like hemolysis, activation of the macrophage–monocyte system, hypersplenism, suppression of bone marrow by TNF-α and peripheral sequestration may act together. Regardless of endemicity or the level of immunity, anemia contributes significantly to maternal and fetal morbidity. Prophylactic iron supplementation is advised during pregnancy, including in malaria-endemic areas. It has a positive effect on mothers and newborn infants.

Iron overload may increase host susceptibility to malaria. Iron supplementation may be detrimental to women with sickle cell trait. In this group, low antimalarial antibody levels and iron overload may act in concert to make women more susceptible to malaria during pregnancy. In fact, the advantages of some hemoglobinopathies (i.e. sickle cell anemia) in protection against malaria have not been clearly proven in pregnancy.

Blood transfusions may be required to correct severe anemia. The risk of transmission of malaria and other infectious agents (i.e. hepatitis B, hepatitis C, HIV), mainly in areas with poor medical facilities, should be weighed against the risk of heart failure and hypovolemic and hemorrhagic shock. Anemia may be chronic and its rapid correction may induce acute heart failure and pulmonary edema. In all instances, blood should be given with strict monitoring. Blood is usually transfused when the hematocrit is below 20%. Antimalarial therapy may be indicated for all pregnant women with severe anemia since placental malaria with negative blood smears can occur, especially in semi-immunes. In areas where transfusion practices involve an increased risk of acquiring blood-borne infections, a more conservative approach is indicated as long as there are no signs of maternal and/or fetal distress.

Liver problems

Mild hepatomegaly may be found in about half of cases of falciparum malaria. Hyperbilirubinemia with clinical jaundice due to hepatic damage with elevated hepatocellular enzymes may be seen in severe malaria, and rarely, malaria-associated severe hepatic necrosis may lead to death. It is important to remember that acute liver failure may complicate pregnancy without malaria.

Spleen problems

Early in the course of malaria, splenic macrophages are activated. Thrombocytopenia and leukopenia occur early in the course of infection, while splenomegaly is rarely seen at this stage. In endemic areas where recurrent or chronic infections are the rule, splenomegaly may be pronounced, sometimes in the form of hyperreactive malarial splenomegaly or tropical splenomegaly syndrome. Rarely, splenic rupture occurs and may cause death.

Cerebral malaria

Cerebral malaria is particularly common in pregnant women and in children. Altered consciousness, confusion, seizures, behavioral disturbances, focal neurologic findings, ataxia and coma are the main features. Patients may deteriorate rapidly, within a few hours. Untreated, this situation may lead to death within a few days. Recurrent convulsions and coma are poor prognostic signs. Supportive treatment includes preventing aspiration, treating hyperpyrexia and administering anticonvulsants. The mortality rate of cerebral malaria during pregnancy is considerably higher than in general. It is not clear if malaria predisposes to pre-eclampsia or eclampsia. In cerebral malaria, hypertension is very unusual, thus distinguishing it from eclampsia. Fever is also not typical of eclampsia.

Hypoglycemia

Hypoglycemia is very common in pregnant women with severe falciparum malaria. Predisposing factors include reduced glycogen stores due to starvation and vomiting, increased metabolic demands during febrile episodes, tissue hypoxia, quinine and quinidine stimulation of islet cells inducing hyperinsulinism, glucose consumption by large numbers of parasites, the hypoglycemic effect of TNF-α and possibly the toxic effect of iron or parasite-specific factors.

Hypoglycemia should be suspected and aggressively treated in any patient, in particular those with abnormal CNS symptoms. Abnormal behavior, sweating, convulsions or sudden loss of consciousness should be considered to be due to hypoglycemia. Correcting hypoglycemia results in their rapid reversal and should be tried immediately without awaiting the results of blood tests. The rapid assessment of blood glucose by a standard finger-prick method is useful.

Glucose solution may be administered orally or, when necessary, by nasogastric tube. The intravenous infusion of 10% dextrose or a therapeutic trial of 25–50 ml of 50% dextrose will rapidly abolish signs of hypoglycemia. Hypoglycemia may be prevented by the infusion of 5–10% dextrose (mainly when quinine is being given). Glucose overload may lead to fluid overload, rebound hyperinsulinism, hypokalemia and metabolic acidosis. Even subclinical maternal hypoglycemia may affect fetal growth and the development of the fetal CNS.

Pulmonary edema

Pregnancy is associated with an increased blood volume. Fluid overload, hyperparasitemia, renal failure and blood transfusions all increase the risk of developing pulmonary edema. The basic pathogenetic mechanism is capillary leak. Iatrogenic fluid overload by infusions, especially during labor, greatly increases the risk of pulmonary edema. After the initial treatment of dehydration when indicated, central venous pressure should be maintained at 0–5 cmH_2O. Pulmonary edema may develop even several days after institution of antimalarial drugs. Respiratory status should be monitored adequately. Treatment is supportive and may include oxygen, diuretics, fluid restriction and even mechanical ventilation.

Bacterial infections

Bacterial infections are not uncommon during pregnancy and the immediate postpartum period. Meningitis and encephalitis are endemic in most malaria zones and may be confused with cerebral malaria and may even occur concomitantly. Pneumococcal infections, gram-negative sepsis, typhoid fever, urinary tract infections and endometritis should also be considered. Immediate diagnosis and treatment according to local epidemiological data are needed. Aspiration pneumonia and sepsis may occur in the severely ill, comatose patient. In summary, bacterial infections mimic as well as complicate malaria.

Renal involvement

Proteinuria is common in pregnancy and malaria. Renal failure is rare. In most cases, urinary output is restored with adequate hydration. The combination of cerebral and renal malaria in pregnancy may mimic eclampsia.

Blackwater fever

This severe form of hemolysis is associated with falciparum malaria and is rare during pregnancy. Large numbers of non-parasitized red blood cells are destroyed, possibly due to antigen–antibody complex formation. Quinine may aggravate this phenomenon. Severe anemia, prostration, chills, vomiting, jaundice and bloody-black urine result in renal failure and even death.

The effect of malaria on labor

Malaria, especially *P. falciparum* malaria in the non-immune host, may induce preterm labor. Fetal distress and prematurity may add substantially to the neonatal morbidity and mortality. Ante- as well as postpartum fever may be the first manifestation of malaria.

The effect of malaria on the placenta

By the fourth month of pregnancy, the placenta becomes a highly vascularized organ. The intervillous spaces serve as preferential sites for parasite development, because they are, in part, sequestered from the immune system. Also, blood flow is sluggish and macrophages are scarce.

In endemic areas, placentas from primigravida are highly parasitized. Even in women living in areas of high endemicity, where immunity to malaria in adulthood is said to be the rule, high-grade placental parasitemia may be found. Parasites may be seen in placental blood smears even when they are absent in peripheral blood. Thus, in some areas, negative blood films cannot exclude the diagnosis of malaria in a pregnant woman.

P. falciparum parasites bind to placental ligands (e.g. chondroitin sulfate A) and selectively sequester in the placenta. Pathological changes include the presence of parasites in erythrocytes, malarial pigment deposits in intervillous spaces, monocytes, trophoblasts and mesenchymal stroma. There is trophoblastic damage with focal necrosis, loss of microvilli, irregular thickening of the trophoblastic basement membrane and protrusion of syncytiotrophoblastic projections into the basement membrane. The severity of these changes is correlated

with the level of maternal and placental parasitemia. Histochemical stains may demonstrate deposits of immunoglobulins G and E, C3 and malarial antigens in the trophoblastic cytoplasm and basement membrane. Clinical manifestations of these pathological changes may include reduced placental weight, decreased nutrient and oxygen exchange between the mother and the fetus and reduced hormone secretion by the placenta.

High-level parasitemia may lead to intrauterine growth retardation, preterm delivery, low birth weight and, possibly, stillbirth. On the other hand, the placenta may serve as a barrier sequestering parasites selectively on the maternal side, thus preventing invasion of the fetal circulation and the resultant possibility of disease in the newborn infant. Parasites are seldom seen in the fetal circulation and in placental fetal blood smears. They are, however, seen much more frequently than the incidence of clinical congenital malaria. The incidence of congenital malaria is very low when compared with the large numbers of women who have malaria during pregnancy.

The effect of malaria on the fetus

Malaria is an important cause of low birth weight in the tropics. Low birth weight is more frequent in primigravidas in areas with intense malaria transmission. In areas where transmission is seasonal or sporadic, the effect of malaria on the fetus is extended to subsequent pregnancies. Growth is adversely affected by the degree of placental parasitemia, maternal nutrition and anemia. Effective antimalarial prophylaxis and iron supplementation during pregnancy have been shown to increase birth weight. Maternal hypoglycemia may cause fetal brain damage. The chronic inflammation of placental malaria may increase the probability of mother-to-child transmission of HIV.

Malaria-associated fever, dehydration, acidosis and placental insufficiency may cause fetal distress and induce premature labor. Prematurity, especially in the malaria-endemic areas of the world, has a great impact, since the medical facilities equipped for treating premature infants are inadequate or non-existent. The association of malaria and abortion or stillbirth is not clear-cut.

Drug therapy of malaria during pregnancy and lactation

Two major issues in drug therapy are addressed: the treatment of disease and the prophylaxis against the acquisition of malaria for both residents of endemic areas as well as traveling women. Data from studies in endemic areas show that malaria prophylaxis during pregnancy is beneficial to the fetomaternal unit. The once unequivocal benefit of large-scale prophylaxis is now problematic, especially in the context of increasing parasite drug resistance and the lack of financial resources in many endemic areas. In areas where antimalarial prophylaxis is effective and financially feasible, this practice should be continued. In all endemic areas, chemical and physical barriers (e.g. mosquito repellents, insecticide-impregnated bed nets, etc.) should be used. Intermittent presumptive therapy is another potential strategy. Close obstetrical follow-up including the frequent measurement of hematocrit and blood smears for malaria detection should be routine.

Recommendations for the treatment of malaria vary in different areas of the world. The changing patterns of drug resistance, mainly in falciparum malaria, necessitate constant review. Treatment is best tailored by specialists who are familiar with the disease and the continually evolving epidemiology of drug resistance. In pregnancy, full doses of antimalarial therapy should be given. The utility of early cesarean section in malaria has not been proven.

Chloroquine is the cornerstone of malaria treatment and prophylaxis. Today, its use in falciparum malaria is limited due to the widespread resistance of *P. falciparum* to this drug. It remains central to the prophylaxis and treatment of *P. vivax*, *P. ovale* and *P. malariae* malaria. Chloroquine has been used for many years during pregnancy and is safe. It crosses the placenta readily. In rats, very high doses are teratogenic, and rare cases of teratogenicity have been described in patients with collagen vascular diseases treated with high doses of chloroquine for years. Doses used for the treatment and prophylaxis of malaria are not teratogenic. In some circumstances, amodiaquine might be considered during pregnancy.

Fansidar is a combination of sulfadoxine and pyrimethamine. It has been used safely during pregnancy without severe adverse effects, although large doses of pyrimethamine in animals may induce folic acid deficiency. The addition of folinic acid may reverse this effect. Sulfa-containing drugs are not considered teratogenic in humans. In rats and mice, cleft palate and thyroid tumors have been described. Theoretically, sulfa-containing drugs may cause neonatal hyperbilirubinemia and kernicterus when used within 2 weeks prior to delivery. The combination of pyrimethamine and sulfa was used for treatment and prophylaxis of malaria until its use was discontinued due to adverse cutaneous reactions and increasing parasite resistance. The drug combination is also used to treat toxoplasmosis during pregnancy.

Mefloquine is considered safe during the second and third trimesters and some will use this drug during the first as well. Safety during the first trimester has yet to be determined. Data on teratogenicity are lacking.

Information regarding the safety of halofantrine during pregnancy is lacking, thus it should not be used.

Quinine is the drug of choice for treating falciparum malaria where the possibility of chloroquine

resistance exists (in most areas of the world). It is usually used in combination with another drug (i.e. tetracycline, clindamycin). High doses of quinine may stimulate the uterus, but at therapeutic doses it can be administered safely, even during the third trimester, with no oxytocic effect. Its hypoglycemic effect is prominent during pregnancy. When given in high doses, quinine is teratogenic in guinea pigs, but not in monkeys. Its possible association with human congenital anomalies (X rating by FDA) has rarely been mentioned in most major reviews on the subject.

Quinidine can be used alternatively when quinine is unavailable. Other than its excellent antimalarial activity, it has a similar hypoglycemic effect. Teratogenicity and oxytocic effects have not been reported in humans. Neonatal thrombocytopenia has been reported.

Tetracyclines are used in combination with quinine for treatment of resistant falciparum malaria. Their administration is contraindicated during pregnancy. Tetracyclines cause fetal bone and enamel abnormalities as well as potentially fatal fatty hepatic degeneration in the pregnant woman. An acceptable alternative is quinine and clindamycin.

Primaquine is used to eradicate the liver hypnozoite stage in *P. vivax* and *P. ovale* malaria, and is usually given for 2 weeks, commencing after the completion of chloroquine treatment. It is given in order to reduce the risk of relapse. It is contraindicated in glucose-6-phosphate dehydrogenase (G6PD) deficiency and may induce hemolysis *in utero* if the fetus is G6PD deficient. Fetal hemoglobin is even more sensitive to its deleterious effects. Primaquine is contraindicated before delivery. Instead, prophylaxis with weekly chloroquine should suppress relapse until after delivery when primaquine can be given to the mother.

Artemesinin derivatives are increasingly given during pregnancy, especially after the first trimester, though data about safety and possible teratogenic effects are lacking. They should be used in combination with drugs such as mefloquine and lumefantrine. To date, however, there is insufficient data about the use of these combinations during pregnancy, especially during the first trimester.

Proguanil has been used along with chloroquine for prophylaxis during pregnancy. It is considered safe for the fetus. Malarone (aotvaquone-proguanil) cannot yet be recommended for the treatment of pregnant women. Proguanil-dapsone is another potential candidate for treating malaria during pregnancy.

The concentration of antimalarial drugs in breast milk is minimal. Lactation is possible while on antimalarials. When indicated, the infant should be given prophylaxis since the concentration of antimalarial drugs in breast milk is not protective. Prolonged administration of tetracyclines to lactating mothers should be avoided. Given that hemolysis in G6PD deficiency is not necessarily dose dependent, primaquine should be avoided while breast feeding infants with this disorder.

Congenital malaria

The incidence of malaria during pregnancy in endemic areas can be high. Placental involvement is found in more than 30% of the pregnancies in endemic areas. The incidence of congenital malaria in infants of immune mothers is estimated to be 0.1–0.3%, but is as high as 10% in non-immune mothers. In endemic areas, malaria parasites have been found in almost 10% of cord blood samples when prospectively studied. Interestingly, congenital malaria is considered a rare disease. The mother does not always have clinical disease. Furthermore, a transient febrile episode during pregnancy due to malaria may go unnoticed. Only a few hundred cases have been described, mainly from non-endemic areas. This is in part due to under-reporting. In non-endemic areas, congenital malaria is seen mainly in infants of travelers to endemic areas and of refugees.

Parasites may infect the fetus *in utero* (congenital acquisition) or may be acquired as a result of the admixture of maternal and fetal blood during delivery (perinatal acquisition). Both these processes may cause malaria in the newborn. Transfer of antimalarial immunoglobulin G during the third trimester may have some protective effect on the fetus as well as on the newborn for the first few months after delivery. In true congenital malaria, the infant is born ill, although this condition is exceedingly rare. Perinatally acquired malaria is much more common, but is difficult to distinguish from vector-transmitted malaria in endemic areas.

The onset of symptoms usually occurs 3–8 weeks after birth, but may occasionally begin within a few hours after delivery and up to 15 months later. When disease starts later than 1 week of age in endemic areas, it is impossible to discriminate between congenital and early perinatally acquired infection.

Symptoms include fever, irritability, lethargy, poor feeding, diarrhea, jaundice, hepatosplenomegaly, anemia, leukopenia, thrombocytopenia and elevated levels of liver enzymes. Complications include coma and seizures, disseminated intravascular coagulopathy (*P. falciparum*), hypersplenism, splenic rupture, autoimmune phenomena, gastrointestinal symptoms with malabsorption, electrolyte imbalance and nephrotic syndrome. Untreated infants may progress to a state of wasting, malnutrition, secondary infection and even death. Manifestations of congenital malaria are not specific and may suggest many other diseases of the newborn. A high index of suspicion is needed in the appropriate epidemiological setting (maternal and travel history).

The early diagnosis of this potentially lethal disease is crucial. Treatment of congenital malaria is with

chloroquine except for the resistant falciparum malaria. Primaquine is not required for treating congenital malaria since there is no liver hypnozoite stage.

Traveling during pregnancy

Women who are pregnant or likely to become pregnant should avoid travel to malaria-endemic areas. The impact of disease on the non-immune pregnant female is great. Other than areas without chloroquine-resistant *P. falciparum*, no chemoprophylactic regimen is likely to be completely effective.

When traveling is unavoidable, women may take chloroquine during pregnancy. Proguanil is used in some areas together with chloroquine for prophylaxis, though the combined use of these two individually safe drugs during pregnancy has not been studied rigorously.

Mefloquine is used as a prophylactic agent in chloroquine-resistant falciparum areas. It may be used during the second and third trimesters of pregnancy, and during the first trimester if intense exposure to chloroquine-resistant *P. falciparum* is unavoidable. In areas of mefloquine resistance (i.e. parts of Thailand) doxycycline is usually used for prophylaxis, but this drug is contraindicated in pregnancy. Women should avoid traveling to these areas during pregnancy. In addition to prophylaxis with antimalarial drugs, other methods for malaria prevention should be stressed (avoidance of being outside in rural areas during the evening and night hours, use of mosquito repellents, bed nets, etc.).

167 Toxoplasmosis: pregnancy, delivery and the effect on the fetus and the newborn

D. T. Spira

Etiology

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii*, an intestinal coccidian parasite of cats and other felines. The parasite was first described at the beginning of the century by Nicolle and Manceau,[1] isolated from the North African rodent *Ctenodactylus gundi.* Thirty years later in 1939, Wolf and Cowen[2] reported the first congenital transmission in man. The importance of the disease was immediately recognized and a large volume of data on epidemiology, serology, clinical picture and experimental systems were available. It took another 30 years for the whole life cycle of the parasite to be elucidated.[3]

Life cycle

The cycle of reproduction of *Toxoplasma gondii*, including the asexual schizogony and sexual gametogony, occurs in the intestinal epithelium of felines. Cats and all the other felines are therefore considered the definitive host of this parasite. Kittens get infected by oocysts excreted in large numbers (up to 10^7/cat/day) in infected cat feces, or later in life by tissue cysts in the prey. The ingested cysts release, in the small intestine, comma-shaped (2–6 mm) parasites, with a single nucleus and the rhoptrie apparatus necessary to penetrate into host cells, in this case the cat enterocytes. Cat enterocytes can be infected either by the eight sporozoites released from oocysts in cat feces, or by thousands of bradyzoites released from tissue cysts found in the organs or muscles of the prey. Both sources of infection initiate in the cat an enteric infection, with the production of micro- and macrogametes, fertilization and development of oocysts discharged in the feces. Considering that the primary infection renders the cat immune, young kittens should be considered the main source of environmental dissemination of the disease. The oocysts are about 9–15 mm in size, extremely resistant, and may remain infective for years.

In the intermediate host, *T. gondii* does not infect intestinal epithelium, rather it penetrates it and is hematogenously disseminated through the body. Parasites enter cells, preferentially phagocytes, although they can infect any mammalian cell except erythrocytes. In the cells, the parasites divide in a unique way known as endodyogony (division within the membrane of the mother cell) and are released when the host cell is destroyed by multiplication of the parasite. The early, fast-dividing stage in the life cycle of *T. gondii* is known as tachyzoite. After a few cycles of division and cell destruction, and concurrent with the development of a specific immune reaction in the intermediate host, *T. gondii* enters a different phase of its life cycle. The parasite now called bradyzoite divides slowly, preserving the host cell and creating a cyst wall within the host cell. The cyst finally outgrows the cell, which at this time disappears, leaving a 100–200-mm large round cyst filled with thousands of dormant bradyzoites. The three parasite stages, sporozoites in the oocyst, tachyzoites in host cells and bradyzoites in tissue cysts, are morphologically and structurally similar and all have the same infectious capabilities. The inactive tissue cysts persist in the mammalian host for many years, either till consumed by a predator or by man in insufficiently cooked meat or till the immune system of the host is compromised, the cysts break down and the dormant bradyzoites are reactivated.[4]

Epidemiology

Distribution of *T. gondii* is worldwide, and the parasite has been found in sheep even in cat-free areas of Australia. From epidemiological studies and comparisons, one can assume that man is infected both by oocysts from infected cat feces, which have

contaminated food or water, and by tissue cysts in undercooked meat. The prevalent source of infection in each country depends on hygiene of food handling and on cooking habits (raw or 'rare' meat). Sheep, pork, cattle and horse meat, and apparently even poultry, have been found as potential sources of infection to man, if consumed insufficiently cooked. High infection rates have been found in most countries surveyed: thus, in Europe 45–80% of women of childbearing age have anti-*T. gondii* antibody; in the US and Canada 10–40%; and in Israel about 30% of adults. In some developing countries up to 90% of the adult populations have been exposed to the parasite. It can be assumed that in countries with lower standards of hygiene, the main source of infection originates from oocysts in cat feces, which contaminate food or water, whereas in developed countries undercooked meat is the main source. The importance to public health of *T. gondii* depends therefore on the method of transmission and the age of primary contact with the parasite.

Immune response

The immune response to *T. gondii* infection in man and in laboratory models is primarily cell-mediated. Both CD-4 and CD-8 lymphocytes as well as natural killer cells are active in the process. Primary *T. gondii* infection induces profound cytokine production, mainly of γ-interferon, tumor necrosis factor-α, interleukin-2 and interleukin-12, and thus stimulation of various immune mechanisms. A 65-kDa heat shock protein expressed on infected macrophages seems to act as a very strong antigen stimulating the responses. It is as if the parasite, instead of using ways to impair immunological recognition and thus to diminish the immune reaction of the intermediate host, advertises its presence inviting a fast and profound reaction, without achieving sterile immunity, thus guiding the life cycle toward bradyzoites and permanent tissue cysts.[5]

Clinical picture

Immunocompetent adult

Toxoplasma gondii in man can be considered the ultimate opportunistic parasite. Infection of the immunocompetent adult is subclinical as a rule, initiating an effective immune response, which abolishes the active stage of infection and causes the appearance of the inactive tissue cyst. Infection during pregnancy of immunocompetent mothers can, in the majority of cases, be considered in this category, as there is no difference in the clinical picture in the pregnant or non-pregnant female.

Immunocompromised host

In AIDS patients, as the paradigm of immunocompromised hosts, toxoplasmosis is severe, and in the great majority of cases considered to be the result of reactivated cysts in the central nervous system. Toxoplasmic encephalitis is the major expression, with lesions, in nearly all cases, in the cerebral hemispheres, but in about 50% also in the cerebellum and in 6% in the spinal cord. Toxoplasmic lesions have also been found in the lungs, kidneys and muscles including the myocardium. The dispersion is evidently hematogenic as parasites have been cultured from blood. *T. gondii* infections have been induced by organ transplantation into non-immune immunosupressed recipients.

Children infected after birth

Of the few newborns and children that develop clinical toxoplasmosis, the majority (about 90%) present with lymphadenitis, mainly of the deep cervical nodes, about 5% with chorioretinitis or cerebral lesions and 1.5% with myocarditis. These cases usually resolve even without treatment, when the parasites transform into the latent tissue cysts.

Congenital toxoplasmosis

This is the most severe presentation of the disease, and has a pathology quite distinct from the other types. There is a profusion of surveys and estimates on the number of infections during pregnancy and the percentage of transplacental infections of the fetus. The latest surveys estimate that only 10% of primary infections acquired during pregnancy are transmitted to the fetus. Of these, 75% induce a subclinical infection, and 15% present with mild and 10% with grave symptoms. In general, the earlier the infection occurs during pregnancy, the lower the chances of transmission, but the higher the probability of serious consequences. Infections acquired later in pregnancy tend to cross the placenta more often, but with a lower chance of inducing pathological changes in the child.

As stated, pathological signs in the pregnant woman are quite infrequent. Posterior cervical lymphadenopathy, fever, sometimes splenomegaly, all disappear after a few days to a week. After 10–14 days the parasite might traverse the placenta and appear in the fetus. *T. gondii* may be found in the cord and membranes, but only infrequently in the villi of the placenta. In the developing fetus, tachyzoites multiply in phagocytic cells, causing local inflammation and necrosis, but the proven neurotropy of the parasite soon concentrates the major damage in the neural tissue of the brain and eyes.

Brain pathology usually appears as glial nodules, microinfarctions and necrosis leading to calcifications. Yellowish necrotic nodules can be observed on the brain surface or in the brain substance. *T. gondii* multiplies in the ependymal cells lining the ventricles. The subependymal area is usually inflamed. The outlet of the ventricular system (aqueduct of Sylvius)

is blocked by granulation tissue and by necrotic debris causing fluid accumulation and hydrocephalus. In the eye, chorioretinitis appears first as small hemorrhages gradually enlarging, bordered by black pigment. The lesions have a predilection for the macular region.

Clinically, chorioretinitis is the most common sign, often causing only minor problems. Punctate lesions in the eye may be harmless unless in the macular region, but some may flare up much later in adolescence and even adulthood. Other symptoms observed at birth that correlate with the acute infection of the fetus, mainly as a result of infections in the third trimester, are fever, jaundice, lymphadenopathy and sometimes dermal lesions. The most severe expression of congenital toxoplasmosis is the so-called 'tetrad of signs': chorioretinitis, micro- or hydrocephalus, cerebral calcifications and convulsions as a result of cerebral damage. Hydrocephalus is the most dramatic but least common of the clinical signs.

In cases of intense damage to the fetus one can expect abortion, fetal death *in utero* or preterm birth. In cases with less intense damage there may be neonatal or infant death, or the infant may survive with defects.

Diagnosis

Direct evidence

Parasitological diagnosis of *T. gondii* is limited, and gives false-negative results. Parasites might be found in amniotic fluid by tissue culture or by mouse inoculation. Both tests are difficult, take a long time and are expensive. Attempts to find circulating *T. gondii* antigen do not succeed in all cases of clinically proven infections. Polymerase chain reaction (PCR)-based discovery of *T. gondii* DNA in blood or amniotic fluid is slowly gaining acceptance, but is still not fully reliable.

Serology

Diagnosis of *T. gondii* in man is indirect, based on the presence of specific antibody, seroconversion or relative titers of different immunoglobulin classes. Diagnosis of fetal infection is therefore doubly indirect, as it relies on serology of the mother. Considering that only a small percentage of infected mothers transmit the infection to the fetus, sometimes with grave or even fatal consequences, the reliability of serologic diagnosis and its interpretation are of prime importance.

Different serologic techniques have been employed in the measurement of the various immunoglobulin classes. Each has its advantages and drawbacks, and this is not the place to deal with them. It is sufficient to explain the kinetics of antibody appearance and fading, and the relative sensitivities of the various tests. In general, all antibody classes rise during the second and third weeks postinfection. Immunoglobulin G is the most persistent, with significant titers for years. Considering the ease and reliability of tests based on immunoglobulin G or total immunoglobulins, it is the best way to diagnose 'old' infections at the beginning of pregnancy, thus marking pregnancies with no danger to the offspring.

Immunoglobulins M and A, rising rapidly and fading after 6 months, are the most reliable for establishing and following infection during pregnancy. Considering that as a rule they do not pass through the placenta, positive immunoglobulin M or A in the newborn is diagnostic for *T. gondii* infection. According to accepted algorithms, women negative for antitoxoplasma antibody or with a high titer, pointing to a recent infection in early pregnancy, should be followed during pregnancy and any rise in titer of immunoglobulin M or A antibodies should be carefully evaluated. When there is suspicion of infection, chemotherapy or abortion, depending on the history and stage of pregnancy, diagnostic imaging of the fetus and clinical examinations, should be considered. All cases of positive serology in the newborn, with or without clinical signs, should also receive chemotherapy to prevent late sequelae of the infection.

Treatment

Fortunately, *T. gondii* readily responds to treatment, and the problems are only in the clinical evaluation of whether the parasite has passed through the placenta.

Treatment of the mother

It has been verified that treatment, even of an asymptomatic mother who has acquired infection during pregnancy, greatly reduces the danger of fetal infection and sequelae. In all cases of *T. gondii* infection, a combination of spiramycin and sulfa plus pyrimethamine is recommended. One of the protocols states that if no overt infection of the fetus can be recognized, spiramycin 100 mg/kg/day and 25 mg pyrimethamine and 500 mg sulfadoxine twice weekly should be administered from 16 weeks of pregnancy. If the fetus is presumed to be infected, spiramycin plus 50 mg pyrimethamine and 3.0 g sulfadiazine daily should be given. As the combination of sulfa plus pyrimethamine inhibits folic acid synthesis, it should always be accompanied by 15 mg/day of leucovorin to prevent megaloblastic anemia.

Treatment of the neonate

In cases of an infected child with symptoms, spiramycin 100 mg/kg/day for 2 weeks, followed by alternating 1 month of pyrimethamine 1 mg/kg/day and sulfadiazine 100 mg/kg/day, and 1 month of spiramycin 100 mg/kg/day is recommended. This regimen should continue for 1 year.

Asymptomatic neonates with serologically proven infection should also be treated in the first 2 weeks with spiramycin and then by sulfadoxine–pyrimethamine 1 + 20 mg/kg/week in the first year of life. In all cases close clinical observation is suggested.

Other drugs and drug combinations are certainly possible, thus trimetoprim–sulfamethoxazole and clindamycin can be used. A novel antimalarial drug, Atovaquone, seems to be very effective against *T. gondii*, but large-scale clinical tests in pregnancy and on neonates have yet to be performed.[6]

Prevention

Many European countries have instituted compulsory testing for anti-*T. gondii* antibody during pregnancy, and others are preparing their legislatures for such tests. This approach seems the most promising in the prevention of *T. gondii* damage to the fetus or the neonate. On the personal hygiene basis, avoidance of contact with cat feces and consumption of only cooked or pickled meat and careful handling of raw meat and meat products should be part of health education preceding pregnancy.

168 Fungal infections presenting particular features during pregnancy

M. Dan

Introduction

Among more than 50,000 known species of fungi, only about 200–300 are pathogenic to humans in varying degrees. The clinical manifestations of fungal infections range from bothersome cutaneous or mucosal lesions to invasive disease associated with severe morbidity and high mortality rates, particularly in immunosuppressed patients.

Fungal infections are classified according to the initial site of infection. The superficial mycoses are usually mild infections and are limited to the epidermis, the nails and hair and the mucosal surfaces. The principal pathogens in this group are the dermatophytes and *Candida* species. The subcutaneous mycoses involve the dermis, subcutaneous tissues and bone. They are usually acquired by traumatic inoculation of organisms of environmental origin. The systemic mycoses usually occur following inhalation of spores from the environment. The infection often disseminates from the lungs to various other organs. They can be caused by true pathogens, such as *Histoplasma capsulatum* and *Coccidioides immitis*, that invade the tissues and survive in the normal host, producing mild infection of short duration. In the immunosuppressed host, however, the same pathogens can be responsible for life-threatening infections. Alternatively, opportunistic fungi, such as *Aspergillus fumigatus*, mucor and *Cryptococcus neoformans*, are able to invade tissues only in immunocompromised patients. In addition, the commensal *Candida* can disseminate in debilitated patients and cause severe bloodstream infection or invade internal organs, such as the liver and the spleen.[1]

This chapter will discuss only fungal infections that present particular aspects in pregnancy.

Candida infections

Organisms belonging to the genus *Candida* are commensals of the gastrointestinal and genital tracts. *Candida* species usually cause superficial infections of the mucosa, skin and nails. In debilitated individuals, however, the fungus may invade the bloodstream and internal organs. Pregnant women are more prone than non-pregnant women to vaginal colonization and clinical infection with *Candida*. Rarely, the infection can ascend and involve the uterine content, producing chorioamnionitis and congenital candidiasis.

The pathogen and pathogenesis

Candidal organisms are dimorphic fungi, growing as ovoid yeast cells or as pseudomycelium. Blastospores represent the phenotypic form responsible for transmission or spread, and they are often associated with asymptomatic vaginal colonization. Germinated yeasts, on the other hand, produce mycelia, which can invade tissues and are associated with symptomatic disease. Although *Candida albicans* is the species most commonly isolated from the vagina, at least eight other members of the genus are recognized as human pathogens (*Torulopsis glabrata*, *Candida tropicalis*, *Candida parapsilosis*, etc.).

Candida organisms reach the vagina from the perianal area. In order to colonize the vaginal mucosa, the yeast must first adhere to the vaginal epithelial cells. It has been shown that fucose disaccharides serve as receptors for *Candida* ligands.[2] *C. albicans* adheres more avidly to the vaginal epithelium than do non-albicans species. Although there is a considerable interperson variation with regard to vaginal cell receptivity to *Candida* adherence, vaginal cells from women with recurrent vulvovaginal candidiasis do

not show increased cell affinity for *Candida*, and all *C. albicans* strains appear to adhere equally well to epithelial cells.[3] In many women *Candida* inhabits the vagina in low numbers without causing symptoms. The transition from a vaginal commensal to a pathogen that causes symptoms probably depends on factors related to the organism and to the vaginal environment. Germination of the yeast enhances colonization, facilitates tissue invasion and precipitates symptomatic vaginitis. Epithelial cell damage and mucosal inflammation can result from direct hyphal invasion of tissues or hypersensitivity reaction.[3,4] *Candida* elaborates proteolytic enzymes, toxins and phospholipases that may be associated with virulence.[3] Candidal vaginitis occurs predominantly in women of child-bearing age, suggesting that gonadal hormones may play a major role in the pathogenesis of this entity. Indeed, during pregnancy the vagina is more susceptible to candidal infection, resulting in a higher incidence of colonization and symptomatic vaginitis, particularly in the third trimester. Symptomatic recurrences are more common, and cure rates are significantly lower during pregnancy.[5–7] However, other studies have suggested that the risk of *Candida* vulvovaginitis in pregnant women does not differ significantly from that in other gynecological patients.[8,9] Estrogens provide a carbon source for *Candida* growth and germination by increasing the glycogen content in the vaginal mucosa. These hormones also enhance vaginal epithelial cell avidity to *Candida* adherence, and facilitate yeast mycelial formation. It has been reported that peripheral blood lymphocyte responses are depressed during pregnancy and oral contraceptive use.[10–12] Cytoplasmic receptors for female reproductive hormones have been documented in yeast cells.[10,13] Data on the risk of *Candida* vulvovaginitis in women on oral contraceptives are conflicting; increased vaginal colonization rates have been documented mostly with high-estrogen oral contraceptive use, while studies on low-estrogen pills have not found an increase in occurrence of *Candida* vaginitis.[3,14]

The natural vaginal flora is thought to provide a colonization resistance barrier and prevent candidal germination and mucosal invasion. It has been suggested that lactobacilli compete with *Candida* for nutrients and interfere with candidal adherence to vaginal epithelial cells. Lactobacilli also elaborate bacteriocins that inhibit yeast proliferation and germination. Reduced numbers of lactobacilli were found in vaginal cultures obtained from women with symptomatic *Candida* vaginitis. The association between antibiotic use, increased colonization rates and precipitation of symptomatic *Candida* vaginitis is explained by the suppressive effect of antibiotics on the normal protective bacterial flora of the vagina.[3]

Other host factors that may contribute to the increased incidence of candidal vaginitis include (1) uncontrolled diabetes mellitus;[15] (2) increased local perineal moisture and temperature resulting from the use of tight, poorly ventilated nylon underclothing and (3) a high-carbohydrate diet.[14]

Cell-mediated immunity is considered to be the most important defense system in preventing mucosal invasion by *Candida* species. It has been demonstrated that cytokines can reduce hyphal formation.[16] Polymorphonuclear leukocytes and monocytes play an important role in limiting systemic candidal infection and deep tissue invasion, while humoral immunity is only marginally involved, if at all, in protecting against vaginal yeast infection.

Recurrent vaginitis is not usually associated with any precipitating or causal event. Three possible mechanisms have been proposed to explain recurrent candidal infections. First, repeated fungal reinoculation of the vagina from the intestinal reservoir is possible. Isolates from the vagina and the rectum are often of the same biotype. However, recurrences of candidal vaginitis have been demonstrated in the absence of *Candida* growth in rectal cultures,[17] and reduction of intestinal yeast carriage by nystatin treatment did not prevent recurrences of vaginal candidiasis. Second, sexual transmission may also be suggested due to the increased penile colonization by identical strains of *Candida* in male partners of women with recurrent vulvovaginal candidiasis. However, treatment of sexual partners does not prevent recurrences in women.[3] A third recurrence mechanism is relapse of persisting carriage in the vagina: following effective antimycotic treatment with mycologic eradication, an identical strain may be recultured in a quarter of the women within 4–6 weeks of therapy. Hence, recurrence is rather due to relapse than to reinfection. More recently, it has been suggested that idiopathic recurrent vulvovaginal candidiasis may result from a local dysfunction of cell-mediated immune mechanisms in the vaginal mucosa.[18]

Although *Candida* colonization of the vagina is common in pregnant women, ascending infection resulting in chorioamnionitis rarely occurs. *Candida* can cross intact membranes, and ruptured membranes are not a prerequisite for intrauterine invasion by *Candida*. Several reports have suggested, however, an association between intrauterine infection and the presence of a retained intrauterine device (IUD) or other foreign materials, such as cerclage sutures.[19–24] Mothers with *Candida* chorioamnioitis and premature labor have delivered at an earlier date when an IUD was present (mean gestational age, 25 weeks) than in its absence (mean, 31.5 weeks).[25] Very rarely *Candida* infection can further disseminate in the

pregnant woman and become systemic, even in the absence of a particular predisposing factor other than the pregnancy state.[26]

Epidemiology

In most patients *Candida* infections are caused by organisms from the individual's own endogenous flora in the gastrointestinal and genital tracts. The pathogen may, however, be transmitted from person to person: neonatal oral candidiasis is more common in infants born to mothers with candidal vaginitis, suggesting that the infection may be acquired during passage through the birth canal.

About 75% of women will have at least one episode of vulvovaginal candidiasis during their child-bearing years, and approximately 40–50% of these will experience a second attack.[27] Some 5% of adult women suffer from recurrent, often intractable, episodes of candidal vaginitis.[3] Approximately 20% (range, 10–55%) of healthy, asymptomatic women of reproductive age harbor *Candida* in their genital tract at any point in time. A total of 25–40% of women with positive vaginal cultures for *Candida* are free of complaints. Asymptomatic vaginal colonization with *Candida* is increased in pregnancy: 30–40% of pregnant women carry the yeast in their lower genital tract. The incidence of symptomatic vulvovaginal candidiasis has been reported to be 2–20-fold higher during pregnancy than in non-pregnant women.[28] Other factors associated with increased carriage rate include estrogen-containing oral contraceptives, uncontrolled diabetes mellitus, corticosteroid therapy, antimicrobial therapy and tight-fitting synthetic underclothing.[14]

Candida is the most common cause of vaginal infection in Europe, while in North America it is the second most common (after bacterial vaginosis). In both areas the incidence of candidiasis has shown a sharp increase in the last decade.[3]

Candida species were found in 10% of positive amniotic fluid cultures in women with preterm labor.[24] In a study of 3500 placentas from high-risk pregnant women, *Candida* chorioamnionitis and funisitis were found in 18 (0.5%) cases. In eight (45%) of these patients, an IUD was present *in utero*.[21] In another report of six cases of *Candida* chorioamnionitis, a retained IUD was noted in three (50%) of the patients.[22]

Clinical manifestations

Characteristically, symptoms of vulvovaginal candidiasis are exacerbated in the week preceding the onset of menses. Vulvar pruritus is the most frequent symptom; vulvar burning, dyspareunia and external dysuria commonly occur. Vaginal discharge is often minimal and typically cottage cheese-like, although it can vary from watery to homogenously thick. On examination, the labia and vulva are erythematous and edematous; the vaginal mucosa is also erythematous and an adherent white discharge is typically noted. Symptoms are usually milder when infection is caused by *T. glabrata*.

Candida chorioamnionitis often presents with premature labor. The fetus is often affected: congenital candidiasis characteristically presents with skin lesions or erythematous rash seen at birth. *Candida* can be cultured from specimens of amniotic fluid, placenta and lesions of the newborn. Infection is often mild in term neonates: systemic disease is rare and the cutaneous rash often clears spontaneously. In preterm infants, on the other hand, disseminated disease frequently develops, and mortality is high. Early initiation of systemic antifungal therapy can improve survival rates.[29]

Laboratory diagnosis

Symptoms and signs of *Candida* vulvovaginitis are often non-specific and should not be used for establishing the diagnosis. Culture of vaginal discharge cannot distinguish between colonization, however the presence of large numbers of organisms is characteristic of symptomatic vaginitis.

The diagnosis of vulvovaginal candidiasis should be based on the microscopic examination of vaginal secretions. A saline preparation (wet mount) will often identify yeast or mycelia and will allow the consideration of other causes of vaginitis, such as trichomoniasis and bacterial vaginosis (presence of clue cells). The 10% potassium hydroxide preparation is more sensitive than the wet mount in identifying yeasts. Alternatively, the organisms can be easily seen on a gram-stained smear. The pH of vaginal secretions is usually normal (< 4.5) in *Candida* vaginitis, and a finding of a higher pH indicates an alternative or concomitant condition. Culture of vaginal secretions should be considered in the presence of high clinical suspicion of candidal infection and negative microscopic results.[3]

Diagnostic amniocentesis for microbiologic evaluation of the amniotic fluid should be considered for all pregnant women with retained IUD and preterm labor with or without intact membranes.

Treatment

Vaginal fungal infections are easy to treat, but may be difficult to cure. This is at least partially due to the fact that the presently available antimycotic drugs are rather fungistatic than fungicidal. There is no indication that formulation influences therapeutic efficacy; the patient's preference should dictate which formulation is used to deliver the medication. However, relief of symptoms is achieved earlier with topical drugs than with those administered systemically. Among the available agents (Table 1), nystatin is the only polyene derivative, while the rest belong to the azole group. The average mycologic cure rate with

Table 168.1 Drugs recommended for the treatment of *Candida* vaginitis

Drug	Formulation	Dosage	Category*
Clotrimazole	Cream 1%	5 g × 7–14 days	B
	Vaginal tablet		
	100 mg	100 mg × 7 days	
	200 mg	200 mg × 3 days	
	500 mg	500 mg single dose	
Miconazole	Cream 2%	5 g × 7 days	B
	Vaginal suppository		
	100 mg	100 mg × 7 days	
	200 mg	200 mg × 3 days	
	1200 mg	1200 mg single dose	
Econazole	Vaginal tablet 150 mg	150 mg × 3 days	
Ticonazole	Cream	5 g × 3 days	
	2%	5 g single dose	
	6.5%		
Terconazole	Cream	5 g × 7 days	B
	0.4%	5 g × 8 days	
	0.8%		
	Vaginal suppository 80 mg	80 mg × 3 days	
Nystatin	Vaginal tablet 100,000 U	100,000 U × 14 days	B
Fluconazole	Oral tablet 150 mg	150 mg single dose	C
Ketoconazole	Oral tablet 200 mg	400 mg × 5 days	C
Itraconazole	Oral tablet 100 mg	200 mg × 3 days	C
		400 mg single dose	

*Food and Drug Administration Fetal Risk Drug category[32]

nystatin is 75–80%. There is no evidence of increased congenital anomalies when used during pregnancy:[30] it is classified in the B category of the Food and Drug Administration Fetal Risk Drug Summary. The various azole agents are of comparable efficacy, although they achieve slightly higher clinical and mycologic cure rates (85–90%) than does nystatin. In two studies miconazole was more efficacious than nystatin in treating vulvovaginal candidiasis during pregnancy.[28,31]

Clinical trials have shown that short courses and single-dose regimens of most azole agents are as effective as longer courses.[3] It seems reasonable, however, to use short regimens only in patients with infrequent episodes of mild to moderate severity.[3] During pregnancy, clinical response tends to be slower and recurrences are more frequent. Although single high-dose therapy with clotrimazole has been efficacious in pregnant women, it is generally recommended to prescribe topical antifungal agents for longer periods of 1–2 weeks. Side effects are minimal and consist most often of local burning and discomfort. Although azoles may inhibit estrogen and testosterone biosynthesis in animals and are embryotoxic in high doses in rodents, there is no evidence for an increase in human teratogenesis, including after first-trimester topical exposure. Most authorities believe that topical azoles are safe to use after the first trimester of pregnancy and that treatment during the first trimester should be reserved only for severe infections.[30] Clotrimazole and miconazole are category B drugs.[32]

The oral antimycotic agents – ketoconazole, fluconazole and itraconazole – are highly effective in achieving clinical and mycologic cures in acute candidiasis. Clinical results are similar or minimally superior to those obtained with topical agents. Most women consider oral therapy more convenient. However, oral therapy is more expensive and might be associated with higher rates of side effects, toxicity and teratogenicity. Ketoconazole therapy is accompanied by gastrointestinal upset in 10% of the cases. Of more concern is the risk of hepatotoxicity, which although rare (1/10,000–150,000 women treated) can be fatal.[3] Similar side effects are much less frequent with fluconazole and itraconazole. Ketoconazole also has antiandrogenic properties in humans. High doses of the drug are teratogenic in rats (cleft palate and patent incisive foramena) and embryotoxic in rabbits.[30] Animal embryotoxicity consistent with inhibition of estrogen synthesis was also documented with high dosages of fluconazole (cleft palate, abnormal craniofacial ossification).[33] A follow-up study conducted among 289 women who had taken fluconazole at some time during the months before or during pregnancy, did not reveal any harmful effects.[34] Nevertheless, oral azoles should be avoided in pregnancy (category C drugs).

Treatment of recurrent and chronic vulvovaginal candidiasis remains unsatisfactory. First, the diagnosis of *Candida* infection should be confirmed and the *Candida* species identified. Possible underlying conditions, such as uncontrolled diabetes mellitus, use

of corticosteroids and other hormones, should be recognized and treated. Although most episodes of vulvovaginal candidiasis will respond to standard therapy, definitive eradication of the organism is often impossible and most women require long-term suppressive drug administration. Good results are obtained with intravaginal clotrimazole 500 mg weekly or oral fluconazole 150 mg weekly. Discontinuation of maintenance therapy usually results in resurgence of symptomatic infection in more than half the patients.

Vaginal infections caused by uncommon *Candida* species, such as *T. glabrata*, *C. tropicalis* and *Saccharomyces cereviceae*, may not respond to conventional therapy. *T. glabrata* is inherently resistant to fluconazole. Its response to therapy with other drugs is quite unpredictable. Cases not responding to clotrimazole may still be cured by intravaginal nystatin, flucytosin or boric acid 600 mg twice daily for 2 weeks. The latter two agents should not be used in pregnant women.[3]

A number of other therapeutic approaches of unproven value have been recommended for prevention of recurrence of vulvovaginal candidiasis: oral nystatin to eradicate the gastrointestinal reservoir, treatment of male sexual partner, ingestion or local application of yoghurt, and use of *Lactobacillus acidophilus* capsules.

The optimal management of *Candida* amnionitis has not been established yet. Indications for and against the use of oxytocin to effect delivery rather than the continuation of tocolysis and systemic antifungal therapy are unclear, and no conclusions can be drawn from the insufficient data currently available. Amphotericin B has traditionally been the standard of treatment for systemic fungal infections; however, experience with the use of this agent in pregnancy is limited.[35] The pharmacokinetics of amphotericin B during pregnancy seem to be similar to those in non-pregnant women.[36] Intravenously delivered amphotericin B crosses the placenta and achieves effective concentrations in placental tissues and cord serum.[35] In most reported cases (~80%), the mother and infant tolerated therapy well, and there are no reports of teratogenesis.[37] However, toxicity in the form of renal function impairment and hypokalemia can occur in both in the same manner as described in non-pregnant patients, and appropriate monitoring is mandatory. Amphotericin B is a category B drug according to the classification of the Food and Drug Administration Fetal Risk Drug Summary,[32] and its use is usually indicated in serious fungal infections. Fluconazole has been demonstrated to be of comparable efficacy to amphotericin B in immunocompetent patients with systemic *Candida* infections.[38] It has the advantage of being markedly less toxic and showing good gastrointestinal absorption and cerebrospinal fluid penetration. However, because the drug has been shown to be embryotoxic in animal models,[33] its use in pregnancy should be avoided (category C drug).

There is no consensus about whether *Candida* colonization during pregnancy should be looked for and treated to prevent intrauterine infection. Vaginal antifungal prophylaxis should probably be considered for pregnant women with *Candida* colonization and risk factors, such as retained IUD and previous preterm delivery with no other identifiable causes.

Coccidioidomycosis

Coccidioidomycosis is most often a mild respiratory disease, occurring predominantly in endemic areas; only a minority of symptomatic patients experience a severe course. Pregnant women with coccidioidomycosis are at higher risk for dissemination and mortality than non-pregnant women.

The pathogen

C. immitis is a dimorphic fungus that exists in the soil in the mycelial phase. The mycelial growth results from apical elongation into branching, septate hyphae. With maturity, alternating compartments lose their cytoplasm. The walls of these degenerating cells are easily fractured and the infectious spores, the arthroconidia, can be released. The arthrospores are dispersed in dust in the air to infect new sites in the soil (saprophytic cycle). If inhaled by an animal host, the spores become spherical and develop a thick wall. These spherules reproduce by formation of internal spores (endospores). A single spherule may produce as many as 800 endospores. When the spherule ruptures, the endospores are released and each in turn can transform into a new spherule (parasitic cycle). If returned to the soil, the endospore develops into hyphae.[39]

Pathogenesis

Inhalation of the arthrospores into the lower airway triggers a complex immunologic response involving macrophage-mononuclear cells, neutrophils, complement activation and stimulation of T-lymphocytes.[40] Spherules and endospores are quite resistant to killing by neutrophils or products of oxidative metabolism. Spherule-produced substances can have a suppressive effect on cell-mediated immune reactions. Overall, T-lymphocytes play a major role in anticoccidioidal immunity. Monocytes recruited to the site of inflammation process the fungal antigens. This is followed by clonal expression of T-lymphocytes bearing receptors to coccidioidal antigens. The development of the specific cell-mediated immune response is essential for resistance to reinfection.[41]

The pathologic findings in coccidioidomycosis resemble those seen in tuberculosis, with granulomatous reaction, caseation and fibrosis. Although endosporulating spherules are the characteristic tissue form of the fungus, hyphae can be found in most pulmonary cavities. If the initial infection in the lung

is not contained by the host defenses, progressive pulmonary disease or dissemination can occur. Conditions that predispose to expansion of the infectious process include large fungal inoculum and an immunosuppressive state of the patient. It is possible that T-suppressive cells and/or macrophage suppressors play a role in the fungal-specific immune suppression that is seen in severe forms of coccidioidal disease. Dissemination may involve almost any organ of the body at one or more sites, although the heart and gastrointestinal tract are rarely affected.[40]

The increased rate of dissemination in pregnant women is attributed to the relative immunosuppression associated with pregnancy and an agonist effect of 17β-estradiol and progesterone on the growth of *C. immitis*. A specific binding site for progesterone has been identified on the fungal cell wall.[42,43] Coccidioidal disease during pregnancy is associated with the tendency for spontaneous abortion in the first trimester and for premature labor in later gestation.[44] Rates of fetal loss as high as 43% and prematurity rates of 29% have been reported.[45] Although dissemination of infection during pregnancy can involve the placenta, there is no evidence for transplacental spread of the fungus.[46] It is postulated that the large size of the spherules and the acute thrombotic and chronic granulomatous reactions in the placenta protect villous capillaries from transplacental spread.[46] Neonatal infection is probably acquired following aspiration of infected decidua or postnatal inhalation.[46]

Epidemiology

Coccidioidomycosis is endemic in areas characterized by arid to semiarid climates, alkaline soil and sparse flora. The short rainfall season favors mycelial proliferation in the soil, and the long summer period allows the production of large numbers of arthrospores and their dispersion in the air. The majority of infections occur in seven southwestern states of the USA and in certain areas of Central and South America (Mexico, Guatemala, Honduras, Venezuela, Paraguay and Argentina).[47] Cases can occur, however, outside these endemic areas in individuals who have visited endemic regions (exposure of only a few hours may suffice), or as reactivation of infection in former residents of endemic areas, or as infection acquired from fomites originating in endemic areas (e.g. fruit, cotton).[48] About 20% of coccidioidomycosis cases are seen by physicians outside endemic zones.[49]

Infection is almost always acquired by inhalation of soil dust contaminated with arthrospores. Person-to-person transmission can occur only in special circumstances when the fungus reverts to its airborne form in contaminated secretions.[50]

In parts of the endemic regions more than 90% of inhabitants have had the infection. In the USA about 20,000 cases of mild coccidioidomycosis and 200 cases of severe disease occur each year, with nearly 60 deaths.[51] In southwestern USA the average annual incidence among young adults is 0.4% of the susceptible (i.e. skin-test negative) population.[52]

In endemic areas, 1 in 1000 (in the 1940s) to 1 in 5000 (in the 1980s) pregnant women have had coccidioidomycosis.[44,53] The dissemination rate during pregnancy is 40–100 times that in the general population. The dissemination and mortality rates increase as pregnancy advances: the estimated first-trimester dissemination rate is 23%, second trimester, 59% and third trimester, 68%.[54] The risk of death is nearly 100% in untreated pregnant women as compared to 50% in non-pregnant patients.[45]

Clinical manifestations

About 40% of those infected develop symptoms, the incubation period being 1–4 weeks.[40] The most common symptoms are fever and pleuritic chest pain mimicking a flu-like self-limited illness. Cough, headache, myalgia, arthralgia, malaise, night sweats and loss of appetite are often present. A mild diffuse erythematous or maculopapular rash (toxic erythema) can develop in about one-half of patients, while one-third of infected individuals suffer from erythema nodosum (2–11 times more common in women) or erythema multiforme. Segmental lung infiltrate is the most common radiologic finding, although other abnormalities, such as hilar lymphadenopathy, pleural effusion, nodules or cavities can be seen; these usually last a couple of weeks. Eosinophilia in the range of 5–10% of the peripheral white cell count is often noted in primary infection. Marked elevation of the peripheral eosinophilic count has been proposed as an indicator of non-meningeal dissemination.[55]

In about 5% of infected patients a nodule or cavity can persist for as long as 2 years. Most of these patients are asymptomatic, although hemoptysis can occur. Some patients do not follow such a benign course, but rather develop an acute progressive pneumonia that can be fatal. In other patients, in particular diabetics and immunosuppressed individuals, the lung infection progresses to a chronic pulmonary disease mimicking tuberculosis. Cavities are commonly seen, but bronchiectasis, emphysema or bronchopleural fistula can also develop. The disease may wax and wane over many years with fever, cough, chest pain and weight loss.

About 0.5% of infected individuals develop extrapulmonary disseminated disease. Dissemination occurs more often in men (who are five times more predisposed than women), immunocompromised hosts (with AIDS, malignancy, immunosuppressive or corticosteroid therapy), pregnant women and dark-skinned races. Dissemination can occur within a few weeks of initial infection or as reactivation of a previous quiescent infection in individuals who later become immunosuppressed. The clinical manifestations of disseminated disease range from an indolent chronic illness that persists for months or years to a fulminant illness that is often fatal within weeks if

untreated. The organs most often involved are the skin and soft tissues, bone, joints and meninges; one or more sites may be affected. Cutaneous and soft tissue involvement is common and of varied presentations: verrucous papules, ulcers, erythematous plaques and nodules. Osteomyelitis occurs in about 40% of patients with disseminated disease. Most cases are asymptomatic or there are complaints of a dull pain. On radiography the bony lesions may be lytic or sclerotic. The infection may spread into contiguous joints or adjacent soft tissues causing subcutaneous abscesses, which often drain through spontaneously formed sinuses. Meningitis is the most serious manifestation of disseminated coccidioidomycosis, often complicated by hydrocephalus. Central nervous system involvement occurs in approximately one-third of pregnant women with disseminated disease. Although the onset is often insidious and fever is minimal or absent, the disease is fatal if left untreated. Other possible sites of infection include lymph nodes, liver, spleen, adrenal glands, eye and peritoneum.[40]

Women with a history of antecedent infection are not usually considered to be predisposed to relapse during pregnancy if they have a positive skin test before conception. Some authors recommend that patients with prior disseminated disease be considered at risk for relapse during pregnancy.[54]

Neonatal infection is characterized by gradual and non-specific onset of symptoms. Gastrointestinal manifestations may predominate over the classic fever and respiratory symptoms. Consequently, there is usually a low degree of clinical suspicion, as shown by the fact that more than half of the reported cases are diagnosed only at postmortem examination.[50]

Laboratory diagnosis

Mycological diagnosis

Microscopic examination of a standard 10% potassium hydroxide preparation or a wet mount preparation of clinical material can be diagnostic if the characteristic large thick-walled endospore-containing spherules are seen. Immature spherules can, however, be confused with other yeasts and some pollens. Visualization of the organism in cerebrospinal fluid is extremely rare. *C. immitis* can be isolated from various clinical specimens, although spinal fluid culture is positive only in about one-third of the cases. Several saprophytic fungi resemble *C. immitis* on ordinary media and a special medium containing cycloheximide should be used to inhibit the saprophytes. Identification of the organism by its morphologic characteristics is difficult even in the most experienced hands and confirmation can be achieved by using special media and incubation conditions, injection of a suspension of sporulating cultures into rodents or testing with reference antisera. Cultures of *C. immitis* represent a severe biologic hazard, and specimens and cultures should be handled only by experienced laboratories using appropriate safety equipment and procedures.[40]

Serology

Serum immunoglobulin M antibodies to the mycelial antigen coccidioidin can be demonstrated by several methods, 1–3 weeks after the onset of symptoms of primary infection in 75% of patients, and disappear within 4 months. Serum immunoglobulin G antibodies appear 4–12 weeks after onset of infection and may last for 6–8 months. Immunoglobulin G titers correlate with disease progression or recovery. Elevated titers of complement-fixing immunoglobulin G antibodies (CFA) are the hallmark of disseminated disease: 60% of patients have titers of $\geq$1:32, and in 40% the titers are $\geq$1:64. Titration can also be carried out with the immunodiffusion test, which is sensitive and simple to perform. In meningeal disease, serum titers remain low or absent, while in the cerebrospinal fluid, CFA are initially present in 70% of patients and in almost all of them as the disease progresses. The CFA titers in the spinal fluid parallel the course of the meningeal disease. Occasional cross-reaction can occur in patients with histoplasmosis or blastomycosis.[56]

Skin tests

Skin tests for coccidioidal antigens (coccidioidin, spherulin) give positive results (> 5 mm induration) 10–45 days after infection, usually before the first serologic reactions are detectable. By 1 month after onset, almost every symptomatic patient has a positive skin test. Anergy is common in disseminated disease. Skin testing can be useful if a conversion from a negative to a positive result is documented, or as a preliminary indication of infection while awaiting serologic results.[40]

Treatment

Although most patients with symptomatic primary infection recover without treatment, chemotherapy is indicated in some circumstances. These include severe disease, symptoms persisting for more than 6 weeks, rising or elevated titers of immunoglobulin G > 1:64, immunosuppression, presence of concurrent disease (diabetes mellitus, chronic lung disease) likely to be adversely affected by the infection, pregnant women, infants, and dark-skinned persons. Treatment is almost always indicated in extrapulmonary disease.

Amphotericin B given intravenously in doses of 1–1.5 mg/kg/day to a total dose of 1–2.5 g is the standard regimen in disseminated coccidioidomycosis. Smaller doses, 0.6 mg/kg/day (0.5–1.0 g total dose), may suffice in primary infection. Some authors recommend addition of local administration of the drug (irrigation of sinuses, instillation of abscesses or intra-articular therapy). Intrathecal therapy with amphotericin B is the traditional treatment modality

in coccidioidal meningitis. The daily dose should be gradually increased as tolerated to 0.5–1.0 mg. Intrathecal administration of amphotericin B is associated with neurotoxicity and local reactions that can be reduced by concomitant intrathecal administration of hydrocortisone. Treatment should continue until 3 months after the spinal fluid CFA has disappeared, with follow-up of spinal fluid serology for at least 2 years.[57]

If active infection is present during pregnancy, some authors recommend considering abortion or early delivery (depending on the stage of pregnancy).[40] Good maternal and neonatal results have been obtained, however, with amphotericin B therapy of disseminated fungal infection during pregnancy. Aggressive use of the drug has significantly improved the previously often fatal maternal outcome.[46]

Alternative regimens for the treatment of coccidioidomycosis include the azole drugs, which have the advantage of good intestinal absorption and a low toxicity profile. They are, however, contraindicated in pregnancy (see section on candidiasis). Most experience has been acquired with ketoconazole (400 mg once daily) and itraconazole (200 mg twice daily) in non-meningeal coccidioidomycosis. Relapse rates of 25–30% even after 12 months of treatment have been reported. The best results have been obtained in patients with cutaneous or joint involvement. Similarly, good results have been obtained with fluconazole (400–600 mg once daily). Duration of azole therapy should probably be 6 months after disease activity has become undetectable or 12 months in total.[40]

Chemotherapy should often be supplemented with surgical measures: removal of pulmonary cavities is indicated if persistence, enlargement, recurrence or hemoptysis occurs. In musculoskeletal involvement, infected bone or synovium should be resected, and adjacent soft tissue pus drained. Immobilization is an important part of the treatment.[40]

169 Mumps in pregnancy

A. Morag

Introduction

The word 'mumps' probably derives from the British word 'to mump', which means to grimace or grin. Thus, the name of the disease likely refers to the marked parotid swelling, which is the most common manifestation of infection with this virus.

Mumps is an acute generalized viral infection that occurs primarily in school-age children and adolescents. The disease caused by this virus is usually benign and self-limited, with about 30% of those infected not showing any clinical manifestations.

The agent

Mumps virus is an RNA virus, a member of the Paramyxoviridae family, which also includes some of the other common causes of childhood infections, such as parainfluenza, measles and respiratory syncitial viruses.

The complete mumps virion has an irregular spherical shape with a diameter averaging 200 nm. The external surface is regularly studded with glycoproteins possessing hemagglutinin, neuraminadase and cell-fusion activity. Mumps virus has a lipid envelope, is ether-sensitive and is stable at 4°C for several days and at −70°C for years. The virus can be propagated in various tissue cultures (see diagnosis), and causes cytopathic effects, with eosinophilic cytoplasmic inclusions.

Epidemiology and clinical manifestations

During mumps infection the virus is shed heavily in respiratory secretions. Transmission, therefore, is by droplet infection or fomites, and the virus enters through the nose or mouth.[1] Mumps virus has also been recovered from the urine of infected individuals.[2]

Mumps is endemic throughout the world. There are no known immunologic differences among the various strains of mumps virus, and natural infection with wild-type virus or immunization with live-attenuated mumps virus vaccine, provides long-lasting immunity.[3] In the United States, before the introduction of vaccine in 1967, epidemics occurred every 2–5 years, with peak incidence between January and May.

Man is the only known host for the mumps virus in nature. The virus is uncommonly observed in infants less than 1 year of age, and primarily infects young children during their early school years.[4] Due to mass immunization programs the occurrence of mumps has shifted from younger to older children and adolescents. In recent years, only 25% of cases have occurred in the 5- to 9-year age group, and more than 50% have occurred in the teenage group. In Western countries, about 10–20% of the adult populations have no demonstrable antibodies against the mumps virus. This susceptible postpubescent population is at risk of the increased severity and higher complication rate seen in mumps infection within this age group.[5]

With a 10–20% susceptibility in this population, mumps infection can occur during pregnancy. The incidence of mumps infection during pregnancy in the United States is estimated to be between 1 in 1000 and 1 in 3000.[1]

The incubation period of mumps averages 14–18 days. Following a short prodromal period, which comprises non-specific complaints such as fever, anorexia, myalgia and malaise, the parotitis becomes evident in about 60–70% of infected individuals. The parotid and sometimes other salivary glands are swollen and tender, with symptoms lasting about 1 week.[3] The patient may have difficulty with pronunciation, and mastication and ingestion of citrus juices typically exacerbates the pain. Fever up to 40°C is often observed during the phase of parotitis.

Involvement of other organs is sometimes observed in addition to the salivary glands. Epididymo-orchititis is observed in 25% of cases in postpubertal men[6] and oophorititis in 5% of infected postpubertal women. Orchitis is usually unilateral and very rarely causes sterility. Oophoritis is manifested with fever, nausea, vomiting and lower abdominal pain. Impaired fertility and premature menopause have been reported as a consequence of ovarian involvement, but this is very rare.[7]

Involvement of the central nervous system is quite common in mumps. Cerebrospinal fluid pleocytosis is

observed in about half of the cases. Clinical meningitis occurs in 1–10% of individuals with mumps parotitis; on the other hand only 40–50% of patients with mumps meningitis have parotitis.[8] Mumps encephalitis is rare, and occurs in about 0.1% of mumps cases.

Mumps-associated pancreatitis is a late effect of mumps infection. It is usually diagnosed on the basis of mild clinical symptoms, but can be manifested by severe epigastric pain and tenderness accompanied by fever, nausea and vomiting. There is still controversy concerning the possible association of mumps and the development of diabetes mellitus.[9]

Deafness secondary to mumps labyrinthitis is a rare complication of mumps virus infection.[10] This hearing loss is severe and of sudden onset.

Other mumps-associated complications may include thyroiditis, myocarditis, arthritis and renal involvement.[10]

Mumps in pregnancy

When mumps occurs in pregnant women, the illness is generally benign and not more severe than it is in other adult women.[11] In pregnant women as well as in the population as a whole, deaths from mumps are exceedingly rare.

Effects of gestational mumps on the fetus

Abortion

Gestational viral infections have been extensively investigated by Siegel and associates.[12] They observed excessive fetal deaths when mumps developed during the first trimester but not during the second and third trimesters.[12] Many other reports describe isolated cases of abortion associated with gestational mumps, nearly all of these occurring in the first 4 months of pregnancy.[13] In one instance, mumps virus was isolated from a 10-week-old fetus spontaneously aborted 4 days after the mother developed clinical mumps.[14]

Prematurity

In the only prospective study of low birth weight in relation to maternal mumps infection, no significant association was found. However, analysis of data showed that the effect was greatest when mumps occurred in the first trimester.[15]

Congenital malformations

Evidence in experimentally infected animals suggests that mumps virus can cross the placenta, infect the fetus and induce congenital malformations.[16]

Definitive evidence of a teratogenic potential for mumps virus in humans is yet unclear. Many reports describe the occurrence of congenital malformations after gestational mumps, but no data are available concerning the occurrence of similar anomalies in matched controls. Malformations described as associated with gestational mumps include chorioretinitis and optic atrophy, intestinal atresia, corneal cataracts, urogenital anomalies, hydrocephalus and others.[17]

Endocardial fibroelastosis

In the 1960s, St. Geme and colleagues suggested an association between endocardial fibroelastosis and mumps virus infection.[18] They reported that a high proportion of children with primary endocardial fibroelastosis exhibit cutaneous delayed hypersensitivity to mumps virus antigens and that their mothers often had mumps or exposure to mumps during gestation. An experimental model in the chicken supports a possible association between mumps and the occurrence of cardiac lesions in the developing fetus. Definite evidence for such an association does not exist.

Laboratory diagnosis

Isolation of mumps virus from clinical specimens

Mumps virus is readily isolated in various tissue culture cell lines. The most commonly used are Vero, human embryonic kidney and chick embryo fibroblasts.[1] The virus can be isolated from urine during the period from 6 days before to 15 days after the onset of parotitis, and from saliva from 7 days before until 9 days after the onset of salivary gland enlargement.

Serological diagnosis

The most commonly used serological test today is an enzyme linked immunosorbent assay detecting specific immunoglobulin G or M antibodies to mumps virus. Serological diagnosis can also be made by determination of neutralizing and other types of specific antibodies.[4]

Prevention and treatment

Active immunization with the Jeryl Lynn strain of attenuated mumps virus vaccine has been available in the United States since 1967. A single subcutaneous immunization produces protective levels of mumps-neutralizing antibodies in more than 95% of vaccines, and adequate titers are maintained for more than 10 years.[19]

All children over 12 months of age should be immunized. Vaccination should take place at 12–15 months of age and again at 5–12 years of age, as a part of combined measles–mumps–rubella viruses' vaccine (MMR). As with other live virus vaccines, mumps vaccine should not be administered to pregnant women and immunocompromised patients. Treatment for mumps patients is only symptomatic, as there is as yet no antiviral agent efficiently active against the mumps virus.

170 Measles in pregnancy

A. Morag

Introduction

Measles virus is a member of the family Paramyxoviridae and the genus *Morbillivirus*. This virus has a single-stranded RNA genome and a lipoprotein envelope that contains proteins associated with hemaglutinating, hemolyzing and membrane fusion properties of measles viruses.[1]

Epidemiology and clinical manifestations

Man is the natural host for measles virus, although other primates are susceptible to naturally transmitted measles infection. Measles occur in all parts of the world inhabited by man. Climate and natural boundaries influence the occurrence of measles only to the extent that they limit contact between susceptible and contagious individuals.

From 1912 to 1959, 200,000–600,000 cases of measles were reported annually in the United States, and the morbidity rate remained relatively constant at 200–500 cases per 100,000 per year.[2] With the introduction of the measles vaccine in 1963, the annual number of reported cases fell rapidly. With the improvement of vaccination programs in the early 1980s the annual rate of reported cases reached less than 2 cases per 100,000.[3] Within more than 30 years of the introduction of the measles vaccine, the age-specific incidence of measles shifted upward as the overall incidence of measles declined. Measles today occurs primarily in preschool children, and to a lesser extent in school children, probably due to primary vaccine failures. Measles occurs less frequently during pregnancy than mumps or chickenpox.[4] Measles is the most communicable of the childhood exanthems.[5] Transmission is by infected droplets entering the respiratory system of a susceptible individual through the nose or oropharynx, and probably also through the conjuctival mucosa. A person with measles is capable of transmitting infection from as early as 3 days prior to the onset of symptoms, and until the rash desquamates.[6] Infectivity is maximal during the prodrome.

The incubation period of measles is 10–14 days. A prodromal phase lasting several days is manifested by fever, malaise, anorexia, conjunctivitis and respiratory symptoms such as coryza and cough. Shortly before the appearance of systemic skin rash, a pathognomonic sign of measles, Koplik's spots appear as lesions resembling grains of salt or sand, on the inflamed, reddish, buccal mucosa. The skin rash is systemic and is erythematous and maculopapular.[7] At that time the patient is very sick. The appearance of the rash coincides with the appearance of serum antibody and the termination of communicability of the disease. Although measles virus has been isolated from the skin lesions in the early stage of the rash, it has been postulated that the rash might be a reaction of hypersensitivity of the host to the virus. The rash lasts for about 5 days, and a few days later the fever goes down and the patient feels better.

Complications of measles are often in the respiratory tract or the central nervous system, manifesting as pneumonia (measles virus or bacterial) and as encephalitis.

Modifications of the clinical presentation of measles have been observed in various forms:

(1) Modified measles, which is very mild measles occurring in individuals with some degree of passive immunity to the virus.
(2) Atypical measles, which is a phenomenon believed to be a result of hypersensitivity to measles virus in a partially immune host.[8] It has been described in individuals who are exposed to the live measles virus (wild or attenuated) some years following immunization with killed measles vaccine. The clinical syndrome may be very severe with hemorrhagic phenomena, pneumonia, hepatic involvement and high fever.
(3) Measles in the altered host often occurs as a very severe disease with increased risk of mortality. This has been observed in immunocompromised patients (either due to underlying disease or chemotherapy[9]) and in malnourished children, mainly in Africa.[10]

Diagnosis

Clinical diagnosis is often achieved in a patient with severe respiratory tract illness, conjunctivitis, Koplik's spots and rash.

Laboratory diagnosis is more often made by serology, demonstrating specific antibodies of the M and G classes of immunoglobulin, most commonly by enzyme linked immunosorbent assay. Virus isolation is also possible, but it is more difficult to perform, and is less often used as a routine diagnostic approach.

Measles in pregnancy

When measles occurs in adults, it is often a more severe illness than in children. In patients with measles reported to the Centers for Disease Control and Prevention in 1991, the incidence of complications was higher in those over 20 years of age than in children.[11] Measles can be severe during pregnancy and has been associated with spontaneous abortions and premature delivery. However, in contrast to rubella, measles virus is not known to cause congenital anomalies of the fetus.[12] Measles in the newborns of mothers with measles may be severe, and it is therefore recommended that such newborns be passively immunized with human immunoglobulin at birth.[13]

Treatment and prevention

There is no specific antiviral therapy against measles virus infection. The patient should be given supportive therapy, such as antipyretic and fluids, as indicated. Bacterial superinfection should be treated promptly, directed against the causative bacterial agent.

Prevention can be accomplished by passive or active immunization. Measles virus infection can be very effectively prevented or modified to a less severe illness by early postexposure administration of human gamma-globulins.

Immunoglobulins should be administered to individuals at risk of developing severe or fatal measles, such as children receiving chemotherapy or radiotherapy, or children with deficits in cell-mediated immunity for various reasons. Also at increased risk are babies younger than 1 year of age, including newborns whose mothers have measles.

Passive immunization should be given within 6 days after exposure. Later administration is usually without any beneficial effect. Infants younger than 1 year of age who receive human immunoglobulin (dosage 0.25 ml/kg intramuscularly) should be given active immunization at 15 months of age.[14] Active immunization is by live attenuated measles virus vaccine, incorporated into the combined mumps–measles–rubella vaccine (MMR). The current recommendation is the administration of two doses of MMR, the first at 12–15 months of age and the second in childhood.[15] Live measles vaccine is contraindicated in persons with deficits in cell-mediated immunity and in pregnant women. It is currently recommended that children with HIV infection should be vaccinated with measles vaccine at the age of 15 months.[14]

171 Antimicrobial drugs in obstetrics and gynecology

M. Shapiro

Introduction

Since only a few antimicrobial drugs have been shown to be completely non-toxic when given to pregnant women, and the teratogenic potential of the majority of antimicrobial agents is unknown, these drugs should generally be avoided during pregnancy. On the other hand, the patient's best interest may require that an antimicrobial drug be administered. Studies in animal models offer some information but may be unreliable in predicting human teratogenicity. Thus, the administration of an antimicrobial drug should always be a carefully considered action in which a balance is struck between the needs of the mother and the possible adverse effects of the drug. Most drug-associated congenital abnormalities are produced during the first trimester while differentiation of the embryo is occurring. There is a smaller risk during the second and third trimesters because most organ systems are developed by this time, and it is the metabolic processes that are at most risk. Almost all antimicrobial agents administered to the lactating mother can be detected in her milk. Although detrimental effects to the newborn have only occasionally been encountered, there are possible dangers, especially when large doses of antimicrobial agents are given to premature infants or to those with impaired drug elimination pathways.[1]

The Food and Drug Administration (FDA) has established a Fetal Risk Summary, which divides drugs into categories based on accumulated safety data from animal and human studies (Table 171.1). Category A drugs represent no fetal risk. Currently, there are no antimicrobial agents that fall into this category. Category B drugs are relatively safe to use during pregnancy. If possible, agents should be selected from this category. A designation of category C means that the fetal risk is unknown. These agents should be used only when there is no safer alternative, or when the benefit outweighs the risk. Although there is some evidence of fetal risk in category D, it may be necessary to use these drugs for life-threatening or serious infections for which safer drugs cannot be used or prove ineffective. Drugs listed as category X cause abnormalities and are contraindicated for use in pregnancy. The risk of using these antimicrobial agents in pregnant women clearly outweighs any possible benefit. A

Table 171.1 Pregnancy categories for drugs (Food and Drug Administration)

Category	Description
A	Controlled studies fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence for risk in later trimesters); the possibility of fetal harm appears remote
B	Fetal risk not demonstrated in animal studies, but there are no controlled studies in pregnant women or animal reproduction studies have shown an adverse effect that was not confirmed in controlled studies in women during the first trimester (and there is no evidence of risk in later trimesters)
C	Either animal studies have revealed adverse effects on the fetus (teratogenic, embryocidal or other) and there are no controlled human studies or studies in animals and women are not available
D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g. if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective)
X	Studies in animals or humans have demonstrated fetal abnormalities or there is evidence for fetal risk based on human experience or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant

Table 171.2 Antimicrobial agents in pregnancy

Generally contraindicated:
flucytosine, ganciclovir, griseofulvin, nalidixic acid, nitrofurantoin,* primaquine, quinine, quinolones, streptomycin, tetracyclines

Try to avoid, use only if essential:
acyclovir, albendazole, amikacin, amphotericin B, chloramphenicol*, cotrimoxazole, erythromycin estolate, ethionamide, fluconazole, gentamicin, itraconazole, ketoconazole, metronidazole, pentamidine, pyrimethamine, trimethoprim/sulfamethoxazole,* vancomycin, zidovudine

Probably safe, use when clearly indicated:
cephalosporins, clindamycin, erythromycin, ethambutol, imipenem, isoniazid, methenamine mandelate, nystatin, penicillin, pyrazinamide, rifampicin

*Contraindicated at term

summary of the use of antimicrobial drugs in pregnancy is given in Table 171.2.

Selecting an antimicrobial drug

The selection of agents for therapy is determined by many factors, including the suspected site(s) of infection (e.g. urinary tract or pelvic infection), the efficacy of the specific antibiotic at the target site (e.g. renal parenchyma, intracellular or extracellular bacterium, vegetation of endocarditis), the severity of illness (e.g. presence of renal function impairment), putative adverse effects of the agent on the mother and fetus and on the environment, and the cost of administering the drug. Whenever possible, a narrow-spectrum drug is to be preferred to a broad-spectrum agent, and single therapy in most instances is preferable to multiple drug use. Pollution of the environment with antibiotics can only lead to a vicious circle involving emergence of increasingly resistant endemic flora that require ever more esoteric and expensive antibiotics for adequate treatment.

Empiric therapy must often be administered before the specific infecting microorganism has been isolated, or before its sensitivity to various antibiotics has been established. In most instances, knowledge of the anatomic site(s) of infection will be apparent (e.g. pneumonia, peritonitis, endometritis, pelvic inflammation). This, together with the circumstances under which the infection developed (e.g. community- or hospital-acquired, immunosuppressed host, postoperative) will provide a reasonable indication of the putative pathogen(s) involved. Antimicrobial drugs can then be administered in accordance with their activity against the suspected microorganisms. Consequently, the physician should be aware of the organisms that are currently the endemic nosocomial pathogens in the hospital milieu, and know their common sensitivity patterns, since these frequently differ among institutions and change over time within the confines of a particular hospital.

The penicillins

Penicillins kill bacteria by attaching to enzymes (penicillin-binding proteins) that are involved in the normal process of synthesizing the cell wall in growing bacteria.[2] In general, these antibiotics are well distributed throughout the tissues of the body, although high doses are needed to achieve bactericidal concentrations in the cerebrospinal fluid (CSF). They are relatively non-toxic, although about 10% of patients will develop an allergic reaction, which is the main adverse effect of all penicillins.[3] A report of penicillin allergy in the past is often misleading and incorrect, and a careful history will often elicit data that will make this highly unlikely, e.g. the patient has since received other penicillin preparations without any adverse reaction. However, patients who are allergic to one penicillin must be regarded as being allergic to all the penicillins.

Penicillin G (benzyl penicillin)

Benzyl penicillin, discovered by Fleming in 1928, was originally active against a wide variety of organisms including gram-positive cocci (streptococci, staphylococci), gram-negative cocci (gonococci, meningococci), gram-negative anaerobic rods belonging to the normal mouth flora and gram-positive anaerobic rods (e.g. *Clostridium* species). In addition, penicillin is also active against many anaerobic, non-spore-forming bacilli (e.g. *Actinomyces*, *Propionibacterium*). However, over the years many bacteria have developed resistance, particularly by acquiring the ability to secrete enzymes (β-lactamases) that destroy the β-lactam ring of the penicillin nucleus,[4] such as staphylococci or *Escherichia coli*, or anaerobic flora of the mouth (*Bacteroides melaninogenicus*). Another important mechanism of resistance is achieved by the bacteria being able to alter the penicillin-binding proteins so that they no longer bind the penicillins well.[5] The most important organisms that have become relatively resistant to penicillin by this mechanism include the pneumococci and some of the viridans streptococci of the oral cavity. Consequently, community-acquired aspiration pneumonia will no longer always respond to penicillin G.[6] On the other hand, β-hemolytic streptococci such as *Streptococcus pyogenes* or group B β-hemolytic streptococci have remained exquisitely sensitive to penicillin G, as have most viridans streptococci and pneumococci. Invasive pneumococcal infections with organisms that are relatively resistant to penicillin G are becoming more common.[7] These organisms respond only to high doses of penicillin G, except in sanctuaries such as the CSF where sufficiently high concentrations of

the antibiotic cannot be obtained to eradicate the infection, necessitating the use of other drugs such as the third-generation cephalosporins.

Treponema pallidum remains sensitive to penicillin, as are most strains of *Neisseria meningitidis*, although the gonococcus has acquired β-lactamases that render it resistant in many areas of the world.

Phenoxymethyl penicillin (penicillin V)

These penicillins have a similar spectrum of activity as the benzyl penicillins, but are less active against the *Neisseria* species. They are administered orally instead of intravenously.

Metabolism, dosage and routes for benzyl and phenoxymethyl penicillins

Benzyl penicillin and phenoxymethyl penicillins are excreted mainly in the urine, and, to a much lesser extent, in the bile. Crystalline benzyl penicillin is administered by intravenous injection, in doses that may range from 1,000,000 units every 6 h, to much higher doses, in the case of pneumonia caused by relatively resistant pneumococci, for example, when 12,000,000 units may be administered daily in six divided doses. In the case of meningitis caused by a sensitive organism, the drug may be administered every 2 h.

Sustained-release intramuscular preparations are also available, and may be used in the case of infection due to a known sensitive organism such as *Streptococcus pneumoniae*. In this case procaine penicillin G may be used in the dose of 600,000–1,200,000 units every 12 h. Benzathine penicillin G results in a very slow release of penicillin from the intramuscular compartment. The usual dose is 2.4 million units of benzathine penicillin at intervals that depend on the indication (mainly syphilis and prevention of rheumatic fever).

Indications in obstetrics and gynecology

Benzyl penicillin is the drug of choice for β-hemolytic streptococcal infections, for the treatment of actinomycosis, which may occur in association with intrauterine device (IUD) usage, and for clostridial infections.

Use in pregnancy

The benzyl penicillins and phenoxymethyl penicillins have been used extensively in pregnancy and are considered safe for the fetus.

Penicillinase-resistant antistaphylococcal penicillins (methicillin, oxacillin, cloxacillin, dicloxacillin, flucloxacillin and nafcillin)

These semisynthetic penicillins, which are resistant to the penicillinases, are used mainly for the treatment of staphylococcal infections. They have a much narrower spectrum of activity than benzyl penicillin. Streptococci are more sensitive to penicillin G, but, except for enterococci which are resistant, will usually respond to therapy with one of the antistaphylococcal penicillins. Although the incidence of interstitial nephritis seems to be more common with methicillin there is no clinical evidence that justifies favoring one of these agents over the others.

In infections suspected to be caused by gram-positive cocci, one of this group of drugs should be used before final identification and sensitivity results are available. Such a situation might include postoperative wound infection, line sepsis, or presence of gram-positive cocci in grape-like clusters in secretions or pus. Staphylococci develop resistance to these drugs as a result of alterations in their penicillin-binding proteins that result in a lower affinity of these enzymes for the antibiotics.[8] If the prevalence of resistant staphylococci is high, then vancomycin should be the drug of choice when gram-positive infection is suspected.

Metabolism, dosage and route

These drugs are excreted in the urine by both glomerular filtration and tubular secretion, and a small proportion is excreted in the bile. Nafcillin reaches high concentrations in the CSF of patients with normal meninges and in those with meningitis.

Methicillin and nafcillin are administered by the intravenous route only, whereas cloxacillin, dicloxacillin and flucloxacillin can be given by the oral route as well. The doses of these drugs vary between 4.0 and 12.0 g/day depending on how serious an infection is being treated.

Indications in obstetrics and gynecology

These drugs are indicated almost exclusively for the treatment of infections due to *Staphylococcus aureus*, including the toxic shock syndrome.

Use in pregnancy

All these drugs cross the placenta, and are not known to cause any fetal damage.

Aminopenicillins (ampicillin and amoxycillin)[9]

Ampicillin and amoxycillin have the same antibacterial spectrum. The only real clinical difference between them is the much increased absorption of amoxycillin from the gastrointestinal tract, so that amoxycillin should be used for oral therapy and ampicillin for intravenous administration when necessary. The aminopenicillins are clinically effective against the same organisms as penicillin G. In addition, they are highly active against gram-negative organisms such as *E. coli*, *Salmonella* spp., *Shigella* spp. (for which amoxycillin should not be used) and *Hemophilus influenzae*. However, the proportion of these organisms in the community, which have acquired resistance to these drugs, is such that ampicillin can no longer be regarded as an adequate empiric choice for

the treatment of severe infections, including urinary tract or pelvic infection, or meningitis, in which these organisms are suspected of being the causative agents. Ampicillin is still the treatment of choice for infections caused by *Enterococcus faecalis* and *Listeria monocytogenes*. Although aminoglycosides are synergistic with ampicillin against the enterococci, this combination is not usually necessary except in situations such as endocarditis where bactericidal activity against the organisms is essential to obtain a cure.

Association with β-lactamase inhibitors (amoxycillin/clavulanic acid, ampicillin/clavulanic acid)

These antibiotics are becoming increasingly popular in clinical practice. The β-lactamase inhibitor potassium clavulanate irreversibly binds and inhibits many bacterial β-lactamase enzymes that are coded for by plasmids, but not by chromosomes. Thus, the addition of the inhibitor to amoxycillin effectively broadens the spectrum of this antibiotic (Augmentin) to β-lactamase-producing organisms such as *H. influenzae*, *E. coli*, most *Bacteroides fragilis* and staphylococci that are not resistant to methicillin. Augmentin plus doxycycline is an excellent oral regimen for the treatment of pelvic inflammatory disease.

Sulbactam is a penicillanic acid sulfone β-lactamase inhibitor, which, in a similar manner to clavulanic acid, extends the effective antibacterial spectrum of this drug when combined with ampicillin (Unasyn). Unasyn has been shown to be effective in soft tissue pelvic infections and in polymicrobial infections.

Metabolism, dosage and route

The aminopenicillins are excreted mainly in the urine, and to a small extent in the bile. The usual oral dose of amoxycillin is 250–500 mg three times a day, and the intravenous dose is 1.0 g three times per day. The usual intravenous dose of ampicillin is 1–2 g every 4–6 h, depending on the severity of the disease. Ampicillin/sulbactam (Unasyn) is available as 1.0 g of sulbactam to every 2.0 g of ampicillin. The usual dosage is 0.5 to 1.0 g sulbactam plus 1–2 g of ampicillin every 6 h.

Indications in obstetrics and gynecology

Ampicillin can be used in the treatment of cystitis in those areas where *E. coli* resistance is rare, but should no longer be used for the initial treatment of pyelonephritis, although its use should be encouraged in urinary tract infections where the organism is known to be sensitive to ampicillin. It is still the drug of choice in infections caused by the enterococcus, and may be used in serious pelvic infections in association with other drugs that are effective against anaerobes and have a wider spectrum of activity against the Enterobacteriaceae.

Use in pregnancy

Ampicillin has been used extensively in pregnancy and is regarded as safe in pregnancy. The β-lactamase inhibitors have been used less frequently in pregnancy, but there is no evidence for their causing fetal abnormalities, and they can be used when indicated.

Carboxypenicillins (carbenicillin and ticarcillin)

These antibiotics are similar to ampicillin but extend the spectrum to indole-positive *Proteus* spp., *Enterobacter* spp. and especially *Pseudomonas aeruginosa*. They have been replaced generally by the ureidopenicillins (see below).

Combination with β-lactamase inhibitors (timentin)

Ticarcillin plus clavulanate extends the spectrum of ticarcillin greatly against β-lactamase-producing strains of *H. influenzae*, *Staphylococcus* coagulase-positive, *B. fragilis*, Enterobacteriaceae and other organisms. Timentin is a reasonable choice for the treatment of soft tissue pelvic infections and polymicrobial infections.

Ureidopenicillins (mezlocillin, azlocillin and piperacillin)

These drugs extend the range of activity of penicillin and ampicillin, and have a similar spectrum of antibacterial activity to the carboxypenicillins (see above), but their range is somewhat wider. Their activity against *Klebsiella pneumoniae* and *P. aeruginosa* is notable. There is no clinical evidence that differences between these antibiotics have any clinical relevance. They have a lower sodium content (1.85–2.17 meq/g) than the carboxypenicillins, and thus have a lesser tendency to produce hypokalemia. Single agent therapy with the ureidopenicillins has been shown to be effective in a wide range of serious infections, including pneumonia, bacteremia, soft tissue infections and intra-abdominal infections. In many hospitals the proportion of Enterobacteriaceae and *P. aeruginosa* that are resistant to these antibiotics may well preclude their use as single drugs in serious infections. In all patients with granulocytopenia and fever of unknown origin, they need to be administered with another drug, such as an aminoglycoside, but care must be taken to ensure that these two drug groups are not mixed in solution before administration.

Combination with β-lactamase inhibitors (piperacillin/tazobactam)

Tazobactam is another irreversible β-lactam inhibitor, which has been combined with piperacillin to increase its antimicrobial spectrum to include Enterobacteriaceae, *B. fragilis* and Staphylococci, and has been successfully used in the treatment of pelvic infections. This drug is especially useful in nosocomially acquired infections, and has been successfully used as a single agent in fever of unknown origin in patients with granulocytopenia.

Metabolism, dosage and route

The ureidopenicillins are excreted primarily by the kidneys, by means of glomerular filtration and tubular secretion. The dose of mezlocillin is 200–300 mg/kg/day; usually 5.0 g four times daily given intravenously. Piperacillin is given intravenously in a dose of 4 g every 4–6 h. Piperacillin/tazobactam is given in the dose of 3 g piperacillin with 0.375 g tazobactam every 6 h.

Indications in obstetrics and gynecology

Clinical investigations have confirmed the efficacy of mezlocillin or piperacillin as single agents for the treatment of mixed aerobic–anaerobic soft tissue pelvic infection, although one study has found the combination of clindamycin and gentamicin to be superior to mezlocillin. However, in another study, piperacillin was approximately equivalent.

Adverse effects of all penicillins

Allergic reactions are the commonest adverse effects encountered with all the penicillins, and may be present in 3–5% of the population and up to 10% of those who have previously received penicillin. Local application of the penicillins should never be used because of the high risk of producing sensitization. It cannot be emphasized strongly enough that cross-allergenicity exists among all the penicillins, and if a true allergic reaction has occurred to any one of the penicillins it must be assumed that the patient is allergic to all penicillins.

Drug fever and various skin rashes are common. Drug fever can be especially difficult to interpret in a patient who is being treated for serious infection, since the clinical picture may be indistinguishable, and a high index of suspicion is essential to make the correct diagnosis. Severe reactions that occur include drug rashes, angioneurotic edema, serum sickness and anaphylaxis. About 5% of patients will show cross-allergenicity with the cephalosporins, which can be useful alternatives in the penicillin-allergic patient, but they should be avoided if there is a history of a type I allergic reaction. Less common adverse effects include hemolytic anemia, granulocytopenia and interstitial nephritis (especially with methicillin). Massive doses, especially in renal failure, may produce neurological symptoms and signs, including hallucinations and generalized convulsions. Electrolyte disturbances may be produced by the high sodium load of the carboxypenicillins and the relatively high potassium load (1.6 meq/1 million units) that can occur with the administration of potassium penicillin G in patients with impaired renal function.

Cephalosporins

These are synthetic β-lactam antibiotics that, like penicillin, interfere with construction of the bacterial cell wall. They have a broad spectrum of activity including an extremely wide range of microorganisms, but the enterococcus is resistant. Resistance among gram-negative bacteria is almost always the result of inactivation by β-lactamases. Classically, these agents have been divided into first-, second- and third-generation cephalosporins, based on their activity and not the chronology of their marketing.

First-generation cephalosporins (the parenteral drugs: cephalothin, cefazolin, cephradine and the oral drugs: cephapirin, cephalexin, cefaclor and cefadroxil)

The antibacterial activity of first-generation cephalosporins is interchangeable practically among the different preparations. The antibacterial spectrum is roughly that of the antistaphylococcal penicillins plus ampicillin, although *H. influenzae*, *E. faecalis* and *L. monocytogenes*, which are resistant to all the cephalosporins, are very important exceptions. They are active against the streptococci (except enterococci) and methicillin-sensitive staphylococci. The cephalosporins must not be used to treat methicillin-resistant staphylococci that may be reported by the laboratory as being sensitive to first-generation cephalosporins since clinical failure is likely. The first-generation cephalosporins are also active against *E. coli*, *Klebsiella* spp. and non-indole-positive *Proteus* spp., whereas *Enterobacter* spp., *S. marcescens*, *Citrobacter*, other Enterobacteriaceae and *P. aeruginosa* are resistant, as are *Chlamydia trachomatis* and mycoplasmas. These drugs are not active against *B. fragilis*, and do not cross the blood–brain barrier in high enough concentrations to be useful in the treatment of meningitis.

Metabolism, dosage and route

All the first-generation cephalosporins are excreted via the renal route, but some (cephalothin, cephradine and cephapirin) are also excreted via the liver, and must thus be given at more frequent dosage intervals. In renal failure, dosage adjustments are necessary. Cephalothin is administered intravenously in doses that vary from 4.0 to 12.0 g/day, depending on the severity of the infection. Since cefazolin is excreted only via the kidneys and thus has a half-life of 1.8 h, it can be given 8-hourly. Cephalexin and cephradine are administered in the dose of 250 mg every 6 h, cefadroxil 1.0 g every 12 h and cefaclor 250 mg daily.

Indications in obstetrics and gynecology

The first-generation cephalosporins are the drugs of choice for prophylaxis in obstetric and gynecological procedures.[10] Although these drugs are not the drugs of choice for many infections, they are extremely useful in patients with delayed-type hypersensitivity to the penicillins, since there is little cross-reaction between the drug groups. However, if there has been a severe reaction to any penicillin in the past (e.g. anaphylaxis) the cephalosporins should be avoided

unless there is no alternative. The first-generation cephalosporins are also useful in the treatment of mild to moderate pyelonephritis, which is caused by organisms resistant to ampicillin and cotrimoxazole, and may be used in other infections that are caused by an organism of known sensitivity, e.g. *K. pneumoniae* pneumonia.

Use in pregnancy

These drugs are considered safe in pregnancy.

Second-generation cephalosporins (cefamandole, cefoxitin, cefuroxime,[11] cefonicid, cefotetan, ceforanide and cefmetazole)

These drugs retain sufficient activity to be effective against gram-positive cocci. Thus, they are indicated when the infecting organisms have not yet been identified and a mixed infection including gram-positive cocci is suspected or has been proven. All drugs of this group (except cefoxitin) show excellent activity against all *H. influenzae*. Cefuroxime should not be used for meningitis, nor should other members of this group. Good activity against *B. fragilis* is shown by cefoxitin, which is thus a useful drug in the treatment of mixed infections with anaerobes, gram-negative aerobes and gram-positive cocci such as occurs in the infected diabetic foot.[12] Cefotetan is also active against *B. fragilis* and has a half-life of up to 4.5 h, so that it need be administered only every 12 h. Penicillinase-producing *N. gonorrhea* are sensitive to cefoxitin and cefotetan. The antimicrobial spectra of cefuroxime, cefonicid and ceforanide are very similar. They do not include *B. fragilis*, and these drugs are not usually used in pelvic infections. *C. trachomatis* and the genital mycoplasmas are resistant to the second-generation cephalosporins.

Metabolism, dosage and route

Most of these drugs are excreted mainly in the urine, and thus need a dose adjustment in patients with renal impairment. For initial treatment of infections with cefoxitin the dosage is 1–2 g intravenously every 6 h, for cefamandole 2–3 g every 6 h and for cefotetan 1–2 g every 8–12 h.

Indications in obstetrics and gynecology

Cefoxitin and cefotetan have been used successfully as single drugs in pelvic infections.

Use in pregnancy

Cefoxitin, cefotetan and cefamandole have been widely used in pregnancy and are considered safe.

Third-generation cephalosporins (cefotaxime, ceftizoxime, ceftriaxone, moxalactam, cefoperazone, ceftazidime, cefsulodin, cefixime and cefpodoxime)

Some of these drugs broaden the spectrum of activity of the cephalosporins against the Enterobacteriaceae, and others against *P. aeruginosa*, but they all show decreased activity against the gram-positive cocci and (except for moxalactam and ceftizoxime) they have no activity against β-lactamase-producing anaerobes such as *B. fragilis*. The third-generation cephalosporins are the drugs of choice in gram-negative bacillary meningitis in adults.[13] Cefotaxime still retains useful, although inferior, activity against the gram-positive cocci and is ineffective against *P. aeruginosa*. Ceftriaxone is almost identical in its antibacterial activity to cefotaxime, having little antipseudomonas activity, but because of its extraordinary half-life (nearly 6 h) it need be given only once daily. On the other hand, ceftazidime has almost no activity against staphylococci, but is as active as cefotaxime against the Enterobacteriaceae and, in addition, is particularly active against *P. aeruginosa*. Ceftazidime has been used successfully as a single drug in the treatment of infections caused by *P. aeruginosa*, including meningitis.[14] Ceftizoxime is similar to cefotaxime in its antibacterial activity, but also has a useful effect on *B. fragilis*.[15] Cefsulodin is used clinically only against *P. aeruginosa*. Against *N. gonorrhea*, activity of cefotaxime, ceftazidime cefoperazone, moxalactam and especially ceftriaxone is excellent.

Metabolism, dosage and route

These drugs differ in their metabolism. Cefotaxime has a short half-life since it is excreted both in the urine and via the bile, and should be administered every 6 h at a dose of 1–2 g per dose. Cefoperazone and ceftazidime are administered at a dose of 2.0 g every 8–12 h. Ceftriaxone, which has the longest half-life of all, is administered at a dose of 2.0 g every 24 h. Cefotetan is given every 12 h at a dose of 2.0 g.

Indications in obstetrics and gynecology

Although some of these drugs have been used as single agents in pelvic infections, the lack of coverage against *B. fragilis* and *C. trachomatis* makes them poor choices in serious infections. Cefoxitin, ceftizoxime and cefotetan do have reasonable coverage against *B. fragilis*. Ceftriaxone is the drug of choice for anorectal gonorrhea.

Use in pregnancy

A suitable choice of a cephalosporin may be confusing. It is most appropriate to use an older or earlier-generation cephalosporin whenever possible, in order to decrease as far as possible the emergence of resistant bacteria. When treating infections where gram-positive cocci are the putative pathogens, such as cellulitis, or in patients with proven staphylococcal or streptococcal (not enterococcal) infections who have a history of penicillin allergy (not type I) cefazolin is probably the drug of choice. It is also the commonest cephalosporin used for surgical prophylaxis. In community-acquired pneumonias, especially in patients with chronic obstructive pulmonary disease or in young children

Table 171.3 Recommended dosages for some parenterally administered cephalosporin antibiotics in adults with normal renal function

Antibiotic	Daily dose (g)	Time between doses (h)	Maximal dose (g/day)
First-generation			
Cefazolin	1	8	4
Second-generation			
Cefoxitin	2	4–6	12
Cefuroxime	1.5	6–8	9
Cefonicid	1	12	2
Cefotetan	2	12	6
Third-generation			
Cefotaxime	2	6	12
Ceftizoxime	2	8	12
Ceftriaxone	1	12	2
Cefoperazone	2	8	8
Ceftazidime	2	8	6

where *H. influenzae* may be the offending pathogen, cefuroxime is preferred. The widespread use of cephalosporins has led to the emergence of the enterococci as nosocomial pathogens. Enterobacteriaceae that are resistant to multiple antibiotics should be treated with cefotaxime, ceftriaxone or ceftizoxime. When *P. aeruginosa* is the offending pathogen, or when a gram-negative hospital-acquired pathogen is suspected, ceftazidime would be the appropriate cephalosporin to choose for initial therapy. Under these circumstances, many infectious disease experts would prefer an aminoglycoside with a ureidopenicillin (e.g. gentamicin or amikacin plus mezlocillin or piperacillin).

Adverse effects of all cephalosporins

The cephalosporins are relatively non-toxic when compared to other antimicrobial drugs. The main adverse effects, as with other β-lactams, are allergic or hypersensitivity reactions that occur in 1–5% of patients, but anaphylaxis is rare.[16] On the other hand, the cephalosporins are a common cause of drug fever, and isolated eosinophilia has been noted in 7% of patients receiving cefoperazone or ceftazidime. Cross-reactions between penicillins and cephalosporins occur in about 5% of cases. Cephalosporins can usually be administered safely to patients who have not had an immediate-type reaction to the penicillins, but should be avoided in patients who have had such a reaction. A positive Coomb's reaction occurs frequently, but is usually not associated with hemolysis. Bleeding due to the inhibition of vitamin K synthesis in the liver has been a problem particularly with moxalactam, but can potentially occur with cefoperazone, cefamandole, cefmenoxime and cefotetan, which also bear the methylthiotetrazole (MTT) group side-chain. This same substitution can also produce a disulfiram-like reaction due to inhibition of the hepatic acetyldehydrogenase enzyme. Ceftriaxone has been associated with the formation of biliary sludge, which may lead to symptoms and signs of cholecystitis, but this phenomenon is reversible on withdrawal of the drug.[17] Rare complications include neutropenia, thrombocytopenia and hepatic dysfunction. Renal failure is highly unlikely, although the combination of gentamicin with cephalothin is probably more nephrotoxic than gentamicin alone.[18]

Superinfections frequently occur, and the wide use of cephalosporins has also resulted in the emergence of *E. faecalis* as a nosocomial pathogen. Candida infections may occur, and are particularly troublesome in severely compromised patients who have received intravenous therapy with broad-spectrum antibiotics for prolonged periods. Dosages for several cephalosporin drugs in severe infections are shown in Table 171.3.

Other β-lactam antibiotics (imipenem and azthreonam)

Imipenem consists of the active principle thienamycin, which is a carbapenem, combined with cilastatin, which has no antibacterial activity but inhibits the enzymatic destruction of thienamycin by the dipeptidase enzymes of the renal tubular brush border and prevents renal toxicity. Imipenem has the widest spectrum of all antimicrobial drugs, including gram-positive cocci and gram-negative bacilli, penicillinase-resistant staphylococci, *P. aeruginosa*, *Acinetobacter* spp. and β-lactamase-producing anaerobes (including *B. fragilis*). The one organism that is consistently resistant is *Stenotrophomonas* (*Pseudomonas*) *maltophilia*. Imipenem has proven very useful in the treatment of hospital-acquired infections, especially when caused by Enterobacteriaceae. When used as a single drug against *P. aeruginosa*, resistant organisms have emerged. This drug should be reserved for serious hospital-acquired infections, both because of its cost and the need to minimize the emergence of resistant bacteria.

The main adverse effects of imipenem are those of all β-lactams, with perhaps a greater tendency to produce neurological adverse effects such as seizures. Rapid infusion may produce nausea and emesis.

Aztreonam is a monobactam, i.e. its basic structure consists of only a single β-lactam ring. This antibiotic is a narrow-spectrum antimicrobial drug, which is very active against gram-negative organisms only, and has no effect on *E. faecalis* or the anaerobes.[19] It has been used as a single drug in severe infections (septicemia, pneumonia, skin and soft tissue) caused by sensitive gram-negative organisms, including *P. aeruginosa*. It has no activity against *C. trachomatis*. The usual dose of aztreonam is 1.0–2.0 g given every 8 h intravenously. Aztreonam accumulates in renal failure in the presence of which the dose should be modified. Aztreonam has been used in combination with other antibiotics such as clindamycin in the

treatment of severe pelvic infections, since it can replace the aminoglycosides for community and (most) nosocomial infections. The chemical structure of aztreonam apparently results in an absence of allergic cross-reactions between this drug and the penicillins or cephalosporins.

Vancomycin[20]

Vancomycin is a narrow-spectrum, complex glycopolypeptide antibiotic, which acts by inhibiting synthesis of bacterial cell-wall peptidoglycan. Its main indication is for therapy of methicillin-resistant staphylococcal infections (both coagulase-positive and-negative), and for treatment of serious methicillin-sensitive staphylococcal infections when the patient is intolerant to the penicillins and cephalosporins. In addition, this antibiotic can be used to treat enterococcal endocarditis in patients who have serious penicillin allergy and cannot be desensitized. Since vancomycin is bacteriostatic to streptococci, it should be combined with an aminoglycoside (streptomycin or gentamicin) with which it is synergistic and bactericidal. Vancomycin is also the drug of choice in resistant *Corynebacterium* spp. infections. It is poorly absorbed when given by mouth, and pseudomembranous enterocolitis caused by *Clostridium difficile* can be treated with vancomycin given orally, in a dose of 125 mg four times daily for 7–10 days, although this should be avoided if at all possible in order to minimize the emergence of vancomycin-resistant enterococci (VREF).

Besides the emergence of resistance among enterococci the main adverse effects of vancomycin include local irritation, so the drug must be given intravenously. If infused rapidly the so-called 'red man' syndrome may be produced, including an erythematous or maculopapular rash involving the upper portion of the body, with or without hypotension and/or syncope. This is not a true allergic reaction, and is probably due to a non-immunologically mediated release of histamine. If this occurs, the drug may be re-administered, provided it is infused slowly. Vancomycin is excreted solely via the kidneys, and the dose must be modified in patients with renal dysfunction, as auditory (and rarely vestibular) damage may be produced. Rarely, drug fever or leukopenia occurs.

Tetracyclines (tetracycline hydrochloride, minocycline and doxycycline)

These antibiotics have similar antibacterial spectra, and exert their antibacterial activity by binding to the 30 S ribosomes where they inhibit protein synthesis. The tetracyclines penetrate well into the body tissues and fluids. They are active against gram-positive cocci including pneumococci and streptococci, gram-negative Enterobacteriaceae including *E. coli*, *H. influenzae* and *K. pneumoniae* and anaerobic bacteria (*Propionibacterium acnes*, *Bacteroides* spp.). However, many of these organisms have developed resistance to the tetracyclines, and these drugs are no longer used as a first-line treatment when serious infections caused by these organisms occur. Chlamydia, mycoplasmas, rickettsiae and some protozoa (including *Plasmodium falciparum*) remain sensitive to these drugs, which are now most frequently indicated for ambulatory infections such as sexually transmitted diseases. Approximately 50% of penicillin-resistant gonococci are also resistant to tetracyclines. The main indications for use of tetracyclines in serious disease are for infections caused by rickettsia (e.g. Rocky Mountain spotted fever, or Q-fever endocarditis), and for brucellosis, relapsing fever (*Borrelia recurrentis*), tularemia, cholera and plague (*Yersinia pestis*).

Metabolism, dosage and route

All tetracyclines are excreted by the kidneys via glomerular filtration. Although they are excreted in the bile, a large proportion is reabsorbed by the gastrointestinal tract. The dose of tetracycline is 500 mg every 6 h, and of minocycline and doxycycline 100 mg every 12 h on the first day, followed by 100 mg every 24 h.

Indications in obstetrics and gynecology

In gynecology, the main indication of tetracyclines is for the treatment of *C. trachomatis*, *M. hominis* and ureaplasma infections.

Use in pregnancy

Tetracyclines cross the placenta readily and are in category D because they are known teratogens. They should be avoided in pregnancy unless absolutely essential (see below).

Adverse effects

The major adverse effects are gastrointestinal intolerance, skin rashes and secondary infections of the mucous membranes with *Candida albicans* (vaginal candidiasis). Fatty necrosis of the liver may be caused by intravenous tetracycline, especially if more than 2 g per day is administered, especially during pregnancy.[21] Minocycline tends to produce dose-related vestibular toxicity, with dizziness, ataxia, nausea and vomiting. Phenytoin and barbiturates may shorten the half-life of doxycycline by increasing hepatic metabolism of the drug. Except for doxycycline, the tetracyclines aggravate renal failure by inhibiting protein synthesis. Because of dose-related yellow mottling, hypoplasia and enamel defects[22] of developing teeth and deposition in growing bones of infants where they may disturb longitudinal growth,[23] these drugs should not be given to pregnant or lactating women or to children under 8 years of age, unless under very

special circumstances, e.g. a short course in Rocky Mountain spotted fever.[24]

Chloramphenicol

Chloramphenicol inhibits synthesis of bacterial protein by binding to the 50 S ribosomal subunit. It is very well absorbed from the gastrointestinal tract even in the presence of food, and is widely distributed throughout the body tissues and fluids. This antibiotic is inactivated in the liver, and may reach toxic levels when the glucuronyltransferase activity is low, as occurs in liver disease or in the immature neonate. Chloramphenicol is excreted rapidly and does not accumulate in renal failure. It is a very wide-spectrum antibiotic, which is effective against most Enterobacteriaceae, and has excellent activity against *B. fragilis*. Chloramphenicol is effective in brain abscesses caused by susceptible organisms. It is an important drug in the treatment of typhoid fever and severe rickettsial infections in patients who cannot receive tetracyclines (e.g. during pregnancy).

The major adverse effect of chloramphenicol is an idiosyncratic aplastic anemia that occurs in 1/40,000 to 1/100,000 courses of therapy, and is almost always fatal. A dose-related bone suppression that reverses when chloramphenicol is discontinued also occurs. In liver disease and neonates chloramphenicol is better avoided, but if it has to be given, serum levels must be measured. Chloramphenicol inhibits the hepatic microsomal enzymes so that the half-life of drugs that are metabolized by this system (e.g. dicumarol, phenytoin, chlorpropamide and tolbutamide) may be prolonged.

Macrolides (erythromycin, roxithromycin, clarithromycin and azithromycin)

These antimicrobial drugs are all macrolides, and have a similar, although not quite identical spectrum (see below). In general, if an organism is resistant to one member of this group, it is with some exceptions resistant to all other members.

Erythromycin

This macrolide antibiotic acts by binding to the 50 S ribosomal subunit, where it inhibits protein synthesis. It is well distributed throughout the body except in the CSF and brain. It is active against most bacteria that are sensitive to penicillin G, and also against staphylococci, although the latter often become resistant when the use of erythromycin is widespread. It is the drug of choice for the treatment of *M. pneumoniae* and *Legionella*,[25] *Hemophilus ducreyi* and *Corynebacterium diphtheriae* infections. Erythromycin is also active against *C. trachomatis*, *M. hominis* and *U. urealyticum*. It can be used in penicillin-allergic patients against *T. pallidum*. *S. aureus* is generally sensitive to erythromycin but resistance does develop during treatment, and while superficial infections caused by staphylococci may be treated with this drug, in severe or deep-seated infections (intra-abdominal abscess) the organism tends to develop resistance, and the macrolides should not be used.

Adverse effects

This is a very safe antibiotic, the most common problem being severe gastrointestinal disturbances. In addition, reversible hepatitis may be produced, particularly, but not exclusively, by the oral estolate. Reversible deafness may be produced by high dosages, especially when renal function is impaired. Erythromycin may increase the serum concentration of cyclosporine because of competition for protein-binding sites. All the macrolides including erythromycin, clarithromycin and azithromycin (see below) interact with terfenadine and astemizole, to produce a prolonged Q–T interval and life-threatening arrhythmias.

Metabolism, dosage and route

Erythromycin can be administered via the oral or intravenous route. Oral preparations include erythromycin base, which requires enteric coating to make it palatable, stearate, which hydrolyzes to the base in the duodenum, estolate and ethylsuccinate, which are acid-stable. Erythromycin is excreted primarily in the bile. The dose of oral erythromycin is 250–500 mg every 6 h. The intravenous form is administered in high doses (0.9 g every 6 h) for *Legionella* infections.

Indications in obstetrics and gynecology

Erythromycin may be used for staphylococcal or streptococcal infections in penicillin-allergic patients (see above). It is especially useful for the treatment of *C. trachomatis* infection in pregnancy when tetracycline is contraindicated.

Use in pregnancy

Erythromycin has been extensively used and is safe in pregnancy.

Clarithromycin

Except for enhanced activity against *H. influenzae* and Mycobacterium–avium complex, the spectrum of activity of this drug is similar to that of erythromycin. The dose varies from 250 to 500 mg every 12 h. The most common side effect is gastrointestinal disturbance, but this is less frequent than with erythromycin. Clarithromycin should only be used during pregnancy when definitely indicated (e.g. infection with Mycobacterium–avium complex).

Azithromycin

Azithromycin has the same general spectrum of activity as erythromycin, although it is slightly less active against the gram-positive cocci, but more active against *H. influenzae*.

Metabolism, dosage and route

Azithromycin is better absorbed than erythromycin. Blood levels of the antibiotic are low, but the levels in the polymorphonuclear leukocytes and in the tissues at the site of infection are 10- to 100-fold higher than serum levels. Moreover, the half-life in the tissues is 2–4 days, thus allowing earlier cessation of therapy while the antibiotic remains active at the site of infection for several more days. The dose is 1.0 g as a single dose for chlamydial cervicitis, and 2.0 g as a single dose for uncomplicated gonococcal infections. For lower respiratory tract infections the dose is 500 mg as a single dose on day 1, followed by 250 mg once daily on days 2–5 for a total dose of 1.5 g.

Use in pregnancy

Currently this drug is not recommended in pregnancy since no data are available regarding its safety.

Rifampicin

Rifampicin, a rifamycin compound, exerts its action by inhibition of DNA-dependent RNA polymerase. This antibiotic has an extremely wide antibacterial spectrum, but is used primarily for the treatment of tuberculosis. In addition, it is remarkably active against both coagulase-positive and coagulase-negative staphylococci. Thus, it is often recommended in infections caused by these organisms that are not responding well to therapy, or that are expected to be difficult to eradicate, e.g. meningitis in the presence of an artificial device, or endocarditis on an artificial valve.[26]

Because of its marked *in vitro* activity against *Legionella* spp. it is also sometimes recommended for treating pneumonia caused by this organism, which does not respond to erythromycin therapy. Among its other indications is prophylaxis of meningococcal meningitis in close contacts of infected patients. The rapid emergence of resistance when rifampicin alone is given is notable. Consequently, rifampicin is usually administered with another antibiotic.

Adverse effects

A red-orange staining of urine, tears and soft contact lenses may occur with short courses of therapy. Gastrointestinal and cutaneous manifestations may occur. Intermittent therapy and administration of doses larger than 1200 mg/day have been associated with an increased incidence of severe side effects, including a flu-like syndrome, hemolysis, renal failure and even shock. Rifampicin is one of the most active inducers of the hepatic microsomal enzymes, and results in decreased efficacy of many compounds, including barbiturates, cimetidine, oral contraceptives, cyclosporine, digoxin, ketoconazole, β-blockers, sulfonylureas, theophyline, thyroxin and warfarin.

Use in pregnancy

Rifampicin may be used for the treatment of tuberculosis in pregnancy.

Clindamycin

Clindamycin is bacteriostatic and acts by attaching to the ribosome where it inhibits protein synthesis. It has a similar antimicrobial spectrum of activity to erythromycin, except that it is much more active against *B. fragilis* and other β-lactamase-producing anaerobes. It is thus indicated in aspiration pneumonia where it may be used as a single drug, although some authorities might still try penicillin G in this situation when the circumstances are not critical. Clindamycin can be used in association with an aminoglycoside in intra-abdominal infections, and also in penicillin- and cephalosporin-allergic patients for streptococcal and staphylococcal infection (but not for endocarditis).[27] It reaches high concentrations in bone, and is useful as a second-line drug in osteomyelitis. Recently, clindamycin has been used as an adjunct therapy in resistant *P. falciparum* malaria.

Adverse reactions

The major serious adverse reaction to clindamycin is the occurrence of pseudomembranous enterocolitis,[28] the result of a toxin produced by a colonic overgrowth of *C. difficile*. The incidence of this complication varies geographically and the onset may occur several weeks after the administration of clindamycin has been stopped. It is not dose-related and may occur after oral or intravenous administration. The patient suffers from diarrhea that may be bloody, abdominal cramps and fever, and the disease may be fatal. Yellow-white plaques on the colonic mucosa may be seen by proctoscopy. The toxin of *C. difficile* can be detected in nearly all patients with this complication. The treatment includes prompt cessation of clindamycin administration, and either metronidazole (250 mg every 8 h) or vancomycin (125 mg every 6 h) should be given orally as therapy against the toxin-producing organism.

Metabolism, dosage and route

Clindamycin is metabolized by the liver, and excreted in an inactive form in the urine. Reduction in dose should be made for patients with liver impairment or severe renal impairment. The dose ranges from 600 mg every 8 h intravenously, to 150–300 mg orally every 6 h. The dose recommended for *C. trachomatis* infection is 450 mg every 6 h.

Indications in obstetrics and gynecology

Clindamycin is indicated in polymicrobial infections of the pelvis including pelvic abscess, tubo-ovarian abscess, endometritis and infection following hysterectomy. In these cases, it should be combined with an aminoglycoside. *C. trachomatis* can be treated with clindamycin, which can also be used for susceptible gram-positive infections including non-enterococcal streptococci and staphylococci. Clindamycin 300 mg every 12 h for 7 days, or clindamycin cream 2% intravaginally twice daily for 5 days are effective in the treatment of bacterial vaginosis.

Use in pregnancy

Clindamycin is probably safe in pregnancy, and if necessary can be used. However, there are no specific infections requiring clindamycin during pregnancy.

Aminoglycosides (streptomycin, kanamycin, gentamicin, tobramycin, netilmicin, amikacin and neomycin)

These antibiotics act by binding to the 30 S bacterial ribosome whereby they disrupt protein synthesis, but are nevertheless bactericidal. They have an extremely wide spectrum of activity, especially on the gram-negative Enterobacteriaceae and *P. aeruginosa*, and are also active against staphylococci. Even though *Salmonella* spp. may be sensitive *in vitro* to the aminoglycosides, they are not effective *in vivo* in the treatment of infections produced by this group of organisms. On the other hand, although aminoglycosides are ineffective against streptococci, they are synergistic with penicillin or vancomycin against these organisms. Uptake of the aminoglycosides by bacteria is oxygen-dependent, so that these drugs do not inhibit anaerobic bacteria. Since these drugs are not metabolized and are rapidly excreted via the renal route only, the half-life increases markedly with declining renal function. In renal failure, it is prudent to avoid the use of aminoglycosides. Serum trough levels should be monitored to prevent accumulation of the drug in the case of poor renal function or in the elderly. On the other hand, the dose may need to be greatly increased if the patient does not respond and the serum levels remain below the maximum peak recommended concentrations.

Streptomycin

Since most Enterobacteriaceae have acquired resistance, this drug is used almost exclusively with other drugs to treat: (1) endocarditis caused by *S. viridans* or susceptible enterococci, together with penicillin or vancomycin (in penicillin-allergic patients);[29] (2) brucellosis, together with tetracycline; (3) tularemia and the plague (as a single drug) and (4) occasionally as one of a combination of drugs in tuberculosis. Streptomycin toxicity is mainly vestibular and auditory and it is the least nephrotoxic of the aminoglycosides.

Gentamicin and tobramycin

These two drugs are very similar with regard to their antibacterial spectrum and pharmacodynamics. They show no clinically important differences, and continue to be the aminoglycosides of choice for serious bacterial infections. Many community-acquired gram-negative infections are now caused by organisms that are relatively resistant, and the use of these drugs in seriously ill patients on admission to hospital (e.g. pyelonephritis with suspected septicemia) is appropriate. Gentamicin or tobramycin are also the aminoglycosides of choice for severe hospital-acquired infections caused by most Enterobacteriaceae and *P. aeruginosa* (e.g. pneumonia, urinary tract infection, septicemia). They are indicated in endocarditis caused by viridans streptococci and enterococci that display high-level resistance to streptomycin. In febrile neutropenic patients, it is appropriate to administer gentamicin or tobramycin in combination with other drugs (e.g. ureidopenicillins or third-generation cephalosporins) that have a better gram-positive spectrum and that can be synergistic against gram-negative organisms such as *P. aeruginosa*. Netilmicin is similar to gentamicin and tobramicin in activity and dosage.

Amikacin

This is the aminoglycoside that is most resistant to the aminoglycoside-modifying enzymes, and should be used empirically when gentamicin resistance is prevalent.

Adverse reactions of aminoglycosides

Adverse reactions include dose-related ototoxicity and vestibular damage[30,31] and renal toxicity. The therapeutic–toxic ratio of all these drugs is low, so that serum levels have to be monitored in these patients who are usually seriously ill, since their renal function often fluctuates and is not reflected immediately by the serum creatinine or blood urea nitrogen. Another important, though rare, event is the production of neuromuscular paralysis, which is enhanced by the presence of curare-like drugs and in patients with myasthenia gravis when very high concentrations of the aminoglycoside are present at the neuromuscular junction.[32] This should be avoided by not giving intravenous bolus injections or introducing large quantities of aminoglycosides into the pleural or peritoneal cavities.

Metabolism, dosage and routes for aminoglycosides

These drugs are administered intramuscularly or intravenously as a single dose or in three divided doses (see Table 171.4). Recently, emphasis has been

Table 171.4 Aminoglycoside doses and recommended serum levels in adults with normal renal function

Antibiotic	Standard dose (mg/kg/day)	Serum concentration (mg/l)	
		Peak	Trough
Streptomycin	15	20–30	<5
Gentamicin	3–5	<10	<2
Tobramycin	3–5	<10	<2
Netilmicin	3–5	<10	<2
Amikacin	15	20–30	5–10

placed on the administration of aminoglycosides as a single daily dose. This is possible because of the prolonged postantibiotic effect of these drugs, of the apparent lower renal and auditory toxicity with this form of administration, and the greater efficacy of aminoglycosides with high peak concentrations. There is great variation in the individual response to aminoglycoside administration, so that serum levels should be monitored, especially in the obese, during the puerperium, and in the presence of renal impairment. The dose has to be modified in accordance with renal function, response to treatment and serum antibiotic levels. Aminoglycosides should not be mixed with β-lactams in the same solution since chelation inactivates the aminoglycoside.

Indications in obstetrics and gynecology

These drugs are used in particular for severe urinary tract infections, and, in combination with clindamycin, for serious soft tissue pelvic infections. Their use is often limited to the initial therapy until culture results are available, after which less toxic drugs may be used in their stead.

Use of aminoglycosides in pregnancy

Streptomycin is known to cause eighth nerve damage *in utero*. Although pregnancy should not be considered an absolute contraindication to the other aminoglycosides, these drugs should be avoided if possible.[33] Only gentamicin is listed in category C. The serum levels attained in pregnancy are lower than expected, because of the increased volume of distribution, and must be carefully monitored. Aminoglycoside doses and recommended serum levels in adults with normal renal function are shown in Table 171.4.

Metronidazole[34]

Metronidazole has been used for many years for the treatment of parasitic infections caused by *Giardia lamblia*, *Entamoeba histolytica* and *Trichomonas vaginalis*, but is now the major drug for the treatment of infections caused by anaerobic bacteria.[35] Its mode of action is not clear, but is thought to be bactericidal via the toxic effect of reductive activation of the compound within the bacterial cell in which there is an interaction with DNA. Metronidazole is most active against the gram-negative anaerobic bacteria, including those that produce β-lactamase, and less active against the anaerobic gram-positive cocci such as peptostreptococci. It is, however, bactericidal against *Clostridium perfringens* and *B. fragilis*, and is thus indicated in the rare instances of meningitis or endocarditis produced by this organism. Metronidazole also has activity against *Helicobacter pylori* and *Gardnerella vaginalis*. Its main indication is in the treatment of deep-seated anaerobic infections, such as in the diabetic foot, intra-abdominal surgical infections and aspiration pneumonia. In all these infections, it should be administered together with a drug that is active against the accompanying aerobic flora that is almost invariably present. Metronidazole is as useful as vancomycin in antibiotic-associated pseudomembranous enterocolitis produced by *C. difficile*.

Metabolism, dosage and route

Metronidazole is very well absorbed, and diffuses well into nearly all tissues. It is eliminated primarily via the liver. Oral doses vary between 2 and 4 g as a single dose (for trichomoniasis) or 250–750 mg every 8 h. Giardiasis is treated with 250 mg tid for 7 days, non-dysenteric amebiasis with 500 mg tid for 10 days, and severe amebic disease with 750 mg tid for 10 days. In bacterial vaginosis, the dose is 500 mg bid for 7 days. For pseudomembranous enterocolitis, the recommended dose is 500 mg tid for 7–10 days.

Indications in obstetrics and gynecology

Metronidazole is the drug of choice in bacterial vaginosis caused by *G. vaginalis*, in association with other anaerobic organisms. Metronidazole gel 0.75% is available for this indication. Since it should not be used in lactating women, it is not used as first-line therapy in deep-seated pelvic infections following labor.

Use in pregnancy

Metronidazole has been used extensively during pregnancy without any apparent problem, but it is recommended that it be avoided during the first trimester of

pregnancy. Lactating women should not receive metronidazole, or breast feeding should be discontinued for 24 h following the administration of a single dose of metronidazole.

Adverse effects

Serious adverse effects are rare. The major toxic reactions are nausea and other gastrointestinal disturbances, an unpleasant metallic taste and peripheral neuropathy following prolonged therapy with high doses in patients with renal insufficiency. An antabuse-like reaction may be seen.

Cotrimoxazole[36]

This drug consists of a combination of sulfamethoxazole (a sulfonamide) and trimethoprim (a diaminopyrimidine), which are sequential inhibitors in the bacterial synthetic chain of folinic acid. Cotrimoxazole is well distributed in the body tissues and fluids, including the CSF. The antibiotic is excreted in the urine and bile, and when the creatinine clearance decreases below 30 ml/min the dosage should be adjusted.

Cotrimoxazole has a very wide spectrum of activity against both gram-positive and gram-negative organisms, but anaerobic organisms are resistant. Its main use is in the outpatient setting for urinary tract infections. The recommended dose is one double-strength tablet (trimethoprim 160 mg, sulfamethoxazole 800 mg) every 12 h. It may also be used in other infections if the organism that is isolated is sensitive *in vitro*. Cotrimoxazole is the treatment of choice for pneumocystis pneumonia infections in patients with AIDS. In this condition, the maximum dose (20 mg/kg/day trimethoprim and 100 mg/day sulfamethoxazole) should be administered orally or intravenously for at least 3 weeks, after which a prophylactic dose should be continued. Another important indication for cotrimoxazole is in patients with infections caused by *Nocardia asteroides*, an important pulmonary and intracerebral pathogen in immunocompromised hosts.

Use in pregnancy

Trimethoprim is in category C and is generally avoided because it inhibits folic acid metabolism. However, cotrimoxazole may be used in pregnancy when indicated and other agents are not available. Sulfonamides are in category B but should be avoided near the end of gestation (third trimester) because of the increased risk of kernicterus in the infant. Kernicterus occurs when the sulfonamide competes with bilirubin for albumin binding, thus causing hyperbilirubinemia. The placenta can clear unconjugated bilirubin, but once the infant is born, it has no elimination mechanism. Infants with glucose-6-phosphate deficiency can develop hemolytic anemia if the mother takes sulfonamides late in pregnancy.[37] At high doses, gross fetal malformations have been reported in animals,[38] but in humans only two studies suggest an association between these drugs and birth defects.[39,40]

Adverse effects

Major adverse effects are rare, but include anaphylaxis, severe cutaneous eruptions, Steven's Johnson syndrome and leukopenia, thrombocytopenia and hemolytic anemia (especially in patients with glucose- 6-phosphate dehydrogenase deficiency). In patients with AIDS, the skin rashes and other toxicities seem to be more frequent. Of special note in these patients is the bone marrow suppression that is engendered by the combination of cotrimoxazole prophylaxis (or therapy) and zidovudine therapy for the underlying AIDS condition.

Nitrofurantoin

Nitrofurantoin is an FDA category B agent. Nitrofurantoin is often an alternative to trimethoprim/sulfamethoxazole for the prophylaxis and treatment of lower urinary tract infections during pregnancy. It has low serum concentrations and, to a very small extent, crosses the placenta.

Use in pregnancy

Teratogenicity or fetal adverse effects have not been observed in animal studies. Several clinical reports support the safety of nitrofurantoin use during pregnancy.[41,42]

Adverse effects

Nitrofurantoin can induce acute hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency or with glutathione-deficient red blood cells. No instances of hemolytic anemia have been reported in newborns. However, the manufacturer cautions the use of nitrofurantoin in pregnant women at term and in infants less than 1 month of age.

Quinolones (norfloxacin, ciprofloxacin, ofloxacin and lomefloxacin)

All the quinolones have a similar structure, are bactericidal and act by inhibiting the enzyme topoisomerase (gyrase) that is required for the supercoiling of DNA strands within the bacterial cell.

The quinolones have a wide spectrum of activity and are particularly effective against the Enterobacteriaceae, including the common urinary pathogens (*E. coli*, *Proteus* spp. and *K. pneumoniae*), *Salmonella typhi* and *S. paratyphi*, and *Shigella* spp. They are also effective against *P. aeruginosa*, even when given orally. With regard to the gram-positive cocci, activity is shown against *S. aureus* and epidermidis,

but against streptococci and anaerobes, activity is borderline to poor, and failures are not infrequent. Consequently, these drugs should not be used in community-acquired and aspiration pneumonias, although they have been very successful in hospital-acquired pneumonia, and urinary activity against *E. faecalis* is often sufficient. The quinolones also have activity against *Legionella pneumophila*, *M. hominis*, *M. pneumoniae* and atypical mycobacteria. Ofloxacin is also recommended for the treatment of infections caused by *C. trachomatis*, and all the quinolones are active against *Neisseria gonorrhea* and *Hemophilus ducreyi*.

Nalidixic acid was the original quinolone, but, because of rapid emergence of resistance, it is used today only for urinary tract infection either as prophylaxis for recurrent acute cystitis, or for therapy. It can also be used as therapy for *Shigella* and other gastrointestinal infections. Norfloxacin is used almost exclusively for infections of the urinary tract, whereas ciprofloxacin, ofloxacin and pefloxacin achieve sufficiently high concentrations within the body fluids and organs to be useful when administered orally. Ciprofloxacin and ofloxacin achieve high concentrations within the macrophages and leukocytes. These drugs can also be administered intravenously in serious infections when oral therapy is contraindicated.

Metabolism, dosage and route

Norfloxacin and ciprofloxacin are excreted by the liver and kidney, whereas ofloxacin and lemefloxacin are excreted mainly by the kidneys. A major advantage of all the quinolones is that they are generally well absorbed following oral administration. Antacids reduce the absorption of quinolones and should not be taken until at least 2 h after taking quinolones. Sucralfate should be administered at least 6 h before any quinolone.

The serum half-lives are prolonged, so they need only be administered twice daily in most instances.

Indications in obstetrics and gynecology

In the community, the quinolones are used for first-line therapy of more serious and complicated urinary tract infections such as pyelonephritis and in patients with kidney stones. The quinolones are also extremely useful in treating uncomplicated gonorrhea, urinary tract infections, diarrheal diseases (including traveller's diarrhea) and chlamydial infections for which ofloxacin has been approved. In the treatment of pelvic inflammatory disease the quinolones need to be combined with an antianaerobic agent such as clindamycin or metronidazole.

These drugs should be used for the oral therapy of infections that would otherwise require intravenous administration of antibiotics. This allows for continuation of therapy of serious infections on an outpatient basis, after they have been controlled during hospitalization, e.g. pseudomonas osteomyelitis. They are generally not used as first-line drugs for the treatment of serious infections within the hospital, although they have proven to be effective in serious infections within intensive care units, in respiratory tract infections, osteomyelitis, infections of the skin and soft tissues, and in intra-abdominal infections when combined with antianaerobic therapy.[43] Although they cross into the CSF, their use in meningitis is anecdotal.

Use in pregnancy

These drugs are deposited in cartilage and result in irreversible arthropathy in animal studies, so that their use in pregnancy is contraindicated.

Adverse effects

The main adverse effects are gastrointestinal, rashes (including photosensitivity) and rarely neurological, including sleep disturbances, acute reversible toxic psychosis and grand malseizures. Because articular damage has been shown in juvenile animals these drugs are presently not approved for use in children under 18 years of age. They are also contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency, in whom they may produce hemolysis.

Antituberculous drugs

Although safety in pregnancy of the drugs commonly used to treat tuberculosis is unknown or poor (Table 171.5), and only ethambutol is in category B, they are not contraindicated during pregnancy because of the risks to the pregnant woman resulting from untreated tuberculosis.[44]

For active tuberculosis, isoniazid and rifampicin are recommended as the initial treatment regimen.[45] Ethambutol should be added unless primary isoniazid resistance is unlikely. Pyrazinamide should probably not be used because of the lack of teratogenic data. Pyridoxine should be added to the regimen to protect against isoniazid neurotoxicity. Isoniazid crosses the placenta, but it appears to be well tolerated. The risk of hepatotoxicity to the mother from this drug may be increased during pregnancy. Neurologic abnormalities have been reported in one small study.[46] Streptomycin (category B) should not be used during pregnancy since it can cause eighth cranial nerve damage and deafness in children born to mothers receiving this drug during pregnancy.

Antifungal agents

Amphotericin B

Amphotericin B (category B) is the treatment of choice for systemic fungal infections, despite the availability of the azole antifungal agents – ketoconazole, fluconazole and itraconazole. Nephrotoxicity and electrolyte wasting are the most significant toxic effects of amphotericin B but they do not occur any more

Table 171.5 Antituberculous agents during pregnancy

Antituberculous agent	Category	Maternal toxicities	Fetal/neonatal toxicities
Isoniazid	C	Hepatotoxicity	Possible neurologic symptoms
Rifampicin	C	Hepatotoxicity, hypoprothrombinemia, bleeding	No known teratogenicity in humans
Ethambutol	B	Optic neuritis	None known
Pyrazinamide	C	Hepatotoxicity	Limited data
Streptomycin	D	Ototoxicity, nephrotoxicity	Ototoxicity

frequently in pregnant women than in non-pregnant women. Teratogenesis or persistent toxic effects have not been found.[47]

Azole antifungals (ketoconazole, fluconazole and itraconazole)

Safety in pregnancy has not been established. Flucytosine is contraindicated during pregnancy because of teratogenic effects observed in rats.[48] Although the manufacturer does not recommend breast-feeding by women using fluconazole, some commentators have concluded that the use of fluconazole is 'probably safe' during lactation.[49]

Antiviral agents

Acyclovir is used in the treatment of herpes simplex virus (HSV) and varicella zoster virus (VZV) infections.[50] Although its safety in pregnancy has not been formally established, in animals it has not caused toxicity or teratogenicity and numerous case reports have been published describing its use in pregnant women with disseminated HSV infections or VZV pneumonia.[51] Of 312 pregnancies followed prospectively, there was no consistent pattern of fetal abnormality or adverse outcome.[52]

Valaciclovir (category C), an acyclovir analog, is rapidly converted to acyclovir in the intestine and liver. It is better absorbed than acyclovir, thus producing higher plasma concentrations of acyclovir. Consequently, the effect on mother and fetus should be similar to that of acyclovir, but this has not been well studied.

Famciclovir (category B), a prodrug of penciclovir, is similar in activity to acyclovir. Its safety during pregnancy is unknown. Ganciclovir and foscarnet (both category C) have activity against cytomegalovirus (CMV). Because of their severe toxicity and the lack of studies of their use in pregnant women, there are no current indications for either agent. The only case in which the benefit of either drug may outweigh the risk is in severe, sight-threatening CMV retinitis.

Anti-human immunodeficiency virus drugs

There are numerous approved agents for use against the human immunodeficiency virus (HIV). Zidovudine (AZT), didanosine (ddI), zalcitabine (ddC), stavudine (d4T) and lamivudine (3TC) all work by inhibiting the reverse transcriptase enzyme produced by the virus. Saquinavir inhibits the activity of the HIV protease enzyme and prevents cleavage of viral protein precursors.

Zidovudine has not been associated with premature births, malformations or fetal distress.[53] It reduces significantly the risk of HIV transmission from mother to infant by 67.5%.[54] Women with CD4+ cell counts above 200 cells/mm^3 and no clinical indications for antepartum zidovudine therapy took the drug from weeks 14–34 of gestation and continuing throughout pregnancy. The infants were then continued on therapy from 8 to 12 h after birth for a 6-week duration.

Didanosine and saquinavir are in category B. Saquinavir has not shown teratogenicity at plasma concentrations in animals up to five times those achieved in humans at the recommended doses.[55] Zalcitabine, stavudine and lamivudine are all category C drugs since at very high doses in some animals they have been shown to be teratogenic or toxic, or to cause early fetal death. Zalcitabine has been found to be teratogenic.

172 Preterm delivery and infections

Y. Baytur and C. Şen

Birth before 37 weeks' gestational age or before 259 days is defined as preterm birth according to the World Health Organization.[1] Preterm birth is the major clinical problem associated with perinatal mortality, serious neonatal morbidity and moderate to severe childhood disability in both developed and underdeveloped countries and its prevention is the major aim of modern obstetrics. At present, there are no effective diagnostic tests for preterm birth and there are no effective treatments for this condition. Preterm birth could be qualified according to its clinical presentation: medically induced, preterm premature rupture of membranes (PPROM) and spontaneous preterm labor leading to preterm delivery. We need to be aware that preterm labor is not a disease, but an event that may result from single or multiple, independent or interdependent pathways. The etiology of spontaneous preterm labor is multifactorial, but there is overhelming evidence to implicate infection as a possible cause in up to 40% of cases.[2,3] Systemic maternal infection (e.g. pneumonia, influenza) may cause preterm delivery. However, the frequency in developed countries is low.[4,5] No large clinical or epidemiologic study has implicated viral diseases in the etiology of preterm delivery; however, both cytomegalovirus and herpes simplex virus infections may cause preterm delivery. Both urinary tract infection and periodontal disease may induce labor.[6,7] In a high proportion of pregnancies complicated by preterm labor and preterm prelabor amniorrhexis, the underlying cause may be ascending infection from the lower genital tract. Abnormal colonization of the lower genital tract with microorganisms, such as *Mycoplasma hominis, Ureaplasma urelayticum*, Group B hemolytic streptococci, *Chlamydia trachomatis, Gardnerella vaginalis*, is associated with intrauterine infection, preterm labor and also neonatal adverse outcome, such as cerebral palsy, chronic lung disease of prematurity and fetal inflammatory response syndrome (FIRS).[5,8] Positive amniotic fluid cultures, with organisms commonly found in the vagina, are present in about one-tenth of pregnancies in preterm labor with intact membranes and in more than one-third of cases with preterm prelabor amniorrhexis.[2] Vaginal organism first ascends into the chorioodecidual space and stimulates an inflammatory reaction in the placenta, membranes and decidua. Preterm labor and delivery are then caused by a maternal and fetal response to this inflammatory reaction with increased prostaglandins secretion.[8–21]

This chapter will focus on the evidence that infection is causally associated with spontaneous preterm birth and the interactions between microorganisms, cytokines and prostaglandins and also adverse neonatal outcome.

The causes and mechanism of intrauterine infection

In patients with preterm labor and intact membranes, the amniotic fluid concentration of prostaglandins, leukotrienes and cytokines is higher in those with positive amniotic fluid cultures; in this group, tocolytics are less successful in arresting labor than in those with no infection.[2] The most common pathway of intrauterine infection is the ascending route, although transplacental infections, accidental introduction of pathogens into the cavity at the time of invasive procedures and invasion of systemic maternal infections may be involved.[5] According to Romero *et al.*,[22] ascending intrauterine infection is considered to have four stages. Stage 1 consists of a change in the vaginal/cervical microbial flora or the presence of pathologic organisms in the cervix. Some forms of bacterial vaginosis may be an early manifestation of this initial stage. In stage 2 microorganisms enter the cavity and then reside in the decidua. After microorganisms create an inflammatory response in the decidua, they invade the fetal vessels (chorioavasculitis) or membranes (amnionitis), leading to intraamniotic infection (stage 3). Once in the amniotic cavity, the bacteria may gain access to the fetus through various ports of entry (Stage 4). Intrauterine

infection is often chronic and asymptomatic until labor or membrane rupture, without fever, abdominal pain, leucocytosis or fetal tachycardia.[23]

It is necessary to define abnormal genital tract colonization. Lamont[3] defined a classification of abnormal genital flora. He divided abnormal genital tract flora into four groups: (1) pathogens (*Neisseria gonorrhoeae*, *C. trachomatis*, *Trichomonas vaginalis*), (2) Group B hemolytic streptococci, (3) enteropharyngeal organism (*Escherichia coli*, *Enterococcus faecalis*) and (4) bacterial vaginosis-related organisms (anaerobes, *M. hominis* and *G. vaginalis*). A number of studies have shown that abnormal genital tract flora, either in the form of bacterial vaginosis or as bacterial vaginosis-related organisms, such as anaerobes, *Ureaplasma urealyticum*, *M. hominis* or *G. vaginalis*, is associated with preterm birth.[24–26] However, it has also been suggested that lower genital tract colonization with *U. urealyticum, M. hominis* or *G. vaginalis* is not associated with preterm birth.[27–29] On the other hand, these microorganisms are frequently found in the amniotic fluid of the women with premature labor and PPROM.[30,31] In a recent clinical trial, Gerber *et al.*[32] found that polymerase chain reaction testing of second-trimester amniotic fluid for *U. urealyticum* can identify women at risk of subsequent preterm labor and delivery. *U. urealyticum* has been identified in 11% of asymptomatic women who underwent transabdominal amniocentesis at 15–17 weeks' gestation. A subsequent preterm labor occurred in 58% of urealyticum-positive women, compared with 4% urealyticum-negative women.

A case-controlled study showed that cervical infection with *C. trachomatis* at 24 weeks' gestation increases by two to three times the risk of preterm delivery.[33] But the results of studies have been conflicting.[34–36] Romero *et al.*[5] stated that the association with prematurity in women with genital colonization of *C. trachomatis* is unclear, but the treatment is indicated because of serious neonatal adverse outcome, such as pneumonia and ophthalmia neonatarum, in case of vertical neonatal transmission. The presence of *T. vaginalis* in pregnant women was associated with an increased risk of preterm delivery, but the treatment of trichomoniasis with metronidazole (two 2 g doses) in asymptomatic women did not prevent the rate of preterm delivery. Another microorganism that may be related to preterm delivery and prematurity is *N. gonorrhoeae*.[37] It has been recommended to culture samples from high-risk women during pregnancy and to treat with antimicrobial agents. Amoxicillin plus probenecid, ceftriaxone or cefixime may be used as a treatment agent and have similar cure rates.

Group B hemolytic streprococci are worthwhile considering in a class of their own because of the devastating effects that these organisms can have on low birth weight or preterm infants.[37,38] Although asymptomatic bacteriuria with Group B hemolytic streprococci is a risk factor of preterm delivery and its treatment is associated with a reduction in the rate of preterm delivery, colonization of the lower genital tract with Group B streprococci is not a risk factor for preterm delivery.[5]

Asymptomatic bacteriuria is strongly associated with preterm delivery, pyelonephritis and also mental retardation and developmental delay in the fetus.[39–42] Antibiotic administration to patients with asymptomatic bacteriuria is associated with a significant reduction in the rate of preterm birth.[40] The incidence of asymptomatic bacteriuria is reported as 2–14% during pregnancy.[41] Considering the relatively high incidence of asymptomatic bacteriuria during pregnancy and its dangerous results, it has been recommended to screen and treat asymptomatic bacteriuria routinely in all pregnant women.[41–43] Not enough evidence was found to support one approach over the other for the screening and treatment. The gold standard for screening asymptomatic bacteriuria is urine culture and it was recommended by the U.S. Preventive Services Task Force that all pregnant women be screened by urine culture at their initial prenatal visit.[39] However, it was suggested that the routine use of urine cultures in the assessment of preterm labor is costly and adds little value to obtaining a diagnosis except in the presence of specific complaints.[44] The microscopic urinalysis and dipstick urine tests may be used as effective and cheaper alternative methods for detecting asymptomatic bacteriuria.[6,39] The treatment alternatives are single-dose phosphomycin 3 g, one of the β-lactams (amoxicillin, cefalexin, etc.) or nitrofurantoin for 3–7 days.[39]

Screening and treatment of bacterial vaginosis to prevent preterm delivery

According to review articles and meta-analysis, bacterial vaginosis increases the risk of preterm delivery by approximately 40–60%.[3–5,25,45,46] By the time a woman is admitted with preterm labor, there may be irreversible changes in the cervix, which render attempts to inhibit the process unsuccessful. It is important to diagnose and treat abnormal genital tract flora in early pregnancy before the symptoms of preterm delivery. First, it should be defined as abnormal colonization and classification of abnormal genital tract flora in pregnancy. Bacterial vaginosis is a condition in which there is a change in the microbial flora of the vagina characterized by replacement of the lactobacilli by other organisms, such as anaerobic bacteria, genital mycoplasmas, *G. vaginalis*, etc. In most cases, the condition is asymptomatic. The standard method for the diagnosis of this condition is a Gram stain examination of vaginal fluid. However, the studies in the literature that investigated the relationship between bacterial vaginosis and preterm birth have used different criteria and assessment methods based on either clinical finding or Gram staining. Recently, Honest *et al.*[47] have investigated the accuracy of

various types of tests for bacterial vaginosis to predict spontaneous preterm birth in pregnant women. In this study, there were four different bacterial vaginosis testing methods: gram-staining tests using either Nugent's or Spiegel's criteria, gas liquid chromatography and clinical (Amsel's) criteria. They did not find any difference in the accuracy of the various bacterial vaginosis tests for predicting preterm birth in both asymptomatic and symptomatic women with threatened preterm labor. It was suggested that the presence of coccobacilli in Pap smears within 4 weeks before delivery was associated with a more than fourfold increase in the risk of very preterm delivery ($\leq$31 weeks) and the authors concluded that if coccobacilli are detected in Pap smears during the second trimester, antibacterial treatment may lower the risk of very preterm delivery.[48] The detection of fetal fibronectin in cervical/vaginal secretion has been proposed as a marker for clinically silent upper genital tract microbial infections. The relationship between bacterial vaginosis/fetal fibronectin and preterm labor/birth has been investigated.[49] The time interval from gestational age at testing until delivery was significantly shorter for +bacterial vaginosis/+fetal fibronectin and −bacterial vaginosis/+fetal fibronectin groups than for the groups with negative results of fetal fibronectin and bacterial vaginosis. However, it was recommended that the use of the fetal fibronectin test should be limited to its negative predictive value and the use of antibiotics for preventing preterm birth according to positive fetal fibronectin results should be discouraged.[50]

Intrauterine infection may result from a chronic infection early in pregnancy that eventually becomes symptomatic with contractions and leads to spontaneous abortion or preterm labor and birth. Bacterial vaginosis in early pregnancy may be a stronger risk factor of preterm delivery than bacterial vaginosis later in pregnancy. In a meta-analysis that consists of 20,232 women, bacterial vaginosis increased the risk of preterm delivery greater than twofold. Higher risks were found in women who were screened for bacterial vaginosis at <16 weeks of gestation (odds ratio, 7.55; 95% CI, 1.80–31.65) or at <20 weeks of gestation (odds ratio 9.91; 95% CI, 1.99–49.34).[25] Screening after 26 weeks' gestation was associated with 1.4- to 1.9-fold increased risk, whereas screening in the second trimester was associated with a 2- to 6.9-fold increased risk of preterm birth.[45]

Although the results of studies support the theory of a chronic infection starting early in pregnancy, strategies to screen for and treat bacterial vaginosis in pregnancy remain controversial. Screening and treating bacterial vaginosis in low-risk asymptomatic pregnant women are not recommended.[51,52] Tebes *et al.*[53] reviewed the studies on effect of treatment on preterm birth with levels of evidence ranging from I to II between 1994 and 2001. They found that several trials reported a decrease in the incidence of preterm labor when bacterial vaginosis was treated, but most of those trials were performed on women with a history of preterm labor. Therefore, based on these studies and the current guidelines of the Centers for Disease Control and Prevention (CDC), they concluded that treating pregnant women in high-risk populations, who are diagnosed with bacterial vaginosis, provides the clinician with an opportunity to possibly prevent preterm labor in this population. In nulliparous women without a history of preterm birth, treatment is recommended if other risk factors are present (e.g. gonorrhea or chlamidia). But in the general low-risk populations, routine screening is not indicated. The largest trial reported today is the ORACLE II. In this study, 6295 women in spontaneous preterm labor with intact membranes and without evidence of clinical infection were randomly allocated to receive erythromycin, co-amoxiclav, both, or placebo. Antibiotic administration prolonged pregnancy and was associated with a significant reduction in the rate of maternal infection. Unfortunately, antibiotic administration had no significant effect on the primary neonatal outcome, which included neonatal death, chronic lung disease or major cerebral abnormality on ultrasonography before discharge.[54]

Lamont *et al.*[3] criticized the ORACLE study and emphasized three points in this investigation. First, the women were not screened for infection. The etiology of preterm birth is multifactorial and infection is responsible for only 40% of preterm birth. It is logical that antibiotics would not have any beneficial effect on spontaneous preterm labor without infectious etiology. Second, the antibiotics that were used in the study (erythromycin and co-amoxiclav) are not useful in bacterial vaginosis. Finally, one of the study groups received a combination of erythromycin and co-amoxiclav. Since one antibiotic is bactericidal and the other bacteriostatic, the actions are cancelled out. They suggested that the wrong antibiotics were used in the wrong patients too late in pregnancy.

Recently, a meta-analysis including 11 trials with ORACLE study and 7428 women shows a reduction in maternal infection with the use of prophylactic antibiotics but fails to demonstrate a benefit or harm for any of the neonatal outcomes. The authors concluded that antibiotic treatments cannot be currently recommended for routine practice.[55]

However, Lamont *et al.*[45] has used 2% clindamycin vaginal cream for women with abnormal genital tract flora before 20 weeks' gestation and they reported 60% reduced incidence of preterm birth and the need for neonatal intensive care when compared with the placebo. Once the inflammatory mediators, such as cytokines, have increased in fetomaternal tissues, it may be too late or harmful to try and stop labor. Antibiotics alone are unlikely to be helpful at that stage. It is logical that antibiotics used to prevent preterm birth should be given early in pregnancy in high-risk and symptomatic patients with bacterial vaginosis. Although intravaginal treatment may be

effective on infections localized to the vagina, in late stages, systemic rather than local vaginal antibiotic regimens should be used.

Role of cytokines and other inflammatory mediators in preterm birth

Patterns of expression of cytokines in the fetal membranes and decidua suggest that inflammatory activation occurs modestly with term labor, but much more robustly in preterm delivery, particularly in the presence of intrauterine infection. The placenta and extraplacental membranes are sources of a large number of cytokines, chemokines and related factors.[11] In addition, infiltrating inflammatory cells, especially monocytes/macrophages, produce these cytokines in intrauterine tissues as the host reaction to infections.[10] Therefore, microorganisms that gain access to the fetus may elicit a systemic inflammatory response syndrome, which is characterized by the increased concentration of interleukin-6 (IL-6) and other cytokines, as well as cellular evidence of neutrophil and monocyte activation.

Recent studies with complimentary DNA (cDNA) array identified a cluster of inflammation-associated genes upregulated with labor both at term and preterm with infection and without infection.[56] Normal-term labor is associated with only a modest upregulation of these chemokines and cytokines. In contrast, preterm deliveries complicated with chorioamnionitis are associated with a dramatically elevated expression of a number of genes and proteins, particularly those of the chemokine class. However, chemokine expression is also elevated in gestational tissues with preterm labor that have no evidence of infection. It was suggested that an incidental exposure of infection may elicit an inappropriately robust immune response in some women, which fails to resolve and commences a feed-forward inflammatory loop, triggering parturition.[11]

Major attention has been focused on the role of proinflammatory cytokines, such as IL-1β, TNF-α and IL-8. However, other proinflammatory and anti-inflammatory cytokines together with chemokines increase with preterm labor; examples include IL-6,

IL-10, granulocyte macrophage-colony stimulating factor (GM-CSF), G-CSF, leukemia inhibitory factor, platelet-activating factor (PAF), macrophage inflammatory protein (MIP)-1α, RANTES (regulated on activation, T-cell expressed and secreted) and growth-related oncogene-α.[5,8,10,11] Human decidua produces IL-1 and TNF-α in response to bacterial products, such as lipopolysaccharides (LPS).[57] Human amnion and chorion also have the ability to produce cytokines on stimulation with either LPS or IL-1 and TNF-α.[58] Several cytokines and chemokines in cervicovaginal and amniotic fluids, such as IL-1β, TNF-α, IL-6, IL-8 and monocyte chemotactic protein-1 can be detected before labor onset, particularly in women who deliver preterm with associated intra-amniotic infection.[2,8,11,21,59]

Chemokines play a crucial role in the process by regulating the leukocyte traffic. Leukocytes that are abundant in the majority of tissues from microbiologically confirmed infection-positive pregnancies have been shown to be activated in infection-associated preterm deliveries. The primary cellular source of cytokine production in the presence of intrauterine infection is, therefore, likely to be leukocytes that are recruited into the gestational membranes to fight the pathogen.[11] Recently, intra-amniotic secretion and abundance of epithelial cell-derived neutrophil-activating peptide (ENA-78), a potent chemoattractant and activator of neutrophils, has been studied in term and preterm parturition. It was found that ENA-78 was expressed immunohistochemically in chorionic trophoblasts and amniotic epithelium in term and preterm gestational membranes. ENA-78 increased more in preterm labor than term labor in amniotic membrane and showed a positive correlation with the leukocyte infiltration. More interestingly, in amniotic fluid, ENA-78 levels from pregnancies with preterm labor with intra-amniotic infection were significantly higher than those from pregnancies with preterm deliveries without infection.[60] Neutrophil defensins (HNP 1-3), bactericidal/permeability-increasing protein and calprotectin (MRP8/14) are antimicrobial peptides stored in the leukocytes that act as effector molecules of the innate immune response. The association between the amniotic fluid concentration of these peptides and the microbial invasion of amniotic cavity, PROM and parturition, was investigated. Microbial invasion of amniotic cavity, PROM and preterm parturition, was found to be associated with the increased amniotic fluid concentration of these peptides. Moreover, elevated amniotic fluid levels of these peptides were associated with intra-amniotic inflammation, histological chorioamnionitis and shorter amniocentesis-to-delivery interval in patients with preterm labor and intact membranes.[17]

In contrast to the increase in cytokine production observed in the fetal membranes and decidua during labor, the placenta involves less in the cytokine production. Studies of placental cells and tissue *in vitro* have demonstrated their ability to respond to inflammatory stimuli, such as pathogenic bacteria, LPS or IL-1β, with increased production of cytokines (IL-1β, IL-6, IL-10), chemokines (macrophage chemotactic protein-1, IL-8) and prostanoids.[11] However, the response of the placenta to the stimuli of TNF-α is very weak. The placenta might play a more important role in cytokine signaling in the process of labor and this process may be controlled by suppressors of cytokine-signaling proteins.[11]

The suggested mechanism for the association between intrauterine infection and labor is infection-mediated release of cytokines, which stimulate

production of prostaglandins that induce myometrial contraction, cervical ripening and membrane rupture. IL-1β and TNF-α are known to stimulate prostaglandin biosynthesis in amnion, chorion, decidua and myometrium cells through an increase in cyclooxygenase (COX)-2 synthesis and activity.[10] These cytokines also increase the expression of prostaglandin H synthase (PGHS)-2 and decrease the activity of 15-hydroxyprostaglandin dehydrogenase within the fetal membrane, which is one of the key enzymes for prostaglandin degradation. PGHS-2 can be increased rapidly up to 80-fold in response to cytokines and bacterial endotoxins.[12] IL-1β induces PGHS-2 mRNA expression and prostaglandin E_2 (PGE_2) production in primary human amnion cells, chorion and deciduas. IL-6 has also been shown to stimulate prostaglandin production by the amnion and deciduas.[11] Protein levels of microsomal PGE_2 synthase and COX-2 are stimulated by cytokines (IL-1β and TNF-α) in human placenta and villous trophoblast cultures.[61] Dexamethasone and IL-10 reverse these effects of IL-1β in cultured villous and chorion trophoblast cells.[20,62,63]

Another possible mechanism for preterm labor may be PAF-mediated uterine contractions. IL-1β and TNF-α enhance PAF activity by suppressing the secretion of PAF-acetylhydrolase (inactivating enzyme for PAF). PAF stimulates PGE_2 production by the chorion decidua before labor and it may act synergistically with other stimulatory cytokines in the fetal membranes during labor.[10]

Cytokines increase the level of matrix metalloproteinase (MMP) expression and activity. The concentration of MMP-9 in chorion increases in term and preterm labor. Since this gelatinase enzyme contributes to the controlled degradation of collagen within the fetal membranes, and MMP-9 activity is increased by PGE_2, MMP-9 may be responsible for the PPROM.[11,12] Furthermore, intrauterine infection has been associated with higher MMP-9 concentrations in amniotic fluid, whether or nor membrane rupture occurred. TNF-α also stimulates MMP-1 and MMP-3.[11] Treatment with amniochorion explants with LPS also results in an increase in MMP-2 secretion and release.[64] This effect of LPS on MMP-2 and MMP-9 is inhibited by IL-10. MMP-3 is significantly increased in amniotic fluid of women with term and preterm parturition, but not in those with PROM.[18] Cytokines and prostaglandins may produce apoptotic effect on the membranes and lead to membrane rupture.[65] Expression of proapoptotic genes *bax* and *p53* is increased in the amniochorion of women with preterm PROM, while expression of the antiapoptotic gene *bcl-2* is decreased.[66] It has been suggested that Fas/CD95, a member of the TNF receptor superfamily, which is expressed in the fetal membranes, might play a key role in triggering the apoptosis, particularly in the presence of infection. These cytokine-induced and metalloproteinase-associated pathways may also play a role in cervical ripening. The increase in IL-8 during cervical ripening correlates with increases in leukocyte infiltration and concentrations of MMPs in the tissue.[11] Concentrations of IL-1β, TNF-α and IL-6 in the lower uterine segment also increase with cervical dilatation. IL-1β and TNF-α induce an increased expression of endothelial adhesion molecules with subsequent extravasation of granulocytes in the cervical stroma. The chemotaxis and degranulation of these cells in the stroma are triggered by IL-8. Concentrations of inflammatory cytokines, especially IL-8, in cervicovaginal secretion increases during labor and may be responsible for cervical ripening.[9,11] IL-8 production is activated by fibroblasts and macrophages. It plays a key role in cervical ripening, since this cytokine induces chemotaxis, activation and degranulation of neutrophilic granulocytes with the consequent release of various proteases, including collagenase.

Detection of intrauterine infection and predicting preterm delivery

It is well known that the admission-to-delivery interval is significantly shorter than in those cases with intrauterine infection compared to those without infection in preterm delivery. Attempts at prevention of preterm delivery in those with intrauterine infection have generally been unsuccessful. For avoiding unnecessary use of tocolytics, it is important to define women with intrauterine infection. The diagnosis of intrauterine infection is made by culture of amniotic fluid and fetal blood in PPROM or preterm labor with intact membranes. However, it takes at least 2 days before the results of culture are available and consequently, a series of rapid tests, such as Gram stain of the amniotic fluid, leukocyte count and glucose concentration, have been developed to predict the presence of infection.[2] The detection of proinflammatory cytokines in the amniotic fluid has also been proposed as a rapid test to predict preterm delivery.[67] High concentrations of IL-6, IL-18, monocyte chemotactic protein-1 in amniotic fluid were associated with microbial invasion of the amniotic fluid, intraamniotic infection and prompt delivery.[8,21] However, these tests are required an invasive procedure and it is logical to use a less invasive test for predicting the possibility of preterm delivery.

The concentration of cytokines in the cervicovaginal secretions, maternal and fetal plasma as well as amniotic fluid increases with microbial invasion of the membranes in the preterm labor and PPROM cases. The cytokines and chemokines involved in the infection-induced preterm labor have also been studied for predicting preterm delivery. Cervicovaginal IL-6 demonstrated the ability to predict delivery between 2 and 7 days. Using 35 pg/ml as a cutoff, IL-6 had a sensitivity and specificity of 60% and 77% for predicting delivery within 2 days, and 62% and 80% within 7 days.[68] High concentration of IL-18 in

cervical mucus in contrast to amniotic fluid was not found useful for predicting intra-amniotic infection and prompt delivery.[21] Monocyte chemotactic protein-1 in cervical secretions is elevated in preterm labor and PPROM and correlates to intra-amniotic infection/ inflammation.[8] Another potential marker in cervicovaginal fluid is intercellular adhesion molecule-1 (ICAM-1) in women presenting with preterm labor. Elevated ICAM-1 concentrations in cervical secretions have been shown to predict short intervals to delivery with high specificity. It has been found that, sensitivity, specificity, positive and negative predictive value were 33%, 98%, 75% and 93%, respectively, for predicting delivery within 3 days at 3-ng/ml threshold.[69] However, maternal serum levels of IL-6, IL-8 and TNF-α are not increased in preterm labor patients and the usefulness of maternal serum measurement of cytokines for detecting early fetal infection in preterm labor is doubtful and needs further evaluation.[70]

Although there is an association between infection, cytokine production and preterm delivery, it is not clear that a particular cytokine is required to signal the onset of labor. Studies with the animals showed that infection-induced preterm delivery does not require a specific cytokine.[71,72] However, tocolytics may prevent preterm delivery through the modulation of cytokines. Formoterol, a β2-adrenoreceptor agonist, has potent tocolytic effects in the rats. It is blocked $PGF_{2\alpha}$, IL-1α and IL-6, but not IL-10 in LPS-induced preterm delivery in rats.[73] Intrauterine inflammation is associated with decreased serum progesterone levels and decreased transcription of progesterone receptor-B in animals. It has been shown that medroxyprogesterone acetate (MPA) suppressed the activation of contraction-associated genes and inflammatory mediators and prevented cervical ripening in response to intrauterine inflammation. LPS-induced preterm delivery rates in rats reduced from 100% to 63% and 0% with treatment with progesterone and MPA, respectively.[74] It has also been suggested that treatment with IL-10 prevents LPS-induced preterm delivery in the rats.[75]

Neonatal consequences of intrauterine infection

Intrauterine infection causes several acute or chronic adverse events in the newborn, such as increased incidence of neonatal infections, brain injury, cerebral palsy and chronic lung disease.[76,77] Neonatal sepsis in patients with PPROM is probably acquired *in utero* rather than during delivery. Supporting evidence is provided by the finding that the incidence of neonatal sepsis in pregnancies with positive amniotic fluid cultures is much higher than in the general population. Moreover, the causative organisms in neonatal infections are similar to those in vaginal infections.

It is believed that fetal microbial invasion results in a systemic fetal inflammatory response and this reaction may progress towards serious complications such as cerebral palsy, multiple organ dysfunction and septic shock, if the fetus remains undelivered.[5,13] This condition is named as the FIRS and generally occurs in fetuses of women with subclinical infection. The level of inflammatory cytokines (IL-6) often elevates in fetuses affected by this syndrome. Elevated cytokine levels induce the infiltration of inflammatory cells into the amnion and activate MMP in the fetus. As a result, preterm birth occurs.[5] The high levels of inflammatory cytokines in the fetus are associated with the development of bronchopulmonary dysplasia and periventricular leukomalacia in the newborn.[13,76] Except for the elevation of fetal IL-6 levels, there is still no specific clinical or laboratory sign of the FIRS. Umbilical cord plasma IL-6 concentrations were higher in the neonates born with funisitis than in those without this lesion. Funisitis is associated with amniotic fluid infection, congenital neonatal sepsis and the FIRS.[78] Increased IL-6 levels in the fetal plasma and the presence of the funisitis are used for the diagnosis of the FIRS and histologic findings of funisitis are better specificity and positive predictive value for predicting impaired neurological outcome.[79] Although the FIRS seems crucial to the association between intrauterine infection and white matter disease in human preterm infants, the underlying mechanisms remain unclear. In a rabbit model of intrauterine infection, it has been shown that in the fetuses with both diffuse cell death and focal periventricular white matter cysts mimicking cystic periventricular leukomalacia, a strong rabbit macrophage and inducible nitric oxide synthase immunostaining was observed at the border of these cystic lesions. In contrast, in the fetuses with only diffuse and significant cell death, no inflammatory or astroglial responses were detected in the white matter or hippocampus. In this model, focal white matter cysts are accompanied by a robust inflammatory response, and diffused cell death, which may mimic the white matter and hippocampal damage seen in very and extremely preterm infants, occurs in the absence of a detectable brain inflammatory response.[80] Proinflammatory cytokines, such as IL-6, have been implicated in the mechanisms that are responsible for brain injury in cases of intrauterine infection. IL-6 is a major mediator of the host response to infection and tissue damage and may play a role in the brain injury.

Fetal inflammation has been linked to the onset of labor in association with ascending infection. However, systemic fetal inflammation may occur in the absence of labor when the inflammatory process is secondary to a systemic maternal infection. In the presence of intrauterine infection, for preventing FIRS sequence, the fetus should be delivered timely, but the problems related to prematurity should be considered. The use of antibiotics seems to be not useful because the FIRS sequence has already been started before antibiotic administration. Agents such as anti-inflammatory cytokines may play a role in interrupting this sequence but this should be investigated more.

173 Perinatal infectious morbidity in multiple pregnancies

I. Blickstein and E. L. Yashphe

Introduction

Multiple pregnancies seem to be more prone to perinatal infectious morbidity compared with singleton gestations. Two explanations may support this statement. First, preterm premature rupture of the membranes (PPROM) is more frequent among multiples and, second, the uterine cavity is more likely to be accessed for diagnostic and therapeutic procedures during a multiple gestation. In addition, multiples are exposed to infections via the hematogenic route to the same extent as singletons. Figure 173.1 is a schematic depiction of the possible routes of infection in multiple pregnancies.

In contrast to singletons, the unique situation of discordant fetal infection may be seen in twins and higher-order multiples, whereby only the presenting gestational sac is exposed to ascending infection. In this circumstance, it is possible that the presenting twin somehow protects its non-presenting sib.

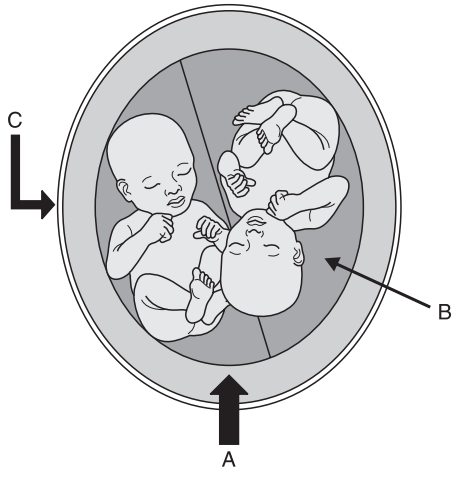

Figure 173.1 Potential routes of infection in multiple pregnancies: (A) ascending infection, (B) infection due to invasive procedures, and (C) hematogenic infections.

In this chapter, we shall discuss several issues related to perinatal infectious morbidity among multiples.

Preterm premature rupture of membranes

A multiple gestation, within an overdistended uterus, is an important risk factor for PPROM, leading to a number of maternal and fetal/neonatal complications. The mother is at a greater risk for developing chorioamnionitis, endometritis, and bacteremia. For the fetus/neonate, the risk for PPROM-related morbidity and mortality are even greater, resulting in premature labor and preterm birth associated with respiratory distress syndrome (RDS), intraventricular hemorrhage (IVH), septic morbidity, and necrotizing enterocolitis (NEC).

The incidence of PPROM is higher and occurs earlier in multiple pregnancies.[1] Mercer *et al.* compared 99 twin with 99 well-matched singleton pregnancies complicated by preterm rupture of the membranes. The authors found that PPROM occurs more frequently in twin than in singleton gestations (odds ratio, OR 2.1) and that PPROM at < 26 weeks' gestation complicated 1.4% of twin gestations (18.2% of those with PPROM) compared with 0.52% of singleton gestations (OR 2.71). Despite these differences, the etiology of PPROM in twins seems similar to that in singleton pregnancies with the main identifiable cause being maternal genital tract infection. Uterine overdistention, however, may also play a role in multiple pregnancies. Not surprisingly, membrane rupture usually occurs in the presenting sac, but may develop in the non-presenting sac following invasive procedures. Management of PPROM in twins depends on the presence or absence of clinical maternal infection, labor, gestational age, and fetal well-being. The management algorithm includes administration of antibiotics and steroids, whereas immediate delivery

is usually reserved for cases with clinical evidence of intra-amniotic infection, fetal distress, established lung maturity, or more advanced gestational ages.

Several studies examined the perinatal outcome after PPROM in twin compared with singleton gestations. Mercer *et al.*[1] found no significant differences in infectious morbidity in terms of chorioamnionitis and postpartum fever between twin and singleton gestations despite the presence of an intact amniotic sac in the second twin. In contrast, Myles *et al.*[2] observed a somewhat higher incidence of chorioamnionitis in singleton pregnancies and explained this finding by the longer latency period among singletons – as was also observed by Bianco *et al.*[3] and Mizrahi *et al.*[4] The latter group compared perinatal outcomes in spontaneously conceived 435 sets of twins and 4754 singletons born preterm. Twin gestation had significantly lower rates of PPROM and clinical chorioamnionitis (12.2% vs.17.3%, and 1.8% vs. 5.2%, respectively).

In the case of multiple gestations, which are at a greater risk of very preterm birth, the management of extremely PPROM (EPPROM, < 25 weeks' gestation) seems to be more pertinent. In a recent series of 47 pregnancies including 10 twin and 2 triplet gestations, the comparison of multiple with singleton pregnancies with EPPROM at the same median gestational age (22 weeks) revealed that fewer infants of a multiple pregnancy were considered viable and admitted to the neonatal intensive care unit (NICU).[5] Among those who were admitted, mortality rate was almost twice higher despite a similar incidence of serious sequelae.[5]

Finally, it should be remembered that multiple pregnancies are the best example of how imaginative diagnostic as well as therapeutic methods are implemented in modern perinatology. The invasive nature of most of them undoubtedly increases the risk of PPROM and infection. For example, laser treatment of twin–twin transfusion needs several ports of entry, amniocentesis for dizygotic twins usually needs two punctures, and even simple lung maturity testing needs needle insertion into both sacs.

Endometritis

Women with multiple gestations are at an increased risk for several maternal complications compared to women carrying singletons. Endometritis, an infection of the endometrium or decidua, with and without extension to the myometrium and parametrium, is the most common cause of postpartum fever. Risk factors for this condition include prolonged rupture of membranes and labor with multiple vaginal examinations, both of which may be more prevalent in multiple pregnancies and births. One might therefore expect to find more cases of endometritis following multiple pregnancies.

One large historical cohort study, addressing maternal complications, evaluated 885,338 gestations, of which 15,484 were twin gestations, delivered in Latin America.[6] A significant association between multiple pregnancies and puerperal endometritis was found, with a higher risk among nulliparous mothers. The larger placental bed in multiple pregnancies and the higher cesarean section rate (2.5 higher compared with singleton pregnancies) were the explanation for these findings.

As noted above, prolonged rupture of membranes is a significant risk factor for both maternal and neonatal infections. Indeed, the higher incidence of PPROM in multiple pregnancies increases the risk for endometritis, and this risk correlates with the latency period between membrane rupture and delivery. The question whether the mode of delivery affects the risk of maternal infections is particularly pertinent because many clinicians suggest a cesarean birth in the majority of twin pregnancies and in practically all triplet pregnancies.[7] This question was studied by Suonio and Huttunen,[8] who prospectively compared the infectious complications of 122 consecutive abdominal twin deliveries with 761 singleton abdominal births. The incidence of endometritis was nearly threefold after twin deliveries and the incidence of abdominal wound infections nearly twofold compared with singleton abdominal pregnancies. The risk of amnionitis was increased 10-fold when 6 h elapsed after rupture of the membranes in abdominal twin delivery, but no such connection was found between amnionitis and endometritis in singleton abdominal deliveries. The authors performed a multiple regression analysis and found only two risk factors for puerperal endometritis after abdominal twin delivery: age under 25 years and an interval of more than 6 h from rupture of membranes to delivery. In contrast, a retrospective study of 93 consecutive triplet pregnancies with 71% vaginal delivery found that vaginal delivery had no deleterious effect on neonatal and maternal outcomes; however, endometritis was slightly more frequent in the group undergoing trial of labor as compared with the group delivering by planned cesarean section.[9]

A study examining 718 twin births found that the endometritis rate was higher in the cesarean group than in the vaginal group.[10] In the subgroup of vaginal births, the incidence of endometritis was similar in those deliveries with and without manipulations. The length of time between delivery of twin A and twin B did not affect the endometritis rate.

Discordant infection/inflammation by chorion type

A unique situation exists in multiple pregnancies whereby an ascending genital infection may not affect both gestational sacs, resulting in discordant infection or inflammation. Mazor and coworkers[11] evaluated microbial invasion of the amniotic cavity by transabdominal amniocentesis under sonographic guidance in multiple pregnancies. Amniotic fluid from both sacs was cultured for aerobic and anaerobic microorganisms

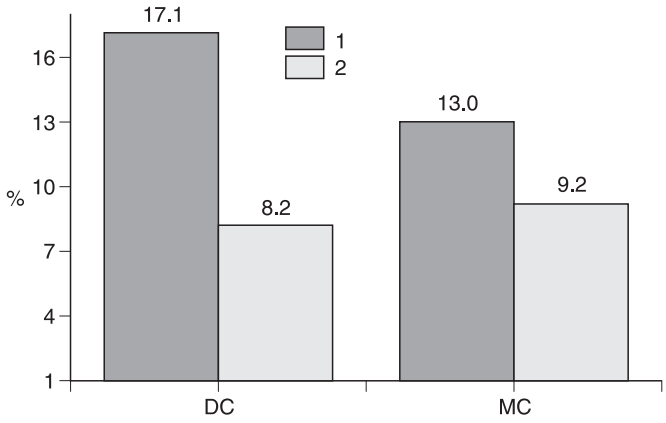

Figure 173.2 Frequency (%) of chorioamnionitis by chorionicity and presentation. 1, Presenting twin; 2, non-presenting twin. DC, dichorionic; MC, monochorionic. Adapted from Phung *et al.*[12]

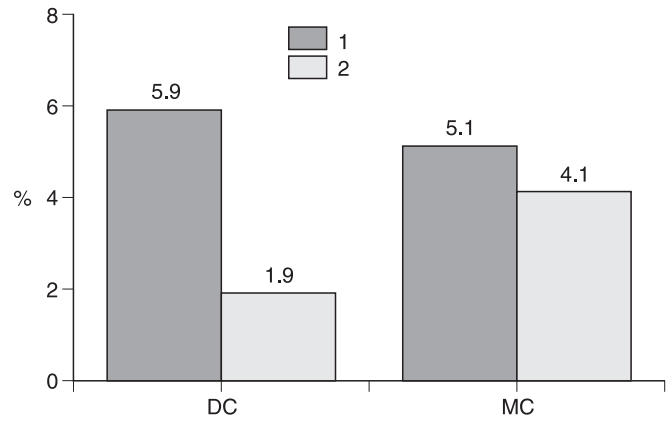

Figure 173.3 Frequency (%) of chorioamnionitis and funisits by chorionicity and presentation. 1, Presenting twin; 2, non-presenting twin; DC, dichorionic, MC, monochorionic. Adapted from Phung *et al.*[12]

as well as for *Mycoplasma* species. Amniotic fluid was obtained from 74 patients. Sixty-eight women delivered prematurely (91.9%). Amniotic fluid culture results were positive for microorganisms in nine cases of the 74 patients in the study cohort, including five isolated from the presenting sac (55.6%), three from both sacs (33.3%), and one from the upper sac (11.1%). Patients with a positive culture had a higher incidence of clinical chorioamnionitis than those with a negative culture.

The so-called Northwestern Twin Chorionicity Study[12] examined the question whether discordant inflammation depends on chorionicity. The authors retrospectively analyzed 1156 twin placentas to evaluate the association between chorionicity and discordant chorioamnionitis and funisitis in twin gestations. This study found that in the case of chorioamnionitis in dichorionic twins (with either separate or fused placentas), the non-presenting twin was less frequently affected than the presenting twin. Such discordant inflammation was not apparent in monochorionic twins (Figure 173.2). The results were somewhat accentuated in the case of funisitis – a more advanced state of inflammation (including inflammatory evidence within the walls of umbilical vessels or in Wharton's jelly) (Figure 173.3). Whereas the difference between dichorionic and monochorionic twins persists, discordant funisitis was greatest among separate dichorionic twins, less so among fused dichorionic twins, and absent among monochorionic twins. The interpretation of these results was that the dichorionic placentas confer significant protection against the spread of chorioamnionitis from the presenting to the non-presenting sac. The difference between the separate and fused dichorionic twins implies that the paranchymal separation between these placentas and not the dichorionic septum might be responsible for the protection. In simple terms, the different morphologic features of a four-layer intertwin membrane and the separate placentas may restrict the spread of inflammation.

More intriguing and somewhat puzzling is the finding of twins discordant for infections with a presumably hematogenic spread.[13–16] For example, Vogler and coworkers[13] described a stillborn male twin from a diamniotic–dichorionic pregnancy with disseminated cytomegalovirus (CMV) identified morphologically and the other was liveborn without clinical or laboratory evidence of CMV infection. The placenta of the affected twin had chronic villitis but that of the liveborn was normal. The authors suggested that dissimilar immune responses between the affected and unaffected twin and direct extension of uterine CMV infection to only one twin might be responsible for the discordant infection. Similarly, Barlow and Mok[14] described twin girls born at 37 weeks' gestation to a mother infected by human immunodeficiency virus (HIV) and hepatitis C virus. Twin A had symptomatic HIV infection by 9 months but was negative for hepatitis C virus antibody and RNA whereas twin B became HIV antibody negative by 15 months but was positive for anti-hepatitis C virus and RNA.

The discordant infection with HIV is particularly important (see below).[15,16] For example, the acquired immunodeficiency syndrome-related complex was identified in a mother and one of her dizygotic twins. Generalized lymphadenopathy was first noted in the infant at age 17 months. Both parents and the patient had hypergammaglobulinemia, low T-helper-to-suppressor-cell ratio, and positive serum antibody to HIV. The twin brother was in good health with a normal immunologic profile and negative antibody to HIV.[13]

Infection and delayed interval delivery

When a multifetal pregnancy is complicated by PPROM and premature labor, in particular at a previable stage, it may be possible to deliver the presenting fetus and to salvage, by delayed interval delivery, the second twin (or more fetuses in higher-order

pregnancies). In this circumstance, precious time may be gained, thus reducing the risks of prematurity for the undelivered fetus(es). Because of the rarity of this situation, the literature on the subject comprises case reports and relatively small series. In addition, a publication bias may exist, whereby successful cases are reported whereas complicated cases are not published. In order to consider delayed interval delivery after PPROM of one gestational sac, a number of conditions must be met: most important, intra-amniotic infection should be excluded. If the situation is appropriate, management comprises high ligature of the first twins' cord, strict bed rest, aggressive tocolysis, prophylactic antibiotics, and steroids. The use of cervical cerclage is controversial, and the use of anticoagulation may be considered in some cases.[17] A recent retrospective cohort study matched delayed deliveries with twin pairs that were delivered without delay and compared the perinatal outcomes and infant survival.[18] The mean duration of delay was 6 days. The authors found that 56% of the delayed second twins survived to 1 year of age compared with 24% of second twins born immediately.

Conceptually, one should assume that the birth of the presenting fetus was a result of an infectious or inflammatory process. Therefore, with the success rates in mind on the one hand, and the alternative of delivering multiples before or at the limit of viability on the other, it is important to consider the risk of chorioamnionitis in such cases.

Chorioamnionitis seems to be a universally accepted contraindication to attempting delayed interval birth in a multiple gestation. However, Watson and McNelis[19] maintained that infection is not an absolute contraindication for such a heroic procedure, and present a delay of 88 days between the birth of the two infants, in which chorioamnionitis was observed immediately after the delivery of twin A and successfully treated with antibiotics. On the other side of the scale, Hoffman and Sciscione[20] reported on a woman attempting interval delivery of triplets at 21 weeks who developed severe septic complications including chorioamnionitis, acute RDS, and tubular necrosis 7 days after delivery of the first fetus.

Delayed interval delivery is discussed in length elsewhere in this book. However, it is our personal view that the risk of intrauterine infection (up to 30%) and maternal sepsis (about 5%)[21] should deter both clinicians and patients from attempting this kind of formidable birth when chorioamnionitis is not categorically excluded. Having said this, it seems that delayed delivery remains a therapeutic option in selected cases for improving the survival rates of the remaining fetuses in correlation to the latency period achieved.[21]

HIV in twins

There are two pertinent questions related to the occurrence of congenital HIV infections: when does transmission of infection occur during the peripartum period and what role does the mode of delivery play in determining the risk of infections? Because twins share the same uterine environment as well as genetic similarities, the evaluation of outcomes in twins delivered to HIV carriers may lead to better understanding of the transmission of different infectious agents, including HIV.

Several studies indicate that the majority of infections occur during labor or delivery and not antepartum. In this scenario, despite cases of intrauterine infection, transmission occurs mainly due to exposure of the newborn to blood, mucus, and other secretions during the passage through the birth canal. Therefore, one would expect to find a higher transmission rate among first-born twins (similar to that found in singletons) compared with second-born twins. The results of some studies concur with this hypothesis; however, other studies found that infections were more concordant than would be expected by chance.

In an international study, 66 sets of twins were evaluated. This registry found HIV-1 infections to be more common in first-born than in second-born twins.[22] A higher concordance was found in monozygotic than dizygotic twins, implying that infection *in utero* may exist at least in some cases. Another study of 115 pairs confirmed these results and concluded that HIV infection of second twins occurs predominantly *in utero*, whereas the infection of the first twins occurs mainly intrapartum.[23]

In contrast to the above-mentioned findings, more recently, a large study that examined 315 twin pairs in Africa found different results.[24] This group found that birth order has no effect on the infection rate, either *in utero* or perinatally in vaginal deliveries. Others found similar results, albeit in a much smaller sample.[25] If indeed the major mode of transmission is the passage of the neonates through the birth canal, cleansing of the birth canal with virucidal agents or a cesarean delivery could reduce the risk of transmission. In Africa, cleansing the birth canal during labor did not seem to reduce the risk of infection, but these results should be interpreted with caution because the prevalent breast-feeding among the HIV-infected women and the potential transmission during lactation cannot be excluded. Elective cesarean birth, on the other hand, can minimize the risk of transmission by reducing the newborn's contact with maternal infective secretions and the potential exposure to contractions associated with labor and 'micro' maternal–fetal blood transfusions during contractions. Many studies found a reduction in transmissions when a cesarean section was performed – up to 81% reduction in one study.[24] This is especially true after decreasing the viral load pharmacologically, although a substantial proportion of first- and second-born twins delivered in this way were found to be infected. Indeed, several researchers[25] believe that viral load reduction may have a greater implication on infection rate than the change in the mode of delivery. Several

studies found discordant HIV infection in twins, but also found different quasispecies of the virus in the two sibs,[26] as well as a different immune response to the virus in the years following birth.[27]

These conflicting findings in twins highlight the controversial nature of this issue. Because of the rare occurrence of the combination of HIV and twins, better understanding is expected only with a large sample of cases.

Summary

Multiple pregnancies are associated with increased risk of infectious perinatal morbidity such as chorioamnionitis and endometritis, mainly as a result of more frequent PPROM and higher cesarean section rate. In addition, the uterine cavity is more likely to be accessed for diagnostic and therapeutic procedures during a multiple gestation. Finally, multiples are exposed to infections via the hematogenic route to the same extent as singletons. In contrast to singletons, a unique situation of discordant fetal infection may be seen in twins and higher-order multiples, whereby only the presenting gestational sac is exposed to ascending infection. This circumstance is an excellent opportunity to study the relative role of hematogenic and contact disease transmission during parturition in cases of blood-borne infections such as HIV.

SECTION XVIII

Labor and delivery

Section Editors: **W. Cohen and D. Weinstein**

174 The assessment of labor

W. R. Cohen and E. A. Friedman

Assisting women during their labor and delivery is a remarkable privilege and a weighty responsibility. To do it well requires a clear and comprehensive understanding of the physiology of labor and delivery, sensitivity to the emotional and physical needs of the parturient, fine clinical judgment, and good dexterity. The oversight of labor and delivery is among the most challenging and important endeavors undertaken by obstetricians and midwives. That oversight is important to all pregnancies; it takes on special importance when the prenatal course has been complicated by maternal or fetal compromise or when certain risk factors for adverse outcome are present. The management of labor often requires complex decision making, and combines the need for skillful physical examination and the interpretation of high technology data in a serial fashion. Although most labors will progress normally, the sapient observer will be able to distinguish those that can benefit from some medical intervention.

From the perspective of the obstetrician, a finite number of clinical features of labor are readily determinable that can potentially help establish whether a labor is normal. These are the frequency, intensity, and duration of uterine contractions, the effacement and degree of dilatation of the cervix, and the descent of the fetus through the birth canal. In addition, related details about pelvic architecture, fetal position, attitude, and cranial molding can be ascertained, and assessment of fetal oxygenation and the presence of infection carried out. Information about all of these factors must be integrated and interpreted periodically during labor to assess the probability that a safe vaginal delivery can occur. When that probability is low, the obstetric attendant will opt for cesarean delivery as the best alternative for mother and fetus.

While uterine contractions are of obvious importance in labor, information about the contractile pattern of the uterus is relatively little information as to whether the labor is normal or not.[1,2] We recognize, of course, that neither cervical dilatation nor fetal descent is possible without a sequence of strong coordinated uterine contractions. Nevertheless, because we are unable to utilize specific information about the nature of the contractility pattern to assess the labor clinically, we must focus on other features to help determine whether or not the labor is normal. In this regard, two features of labor, cervical dilatation and fetal descent, constitute the essential functional components of the work necessary for the pregnant woman and her uterus to achieve in order for delivery to occur.

During normal labor rather characteristic, reproducible patterns in the course of progressive cervical dilatation and fetal descent occur.[3–5] These characteristics have allowed the development of a practical tool for following the course of an individual parturient's labor and thus provide objective evidence for determining if her labor is normal. Furthermore, this approach has permitted analysis of labor data derived from large numbers of patients to help elucidate the types and causes of abnormalities that arise, the efficacy of various therapies for each of them, and the prognosis for mother and fetus according to the type of labor pattern and treatment given.[3] This information in turn can be used by obstetric attendants to help manage individual patients optimally.

The labor graph

A pictorial representation of the labor process can be obtained by using a simple square-ruled graphic template (Figure 174.1). The horizontal axis of the graph represents time elapsed during the patient's labor, in hours. The origin is the onset of labor, although this is not always precisely determinable. To avoid confusion or difficulty in this regard, use the pragmatic criterion of the time when the patient perceived the onset of regular uterine contractions. Defining the onset of labor in this way avoids the dilemma of having to identify labor more arbitrarily on the basis of the cervix having achieved a certain degree of effacement or dilatation.

The vertical axis of the graph is divided into 10 equal segments. Two scales are designated, cervical dilatation and fetal station. Each division on the dilatation scale represents a centimeter of dilatation,

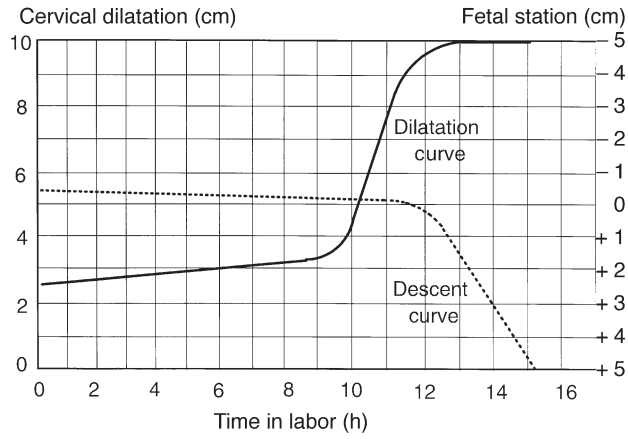

Figure 174.1 Characteristic patterns of normal cervical dilatation and fetal descent as depicted graphically against elapsed time.

ranging from 0 (closed cervix) to 10 cm (full cervical dilatation). The choice of 10 cm for full cervical dilatation is a practical approximation because the cervix will only dilate sufficiently to permit the fetal presenting part to traverse it. Since most term-sized fetal heads are approximately 9.5 cm in diameter this number would be more accurate, but in most cases it makes little practical importance. However, for preterm or very large fetuses upward or downward scales of adjustment would represent the true measure of cervical dilatation needed to accommodate passage of an individual fetal head.

Each division of the fetal station scale depicts a centimeter of station, defined as the level of the forward leading edge of the fetal presenting part with reference to the plane of the ischial spines. The range extends from −5 (5 cm above the referent plane, or about the level of the true inlet of the maternal pelvis) through station 0 (the referent plane of the ischial spines) to station +5 (5 cm caudad to the plane of the ischial spines, or the station at which crowning of the fetal head occurs at the vaginal outlet). The use of this system provides an accurate means to assess the rate of descent of the fetus through the birth canal.

One constructs the patterns of cervical dilatation and fetal descent by simply entering each clinical observation at the appropriate place on the graph (Figure 174.1). As additional data are collected from the sequential examinations done during labor, each dilatation and station observation is entered at its appropriate position. In this way the patterns of dilatation and descent are traced and observed prospectively while the patient's labor is evolving, providing a simple, utilitarian, visual tool to evaluate labor progress in real time. The addition of other pertinent information to the labor graph can also be helpful. Thus, the relationship of dilatation and descent to events such as rupture of fetal membranes, analgesic or anesthetic administration, or the effects of oxytocin can be visualized readily.

The graphic method of labor analysis should be mastered and employed by all who care for women during labor. This recommendation notwithstanding, it is obvious that labor curves cannot be used in a clinical vacuum. They provide information vital to clinical decision making, but which must be integrated with other obstetric data. For example, information obtained from the labor curves must be assessed in the context of that derived concerning cephalopelvic relationships, pelvic architecture, effects of medications, state of fetal oxygenation and maternal condition in order to make the most enlightened clinical judgments.

Normal labor pattern

While labor may be properly considered to begin with the onset of regular uterine contractions that lead ultimately to cervical dilatation and descent of the fetus through the birth canal, biochemical and biophysical preparation of the cervix and uterus begin well in advance of that time. These changes are most evident clinically in the maturation (ripening) of the cervix and the development of the lower uterine segment, as well as the increasing frequency and intensity of Braxton–Hicks contractions.[6,7] These events are, to a variable degree, completed before the onset of labor. The extent of this prelabor maturation governs the duration of the *latent phase* of labor. The latent phase, which commences with the onset of labor, is characterized by little or no cervical dilatation for some time despite the presence of uterine contractions that may be quite strong. Notwithstanding the absence of dramatic changes in dilatation, many important events are taking place in the cervix during this portion of labor. Biochemical modifications of the connective tissue and ground substance occur, extensions of the process of cervical maturation or ripening that, as noted, often has begun prior to the onset of labor. This breakdown of dense connective tissue within the cervix results in a clinically palpable softening and an increase in compliance that are necessary preliminaries to the more active dilatation that will occur later.

The latent phase is followed in due course under normal circumstances by an *active phase*. Together, latent and active phases comprise the *first stage* of labor. The active phase is characterized normally by rapid and progressive change in cervical dilatation, continuing in a linear fashion without interruption until it ends at the onset of the second stage, when the cervix has retracted around the maximum diameter of the presenting part and is said to be fully or completely dilated. The beginning of the active phase can be identified on the graphic pattern by the upswing of the dilatation curve. Interestingly, this generally occurs without any discernible objective change in the uterine contractile pattern and often without a subjective change in the parturient's perception of her contractions.

It is during the active phase that most of the cervical dilatation is achieved. Although on average

the active phase begins when the cervix has reached about 4 cm dilatation, it often starts with a smaller or larger dilatation; the degree of dilatation cannot, therefore, be used as the sole indicator that the labor is in the active phase.[3,4,8] Some demonstration that the rate of dilatation has accelerated is necessary.

The active phase is divisible into three recognizable components. It starts with an initial acceleration phase, followed by a central linear phase of maximum slope, and is concluded by a terminal deceleration phase. The acceleration phase represents the transition from the nearly flat slope of the latent phase to the rapid dilatation of the phase of maximum slope. The latter typically traces a straight line in the labor graph proceeding quickly to about 8–9 cm when, at the onset of the deceleration phase, the curve appears to slow down. There is no true slowing as the name implies, but rather an artifactual appearance of slowing of cervical dilatation just prior to the second stage. The cervix continues in fact to dilate at the same rate, but as it retracts around the presenting part the edges of the cervix are moving more cephalad than laterally; hence the lateral change in dilatation measured clinically and plotted on the curve slows. Uterine contractions often increase in frequency, intensity and duration at about this time, and simultaneously the patient's perception of discomfort from the contractions is often markedly enhanced. This portion of labor has sometimes been called transition.

The curve of fetal descent is likewise divisible into phases similar to, but not completely congruent with those of the dilatation curve. It also begins with a latent phase starting at the onset of labor, but the latent phase of the descent pattern does not end at the same time as the beginning of the active phase of dilatation. It continues thereafter, not concluding until the dilatation curve has completed almost all of its active phase. The active portion of the descent curve generally begins somewhere at or beyond the midpoint of the phase of maximum slope of dilatation; it ordinarily reaches its own maximum slope at the onset of the deceleration phase of dilatation and no later than the beginning of the second stage.

Once the active phase of descent begins, one can expect fetal descent to continue without interruption until the presenting part encounters the pelvic floor. While the descent pattern is usually represented as hyperbolic in shape, it does have a deceleration phase – more correctly, a perineal phase-which is too short in the usual clinical situation to be apparent in the graphic pattern. The constant interrelationship between the dilatation curve and the descent curve is an important clinical diagnostic feature to aid in disclosing the presence of labor abnormalities.

Table 174.1 Limits of normal labor pattern components

Component	Nulliparas*	Multiparas
Latent phase duration (h)	20	14
Maximum slope of dilatation (cm/h)	1.2	1.5
Deceleration phase duration (h)	3	1
Maximum slope of descent (cm/h)	1.0	2.0

*Includes parous women who have never had a vaginal delivery[46]

Abnormal labor patterns

The analysis of cervical dilatation and fetal descent patterns in large numbers of cases allowed a detailed analysis that provided information about the statistical distributions of various aspects of the cervical dilatation or fetal descent vs. time relationships. Thus, the mean, central tendency, the 5th and 95th percentile confidence intervals, and the range of each measured duration and slope could be determined. Limits of normal for each of the definable components were determined based on these confidence intervals (Table 174.1).[3–5,9]

Labor disorders may be categorized into three groups, based on similarities in their attributes and prognostic implications: prolonged latent phase; protraction disorders (of dilatation and descent); and arrest disorders (arrest of dilatation or descent, prolonged deceleration phase, and failure of descent) (Table 174.2; Figure 174.2).

A *prolonged latent phase*, which often reflects inadequate prelabor cervical ripening or some other factor inhibiting progression into the active phase, is diagnosed when the duration of the latent phase exceeds 20 h in the nullipara and 14 h in the multipara.[10,11] A *protracted active phase* of dilatation and *protracted descent* are diagnosed when dilatation or descent occur in a linear progressive manner during their active phase, but at a rate below the critical limit of normal (the 5th percentile derived from a series of labors uninfluenced by medical intervention).[10,12,13] An *arrest of dilatation* is identified when, having entered the active phase, dilatation ceases for a period of at least 2 h.[10,14] (Although this is the standard definition, some data indicate that 1 h of arrest of dilatation is sufficient to make a diagnosis.)[15] The analogous disorder of descent, *arrest of descent*, can be diagnosed when active descent has ceased for a period of 1 h.[10,16]

A special kind of dilatation abnormality, a *prolonged deceleration phase*, reflects a delay in the terminal portion of dilatation and is diagnosed when the duration of deceleration of the dilatation curve exceeds 3 h in nulliparas or 1 h in multiparas. If expected descent does not begin when normally anticipated, i.e. during the later portion of dilatation or by the onset of the second stage, a *failure of descent* can be said to exist.[3]

Table 174.2 Abnormal labor patterns as defined by dilatation and descent curves

Dysfunction	Nulliparas	Multiparas
Prolonged latent phase	>20 h duration	>14 h duration
Arrest of dilatation	2 h without progress in active phase	2 h without progress in active phase
Arrest of descent	1 h without progress after active descent has begun	1 h without progress after active descent has begun
Prolonged deceleration phase	>3 h duration	>1 h duration
Failure of descent	No descent by deceleration phase or second stage onset	No descent by deceleration phase or second stage onset
Protracted dilatation	< 1.2 cm/h slope	< 1.5 cm/h slope
Protracted descent	< 1.0 cm/h slope	< 2.0 cm/h slope

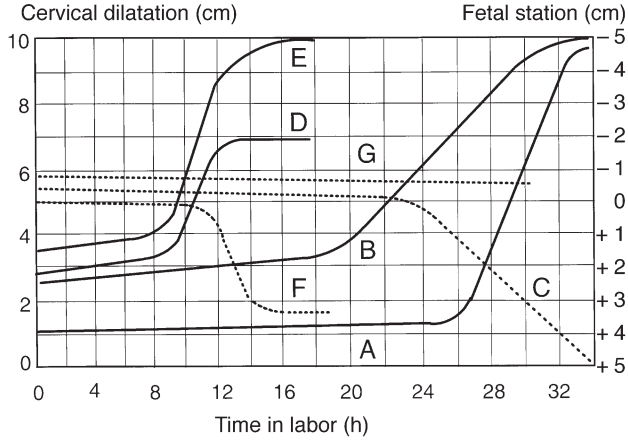

Figure 174.2 Labor disorders that can be identified on the basis of deviations from the expected normal durations, slopes, and patterns of the dilatation and descent curves are illustrated graphically: (A) prolonged latent phase; (B) protracted dilatation; (C) protracted descent; (D) arrest of dilatation; (E) prolonged deceleration phase; (F) arrest of descent; (G) failure of descent.

Prolonged latent phase

Labors with the descriptively named prolonged latent phase are characterized by little or no change in cervical dilatation despite many hours of regular uterine contractions. The differentiation between a prolonged latent phase and false labor (which underlies about 10% of diagnoses of prolonged latent phase) can seldom be made with any degree of certainty, except in hindsight. The latent phase can be prolonged by the administration of narcotics or sedative agents for pain relief. Peridural anesthesia has the capacity to prolong the latent phase considerably, probably because uterine contractility is more easily inhibited by analgesia and anesthesia during this time of labor. Frequently (nearly 20% of those with this labor disorder) the cervix has failed to achieve the essential prelabor maturation and preparation expected. That is, the cervix is long, closed and resistant, rather than more favorably soft, effaced and partially dilated. In such cases, one can expect the latent phase will take a long time to modify the cervix in anticipation of later active dilatation.

While the diagnosis of prolonged latent phase sometimes lacks precision because of the difficulty of ascertaining the exact time of labor onset, the simple recognition of the fact that the latent phase may be normally quite long is of considerable importance in the management of labor. Prolonged latent phase *per se* does not appear to confer an increased need for operative delivery and is not a predictor of more serious active phase disorders strongly associated with the need for cesarean delivery. Moreover, its presence does not appear to increase perinatal morbidity.[17–19] Ignorance about the normal course of the latent phase sometimes leads nevertheless to unnecessary cesarean section under the erroneous assumption that continuous progress should be expected in all phases of labor, or that very long labors are always abnormal. Concern is sometimes raised during the latent phase about the station of the fetal head. A fetal head floating above the pelvic brim in early labor is a risk factor for cesarean delivery later in labor[20]; but this is true whether or not the latent phase is prolonged.

Treatment of a prolonged latent phase may consist of active efforts to stimulate uterine contractility or heavy maternal sedation (Figure 174.3). Both are equally effective. The conversion to active phase labor generally occurs within 3 h. The choice between uterine stimulation and therapeutic rest for treatment of prolonged latent phase depends on the clinical situation. Concerns exist about transient fetal deoxygenation occurring with some kinds of narcotic drugs,[21] but no adverse outcomes after this kind of treatment for prolonged latent phase have been recognized. The approach does not seem to be associated with an increased rate of newborn depression, although if the mother delivers unexpectedly early a narcotic antagonist should be available for

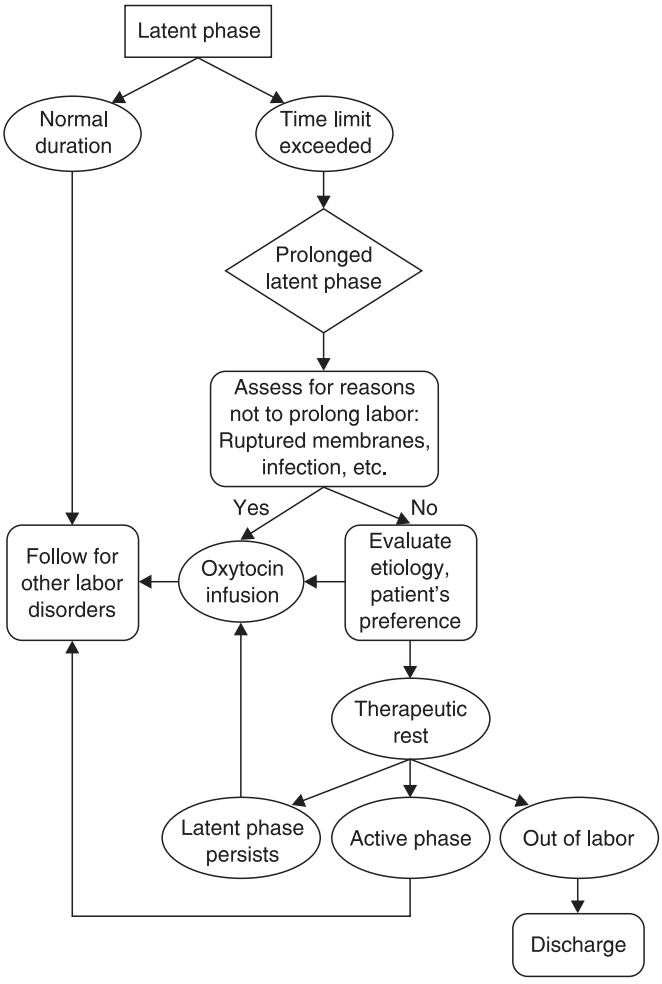

Figure 174.3 Management of the latent phase of labor. Prolonged latent phase is diagnosed when more than 20 h in a nullipara or more than 14 h in a multipara have elapsed. Oxytocin stimulation and narcotic sedation are equally effective treatments, and are chosen according to patient preference and the presence of factors that militate against prolonging the labor.

administration to the newborn. Whenever a fetal or maternal condition exists that could be worsened by prolonging labor, active intervention should be used, unless there is a contraindication to the administration of oxytocin. Similarly, when there is a reason to minimize the duration of labor (e.g. infection, pre-eclampsia) it is reasonable to intervene in the latent phase even before it reaches the limit of normal. The presence of prolonged ruptured membranes, preeclampsia, early intrauterine infection or certain acute maternal diseases thus favor an approach of active stimulation of labor. The mother's wishes should be taken into consideration as well. Some prefer oxytocin stimulation; others welcome the interposition of some rest into an arduous and stressful experience.

Prolonged latent phase is almost always innocuous with regard to its potential impact on mother and fetus. It responds to treatment in most cases (about 85%), and affected patients have no increased disposition to develop more serious labor aberrations. The fetuses of women whose labor is complicated by prolonged latent phase generally do well and can be expected to suffer no adverse consequences.[11,17–19]

Protraction and arrest disorders

The obstetric conditions associated with protraction and arrest disorders are similar but the therapeutic approaches to them differ (Figure 174.4).[10,13,14] Both dysfunctions are observed in association with cephalopelvic disproportion, malpositions, excessive sedation or anesthesia, and uterine infection.[3,22,23] Myometrial contractile dysfunction, which may be primary or a consequence of the preceding factors, may also cause or contribute to active phase dysfunction. Evaluation of a parturient with an active phase labor abnormality requires a search for associated, etiologic, or predisposing conditions. Careful clinical cephalopelvimetry is useful to determine the likelihood of disproportion. Assessment of factors such as pelvic architecture, fetal position and attitude, the degree of molding of cranial bones, and of dynamic aspects of cephalopelvic relationships allows a reasonable judgment to be made about the probability of disproportion. In addition, vaginal examination during the peak of a contraction in advanced cervical dilatation with gentle fundal pressure applied (the Müller–Hillis maneuver) provides useful assessment of the degree of descent, rotational tendencies, and attitudinal changes likely to occur with subsequent contractions.[24] Malpositions occur commonly, and can probably cause or, at times be a consequence of, active phase disorders. Labors affected by a protraction disorder tend to be sensitive to the inhibitory effects of sedation and anesthesia; thus, these factors may aggravate an already existing functional abnormality, rather than cause it.

If cephalopelvic disproportion seems unlikely and position of the fetal head is normal, assessment of uterine contractility, a search for chorioamnionitis, and evaluation for the presence of drugs or other factors that might inhibit labor are necessary. The risk of dysfunctional active phase labor may be increased in older mothers,[3,25] but diagnosis and therapy should not be influenced by maternal age.

No form of therapy has been shown effective in correcting the slow rates of dilatation and descent in protraction disorders that arise *de novo*. No matter how much one may attempt to encourage contractility with oxytocin, it does not appear to alter the dilatory course of labor significantly. Amniotomy, though it may be advisable in order to provide access for direct fetal heart rate monitoring to assess fetal oxygenation optimally in the presence of a protraction disorder, may actually result in superimposition of an arrest disorder.

Given the absence of benefit from ecbolic agents and their potential harm, they are best avoided for treating patients with a protraction disorder. This leaves very little in our therapeutic armamentarium.

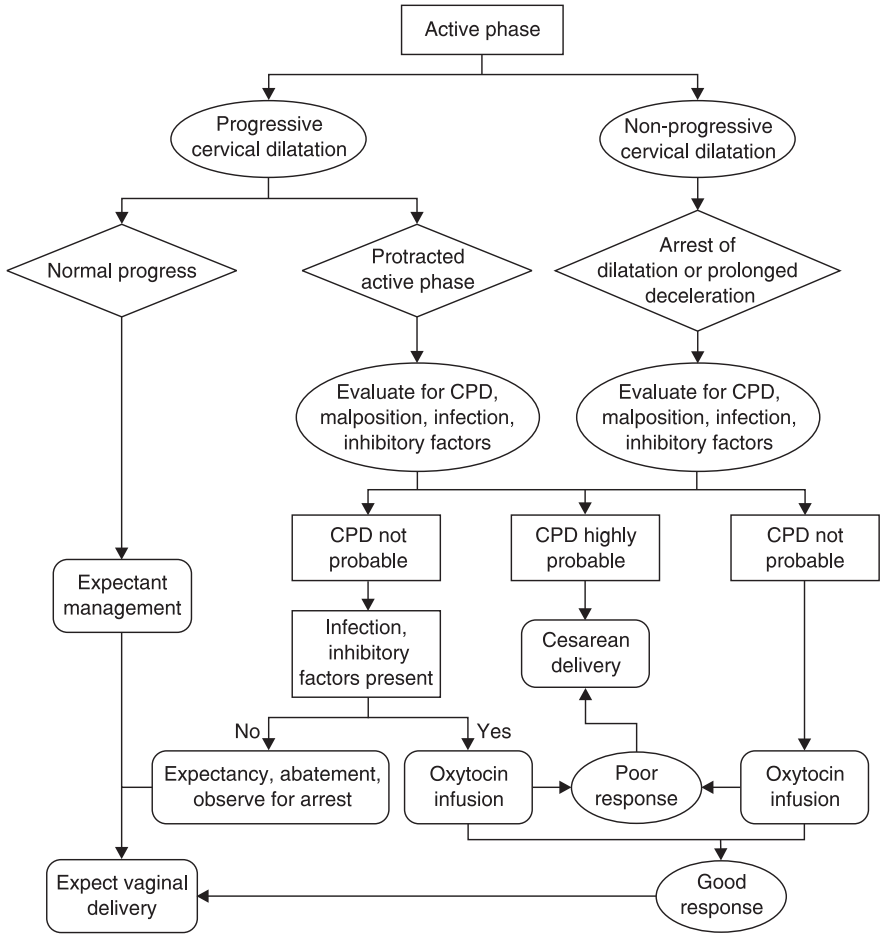

Figure 174.4 Management of the active phase of labor. Active phase abnormalities are frequently associated with cephalopelvic disproportion (CPD), and thorough clinical cephalopelvimetry is therefore important. A good response to oxytocin in an arrest disorder is defined as one in which the postarrest slope is equal to or greater than the prearrest slope. In protraction disorders it is when the rate of dilatation or descent becomes normal.

We recommend that, once the condition is diagnosed (and cephalopelvic determined to be unlikely), the patient be advised of the nature of her condition and the fact that the labor is likely to be quite prolonged and uncomfortable. Women with a protraction disorder need intense psychologic and social support coupled, when possible, with the avoidance of medications likely to retard progress further. Thus, expectancy and careful observation for adverse maternal or fetal development are essential. Oxytocin may be of therapeutic value if the protraction disorder appears to have resulted from some inhibitory influence. For example, if the protraction dysfunction was provoked by conduction anesthesia or by drugs that have the potential to suppress contractility, oxytocin may override these inhibitory influences and restore normal dilatation. One randomized trial suggested that oxytocin stimulation increased the rate of dilatation in what was termed 'primary dysfunctional labor', a diagnosis that probably included protraction disorders; but the degree of enhancement was not documented, and many patients responded to placebo infusion.[26] The role of epidural anesthesia in altering the course of labor is controversial. The best information supports the idea that a properly administered epidural (i.e. one using proper anesthetic or analgesic drugs in appropriate concentrations and achieving an optimal level of sensory block) probably has little or no influence on the first stage of labor.[27,28] It may, however, lengthen the second stage because the sensation of the urge to push is blunted and bearing-down may be less effective because of motor blockade.

The maternal and fetal outcome after protraction disorders is not optimal. A substantial number, at least 25–30%, will require cesarean delivery because of presumed cephalopelvic disproportion. Cesarean section should also be considered whenever there is any evidence of irremediable fetal distress or when signs of chorioamnionitis develop at a time when vaginal delivery is not likely to occur soon. If an arrest disorder should supervene, the prognosis for vaginal delivery worsens because disproportion becomes increasingly likely.

Fetal prognosis depends principally on the method of delivery that follows the protracted labor. If

delivery can be achieved spontaneously by the vaginal route or by cesarean section, there is no discernible difference in outcome from that of infants born after normal labor patterns, provided there is no intervening factor placing the fetus in jeopardy. Operative vaginal delivery, however, carries a worse prognosis for the fetus. There is a threefold or greater increase in perinatal mortality associated with both low forceps and midforceps delivery.[17] A long-term deleterious impact on speech, language, hearing, and I.Q. also occur with increased frequency.[18,19]

Arrest disorders are arguably the most important labor aberrations because of their very common association with cephalopelvic disproportion.[14–16,22,29] When one or more of these abnormalities occurs, there is at least a 40–50% likelihood that cesarean delivery will be necessary because of disproportion. The treatment of arrest disorders is uterotonic stimulation, unless there is evidence of abnormal fetal heart rate patterns or compelling indications of disproportion. It is important to remember that progress can be achieved by oxytocin even in the face of major degrees of disproportion. This means that one cannot use oxytocin infusion as a clinically reliable 'test of labor' to demonstrate the presence or absence of disproportion. It becomes essential, therefore to ensure that disproportion is ruled out as best as possible by evaluating the maternal pelvic architecture and capacity, the fetal head dimensions, molding, cranial bone overlapping, and the aggregate of cephalopelvic relationships. When using the Müller–Hillis maneuver, if the head is felt to advance 1–2 cm, often in association with appropriate rotation and flexion, one can be confidently assured that no disproportion exists at that level of the pelvis. If the head is fixed instead, with no compensatory room palpable around it to permit additional descent without extreme molding, this represents clinically evident cephalopelvic disproportion. In that case, cesarean delivery would be acceptable with no further trial of labor. When disproportion has been reasonably excluded, oxytocin stimulation can be expected to correct the arrest and result in vaginal delivery in due course. If an error has been made – that is, if one has failed to detect disproportion that actually does exist – the subsequent pattern of dilatation and descent will usually serve as a telltale indicator. The postarrest slope of the curve (the measurements of the rate of progress achieved after oxytocin is begun) should be at least as great as the prearrest slope; if not, special care must be taken to reevaluate the maternal pelvis and its relation to the fetal head before allowing labor to proceed.

Patients treated with oxytocin who have normal postarrest slopes can be expected to deliver spontaneously without further complication. Instrumental delivery is best avoided in these cases because of the adverse impact it may have on the fetus. Overall, fetal prognosis is poorer after labor complicated by an arrest disorder. Although this can probably be minimized by adequate fetal surveillance, careful assessment for cephalopelvic disproportion, and use of the postarrest slope for verification of adequate pelvic capacity, results are still not quite optimal. Outcomes are worsened when the delivery procedure that follows the arrest disorder is low forceps or midforceps. Comparably adverse long-term results are also seen with increased frequencies of abnormal cognitive test results and lowered intelligence quotients. These data suggest that there may be an intrinsic adverse impact from the labor abnormalities that constitute the arrest disorders, and that this deleterious influence is enhanced by attempts to effect delivery by the vaginal route.[17–19]

When oxytocin is given for the treatment of an arrest disorder, about 85% of those patients who respond with dilatation that resumes at or above the prearrest rate of dilatation will have done so within about 3 h of having the infusion initiated.[3] Most such patients will eventually deliver vaginally without complication. If there has been no progress, or the new slope of dilatation is lower than the prearrest slope, it may generally be assumed that cesarean delivery is necessary. More prolonged oxytocin administration should be used only when the clinical situation suggests a high likelihood of a safe vaginal delivery. In some women arrest disorders resolve without the need for oxytocin. This may occur spontaneously, or as a result of awaiting abatement of inhibitory factors such as excess anesthesia or infection.

The goal of oxytocin infusion should be individualized, but should generally be the achievement of firm contractions (about 50 mmHg in amplitude) that occur every 2–3 min. Use of a quantitative measure of contractility, such as Montevideo Units is sometimes helpful; but the relation between contractility assessed in this way and the likelihood of change in cervical dilatation and descent has not been defined clearly.

Many obstetricians use artificial rupture of the fetal membranes as a means to accelerate labor and, specifically, to treat arrest disorders. This is based on the widely held notion that rupture of the membranes stimulates labor progress. The evidence for the latter is controversial. While rupture of membranes can certainly induce labor in some women, it is less clear that the progress of an already-established active phase can be augmented by rupturing membranes. Such an effect, if it exists, must be modest.[30–32] There are probably some situations in which rupture of membranes in an arrest disorder can effect change. The few patients who do respond do so promptly. There is, nevertheless, a virtue of ruptured membranes in the presence of an arrest disorder. It allows direct fetal heart rate monitoring, providing the most precise data for heart rate pattern interpretation. This is of importance because of evidence that dysfunctional labors may predispose to abnormal fetal heart rate patterns.[33]

Also of potential use in the presence of arrest or protraction disorders is changing maternal position.

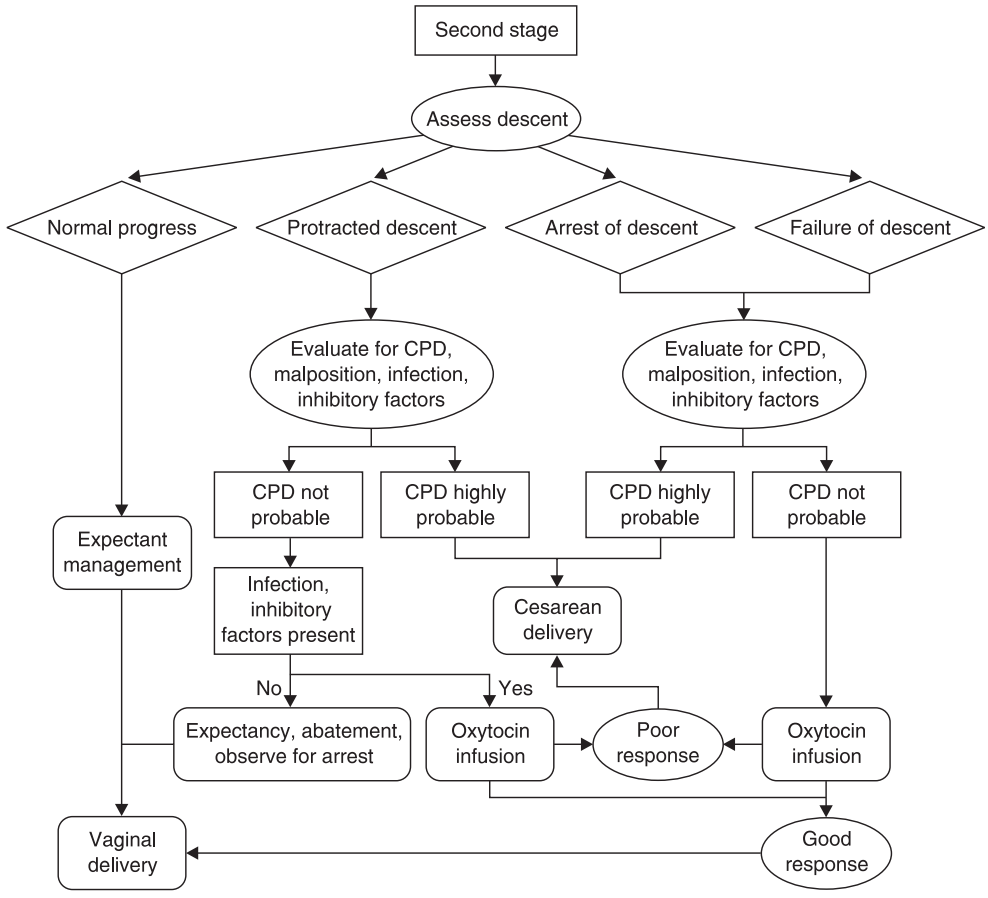

Figure 174.5 Management of the second stage of labor. Progress is measured by the rate of descent rather than by elapsed time. Fetal position, station, attitude and cranial molding should be assessed at each examination. A good response to oxytocin in an arrest of descent is defined as a postarrest slope equal to or greater than the prearrest slope of descent. In protracted descent it is when the rate of descent is normalized. CPD, cephalopelvic disproportion.

Using upright postures (squatting, standing, etc.) may benefit some labors by altering pelvic diameters or increasing uterine contractility.[34–38] While convincing objective proof of the efficacy of position changes is lacking, they can cause no harm, and may do some good. They should be tried.

A prolonged deceleration phase has the same associations and etiologies as arrest disorders, and should be assessed and treated in much the same manner. It is of particular importance because of its strong association with disproportion,[3] as well as with an increased risk of shoulder dystocia if vaginal delivery occurs.[39] It is frequently accompanied or followed by failure of descent, and the combination of these disorders makes safe vaginal delivery unlikely.

The second stage

The *second stage* of labor, which extends from complete cervical dilatation to delivery of the fetus, involves the major portion of fetal descent and rotational movements (Figure 174.5). The efficiency of the descent mechanism is assessed by measuring the rate of descent of the presenting part through the birth canal. This is preferable to judging the second stage solely by its length. In fact, second stage duration has little significant influence on neonatal or maternal morbidity or mortality,[40–43] except when it is exceptionally long (more than 3 h).[42] In that case the very high frequency of cesarean delivery has an effect on maternal outcome.

The rate at which active descent occurs is governed by several factors, including uterine contractile force; voluntary maternal expulsive efforts; fetal size, position and attitude; the deformability of the fetal head; pelvic architecture; and the characteristics of the pelvic of pelvic floor. Each should be assessed clinically to help judge the likelihood of vaginal delivery. In this regard, all obstetricians should be capable of performing a thorough and systematic examination of the pelvis and the cephalopelvic relationships. Information from such an evaluation is necessary to make informed judgments about delivery.[40] For example, an arrest of descent often occurs in the midpelvis with a posterior position of the occiput. This may be an entirely appropriate position in a large pelvis with anthropoid features. In such a case, if the sacrum is inclined posteriorly and the sidewalls parallel and minimal fetal cranial molding, the arrest may be due to factors other than disproportion. Continuing a trial of labor might be appropriate. If, however, the arrest occurs in a pelvis with a flattened sacral curve (preventing further

descent as a posterior) and a narrow interspinous dimension or convergent sidewalls (resisting anterior rotation), with considerable overlapping of the cranial plates evident, safe vaginal delivery may be far less likely and cesarean section a reasonable option without further labor.

Precipitate labor

While most concerns about dysfunctional labor have focused on abnormally slow or arrested parturition, excessively rapid labor may also have important consequences. *Precipitate labor* has been defined in two ways: labors that are exceptionally short (usually < 3 h); labors in which there is abnormally rapid cervical dilatation or fetal descent. There is greater virtue in the latter approach because it excludes labors that are short simply because the latent phase is short (usually related to advanced cervical ripening prior to labor onset). There is evidence that the excess morbidity that can accrue to fetuses exposed to very short labors (meconium passage, abnormal heart rate patterns and low Apgar scores) affects predominantly those with precipitate dilatation or descent.[44] These are defined by rates greater than 5 cm/h in nulliparas and 10 cm/h in multiparas.[3] Of course, spontaneous precipitate labor can generally be neither predicted nor prevented. When oxytocin is being used to stimulate contractility, however, it is important to avoid provoking excessive uterine contractility forces leading to high rates of dilatation and descent.

Conclusion

The approach to the assessment of labor outlined above requires a disciplined style of evaluation and treatment. This allows a considerable degree of evidence-based clinical objectivity to be combined with clinical art to yield optimal results for both mother and fetus. If we aspire to a uniform standard of nomenclature, we will enhance communication, permit objective study of labor, and maximize outcomes.[45]

Oxytocin or therapeutic rest may be used with equivalent benefit for prolonged latent phase. Expectancy and support are most appropriate for protraction disorders and oxytocin stimulation is best for arrest disorders, provided that cephalopelvic relationships have been judged adequate. If there is a high likelihood of disproportion based on clinical examination associated with either a protraction or arrest disorder, cesarean section is recommended as the option most compatible with safety. Such decisions must always be made in the context of assessing all available pertinent clinical data, with the parturient's full understanding of the situation, and with her participation in decision making when appropriate. The obstetrician cannot always guarantee a good outcome for every labor; but through application of the principles of assessment outlined in this chapter, one can maximize diagnostic accuracy and patient safety in the context of a satisfying and emotionally enriching birth experience.

175 Induction of labor

I. Z. MacKenzie and K. Duckitt

Introduction

The need to time delivery has been recognized and practiced for centuries. Although the indications have doubtless changed during the past 200 years, with the emphasis on fetal rather than maternal health in recent times, effective and safe methods of achieving delivery must always have been the primary objectives. Most methods of inducing labor employed before the 20th century involved mechanical manipulations, including Galvinism, repeated pressurized douches, extra-amniotic aqua picea, tents, bougies and catheters. The use of threats, incantations and chants was doubtless popular when nothing else was to hand, while the administration of potions and latterly castor oil, quinine, and posterior pituitary extract was also utilized. During the past 50 years, labor induction has mostly involved combining the recognized advantages of physical stimulation with a pharmacologic myometrial stimulant.

During the 1980s and 1990s, patients' acceptance of when and how delivery was achieved became a significant and sometimes overpowering consideration; this has not necessarily always been in the long-term best interests of mother or baby. In some countries, the fear of legal redress if the pregnancy outcome is not entirely favorable has become of such concern that patient demands are frequently acquiesced to, and in many cases requests for delivery by cesarean section are agreed to even without a clear medical indication. This chapter appraises the indications for and methods of labor induction and augmentation. It reviews their virtues and risks, together with an assessment of the views of the women whose labor has been induced and a consideration of the economics of such intervention.

Definition and rates of labor induction

It is difficult to compare the rates of induction between obstetric units, states or countries because of variations in the definition of induced or augmented labor. Examples of the differences that exist and which will influence calculations of induction rates include the following:

(1) When the membranes have spontaneously ruptured at term but labor has not established, to stimulate labor is variably called induction or augmentation;
(2) When efforts are made to ripen the unfavorable cervix and labor commences, is variably listed as induced or spontaneous labor; and
(3) There may be ready resort to elective prelabor cesarean, particularly if the cervix is unfavorable: should such cases be included with the statistics for labor induction?

The first two examples should logically be included in labor induction statistics. The concept of 'cervical ripening' was widely acknowledged and introduced into clinical practice by the late 1970s with the adoption of local prostaglandin administration. The changes that occur in cervical form during the latter weeks of pregnancy are accelerated as labor establishes and are thus not physiologically separable. It seems inappropriate therefore to consider therapeutically-induced cervical ripening and labor induction as two distinct entities. Elective prelabor cesarean section should be included with inductions under the all-encompassing title of 'timed' deliveries.

In England and Wales between 1980 and 1995 the induction rate varied between 16.8% and 20.6% (Figure 175.1).[1] This trend continued with just over 20% of births being induced in 2002–2003.[2] The equivalent rate for induction of labor in the USA in 2002 was 20.5%.[3]

Indications for labor induction

The indications for labor induction may be subdivided into maternal, fetal, or social, or a combination of these, and such indications may either be indicated or anticipated. Table 175.1 illustrates many of the indications that are widely acknowledged. An example of the relative frequency with which the indications occur is shown in Table 175.2 of data derived

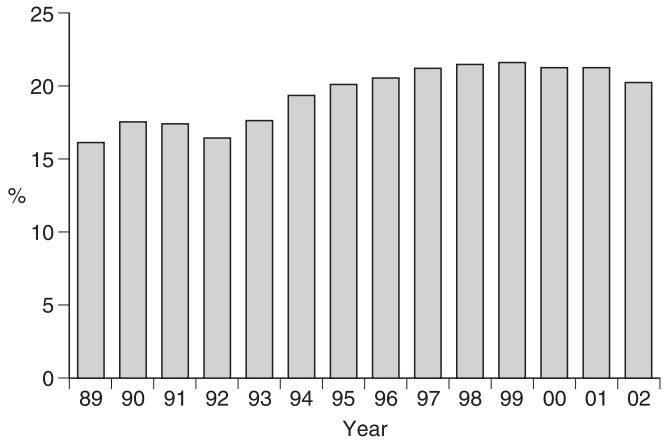

Figure 175.1 Induction rates for England and Wales, 1989–2002.

from the Obstetrics Department in Oxford for 5980 labor inductions during 2000–2004.

Specific definitions and the relative importance of the various indications for labor induction vary among obstetricians and countries. 'Post-term pregnancy' leading to induction is probably the commonest indication in many units, but definitions may include any gestation beyond 40 completed weeks; cephalopelvic disproportion may be managed by early induction at 38 weeks of gestation or ignored in the belief that spontaneous labor is to be preferred and results in a more favorable outcome. Some obstetricians consider that cervical state should determine the timing of delivery, particularly when 'post-term pregnancy' is the indication for induction; it should, however, be recognized that there is often a poor relationship between cervical favorability and gestational age.

Hypertensive states constitute the second most common primary indication for labor induction in many obstetric units, generally because of anticipated fetal or maternal problems rather than because of evidence of deteriorating ill health for mother or baby. The remaining unspecified indications are varied, some probably universally accepted, such as recent or current antepartum hemorrhage, diabetes mellitus, red cell isoimmunization, demonstrable placental failure and previous unexplained post-term stillbirth, and others with little logic, such as fetal macrosomia and suspected cephalopelvic disproportion.

Labor induction performed for maternal request or convenience at term is widely frowned upon. However,

Table 175.1 Common indications for induction of labor

	Fetal	Maternal	Social

Table 175.3 Components of Bishop's pelvic scoring system[4]

	Score			
	0	**1**	**2**	**3**
Station of presenting part	−3	−2	−1.0	+1
Cervical dilatation (cm)	Closed	1–2	3–4	5+
Cervical effacement (%)	0–39	40–59	60–79	80+
Cervical consistency	Firm	Medium	Soft	
Cervical position in pelvis	Posterior	Mid	Anterior	

the reluctance to accommodate such requests, believing that it is not in the best interests of mother or baby, is at variance with the willingness to allow patients to opt for delivery by elective cesarean section, usually performed before full term, particularly in cases such as breech presentation or previous delivery by section. Such reluctance is not logical. As demonstrated later, the rates of failed induction should be very low if the induction is managed correctly, and the fear of this should thus be limited.

Methods of induction

Cervical condition exerts a significant influence upon induced labor outcome, and in consequence the decision about how to induce labor must take account of the favorability of the cervix. To assist the obstetrician in deciding how to induce labor, a cervical scoring system is used. More than 12 different pelvic or cervical scoring schemes have been described during the past several decades, but that described by Bishop[4] is the one most widely employed (Table 175.3). An objective cervical scoring system is also essential as a research tool to enable comparisons of different induction methods and protocols to be made and to allow new methods to be developed and introduced.

Two different approaches to induction are employed: one relies on mechanical stimulation to provoke cervical effacement, dilatation and ultimately uterine contractions; the other uses pharmacologic agents to modify cervical form, with or without stimulating uterine contractions. Frequently, a combination of both approaches is used. As a general principle, the simplest inductions, those which probably precede the spontaneous onset of labor by a few hours to a day or two, rely upon mechanical techniques alone, while the most difficult inductions are often managed with pharmacologic agents, frequently involving more than one drug and often combined subsequently with a mechanical stimulus. Figure 175.2 lists the various techniques or agents used with reference to cervical condition.

Prior to the induction being started, a final check should be made to ensure that the indication to induce still pertains, and any specific labor management that may be required as a consequence of the indication should be reaffirmed. Palpation of the abdomen should confirm that the fetal lie is longitudinal and the presentation is as anticipated; the fetal heart beat should be present and healthy unless fetal death is the indication for the induction. Induction should not proceed if the fetal lie is not longitudinal; manipulation of the fetus to a longitudinal lie followed by management to ensure that the lie remains stable during the induction process can be employed.

The place for the routine use of continuous electronic fetal heart rate monitoring and intrauterine pressure measurement has still not been proven. The reliance on continuous electronic heart monitoring has unfortunately led to less clinical attention being paid to the duration and intensity of uterine contractions; this should be discouraged since valuable information about labor progress is often overlooked. A return to more clinical vigilance of uterine contractility, which remains an important part of the management of labor, is to be encouraged. Adequate analgesia should be available, as for spontaneous labor, and ideally should include the simple approaches such as, inhalational gases, parenteral narcotics and regional amnesia: some of the newer approaches including transcutaneous electrical nerve stimulation, massage techniques, aromatherapy and use of a birthing pool, although claimed to be beneficial, have not yet been shown objectively to offer any advantage.

Induction when the cervix is favorable (Bishop score > 6)

With a ripe or favorable cervix, mechanical methods of induction, which probably act by stimulating release of endogenous prostaglandins, and thereby promote uterine contractions, are frequently all that is required to achieve established progressive labor.

Membrane sweep and cervical stretch

When the cervix is particularly ripe, simple cervical examination and stretching of the membranes off the lower uterine segment can be very effective. Performed using a sterile glove, introducing one or two fingers through the cervix and stretching the os, this produces further dilatation; in addition, one of the fingers is swept around the internal surface of the cervix, dislodging the membranes from the cervical surface. When performed daily over 3 days, labor is induced in 69% of cases, depending upon the degree of cervical favorability at the time of the initial examination.[5]

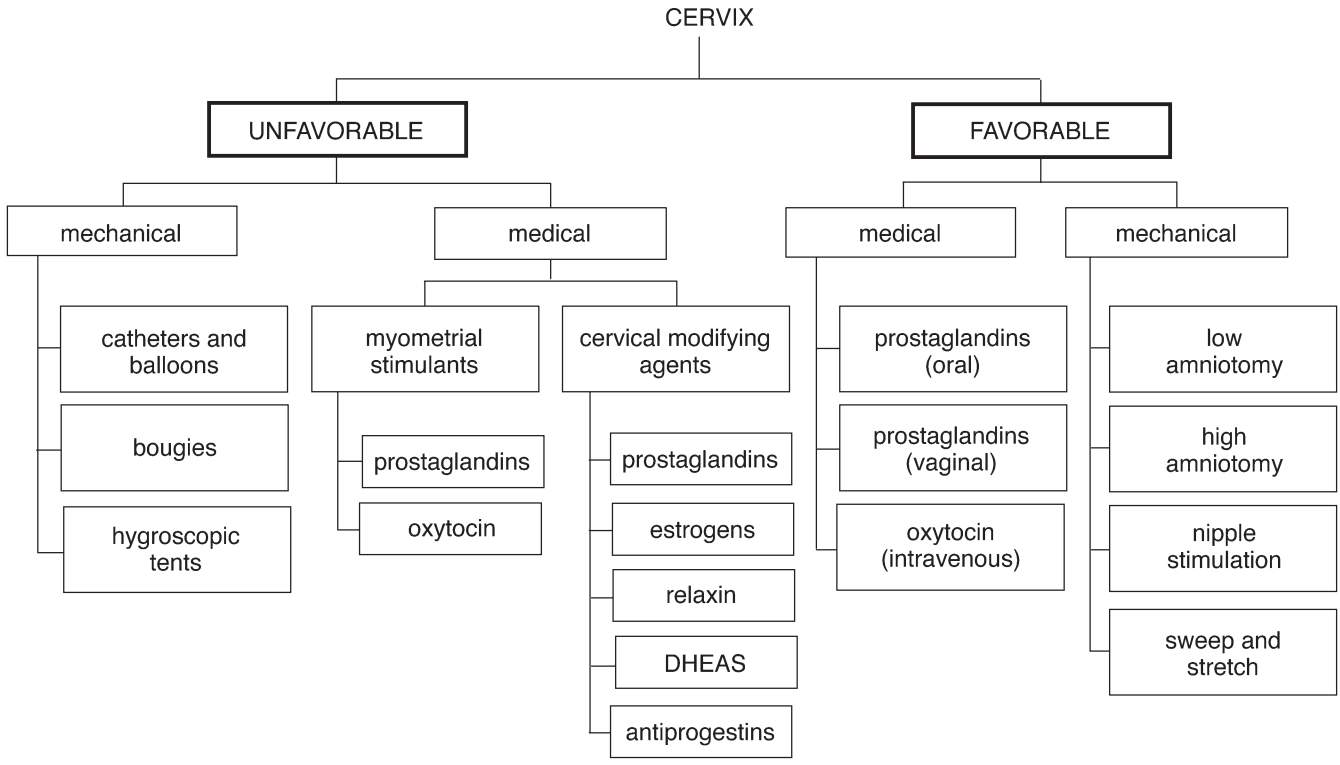

Figure 175.2 Therapeutic agents and devices that have been used for the induction of labor, according to the state of the cervix. When indicated, either low amniotomy is performed after the administration of the oxytocic agent when contractions are occurring, or an oxytocic is given, once the mechanical effect upon the cervix has been achieved. The timing for these additional therapies will depend upon circumstances and obstetrician preferences. DHEAS, dehydroepiandrosterone sulfate.

Sweeping of the membranes, performed routinely in women at term, is associated with a reduced duration of pregnancy and a reduced frequency of pregnancy continuing beyond 41 weeks [relative risk (RR) 0.62, 95% confidence interval (CI) 0.49–0.79] and 42 weeks (RR 0.28, 95% CI 0.15–0.50). To avoid one additional formal induction of labor, a stretch and sweep must be performed in seven women (number needed to treat (NNT = 7)). Maternal or neonatal infection does not seem to be increased.[6]

Low or forewater amniotomy

Abdominal palpation must confirm that the presenting part, head or breech, is either engaged or apparently securely settled in the pelvic brim; previous placental localization should have been performed in whom placenta praevia had previously been suspected. Amniotomy is usually performed in the labor suite. The maternal bladder should be emptied by spontaneous voiding immediately before the procedure, and ideally the rectum should be empty, if necessary following the prior administration of a suppository or enema. The dorsal or lithotomy position with some mild degree of left lateral tilt is used to reduce the chances of supine hypotension occurring, causing a decrease in placental bed blood flow.

The size and shape of the mid-cavity and outlet of the pelvis are assessed, and stretching of the cervix and sweeping the membranes off the lower uterine segment as described above is performed, at which time it is necessary to ensure the cord is not presenting. The membranes are then ruptured using a pair of toothed forceps, or a purpose-designed instrument such as an amniotomy hook. Amniotic fluid is released, encouraged by controlled elevation of the presenting part. A further check is made to ensure that the presentation is unchanged and the cord is not palpable, and the station and position of the presenting part are noted. The condition of the amniotic fluid is also noted and the fetal heart rate pattern checked to ensure that it is satisfactory. If continuous electronic monitoring is indicated, the preferred electrode can be attached to the most appropriate area of the presenting part before completing the procedure, unless an external ultrasound recording is to be used. Labor is then awaited.

The interval between amniotomy and any pharmacologic augmentation, if required, is variable, ranging from immediately after amniotomy to a delay of up to 24 h. Approximately 98% of women with a high Bishop score will labor after amniotomy alone.[7] Amniotomy with early intravenous oxytocin infusion, however, produces a significant reduction in women undelivered after 24 h compared with those managed by amniotomy alone.[8,9]

Hindwater amniotomy

There are few indications nowadays for using this method of labor induction unless ecbolic drugs are not available. It is usually reserved for inductions when the presenting part is high in relation to the

pelvic cavity and associated with polyhydramnios. The objective is to achieve a controlled release of amniotic fluid from a puncture in the membranes above the level of the presenting part, so reducing the chances of subsequent malpresentation, compound or funic presentation, and placental abruption.

Preparation for the procedure is the same as that described for low amniotomy; every attempt should be made using ultrasound to exclude a posterior placenta implanted low on the uterine wall. A sterilized Drew-Smythe catheter[10] is guided through the vagina and cervix alongside two examining fingers in the vagina, directing the leading end behind the presenting part. With an assistant stabilizing the longitudinal lie of the fetus by continuous pressure against the long axis of the uterus by abdominal palpation, the stylet of the catheter is advanced to puncture the membranes, and the amniotic fluid is allowed to drain through the lumen of the catheter until a sufficient amount has been released and the presenting part has descended and stabilized at or below the pelvic brim, when the catheter is withdrawn. Postamniotomy observations should be performed as for low amniotomy, but with particular attention to the possibility of placental abruption occurring in cases of polyhydramnios. An intravenous infusion of oxytocin may be given prior to the amniotomy or immediately afterwards, to try to ensure that uterine contractility is soon established to help retain the longitudinal lie and the presenting part fixed in the pelvis. Until then, careful repeated palpations are necessary to prevent the lie changing or to identify as soon as possible any deviation from this situation.

Oxytocin

Buccal oxytocin citrate 100–400 units[11] or demoxytocin 50 units[12] given at 30-min intervals as tablets held under the tongue to allow the oxytocin to be absorbed across the buccal mucous membrane is not widely used because of fears of uncertain absorption and unpredictable uterine response, and has thus largely been abandoned.

Protocols using intravenous infusions of oxytocin that are used these days are largely based on the work of Turnbull and Anderson.[13] Although originally given at a constant low dose infusion at less than 10 mU/min, this has been replaced by titrated doses, determined by the intensity and frequency of the uterine contractions. The rate is controlled using either basic clinical observations of contraction rate, duration and intensity, assessed by staff who alter the infusion rate using mechanical pumps and electronic drip counters, or by automatic infusion pumps governed by feedback from intrauterine contraction pressure using solid-state pressure transducers. Concentrations of oxytocin infusates range between 5 and 20 units oxytocin in 1000 ml solution of saline, N/5 dextrose-saline, or 5% dextrose solution. Infusion rates normally start at 1–4 mU/min and increase variably,[14] arithmetically[15] or logarithmically[16] at 15–30-min intervals, often to a maximum of around 32 mU/min, or until satisfactory labor has been established; occasionally higher rates may be required.[16] Most workers consider that the rate required to establish labor should be maintained into the second stage, and increased once the third stage of labor is reached, being maintained for approximately 1 h following delivery of the placenta and membranes. A modification has been suggested, giving 1-min infusions every 10 min,[17] to reduce the chances of unnecessarily overdosing the patient; this approach has not been widely adopted.

Automatically-controlled infusion systems were devised to eliminate the imprecision of clinical assessment of uterine contractions by repeated fundal palpation. The infusion rate is adjusted using a continuous measure of intrauterine pressure obtained with a transcervical intrauterine pressure catheter and either an open-loop infusion system, which requires the rate to be controlled manually once contractions are adequate,[18] or a closed-loop feedback system which allows an automatic decrease in infusion rate and theoretical avoidance of overdosage. Small studies, either randomized[19] or uncontrolled,[20] have produced conflicting results, suggesting that there is probably little advantage from such technology. As a consequence, despite the apparent enhanced safety features, these automated feedback systems have not found wide acceptance.

The place of amniotomy in inductions using intravenous oxytocin continues to be debated. Most obstetricians combine the two, with low amniotomy followed by intravenous oxytocin titration immediately or within 1 h, while some advocate a delay of 4–6 h. Alternatively, a titrated infusion of oxytocin can be started and amniotomy delayed until contractility is established in cases where the presenting part is very mobile at or above the pelvic brim; such a method should reduce the chances of compound presentation and cord prolapse or malpresentation occurring at amniotomy.

Prostaglandins

Potent ecbolics at all gestational ages, the prostaglandins have become the mainstay of labor induction in many countries. They may be administered in a variety of ways (Figure 175.3), the route being influenced by the indication for labor induction and the state of the cervix. The oral administration of prostaglandin E_2 (PGE_2) 0.5 mg tablets taken hourly with an incremental increase of 0.5 mg every 2 h to a maximum of 2.0 mg per hour should establish labor in most cases[21]; some advocate half-hourly medication.[22] Treatment may be continued for a maximum of 6 h or maintained as long as necessary to establish labor. Amniotomy may be performed before prostaglandin treatment, when cervical dilatation starts to occur, when labor begins to establish, or after 6 h. Some clinicians favor leaving the membranes intact unless rupturing them is indicated for other reasons.

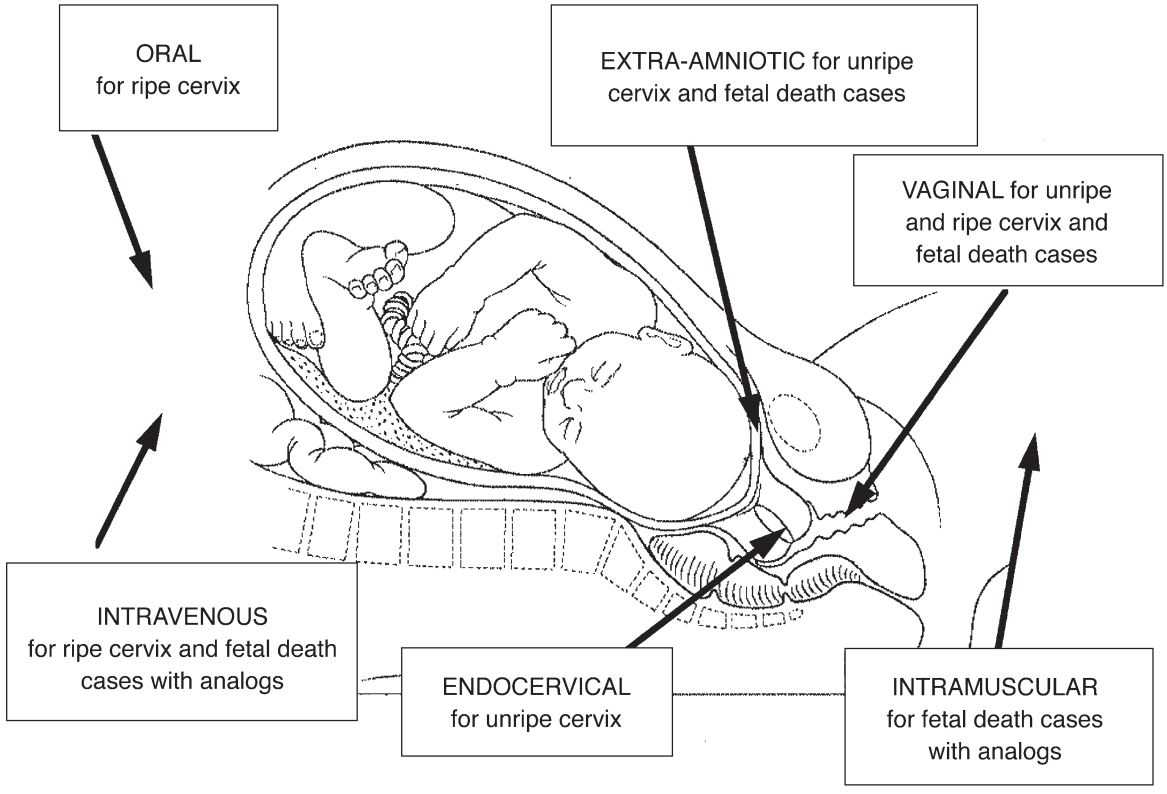

Figure 175.3 Routes of prostaglandin administration for the induction of labor.

Intravenous infusions are not widely used because of the gastrointestinal side-effects and local erythema at the infusion site associated with their use. Infusion rates usually start at PGE_2 0.1–0.5 μg/min or prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) 3–5 μg/min and either remain constant or increase arithmetically or logarithmically at 30-min intervals as necessary to a maximum of PGE_2 2–4 μg/min or $PGF_{2\alpha}$ 18–30 μg/min.[23,24] As with oxytocin, the infusion rate may be adjusted using routine clinical criteria, a peristaltic drip counter or an automatic feedback loop system. The place of amniotomy when using intravenous prostaglandins is similar to that described for intravenous infusions of oxytocin.

A single PGE_2 1–3 μg dose administered into the posterior vaginal fornix as a dry tablet, viscous gel or wax pessary, followed by low amniotomy after 3 h will induce labor in approximately 60% of primiparas and 80% of multiparas.[25–27] Augmentation can be provided with intravenous oxytocin, or repeated prostaglandin treatments at 6 h intervals. Timing of the amniotomy and further oxytocic augmentation is debatable, but most consider that oxytocin should not be administered for at least 3 h after any prostaglandin treatment.

Nipple stimulation

Uterine contractions can be induced by mechanical stimulation of the nipples, even to the extent of apparently causing uterine hypertonus.[28] A systematic review suggests that there is a significant reduction in the number of women not in labor after 72 h, when breast stimulation is compared with no treatment (RR 0.67, 95% CI 0.60–0.70),[29] but this technique has not found a role in common practice.

Sexual intercourse

Sexual intercourse is sometimes advised at term to encourage the onset of labor, with the premise that the high concentrations of prostaglandins in semen, the physical stimulation of the cervix and lower uterine segment leading to endogenous prostaglandin release, or orgasm may encourage uterine contractions. However, evidence to substantiate this advice is lacking. One small randomized clinical trial compared women having sexual intercourse with semen deposit, but no nipple stimulation, for three nights in a row at term, with women who abstained from this activity. There was no change in the Bishop score between the two groups and there was no difference in the number of women who delivered within 3 days of the intervention (46% vs. 47%, RR 0.99, 95% CI 0.45–2.20).[30]

Induction when the cervix is unripe (Bishop score < 7)

The unripe cervix can present a major problem when delivery is necessary and labor induction is indicated; rarely is it a problem for multiparas, except occasionally for those women previously delivered by cesarean section. The concept of cervical ripening or priming involves treatment to render the cervix more favorable, followed by a formal induction method, unless labor supervenes with the 'ripening' procedure. The distinction between ripening and labor induction is artificial;

a subdivision between the latent prelabor phase and the active acceleratory phase is unphysiologic. Such a subdivision may encourage the idea of abandoning the attempt to induce labor if cervical ripening is not easily achieved: when this approach is adopted there must be a question about the wisdom of the initial indication to induce labor.

Ripening may be achieved either medically or mechanically. Two principles of management have been explored using pharmacologic agents in this situation: those that modify the cervix and stimulate uterine contractions (oxytocin and prostaglandins), and those that influence cervical form and consistency, by modifying the cervical ground-substance without seemingly provoking any change in myometrial contractility (estrogens, antiprogestins, relaxin, dehydroepiandrosterone sulfate). Both groups of substances may be used in isolation, or in combination with other modalities of treatment.

Prostaglandins

Both PGE_2 and $PGF_{2\alpha}$ have been used, although there is much less experience reported using $PGF_{2\alpha}$. Various synthetic prostaglandin analogs have been explored for pregnancy termination and in cases of fetal death; there is increasing experience with misoprostol, the PGE_1 analog, for term labor induction with a viable fetus. When the cervix is unripe, local administration routes are most applicable. Oral and intravenous administration of PGE_2 and $PGF_{2\alpha}$ usually result in high rates of side-effects with the doses required to achieve clinical benefit, and are thus not generally used. Although misoprostol can be administered orally and even bucally and sublingually, these routes do not seem as effective as vaginally administered misoprostol.[31–33]

Extra-amniotic infusion or instillation. With prior vulvar and vaginal toilet, and using aseptic techniques, a catheter is guided through the cervical canal with the tip placed in the extra-amniotic space, either by the vaginal examining fingers or under direct vision using a speculum. Once introduced, the catheter can be left in place by distending a self-retaining balloon with 20–50 ml sterile isotonic saline and the catheter connected to an infusion pump, or it can be removed once a single bolus of prostaglandins has been given. If using an infusion the rate commences at PGE_2 20 μg/h, with 10 μg incremental increases at 15-min intervals as necessary using a solution concentration of 1.5–5 μg/ml[34,35] or $PGF_{2\alpha}$ 180–600 μg/ml with similar proportional incremental dose increases; the infusion is maintained until the catheter is expelled into the vagina. Bolus doses of PGE_2 (300–500 μg) or $PGF_{2\alpha}$ (5 mg in 10 ml volumes of viscous gel) can be given as a single instillation, and this is a simpler and equally efficacious method.[36] Amniotomy may be performed once labor is established, and oxytocin augmentation started thereafter. Inadvertent perforation of the fetal membranes is a disadvantage and disturbance of a previously unsuspected placenta previa may provoke excessive hemorrhage, requiring immediate cesarean section.

Endocervical instillation. A catheter is passed into the cervical canal as described above and PGE_2 500–1000 μg in 2–4 ml viscous gel is discharged into the endocervical canal.[37] Subsequent management is as described for the extra-amniotic instillation approach. There must be doubt about the precise location of the gel after initial injection, some probably reaching the extra-amniotic space and some leaking into the vagina. Attempts have been made to confine the drug to the cervical canal using a system of balloons, but the benefits of the system have yet to be demonstrated.[38] Some of the disadvantages of the extra-amniotic approach should be avoided with endocervical instillation, but there must be uncertainties over the duration of the gel being retained in the canal; the method is not particularly suitable for a patient with an uneffaced cervix that admits an examining finger, as occasionally occurs. Endocervical placement may be the most logical, with the prostaglandins being adjacent against the end organ concerned, although studies comparing endocervical extra-amniotic and vaginal protocols suggest the clinical responses are very similar.

Vaginal instillation. Many different vehicles including dry tablets,[24] wax pessaries,[25] viscous gels,[39] non-biodegradable hydrogel polymers,[40] and water-soluble polymers,[41] incorporating many different doses have been tried. There is no clearly established most appropriate protocol to recommend. Published results suggest that PGE_2 (2–5 mg) in biodegradable pessaries and gels and PGE_2 (5–10 mg) in the non-biodegradable formulations as a single instillation are appropriate; the lower doses are probably as effective as the higher ones. A latent period of 12 h is necessary before formal induction is performed in many cases to achieve the desired clinical effect on the cervix. Some protocols use repeated prostaglandin treatments at 6-hourly intervals for three or more doses, and others describe amniotomy and oxytocin titration 15 h after a single prostaglandin treatment unless labor has already supervened. Repeated small doses of PGE_2 0.5 mg at 2–3-hourly intervals have been used,[42,43] but have not been widely adopted. A prospective randomized study examining a single vs. repeat dose after 6 h reports that no advantage is obtained by repeating the dose of prostaglandins, suggesting that the initial exposure to prostaglandins is sufficient to achieve the desired effect on cervical function[44]; it appears that tachyphylaxis may occur in those women with a resistant cervix, and repeated dosing will probably not improve outcome. The controlled release hydrogel pessary,[40] with its maximum release rate of prostaglandins of less than 1 mg/h from a 10 mg reservoir, providing a prolonged source of prostaglandins over many hours, offers potential advantages; in particular, it may be removed from the

Table 175.4 Labor outcome using local prostaglandin E_2 protocols with an unripe cervix

Protocol	*n*	Maximum cervical score	Labor length (h)	Additional oxytocic (%)	Cesarean section (%)	Failed induction (%)
Extra-amniotic 240–480 μg[36]	121	3	10.7	80	14	0.8
Endocervical 500 μg[106]	27	5	10.7	34	7	3.7
Vaginal 3 mg wax pessaries[107]	110	4	16.0	20	21	5.5
Vaginal 2 mg gel[39]	102	3	10.5	76	13	3.0
Vaginal 10 mg hydrogel pessaries[108]	32	3	10.6	72	12	

Table 175.5 Use of misoprostol in pregnancy*

May be considered for cervical ripening or labor induction in hospitalized patients
The dose is 25 μg intravaginally every 3–6 h
A dose of 50 μg every 6 h may be considered in some situations, but is associated with uterine tachysystole and possibly hyperstimulation, and meconium in amniotic fluid
Oxytocin should not be given within 4 h of the last misoprostol dose
Fetal heart rate and uterine activity should be continuously monitored
Misoprostol should not be administered to women with a previous hysterotomy (cesarean delivery or major uterine surgery)

*Adapted from American College of Obstetricians and Gynecologists. ACOG Committee Opinion No. 283. *Obstet Gynecol* 2003;101:1049.

vagina if indicated.[45] Prospective comparative trials are needed to assess the pessary against the alternatives. Table 175.4 summarizes the results from the published literature obtained for nulliparas with an unfavorable cervix undergoing induction using local PGE_2. Prostaglandin $F_{2\alpha}$ 25–50 mg in viscous gel has also been studied, but the objective evidence available suggests that it is less efficient than PGE_2, although it has demonstrable benefits over placebo.[58,59]

Misoprostol is licensed for the treatment and prevention of gastroduodenal ulcers. Its use for induction of labor remains an off-label unlicensed use.[46,47] It is available as 100 and 200 μg tablets that have to be broken to provide 25 or 50 μg doses. It is inexpensive, can be stored at room temperature and is rapidly absorbed from both the oral and vaginal route. Misprostol, administered vaginally, improves cervical ripening compared with placebo.[48] Experience with misoprostol is changing rapidly. Currently the evidence suggests that when compared with vaginal or intracervical PGE_2 or oxytocin, its use at doses of 25 μg every 3 h or more is associated with less epidural analgesia use, fewer failures to achieve vaginal delivery within 24 h but more uterine hyperstimulation. Compared with vaginal or intracervical PGE_2, oxytocin augmentation was less common with misoprostol but meconium-stained amniotic fluid was more common. This may be due to a direct effect on fetal bowel activity. Cesarean section rates did not differ between groups. The optimal dose and timing interval of intravaginally applied misoprostol are unknown. However, there was less uterine hyperstimulation with lower doses (25 μg every 4 h or less) as opposed to higher doses of misoprostol. More limited information on these lower doses suggest equivalent efficacy to conventional methods of induction.[48] More comparisons between different doses of oral misoprostol and vaginal misoprostol are required. Reports of uterine rupture following labor induction with misoprostol, even in unscarred uteri, are a cause for concern.[49–52] The use of misoprostol has been endorsed by ACOG[53–55] (Table 175.5) but the professional bodies in the UK and Canada remain cautious about its use outside randomized controlled trials.[56,57]

Oxytocin

Intravenous infusions, intramuscular injections, buccal tablets and even nasal sprays of forms of oxytocin have all been used, but in general all have been abandoned in favor of alternatives, if available. Controlled studies have indicated that oxytocin is not very effective when the cervix is unfavorable, especially when compared with local prostaglandins. Prior to the introduction of prostaglandins, inductions were managed by repeated infusions or buccal courses of oxytocin over 8–15-h periods, with breaks overnight and repeated the next day and as often as necessary until labor was induced, or the attempt at induction abandoned.

Estrogens

Estradiol 150–300 mg in viscous gel extra-amniotically, endocervically or vaginally, or estradiol 10 mg intramuscularly and estriol 150–250 mg in viscous gel extra-amniotically, can produce improvement in cervical scores with minimal myometrial stimulation.[60,61] When formal induction is performed 12–24 h later, there appears to be little improvement in the outcome of labor. However, since estradiol has a 10-fold

higher estrogenic potency than estriol, and there was a considerable dosage range in these studies, the true value of estrogens for cervical ripening remains uncertain, but present evidence suggests that their role is probably very limited.

Dehydroepiandrosterone sulfate

Intravenous dehydroepiandrosterone sulfate (DHEAS), which is transformed into estrogens in the fetoplacental unit, has been explored as a possible cervical ripening agent, achieving effacement without inducing uterine contractions. The results were not encouraging when DHEAS 100 mg injected intravenously twice a week from 38 weeks of gestation was compared with placebo,[62] and the concept has received little further attention.

Relaxin

Like DHEAS, this has been studied in the human, using purified porcine relaxin 1–4 mg in viscous gel vaginally or endocervically, in the hope that it would have the same properties as exhibited in certain animal species. To date, there have been no well-conducted trials to determine its value for ripening the unfavorable cervix and enhancing the outcome of induced labor without stimulating uterine activity, and more studies enabling a critical scientific assessment to be made are required before considering it to be of any clinical value. With the production of recombinant human relaxin, interest was renewed in studying this polypeptide for induction. Trials to date exploring different dosages, given vaginally, suggest that there is no evidence that 1, 2 or 4 mg cause any maternal or fetal toxicity,[63] but unfortunately there appears to be little evidence of any therapeutic effect.[64] Further studies with larger doses and alternative administration methods are required before large clinical trials can be mounted. Enthusiasm for this agent for labor induction must at present be muted.

Antiprogestins

Epostane, the 3β-hydroxysteroid dehydrogenase inhibitor, and more recently mifepristone, the progesterone receptor blocker, have been shown to have a dramatic effect on reducing the induction-to-abortion intervals during second-trimester therapeutic pregnancy termination.[65,66] Similar benefits might be expected for labor induction at term, but experience reported to date is limited. Labor may be induced following exposure to mifepristone, and cervical condition can be improved; the need for delivery by cesarean section has not been found to be reduced compared with placebo.[67] It had been thought that mifepristone might revolutionize labor induction but experience is still limited and there are no trials that compare mifepristone with alternative methods of inducing labor, e.g. prostaglandins.

Mechanical dilators

Dilatation, and to a lesser extent effacement, can be produced by the introduction of catheters, balloons, bougies and tents into the cervical canal. The devices are introduced most easily using the lithotomy position, taking aseptic precautions; after a variable period the device is either spontaneously expelled or removed. Thereafter, the induction can be advanced either by low amniotomy or administration of an oxytocic. However, results are unpredictable and when assessed objectively such devices probably offer little, if any, benefit.[68] Since intrauterine infection is a theoretical risk, which probably increases with prolonged retention of the foreign body, a careful watch needs be kept on maternal pulse and temperature. The advantages of these methods are their wide availability and the low cost, especially balloon catheters. Storage and preservation of mechanical devices is less problematic than PGE_2, which should be kept at low temperature. There seems little place for this method if prostaglandins are available. However, when compared with prostaglandins and misoprostol their use is associated with significantly less risk of hyperstimulation and fetal heart rate changes, advantages that may be important in high risk cases.[68]

Homeopathy

Homeopathy involves the use, in dilution, of substances that cause symptoms in their undiluted form. A type of herb *Caulophyllum thalictroides* is a homeopathic therapy used to induce labor. Although two small randomized clinical trials have looked at this method of inducing labor there was not enough detail presented to draw any firm conclusions about its effectiveness.[69]

Acupuncture

Although observational studies suggest that acupuncture may stimulate the onset of labor[70–72] and ripen the cervix,[73,74] the only clinical trial to compare acupuncture with no acupuncture in women who were post-term included only 56 subjects and did not lead to any convincing conclusions because of its large loss to follow-up and significant post-randomization exclusions.[75]

Labor induction in specific situations

Post-term pregnancy

The most frequent indication for labor induction in most units is prolonged pregnancy, an indication that stems from the findings of the 1958 Perinatal Mortality Survey of England and Wales[76]; many studies examining this area define post-term pregnancy as one undelivered by the 41st week of gestation determined by menstrual calculation or ultrasound assessment. It is thus performed for anticipated problems derived from statistical analyses, although the principle has been challenged in recent years, with alternative management strategies advocated which involve repeated frequent fetal surveillance methods using a combination of various cardiotocographic and ultrasound monitoring procedures. The end result, if

assessed by need for delivery by cesarean section, suggests that there is no obvious benefit from avoiding induction. A meta-analysis of 19 randomized trials showed that routine induction of labor reduced perinatal mortality (OR 0.20, 95% CI 0.06–0.70) with the benefit being due to the effect of induction of labor after 41 weeks. Routine induction of labor in post-term pregnancies was not associated with an increased risk of cesarean section overall or in any subgroup of women, regardless of parity, state of the cervix or method of induction.[77]

Once the expected date of confinement has passed, and delivery is still awaited, many women are keen to be delivered. In addition, the incidence of meconium staining of the amniotic fluid increases with advancing gestation, and this often influences the care that is provided during labor and the handling of the newborn. It is unlikely that there will be a dramatic change in the incidence of induction for post-term women unless obstetricians are prepared, at the start of pregnancy, to recalculate the expected date of delivery as 42 completed weeks rather than 40 weeks: such a change could reduce patients' demands for induction because of prolonged pregnancy.

Previous cesarean section

Opinions vary over the wisdom of inducing labor in women previously delivered by lower-segment cesarean section; the majority considers that a previous classical section and previous repeated lower-segment sections should usually be considered as contraindications to attempting labor. For those who favor allowing labor induction, the most appropriate method to use is debated. Some believe it only appropriate to induce labor by low amniotomy, others to limit the ecbolic agent to low doses of oxytocin, while there are those who do not restrict the method to be used. There is widespread agreement that a patient should not labor if obvious fetopelvic disproportion is present, if she has delivered previously by cesarean section.

Management of the induction should be little different from other inductions, but perhaps conducted with greater caution. Continuous electronic monitoring of the fetal heart rate is advocated by many, and continuous intrauterine pressure recording by a smaller number.[78] Although logical as a way of anticipating or avoiding scar rupture, the major concern in this situation, experience has not confirmed the benefits of either form of continuous monitoring. It is difficult, therefore, to argue that either should be provided as routine.

A scarred uterus is a stated contraindication for the use of prostaglandins by the pharmaceutical companies marketing PGE_2. Despite this, a survey of 230 consultant obstetric units in the UK found that 78% used prostaglandins in such patients.[79] It has been argued, contrary to the recommendations of the pharmaceutical industry, that PGE_2 might have advantages in patients previously delivered by lower-segment cesarean section, because it produces more physiologic contractions than oxytocin and improves cervical compliance, theoretically reducing the intensity of myometrial contractions necessary to achieve full cervical dilatation. In consequence, there should be less risk of compromise to the scar.[39] Work in recent years has substantiated that view, comparing pressures generated by prostaglandins and oxytocin in spontaneous and induced labor.[13] Personal experience suggests, however, that full dilatation may be achieved too readily in the presence of cephalopelvic disproportion if prostaglandins are used, and thus the obstetrician needs to be particularly aware of this possibility.

Controversy also exists about the extent to which the use of prostaglandins and oxytocin to induce or augment labor increase the risk of scar rupture in women with a previous cesarean. A meta-anaylsis[80] found that oxytocin use was associated with a two- to fourfold increased risk of uterine rupture in two case–control studies; but this finding was not confirmed in cohort studies or controlled trials. In prospective cohort studies, the use of oxytocin (five trials) or prostaglandin (two trials) was not associated with a higher risk of uterine rupture. A large prospective study published subsequently[81] indicated that augmentation of labor with oxytocin and induction of labor, regardless of method, were associated with a two- to fourfold increased risk of uterine rupture compared with spontaneous labor without the use of oxytocin. However, the absolute risk was still very low, with only an 8% prospect of serious perinatal morbidity of death occurring when uterine rupture occurs.

Multiple pregnancy

When multiple pregnancies are considered in texts or monographs, little attention is paid to the place or method of inducing labor. There is thus little information about the experiences of induction using various methods. In a series of 656 twin pregnancies managed in Oxford, labor started spontaneously in 52%, was induced in 35% and elective cesarean section was performed in 13%. Of those in whom labor was induced, prostaglandins were used in 137 and amniotomy and oxytocin without prostaglandins in 91 cases. There appeared to be little difference in the outcomes, although prostaglandins were generally given when the cervix was less favorable and thus any conclusions that may be drawn must be guarded (I. Z. MacKenzie and N. C. Watson, 1996, unpublished data).

The methods described earlier for labor induction are equally applicable to twin pregnancies, and as with other complicated pregnancy situations, continuous electronic fetal monitoring of both babies is considered by some to be essential, but has not been shown objectively to be of any advantage and thus this recommendation has not been substantiated. Since

postpartum hemorrhage due to uterine hypotonia is a recognized added risk of labor for twin pregnancies, it has been suggested that the prostaglandins might be particularly appropriate; this potential advantage has not been proven.

Intrauterine fetal death

When fetal death occurs, spontaneous expulsion will occur in the majority of cases within a few days. Once the diagnosis has been confirmed, evacuation can be arranged at the request of the woman to relieve emotional distress. If the fetal membranes have ruptured, prolonged retention may result in intrauterine infection, and if the dead fetus is retained for longer than 4 weeks, a consumptive coagulopathy may develop.[82] The methods of achieving evacuation are either surgical or pharmacologic, depending on gestational stage and uterine size.

Up to 14 weeks of gestational size, evacuation by cervical dilatation and aspiration under general or local anesthetic is the most expedient management. At later gestations, with the uterus at least equivalent to a 14-week gestation, prostaglandins have revolutionized management. Administration routes appropriate in this situation are illustrated in Figure 175.3 and include intravenous, extra-amniotic, intramuscular and vaginal. In this situation, some of the analogs of the prostaglandins have been used with great success, the fear of ill-effects upon the fetus not being a restricting factor. The oral route is not appropriate with the natural prostaglandins, since the doses required cause very high rates of side-effects. The intra-amniotic route has been used but may be unwise for two reasons: (1) puncturing the fetal membranes by amniocentesis may enhance the possibility of amniotic fluid embolism, a hazard thought to be more common in cases of fetal death *in utero*, and (2) the risk of intrauterine infection may be increased. The few reports of this method for managing such cases have not, however, observed these problems.

Clinical management is essentially the same whichever protocol is used. A check of the clotting status should be made if fetal death is thought to have occurred at least 3 weeks previously, and appropriate investigations should be initiated to assist in determining the etiology for those cases in which death was unexpected. Progress once treatment has started is assessed by vaginal examinations as indicated, and adequate analgesia is provided according to needs. Delivery of the dead fetus and placenta are similar to when the fetus is liveborn, although attempts are made to avoid perineal damage if possible. Administration of ergometrine or a prostaglandin analog should be done to enhance uterine contractility following delivery, thus reducing the chances of excessive hemorrhage occurring from uterine atonia.

The antiprogestins might be helpful in this situation, but physiologically there is little reason to anticipate this with the recognized low levels of progesterone already present in cases of fetal death.[83]

Complications of induction

There are a number of potential hazards for both mother and fetus or neonate from induction of labor, either as a result of initiating labor before spontaneous onset, or as a consequence of the method of induction used. There has been, however, a surprising lack of information about infant development after induced, compared with spontaneous, labor onset. Two small studies that examined babies up to 12 months[84] and 3 years of age[85] suggested there is probably no reason to anticipate any disturbance to development as a consequence of a labor induction with oxytocin or prostaglandins when compared with spontaneous labor or elective cesarean. Some specific complications are, nevertheless, recognized as a consequence of labor induction.

Uterine hyperstimulation

Hypersystole and hypertonia occur during both spontaneous and induced labors. The true incidences are unclear, but hypertonus occurs in about 1 in 500 labors, whether induced or spontaneous.[86] The prostaglandins classically provoke low-amplitude contractions at 1–2-min intervals which are often subclinical and generally do not cause fetal or maternal disturbance. If hypertonus occurs, it can be counteracted by the administration of a tocolytic agent. Subcutaneous and intravenous injections as well as inhalation have been used,[87] although the benefit of the latter route is uncertain. This management strategy can be used either to treat an acute episode and allow labor to continue if the fetus is not distressed and normal uterine contractility is restored, or as a first aid measure while preparing for emergency cesarean section.

Fetal distress

Fetal distress should be expected to occur more frequently during induced than spontaneous labor, since some induction indications, such as those for intrauterine growth retardation, are associated with intrapartum fetal distress. When diagnosed, management will depend upon circumstances at the time, including the degree of cervical dilatation and the suspected cause of the distress, such as abruptio placentae, cord prolapse, hyperstimulation, and previously suspected placental insufficiency; tocolytic therapy may be given prior to emergency cesarean section.[88] The concept of concomitant tocolytic therapy with the administration of prostaglandins for cervical ripening has been examined to try to achieve ripening without myometrial contractions, thus

reducing the chances of fetal distress being provoked. It was concluded, unfortunately, that the tocolysis could reduce uterine activity, but it also reduced the influence of the prostaglandins upon cervical ripening, and thus was considered counterproductive.[89]

Failed induction

There is no universally accepted definition for 'failed' induction. It should perhaps be reserved for those cases in which the cervix does not dilate beyond 3 cm despite adequate and appropriate oxytocic stimulation of good-quality uterine contractions for 8 h in a nullipara and 4 h in a multipara; there should be no fetopelvic disproportion. It is generally confined to nulliparas with an unfavorable cervix at the time of induction, and is a rare complication in multiparas, except those whose only previous delivery was by cesarean section. In the high risk group of nulliparas with an unfavorable cervix, failed induction rates have been reported in 15–35% of cases induced with intravenous oxytocin, and should be no greater than 3–5% of nulliparas induced with local prostaglandins.

Cord prolapse

When the membranes rupture spontaneously during stimulation with an oxytocic, cord prolapse may result. This occurs most commonly with a high presenting part in patients with polyhydramnios and when there is a flexed breech presentation. An urgent operative vaginal delivery may be appropriate if at full dilatation; otherwise delivery is by emergency cesarean section, with measures taken to prevent pressure on the cord at the pelvic brim using the knee–chest position, or the vaginal examining fingers exerting counter pressure against the presenting part. It also occurs with spontaneous labor, when the outcome may be less favorable because of some inevitable delay in diagnosis, the cord prolapse occurring when the membranes rupture spontaneously and staff are not immediately available.

Abruptio placentae

This may occur during the first or second stage of labor, but is most likely to occur when the membranes rupture either spontaneously or at amniotomy, especially in cases of polyhydramnios. In theory, the use of hindwater membrane rupture reduces the chances of this happening. There has been a suggestion that the prostaglandins may predispose to this complication when used for labor induction, but there has been only one report[90] to suggest the relationship, and at present the evidence for such an association is therefore unconfirmed. The lack of such a complication being reported in many large series of labor inductions with prostaglandins suggests that there is unlikely to be any direct relationship.

Uterine rupture

Extremely uncommon in nulliparas, this complication may occur in any labor at risk, whether induced or spontaneous. It is a particular risk in multiparas of high parity and those previously delivered by cesarean section. Clearly this hazard should be recognized in the patient, with staff mindful of the possibility, with facilities available for emergency management when indicated.

Inadvertent preterm delivery

This is a risk with any term induction, whichever method is used. With the widespread use of ultrasound examinations in early pregnancy, there is a belief that this hazard can be eliminated. Cases still occur, however, especially when gestation has been inappropriately reassigned to an earlier expected delivery date by 2–3 weeks using the ultrasound measurements. There is little substantiated evidence of reduced rates of labor induction or of unplanned preterm delivery as a consequence of routine ultrasound dating scans, although routine early pregnancy ultrasound does reduce the incidence of post-term pregnancy (OR 0.68, 95% CI 0.57–0.82).[77]

Hyponatremia

Prolonged infusions of relatively high doses of oxytocin in dilute solutions of saline may lead to severe maternal electrolyte disturbance due to maternal fluid retention. Coma and death have been recorded.[91] Similar derangements in neonatal biochemistry leading to neonatal seizures in severely disturbed cases have also been reported.[92] Caution is therefore essential in those cases when the induction process is prolonged. Close attention should be continuously paid to maternal fluid balance, restricting intravenous fluid intake whenever possible.

Hyperbilirubinemia

The incidence of neonatal hyperbilirubinemia is increased following induction with intravenous oxytocin compared with prostaglandin inductions and spontaneous labor.[93,94] Prostaglandins have been associated with reduced rates of hyperbilirubinemia, possibly because of their apparent steroidogenic properties.[95]

Hypotonic uterine postpartum hemorrhage

Postpartum hemorrhage is more commonly encountered following induced labor than spontaneous labor[96]; the frequency is possibly lower following prostaglandin- than oxytocin-induced labors, but this has yet to be established for certain. The mechanism for this difference in effect is not entirely clear.

Augmentation of labor

For the purposes of this chapter, augmentation of labor refers to stimulating uterine contractions in those women whose membranes have ruptured but labor has not followed. The decision to intervene in this situation is strongly influenced by gestational age, which in turn is influenced by the facilities available to support the very preterm neonate. Apart from the statistical arguments relating to survival chances for the baby, intervention may be precipitated by clinical suspicion of developing intrauterine infection. There would, however, appear to be a lack of logic in waiting until there are clinical signs indicative of sepsis and thus potentially fatal infection: action is then possibly being taken too late.

There have been many studies examining the outcome of 'uncomplicated' cases of ruptured membranes without ensuing labor at full term, and the debate will not be rehearsed here. However, once the decision has been reached to augment labor, the most appropriate way of 'inducing' labor in this situation then needs to be addressed.

Each of the oxytocic protocols described for routine labor induction is potentially appropriate, but it is wise before commencing oxytocic treatment to examine the patient vaginally to assess the state of the cervix and determine whether the forewaters are intact and whether leakage is the consequence of a forewater or hindwater rupture; a forewater amniotomy may then be indicated.

A titrated intravenous infusion of oxytocin, repeated oral prostaglandins or vaginal prostaglandin protocols are widely used. There are theoretical concerns about sepsis with vaginal instillation protocols, and the extra-amniotic and endocervical methods do not seem appropriate, carrying an even greater risk of introducing infection. However, published series have not identified sepsis as a problem using these methods. There have been a number of prospective studies comparing oxytocin with various prostaglandin protocols. It appears fairly certain that PGE_2 offers no advantage over oxytocin for inducing labor in this situation,[97] whether given orally[98] or vaginally.[99,100] The current enthusiasm to explore misoprostol for this purpose[101] needs to be tempered with caution; experience is limited, but the early impression is that that this agent probably offers no advantage over PGE_2 other than economic, but has the disadvantage of a lack of information about fetal toxicology.

Maternal views on induction

Consumer opinion has gained considerable importance, and is now, in the views of some, the only opinion to be considered. Although it is widely suggested that women are against obstetric intervention, surveys of patients' attitudes have produced conflicting results.[102,103] A prospective survey of 352 women conducted in Oxford in 1989, by staff not involved in the decision to advise labor induction, found that 36% of nulliparas and 57% of multiparas wanted to have their labor induced. As expected, a large proportion of women expressed a wish to avoid labor induction in their next pregnancy, an observation that was more frequent among mothers who had just delivered their first baby (62%) compared with multiparas (47%). It would have been surprising if the reverse result had been obtained. Interestingly, patients' understanding of the indication for induction was frequently at variance with that recorded by the obstetric staff who gave the recommendation for labor induction: 276 of the 352 women (78%) gave the same indication for the induction as recorded by the obstetric staff, and the others either did not know why the induction was advised (9%), or gave a different reason (13%) (J. Boland, E. McKinlay and I. Z. MacKenzie, 1990, unpublished data).

Assessing patient's opinion about the way the induction was performed is extremely difficult. Prospective randomization with subsequent questionnaire completion unfortunately will not provide much worthwhile information, since nulliparas will have nothing with which to compare the experience; for multiparas, second labors are known to be associated with more favorable outcomes with regard to labor duration, discomfort, need for assisted delivery and perineal suturing compared with first confinements, and there is a risk that patients' previous experiences would compromise any analyses, potentially rendering the results meaningless. Acknowledging this, Kennedy *et al.*[25] found that induction with prostaglandins was more acceptable than intravenous oxytocin. Among the 352 patients surveyed in Oxford, six of 298 (2%) with an unfavorable cervix who received vaginal prostaglandins were unhappy about the method of induction compared with two of 54 (4%) with a favorable cervix who did not receive any prostaglandins; the other patients in both groups expressed satisfaction with the method of induction used. Four of these eight patients complained that the induction was too rushed or too uncomfortable. Women's views on induction with misoprostol have not yet been published.

Economics of induction

In the UK, and probably in many other countries, financial calculations about patient management have become a major consideration when deciding what medical facilities and treatments should be provided. Cost–benefit analyses have not featured prominently in discussions about the appropriateness of labor induction or the methods used to the present time. The cost of an induction depends on how it is managed and the outcome achieved. A prospective analysis of

Table 175.6 Workload on delivery unit related to spontaneous labor and labor induced with vaginal prostaglandin E_2 (P. Young, M. Vicaretti and I. Z. MacKenzie, 1989, unpublished data)

	Spontaneous labor	Induced labor	*P*-value
n	184	79	
Nulliparae (%)	49	49	NS
Gestation (weeks)	39.7 ± 1.8	39.9 ± 1.4	NS
Oxytocin infusion (%)	29	67	
Duration of infusion (min)	312 ± 216	453 ± 289	0.005
No. of medical visits in labor	1.3 ± 2.1	3.0 ± 2.9	NS
No. of VEs in labor	2.1 ± 1.2	3.1 ± 2.9	NS
Length of labor (min)	378 ± 219	292 ± 204	< 0.003
Time on labor ward (h)	6.8 ± 7.5	9.9 ± 7.8	NS
1-min Apgar < 8 (%)	22	27	NS
5-min Apgar < 8 (%)	2	0	NS
Resuscitation at birth (%)	15	15	NS

Data given as percentages or mean ± SD. VE, vaginal examination; NS, not significant

the workload associated with induction using prostaglandins compared with spontaneous labor was performed in Oxford in 1989 (Table 175.6). These data were not matched and are thus of limited value, but the impression was that labor induction was probably more costly than managing spontaneous labor, although the differences should be small, providing an efficient approach to induction is used. A similar analysis is probably worth performing prospectively, and ideally using random assignment, for women having a labor induction for social reasons at term compared with a conservative non-induction approach. It is possible that patient choice will need to be restricted if induction is confirmed to be more costly than spontaneous labor and resources are limited as in the UK.

Personal experience of costing an induction has been discouraging. The Canadian experience, however, has suggested induction is marginally cheaper than conservative management of post-term pregnancy.[104] In the UK it appears that hospital units are very uncertain of the costs of most procedures; many procedure costings need to be calculated using first principles, but the results cannot be readily confirmed. An analysis of the costs incurred using one or two doses of prostaglandins for labor induction found that the most expensive item is the midwife attending the patient during labor, with cesarean section being the next major factor, largely due to the more protracted hospitalization following delivery.[105] Thus protocols that can reduce the amount of time parturients spend on the labor ward and the need for cesarean section will prove very attractive to those who pay for the care: it is possible that a prelabor cesarean section is economically more attractive than inducing labor in those women with an unripe cervix.

Conclusions

There can be little doubt that the widespread acceptance of locally administered prostaglandins for induction of labor has had a dramatic impact upon the outcome of labor, reducing maternal and fetal morbidity and improving the relationship between doctor, midwife and patient. There are prospects that further improvements may well be achieved, with yet further reductions in failed inductions and the unwanted side-effects that are occasionally seen with prostaglandins. The convenience of misoprostol combined with its low cost makes its use for induction very attractive, particularly in low resource settings, but concerns still exist about its safety and optimal dosing regimen. The goal remains to induce cervical effacement and dilatation with little uterine contractility and thus risk of fetal compromise, followed by a short period of labor and uncomplicated delivery. Whether such a goal can be achieved in the near future remains to be seen.

Not only must efforts continue to be made to develop methods of labor induction that are effective and safe, but these methods must also be shown to be acceptable to women. Additionally, far greater attention will need to be paid to an analysis of the cost–benefit equation. While such considerations are entirely reasonable, we must ensure that safety and acceptability are not demoted in importance at the expense of financial efficiency.

176 Electronic fetal monitoring

B. S. Schifrin, S. Myers, W. R. Cohen and R. Kates

Understanding fetal heart rate patterns

Introduction

The introduction of electronic fetal heart rate monitoring (EFM) more than 30 years ago was accompanied by extraordinary expectations. It was expected that by timely detecting, then intervening in the presence of certain fetal heart rate (FHR) features, EFM would reduce the intrapartum stillbirth rate, enhance neonatal condition, diminish the risk of long-term disability and reduce the cesarean section rate for fetal distress.[1] While indeed the fetal and neonatal death rates have fallen considerably since the introduction of EFM, the risk and severity of neurologic handicap have not.[2,3] Moreover, the rise in the cesarean section rate over the past 30 years has been attributed at least in part to the use of EFM.[4] Clearly, the benefits of EFM, as envisioned by its early enthusiasts, have not been realized.[5,6]

Reservations about the value of EFM prompted a number of randomized controlled trials (RCTs) comparing it with auscultation.[7–9] The nomenclature of FHR patterns, experimental design and indeed the results of these studies diverge widely and permit almost any conclusion about the benefit or lack thereof of EFM or auscultation.[10,11] One may thus conclude from available studies that EFM reduces the risk of neonatal seizures, or increases the risk of cerebral palsy in prematures, or that it is of no benefit at the expense of an increased, presumably unnecessary, risk of cesarean section or that the failure to demonstrate benefit is related to selection bias or other methodological flaws. Furthermore, marked differences exist in the interpretation of FHR patterns even among experts, even when the nosology is agreed upon.[12] Indeed, the trials were premature, not reproducible, beset by technical and statistical difficulties. It is reasonable to argue that the benefits of EFM remain unsatisfactorily tested and that RCTs confuse the issue. Nevertheless, the recommendations by the American College of Obstetricians and Gynecologists, the International Federation of Obstetricians and Gynecologists, the Society of Obstetricians and Gynecologists of Canada, and the Royal College of Obstetricians and Gynecologists, based on the results of these RCTs, all assert that auscultation is equivalent to EFM, that EFM is not required on admission to labor and delivery, that intermittent auscultation is relevant as a primary or indeed the only necessary method of surveillance.[13] While the basis of these guidelines rests with the presumed equivalence of outcome between auscultation and EFM in the RCTs, there is no contemporary study comparing auscultation against no FHR surveillance at all, or any explanation as to why, if FHR is a reflection of fetal health, a technique that inarguably provides more accurate and complete information about it would not be better than one less effective in that regard. Customary auscultation (not part of a controlled study) appears less reliable than structured auscultation with a Doppler device.[10] Others, conceding the extraordinary specificity of the 'reassuring' FHR pattern, advocate alternative strategies for the evaluation of the abnormal tracing including fetal scalp blood sampling, fetal pulse oximetry and computerized evaluation of the fetal ECG.[14–17] Despite the lingering uncertainties about the relevance of EFM, the reproducibility and meaning of FHR patterns and some articles calling for its outright abandonment, there remains virtually universal application of this technique during labor.[6,18]

Pathophysiology

Before discussing the interpretation and management of individual EFM tracings, it is necessary to point out certain physiologic principles of FHR monitoring along with the technical and logistic pitfalls that impede the ability to realize the objectives originally vouchsafed for EFM.

FHR patterns during labor and before are influenced by numerous factors including gestational age and the behavioral state of the fetus (activity level, breathing movements, electroencephalographic pattern, etc.), as well as medications, infection, anomalies, arrhythmias and maternal disease.[19] Beyond these, FHR patterns during labor are also influenced to a considerable degree by uterine contractions and expulsive efforts of

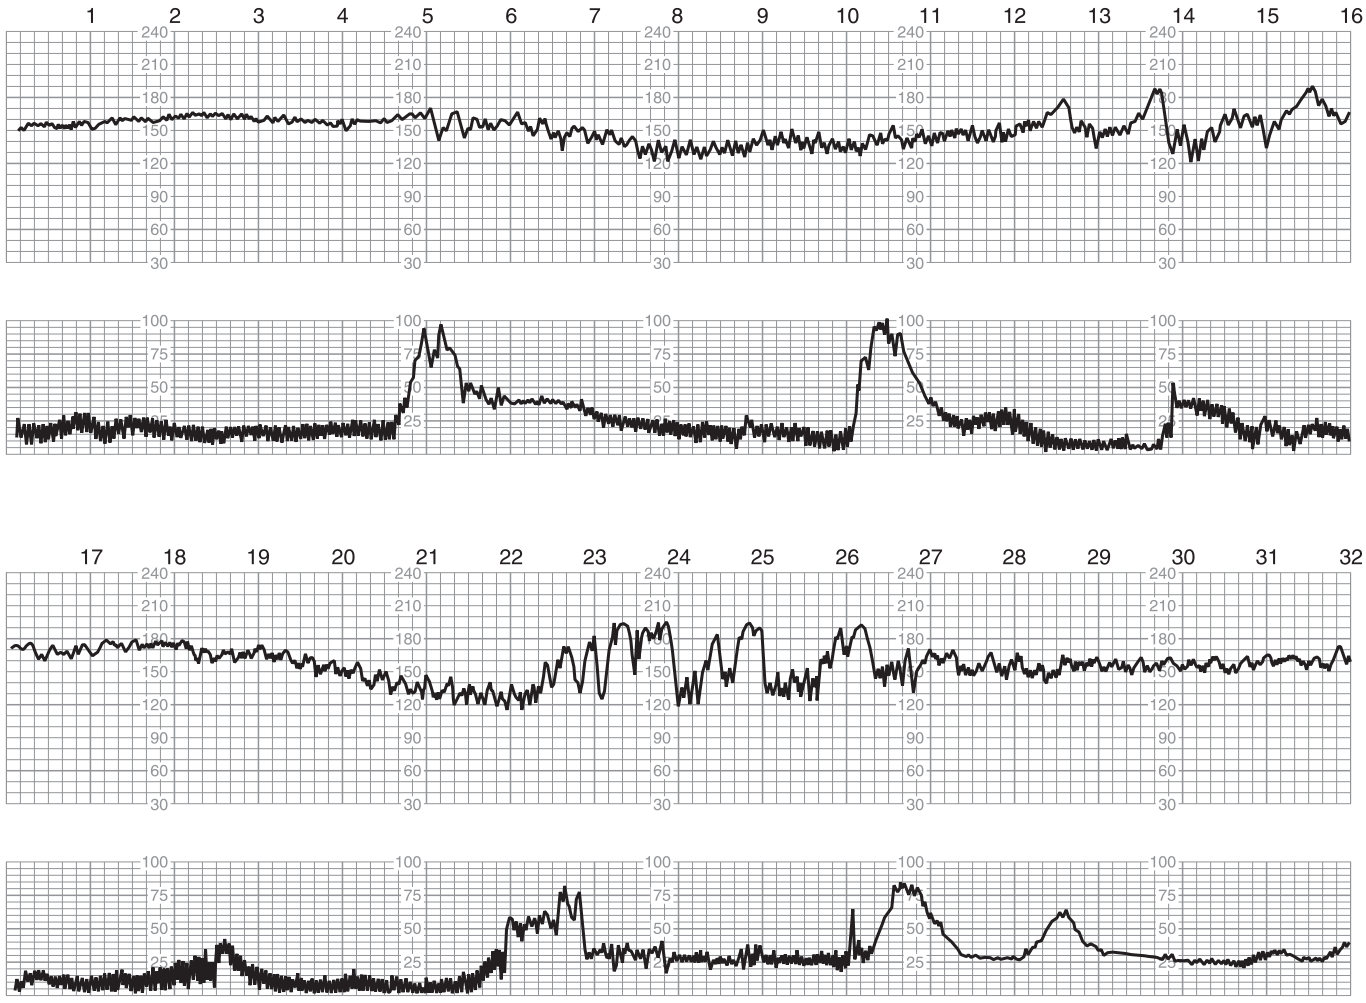

Figure 176.1 Non-decelerative pattern. Reactive tracing. Normal variations in FHR pattern produced by changes in fetal behavioral state. Note the three obvious epochs in top half of the tracing which begins with absent variability and no accelerations. The rate then decreases somewhat with an obvious increase in the variability. The third epoch shows obvious accelerations and variability, but different from that in the previous epoch.

the mother as well as the station, position, attitude and molding of the fetal head, fetal temperature, the presence of infection, and perhaps by dysfunctional labor.[20,21]

The normal-term FHR pattern has identifiable features corresponding to various behavioral states (Figure 176.1). These include a stable baseline rate and absent decelerations and alternating epochs of (a) decreased variability and absent accelerations (sleep/rest) and (b) average variability and accelerations associated with fetal movement (awake/active).[22–29] When present, these features, particularly including the cyclic activity, permit the inference of both normal fetal behavior (neurologic integrity) and absent hypoxia. They represent the fundamental properties of the FHR pattern of the normally oxygenated and neurologically responsive fetus, who will not likely deteriorate from hypoxia, sepsis, or trauma without changes in baseline rate and variability.

As will be discussed below, not all changes in rate and variability represent deterioration, and if only brief segments of the tracing are analyzed some of the normal features of the rest cycle (for example, reduced variability and absence of accelerations) carry the potential for adverse interpretation.[19] Thus, brief periods of absent variability (fetal sleep) and sinusoidal heart rate pattern (fetal sucking), even certain 'late' decelerations (with stable baseline rate and maintained variability) that correspond to periods of active fetal breathing should not be confused with fetal abnormality.[24–26] The evolution of these episodic changes is best evaluated during antepartum heart rate testing in both normal and pathologic pregnancies.[23,27–31] Absent decelerations during labor, these patterns may be observed for reasonable lengths of time before consideration is given to intervention.

The normal baseline FHR is defined as the persistently stable rate in the absence of (or between)

contractions or provocations.[32] The baseline rate can be characterized in a very narrow range, perhaps 5–10 bpm at best, and is usually described according to the rate, the stability of the rate and the presence of short- and long-term variability in the intervals between contractions. Short-term variability represents the abrupt and seemingly random changes between consecutive heart beats (usually only about 1–2 bpm) giving rise to a rather unpredictable, somewhat chaotic pattern of changes. Long-term variability represents the more predictable changes in the oscillations in the rate over many beats, is usually classified according to the range (peak to trough) of heart rates over about 1 min and normally averages about 5–15 bpm. Changes in long- and short-term variability tend to correspond. When only short-term variability is present, however, the tracing is usually considered acceptable. When the long-term oscillations are regular (sinusoidal) with a frequency of about 2–6 cpm and an amplitude of 5–15 bpm it is often referred to as *sinusoidal* if reactivity elsewhere in the tracing is absent. Whether the pattern is intermittent or persistent and reactivity elsewhere is absent, it likely represents an ominous situation in the fetus such as severe anemia, neurologic injury or anomaly.[33–39] However, the most typically encountered sinusoidal pattern is either a variant of normal or the result of narcotic administration and correctable by nalorphine.[40] While most attention has been paid to the abnormalities associated with decreased (< 5 bpm) or absent (< 2 bpm) long-term variability, it is important to emphasize that increased variability, either long- or short-term (> 15 bpm), is no more 'normal' than is decreased variability. Indeed, increased variability may be a harbinger of impending or early hypoxia secondary to alpha-adrenergic activity.[41]

Baseline tachycardia and bradycardia are frequently defined as heart rates outside the range of 'normal' (e.g. 110–160 bpm) for at least 10–15 min.[32] (Indeed the definitions of the various 'guidelines' differ.) Defining fetal bradycardia and tachycardia by some 'normal range' based on cross-sectional studies, however, seems to violate a more physiologic approach of using the fetus as its own control. For example, a fetal baseline rate that rises from 155 to 165 bpm (tachycardia by the above definition) represents much less of a problem than a rise to 155 bpm from a baseline of 110 bpm, even though both of the latter values are in the normal range for the population. The baseline heart rate established on admission should be used as the reference point for subsequent changes. Thus, if the FHR on admission were about 130 bpm, a rise to a persistent 150 bpm should be considered a relative tachycardia while a fall in heart rate to a persistent 115 bpm, even with normal or increased variability would represent relative bradycardia. Neither should be considered part of the normal range of this particular fetus. A number of factors, many of which do not represent hypoxia, may increase the heart rate including fever, cardioactive drugs, maternal dehydration, arrhythmia and hypoxia (with decelerations).

Thus in a review of any tracing, it is important to look at the beginning of the pattern to establish the baseline and ask if the fetal behavior was ever demonstrably normal. As the fetus deteriorates before the onset of labor, behavioral cycles become disrupted with lengthening sleep cycles, disappearance of variability, and sometimes a rise in the baseline. Only then do accelerations disappear, decelerations appear with contractions, the baseline becomes unstable, it falls, and the fetus dies.[42,43] If the fetus enters labor with persistently absent variability, it cannot be defined as having normal neurologic potential. If there has been no preceding testing to help ascertain the acuity of these findings, then the differential diagnosis is broad and includes: drug effect, placental insufficiency, infection, genetic disorders, anemia, neurologic injury (infarction, hemorrhage, asphyxia), congenital anomaly, and tumor.

It is critical to the understanding of FHR patterns to recognize that in the presence of uterine contractions, acute fetal hypoxemia will be reflected by the appearance of decelerations before any rise in the baseline rate or decrease in variability.[43,44] With continued mild to moderate oxygen deprivation, the decelerations persist, accompanied by a rising baseline heart rate and a diminution in baseline variability (and developing acidosis) eventually leading to a fixed elevated rate (rarely above 160 bpm). As the fetus approaches death the baseline falls and becomes unstable; decelerations may be less obvious and less easily separable into type – i.e. late or variable. With severe or profound hypoxemia the initial response may be a prolonged deceleration or bradycardia, which requires immediate attention if not relieved or improving after about 4 min.

To connote significant fetal hypoxemia, therefore, transient decelerations must provoke a rise in a previously normal baseline rate. If the fetal baseline rate is already increased over the initial normal baseline, then no apparent change in baseline will necessarily occur. Irrespective of the deceleration pattern (late, variable, or prolonged), transient decelerations unaccompanied by a rise in heart rate cannot represent developing tissue hypoxia or troublesome ischemia. Similarly, elevations of the heart rate or loss of variability without decelerations during labor also cannot represent ongoing tissue oxygen deprivation. Thus, in the absence of changes in baseline rate and variability there is no meaningful distinction among , late, variable, even prolonged decelerations. Prolonged decelerations (usually in the second stage of labor) arising from a previously normal FHR patterns are rarely of (acid–base) consequence if the deceleration stabilizes at 80 bpm or above, and especially if variability is maintained (*vide infra*).[45,46] If the prolonged deceleration continues to fall below 80 bpm and loses

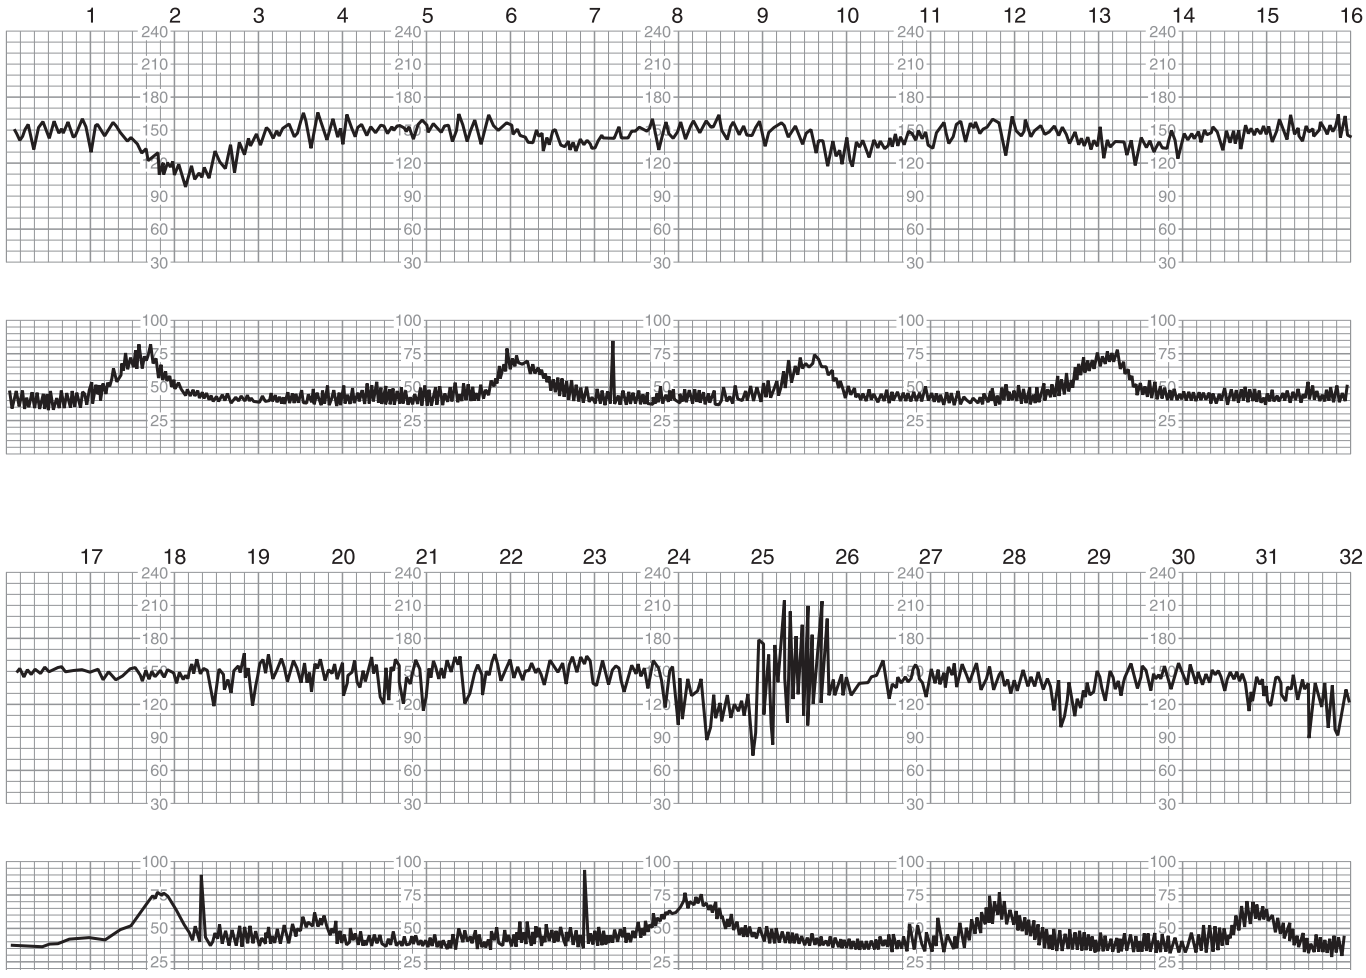

Figure 176.2 Late deceleration pattern in association with fetal breathing movements (FBM). The upper portion of the panel has what appear to be late decelerations. They are not related to hypoxemia; rather, they represent a response to active FBM which, when picked up by the tocodynamometer, are seen as high-frequency low-amplitude spikes. When FBM abate (16–20 min) the decelerations disappear without residual tachycardia or decrease in variability.

variability, the prognosis is much more ominous. Whether or not the deceleration is agonal or not, the first response is to attempt to ameliorate it by position change, the elimination of contractions and, as a minimum, refraining from pushing.

The pattern of decelerations provides important insights into the mechanism of hypoxia: The fetus may suffer hypoxia related either to (1) a decreased availability of oxygen to the fetus (hypoxemic hypoxia) or (2) interference with blood flow to the brain or placenta (ischemic hypoxia). We consider those changes associated with late decelerations *hypoxemic* while those associated with variable or prolonged decelerations of sudden onset *ischemic.* The bases for this distinction derive from the clinical and experimental work of several authors.[44,47–56] The difference is important because of the markedly different ways the fetus responds to such limitations of oxygen, in the speed of deterioration and in the relationship to subsequent injury. Hypoxemia may occur without ischemia, and in this context is rarely associated with organ damage unless there has been considerable neglect. Tissue ischemia, however, may occur in the absence of systemic hypoxemia and cause end-organ injury – sometimes rapidly.[57]

Late decelerations represent an early response to fetal hypoxemia, even before the development of changes in baseline rate and variability.[43,58,59] They may also represent a benign response to a behavioral pattern of normal fetal breathing episodes (Figure 176.2).[26] When associated with a rising baseline rate and decreasing variability, they are accompanied by transient hypotension during the deceleration and a slow decrease in oxygen availability and cerebral blood flow (CBF) and may be tolerated for many hours while the fetus accumulates a metabolic acidosis.[43,58,59] As the hypoxia and acidosis increase, the FHR becomes fixed (absent variability) usually with a relative tachycardia and continuing decelerations. The decelerations at this time might be quite minimal in amplitude, but

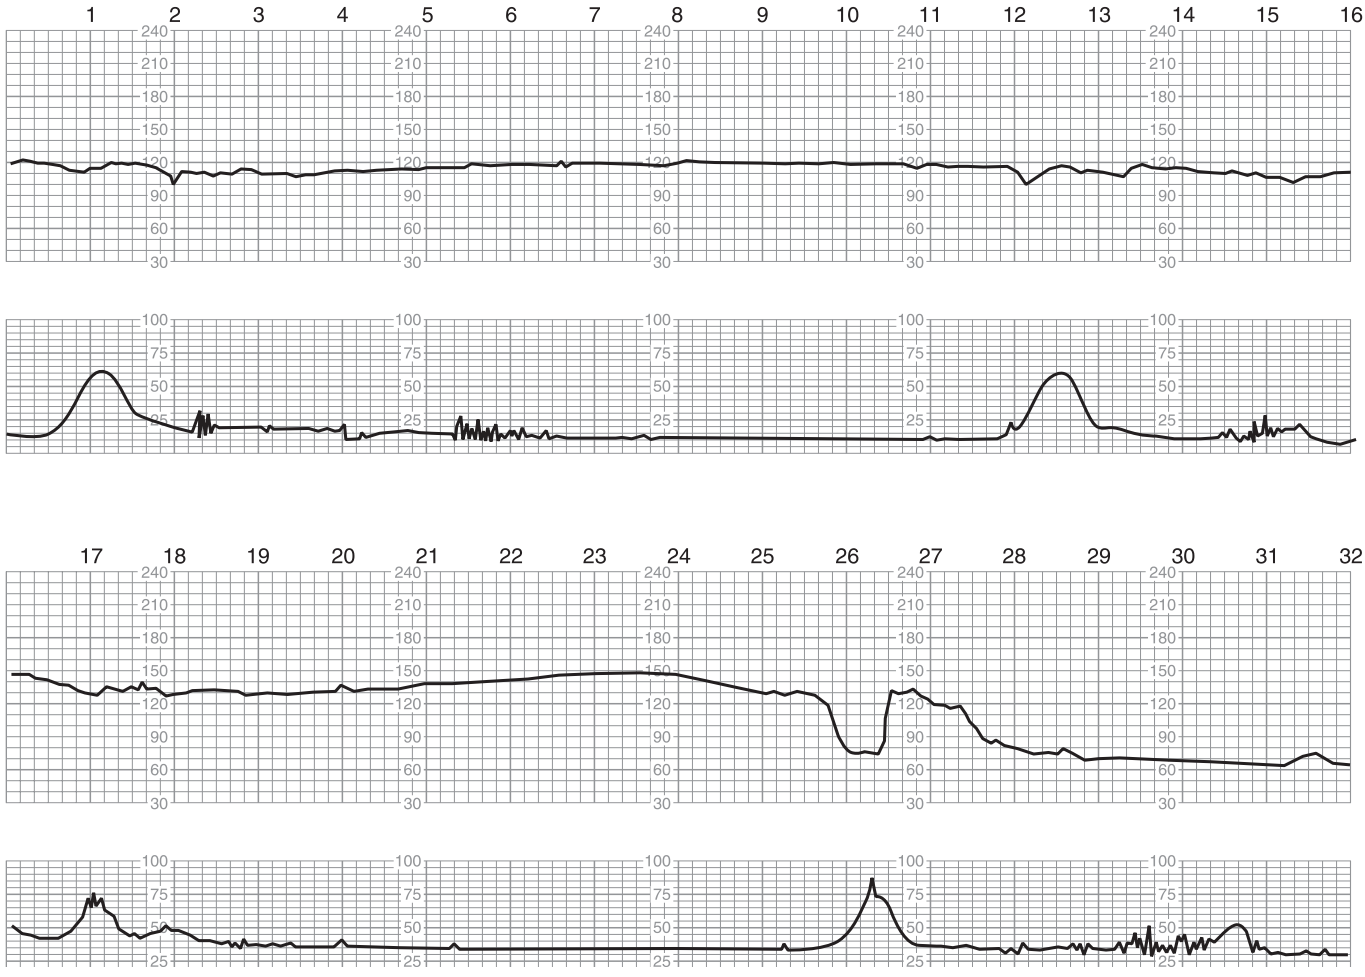

Figure 176.3 In this agonal pattern, death (attributed to a tight knot in the cord) was preceded by absent variability, an unstable baseline, and a terminal bradycardia.

are usually discernible because of the marked reduction in the amount of both long- and short-term variability.

Late in the course of continuing and progressive hypoxia, there eventually comes a point when the severity of the oxygen deprivation and the resulting acidosis and loss of energy substrate conspire so that the fetus is no longer be able to maintain cardiac output to even priority organs. Blood flow to the brain will then diminish and injury will supervene as the fetus approaches death. On the monitor this is revealed as an unstable, slowly oscillating, diminishing heart rate, less obvious decelerations with absent variability, and, eventually, asystole (Figure 176.3).[36,60] As mentioned above, the fetus with this agonal pattern is unlikely to survive or to survive intact after delivery. This is the 'pure' sequence of changes that most likely results in severe acidosis at birth, prolonged, low Apgar scores and severe neonatal hypoxic–ischemic encephalopathy in the immediate neonatal period.[61–64] This agonal pattern requires intervention as rapidly as can be performed with reasonable safety for mother and fetus. While failing to intervene will surely result in fetal death, it must be understood, nevertheless, that this fetus may die or already be seriously handicapped irrespective of the speed of intervention.

It is important here to distinguish between the features of the sudden bradycardia or prolonged deceleration (Figure 176.4) seen commonly at the very end of labor and the 'agonal' pattern (seen at any time) (Figure 176.3). In the prolonged deceleration pattern, the preceding FHR pattern has been normal or contained minimal decelerations unassociated with a rising baseline rate or decreased variability. While the appearance of the sudden prolonged deceleration suggests an acute, ischemic stress, it may not be used to infer injury. At least as importantly, prompt intervention may produce a neurologically intact child. In the terminal decelerative pattern, in which one may often anticipate injury if the infant survives, the preceding pattern reveals absent variability, an unstable baseline rate and nondescript decelerations. Death or injury is probably inevitable and not preventable.

As noted, the initial appearance of late decelerations represents an early marker of hypoxemia, even before the appearance of acidosis. As such it will be, early in

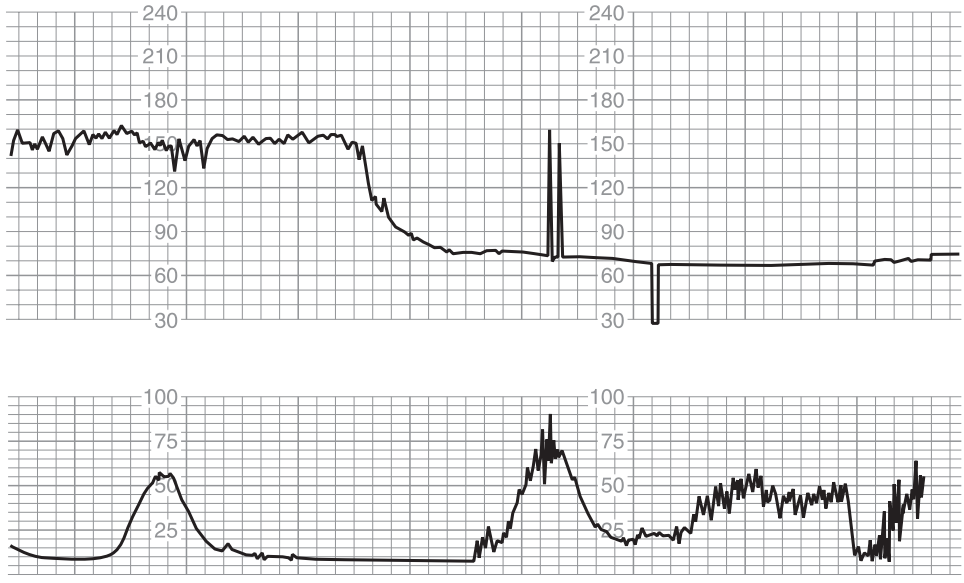

Figure 176.4 A sudden prolonged deceleration preceded by a normal pattern. The presumptive cause was placental abruption and prompt delivery resulted in a good outcome.

the course, a poor predictor of subsequent poor outcome at delivery or long-term outcome.[65] Those factors associated with the early appearance of late decelerations include: fever, frequent or prolonged uterine contractions, maternal hypotension, placental disease, and fetal anemia. We emphasize here that if the mother is febrile, the fetus and placenta are also febrile – at an even higher temperature – with increased metabolic demands.[66,67]

Variable and prolonged decelerations may be considered acute, responses to any diminution in cerebral or umbilical blood flow (ischemia).[19,48,50,68–71] When the cord is compressed, the rapidity of the onset and the depth of the deceleration result from an exuberant increase in fetal peripheral resistance and blood pressure. Head compression causes variable decelerations by a different mechanism, but they are morphologically indistinguishable clinically from those produced by cord compression. When hypoxemia ensues from any cause there may be redistribution of blood flow within the fetus so that flow to the vital structures in the organism, i.e. the brain, the adrenals, the heart and the placenta are maintained and flow to less critical areas (the gut, skin, muscles, etc.) is sacrificed. This is referred to as the 'dive reflex' and is similar to that found in the diving mammal, including the human.[72,73] Under these manifold responses and redirection of blood flow, specific areas of the fetus from which blood has been shunted or where flow has been inadequate may suffer injury in a short period of time, even without ongoing, systemic hypoxia.[57,74] Variable decelerations deteriorate with much the same changes as described for late decelerations above, but the course may be considerably shorter. It is axiomatic therefore, that for this reflex to indeed protect the brain for example, it must overcome any meaningful obstruction to blood flow to the brain.[75,76] Sometimes, as the result of expulsive efforts, malposition of the fetal head and non-progressive labor, cerebral blood flow (CBF) may not be maintained. It is likely that most variable decelerations, especially in the second stage of labor and especially in the OP position, are related to head compression.

This approach to the evaluation of decelerations prompts here a definition of the term 'recovery' from a deceleration. In this context 'total' recovery from a deceleration sequence means a return to the previously normal baseline rate and variability. When the fetus recovers from even significant hypoxia or ischemia, first the decelerations diminish in amplitude and disappear; then the baseline rate and variability return to normal. The disappearance of decelerations alone is insufficient to declare the fetus 'recovered'. Irrespective of the type or duration of the deceleration, recovery as defined here, appears to preclude injury during the episode. On the contrary, abnormalities in the recovery of variable decelerations sometimes called 'atypical' variables, or those with 'slow return', represent the yet unrecovered responses to the hemodynamic changes reflected in the variable deceleration.[70,71] They require no increased attention – provided that the baseline rate and variability recover to their previously normal state before the next contraction.[77]

While many classify the severity of decelerations based on the duration and the amplitude, these factors have not been shown to be predictive of adverse outcome.[78–81] Paul *et al.* showed that the severity of the acidosis accompanying late decelerations was a

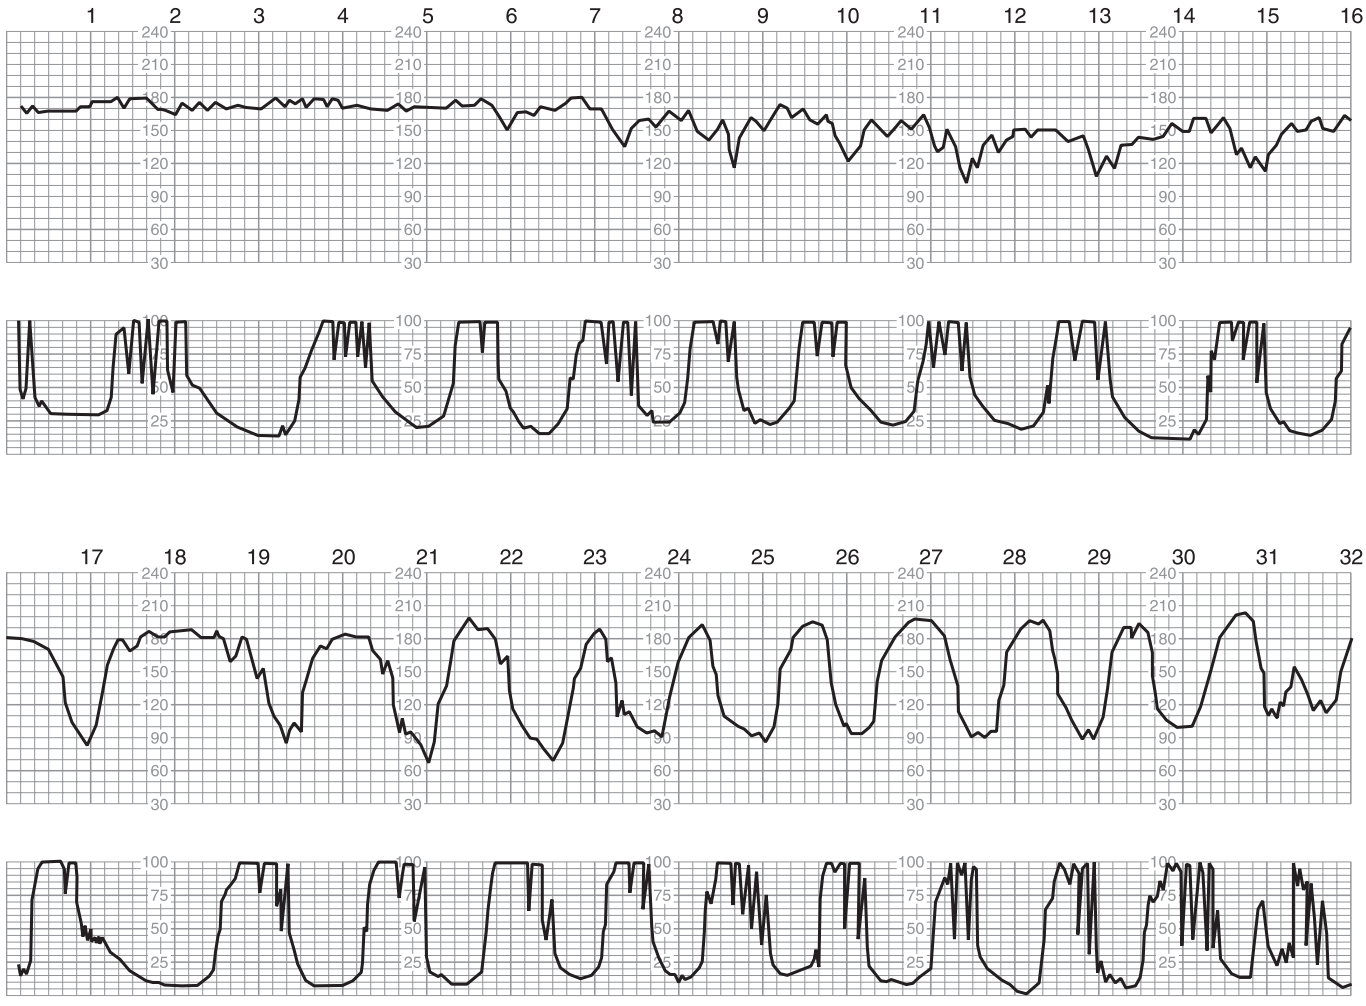

Figure 176.5 Progressive decelerative pattern (variable decelerations). At the start of the second stage of labor the fetal heart rate patterns is normal with absent decelerations. With the onset of pushing the fetus develops a series of variable decelerations with progressively decreasing variability. This represent recurrent ischemic events but the pattern in itself does not permit the diagnosis of injury. The frequency of contractions should be diminished and the patients expulsive efforts moderated.

function of the amount of variability in the baseline and not of the amplitude or the duration of the deceleration.[82] Zalar and Quilligan[83] and Visser *et al.*[42] showed that pH was almost invariably normal in fetuses with poor variability provided there were no decelerations. A similar dichotomous division of pH results was demonstrated with fetal tachycardia.[84] Those fetuses with tachycardia and no late decelerations had normal pH values, while those with late decelerations were more likely to be acidotic. Fetuses with persistent bradycardia during the second stage of labor are frequently, but not invariably, normal.[45,46,85] Here again, other features of the tracing need to be considered.

The most telling parameter in attempting to determine hypoxia is the impact of the deceleration on the subsequent baseline rate and variability. According to this notion, most decelerations developing during labor either represent no significant difficulty for the fetus, or are remediable with conservative care. Thus, careful control of contraction frequency, whether or not oxytocin or prostaglandins are used, minimizing supine hypotension associated with maternal position or epidural anesthesia, and observing the fetal response to maternal pushing in the second stage of labor can forestall decelerations from appearing in the first place. Even when decelerations are progressive, the change from a developing to persistent hypoxia is more or less gradual, in part related to the strength and frequency of contractions and the amount of head or umbilical cord compression due to descent and maternal expulsive efforts (Figure 176.5). Thus in the majority of instances decelerations are correctable, or failing that, permit timely intervention. Occasionally, most especially in the second stage with frequent contractions and unrestrained pushing, the transition from early to advanced hypoxia and ischemia can be abrupt (Figure 176.6).

The second stage of labor

The second stage of labor begins with the completion of cervical dilatation. The frequency of decelerations

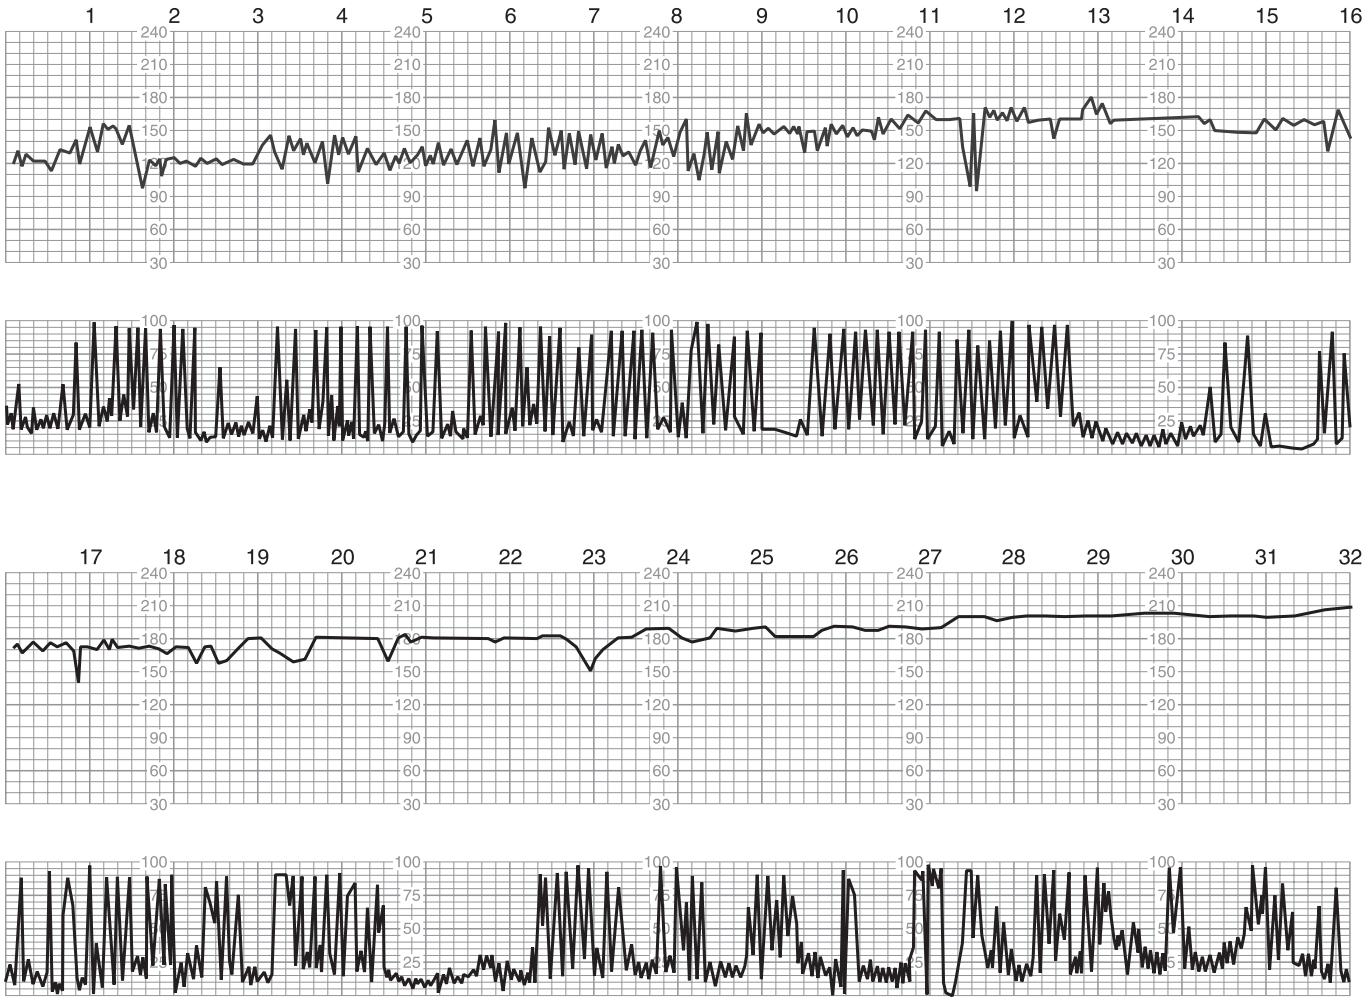

Figure 176.6 Progression of normal decelerative pattern to injury during the second stage of labor in a fetus in occiput posterior position and relentless pushing.[103] The tracing reveals a diminution in baseline rate to 120 bpm from the normal fetal baseline of 135 bpm accompanied by an increase in baseline variability. It is important to emphasize that increased variability is no more normal than is decreased variability. At 18 min the fetus develops a sudden tachycardia and absent variability. Notice also the disappearance of the decelerations. The infant was born with massive intracranial hemorrhage but normal acid–base balance.

usually increases dramatically in the second stage of labor, probably due to the effects of frequent uterine contractions along with the effect of maternal expulsive forces on the fetal head and the cord. While no pattern is unique to the second stage, increased variability, prolonged decelerations and rising baseline are especially common, as are variable decelerations.[19,86] Alterations of the baseline, especially tachycardia, are often associated with acidosis, an effect confirmed in the bovine model.[87] Baseline bradycardia is not uncommon; it is frequently related to the pushing strategy (see below) and only infrequently associated with adverse outcome or acidosis, especially if variability is maintained.[86]

It is widely believed, however, that patterns during the second stage are different and may even require their own classification.[20,46,88] The enormous potential variation in second-stage decelerations makes understandable why so many patterns are other than 'normal' and why in the largest RCT of monitoring, 40% of second stage patterns could not even be classified.[7,88] We emphasize, however, that the principles of interpretation of FHR patterns apply irrespective of the timing of the tracing (antepartum, first stage of labor, second stage of labor).[20]

We believe that decelerations during the second stage are made more difficult to classify not because of inherent changes in their appearance but because of the frequency of contractions and the conduct of maternal pushing. In the first stage of labor decelerations usually induce treatment to diminish the frequency of contractions and avoid additional stresses. In the second stage of labor, maternal pushing is often sustained and encouraged in spite of decelerations. In this situation there may be no opportunity for the fetus to recover from one contraction before the next one begins. Under these circumstances it may not be possible even to determine the fetal baseline rate between contractions.

Table 176.1 Principles of EFM interpretation

- Cyclic activity with accelerations, normal baseline variability and a stable baseline heart rate alternating with epochs of decreased variability and absent accelerations are hallmarks of fetal health
- Accelerations arise out of normal variability during cyclic variation in the baseline heart rate. Accelerations without baseline variability should be considered suspicious. In the second stage of labor, they may represent the maternal heart rate pattern
- Abnormal patterns may represent the effects of drugs, fetal anomaly, fetal injury or infection – not only hypoxia
- Significant hypoxia will not occur without changes in baseline rate and variability. When contractions are present, decelerations appear before changes in rate and variability
- Periods of decreased variability and stable baseline heart rate in the normal range without decelerations may represent quiet fetal sleep. During labor, they are unlikely to represent hypoxia
- Before labor, hypoxic fetuses may have a normal baseline FHR of 110–150 bpm with no accelerations and baseline variability of < 5 bpm for < 40 min. During labor the additional presence of decelerations is required for the presumptive diagnosis of hypoxia
- With diminished baseline variability < 5 bpm even shallow late decelerations < 15 bpm are ominous in a non-reactive trace
- During labor, too frequent contractions represent a threat to the fetus irrespective of the presence of abnormal heart rate patterns
- Abruption, cord prolapse, and scar rupture can cause acute hypoxia and should be suspected clinically. (May give rise to prolonged decelerations/bradycardia)
- Fetal hypoxia and acidosis may develop faster with an abnormal trace when there is scanty, thick meconium, intrauterine growth retardation, intrauterine infection with pyrexia and/or pre-or post-term labor
- In preterm fetuses (especially < 34 weeks), signs of hypoxia and acidosis (the presence of an abnormal trace) [increase the likelihood of respiratory distress syndrome and may contribute to intraventricular hemorrhage] warrant earlier intervention than in the term fetus
- Hypoxia can be aggravated by excessive uterine activity (e.g. oxytocin), maternal hypotension (epidural analgesia) and by mechanical/traumatic stresses (difficult operative delivery)

As a result, decelerations may pile one on top of the other, creating virtually any type or duration of deceleration pattern, including prolonged deceleration.

Focusing specifically on the second stage draws attention to the role of head position, compression and reduction in brain blood flow in the etiology of fetal cardiac decelerations during this period. Fetuses in the occiput posterior position, for example, demonstrate an increased likelihood of decelerations and adverse outcomes.[89,90]

Many of the cases in which the FHR pattern deteriorates during the second stage are related to excessive frequency of contractions and unrestrained maternal bearing down.[19,91,92] Safety requires that contractions appear no more often than every 2 min or more preferably, no more than 7 in 15 min, and that pushing with the contraction be resumed only if the baseline heart rate and variability have recovered to their previously normal levels (see definition of recovery above). Determining the significance of second stage decelerations is best approached by analyzing them in the absence of pushing. This requires both diminishing the frequency of contractions when necessary (by reducing the oxytocin infusion rate) and curtailing the mother's pushing. Thus, if the deceleration is prolonged beyond the contraction or the baseline rate is rising between contractions the expulsive efforts of the mother must be temporarily modified. This may require some effort and discipline, especially if the mother is not receiving analgesia or epidural anesthesia. Failing this, the practitioner exhorts the patient to push exuberantly in an attempt to 'outrun the fetal distress', but succeeds only in precipitating an unremitting, prolonged deceleration. Alternatively, he or she may be tempted to undertake a potentially difficult operative delivery that is often unsuccessful. It must be remembered that the first objective of fetal surveillance is to keep the fetus out of harm's way; that is a more effective approach than rescue. Principles of interpretation are summarized in Table 176.1.

Pitfalls

Given all the insights that fetal monitoring provides about the condition of the fetus, it is necessary to explore why it is subjected to so much criticism and skepticism about its value. We will not deal further with the several randomized clinical trials relating to

the subject, whose merits and limitations have been discussed elsewhere.[93–96] Rather, we will focus on those relevant technical and philosophical issues that have not received broad discussion in the literature.

Nomenclature

While several attempts have been made to standardize nomenclature,[88,97–100] it is clear that diverse systems of limited compatibility are in vogue throughout the world and receive inconsistent interpretation.[101] It is also clear that these classifications function primarily to direct attention to phenomena within the tracing (decelerations, variability, tachycardia, etc.); they do little to explain the source of the heart rate pattern abnormalities or the probability that they arise from clinically important pathology. Moreover, in each case, the classification is deemed relevant only to the detection of hypoxia and acidosis and not in relationship to neurologic integrity and behavior.[102–105]

These drawbacks have doubtless contributed to the current official disparagement of the term 'fetal distress', and to general skepticism about EFM. As the term is commonly employed, "fetal distress" refers to an abnormal heart rate pattern thought to represent oxygen deprivation. The distress is seldom qualified further or quantified at all. In addition, there are clearly other kinds of stress, some potentially as devastating to the fetus as systemic hypoxia. These include infection, anemia, arrhythmia, anomaly, and localized ischemia of the brain or other organs related to perfusion or mechanical trauma. The more in-vogue but vague and imprecise terms 'fetal intolerance to labor' and 'non-reassuring fetal status' however, surely underscore the failure of current classifications to provide insight into the mechanism(s) of the problem, the likelihood of recovery, the interaction among various heart rate patterns or a basis upon which to relate the events of labor to subsequent outcome. This helps us understand why there are no useful computerized models for the interpretation of intrapartum FHR patterns and even why 'alarm' systems are so readily abandoned.[106]

The problem of nomenclature is best illustrated by a brief discussion of the requirements for a 'reactive NST'.[107] In designating an NST tracing as 'reactive' we do not mention the specific baseline rate if it is in the normal range, or the amount of variability, or the fact that there are periods of time when the baseline variability is poor or absent (Figure 176.1). The entire pattern has a name – the reactive NST.

Technical issues

Technical issues must be understood as well. Abnormalities of the tracing are found predominantly during the expulsive phase of labor when technical difficulties are most likely to interfere with proper registration. The source of the FHR and uterine contraction signals (internal or external) will influence both the accuracy of the interpretation and the potential for misrepresentation of the baseline rate and the variability. Indeed, the monitor may mistake the maternal heart rate pattern for the fetal pattern with sometimes catastrophic results.[108,109] Under these circumstances, the 'baby has been lost' on the monitor and deterioration has not been appreciated. This situation has become commonplace in medical malpractice cases.

Correlation with outcome

The correlation of FHR patterns with outcome was originally confined to measures of immediate neonatal condition based on the potential effects of oxygen deprivation: neonatal death, pH of umbilical cord blood, Apgar scores, or need for neonatal intensive care.[84,110–114] While a normal intrapartum FHR pattern virtually excludes the presence of acute fetal hypoxia, and while abnormal patterns show an increased likelihood of acidosis and neonatal depression, most abnormal patterns fail to show any correlation with hypoxia or adverse outcome. The presence of a normal pattern, especially one with evidence of normal fetal behavioral states, correlates strongly with normal long-term neurologic outcome.[115–117] Abnormal FHR patterns, both before and during labor, are indeed associated with abnormal neurologic activity, including subsequent cerebral palsy.[65,102,118,119–123] Nevertheless, most abnormal patterns, when defined traditionally based on presumptions about the presence of hypoxia, show only a poor correlation with adverse outcome.[65,119] These generalizations apply despite differences in classification of FHR pattern.

As originally conceived, EFM was predicated on the benefits of the early detection of and timely intervention for fetal hypoxia. The test of hypoxia was the presence of certain specific decelerations. So unique were the *individual* decelerations thought to be in 1967[124] that they were named according to the presumed mechanism. Thus, late decelerations were thought to represent 'uteroplacental insufficiency', variable decelerations to 'cord compression', and early decelerations to 'head compression'. It is now clear that this represents a simplistic view of FHR patterns. Variable decelerations, for example, are caused by both umbilical cord compression and (probably more commonly) by fetal head compression. Early decelerations are pathophysiologically probably the same as variable decelerations. Late decelerations may occur other than in the context of hypoxia.

Figure 176.7 (bottom half) illustrates the importance of understanding the provenance of the patterns. It illustrates a series of combined variable and late decelerations and absent variability. There is a very high likelihood of a poor outcome associated with such a pattern. If the FHR recording preceding this

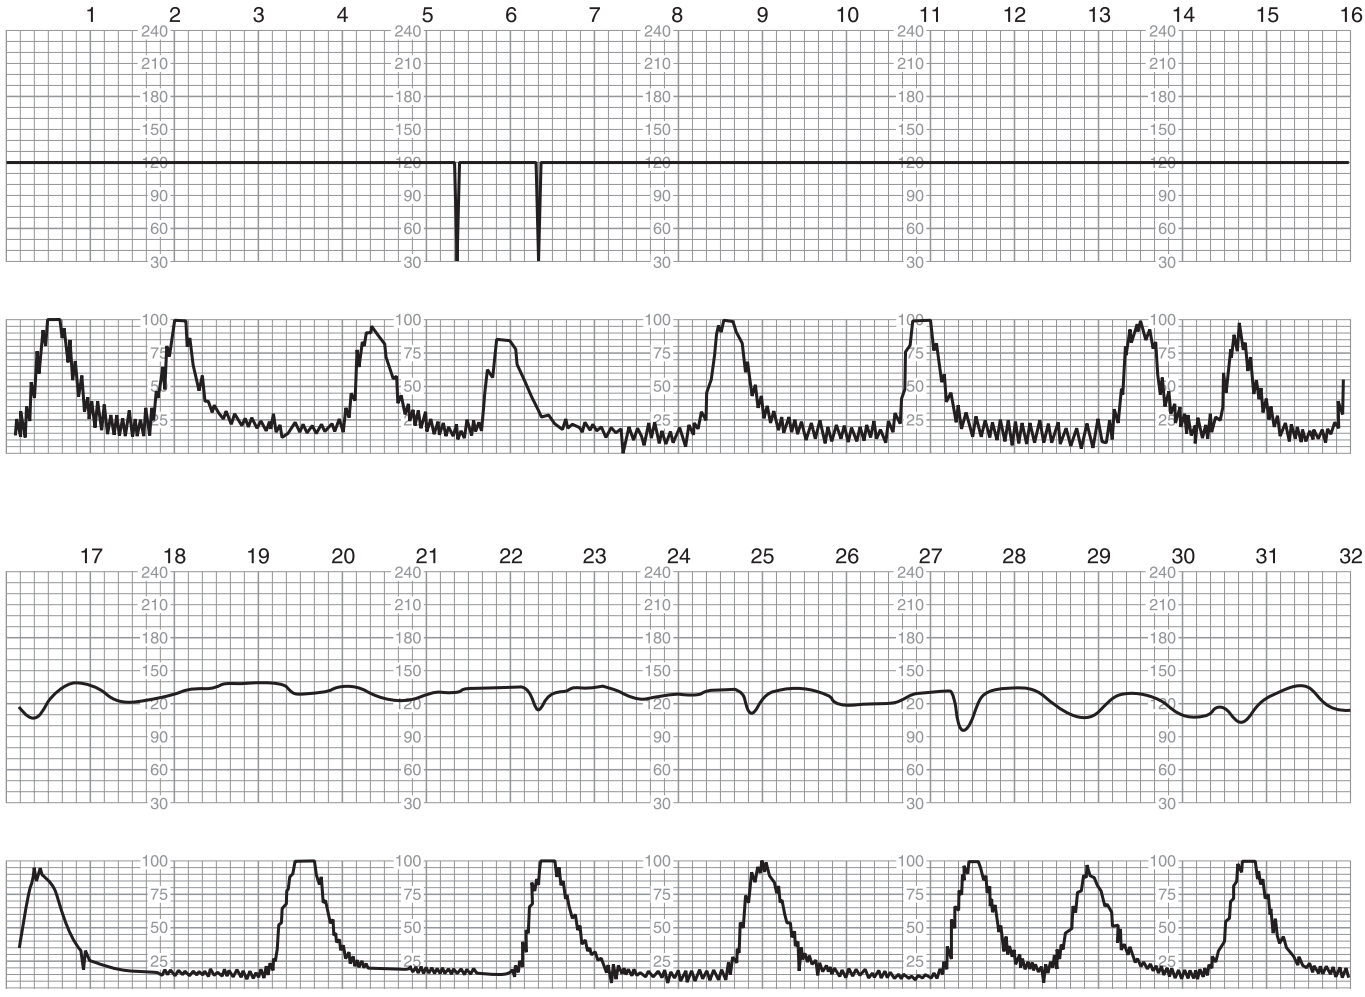

Figure 176.7 Pattern of injury. Note the persistent absence of baseline variability as well as the absence of decelerations in the top panel. In the bottom panel, several hours later, we find the combination of absent variability and small variable decelerations with overshoot and late decelerations in the presence of a stable baseline rate. This sequence and the absence of any normal tracing suggest that that threshold of injury had been crossed by the time monitoring was initiated. The infant was found to have low Apgar scores at birth but normal cord blood gases. The infant subsequently developed cerebral palsy.

tracing was normal then the progression of the pattern from normal to ominous suggests an acute and ongoing problem that could (and may already have) progressed to brain injury. If, however, the fetus was admitted with diminished variability, even absent decelerations (as in this case – top figure), then it is likely that the fetus was already injured at the time of admission.

FHR patterns and the diagnosis of neurologic injury

To understand the potential for using FHR patterns to detect neurologic injury, consider a principle widely used for the neurologic evaluation and prognosis of a person after a near-drowning accident. Irrespective of the severity of immediate asphyxia and neurologic manifestations thereof, the diagnosis of permanent neurologic injury must await the resolution of acidosis, hypoxia, and cerebral edema. Only then does a neurologic prognosis become reasonable. In the studies of Ikeda *et al.* on fetal lambs, the umbilical cord circulation was interrupted completely to a level of profound hypoxia and acidosis (pH < 6.9, and base deficit > 20 mmol/l).[35,125] The occlusion was then relieved, and the lambs were allowed to recover. Their brains were later examined for the severity of injury. The authors found no correlation between the duration of the fetal bradycardia or the severity of the hypoxia or acidosis and the severity of brain injury. Several features of this study appear to have critical relevance to the analysis of intrapartum events and their relationship to injury. The mechanism of injury in the animal studies was an acute abrupt and

profound ischemic assault reaching extraordinary levels of hypoxia and acidosis. But, although the FHR responded to this oxygen deprivation and severe acidosis, the duration of the bradycardia was not directly related to the severity of the neurologic injury. The factors that did correlate to the severity of injury were the (1) duration of the diminished perfusion of the brain (the ischemia), which could be measured in the experiment, but cannot be measured directly in the human fetus and (2) the appearance of the FHR pattern *after the event*. Of clinical importance was the observation that, despite the duration and the severity of the assault, when the obstruction to blood flow in the umbilical cord was removed, the pH and the base deficit returned to normal, but the injury remained. These experiments revealed the potential for acid–base (but not histologic) recovery of an obvious and severe asphyxial insult, the variability of neurologic injury among fetuses exposed to the same severe insult and extreme values of acidosis, and the potential relevance of the FHR pattern that occurs in the wake of a severe ischemic insult. No estimate of severity could be gleaned from the type or duration of the FHR pattern during the acute episode. Similar conclusions can be drawn from other experimental data.[126]

These findings contradict the prevailing opinion that for acute intrapartum asphyxia to be diagnosed, there must be evidence of abnormalities in Apgar score and pH at birth.[61,64] That may be reasonable for a model of injury that is one of progressive systemic hypoxia with relentless deterioration of the pH, and severe systemic manifestations of hypoxia at the end of labor. It makes, however, no concession for injury by any other mechanism (e.g. mechanical trauma, pure ischemia), or for the likelihood that host or environmental factors influence the vulnerability of individual fetuses to injury, even when exposed to the same degree of oxygen deprivation. It also makes no accommodation for a profound hypoxic event from which the fetus has recovered metabolically but not neurologically, and gives no consideration to the baseline condition of the fetus at the time the acute insult occurred. The issue is complex, and too poorly understood at this time to allow such definitive requirements.[102,127]

Clinical FHR tracings illustrate that the fetus may be injured during an hypoxic/ischemic episode from which it recovers from the hemodynamic and metabolic standpoints, but not from a neurologic one.[102,103,105,128] Decelerations need not be present to consider the potential for adverse neurologic consequences on the basis of the tracing. In this respect the diagnosis is a neurologic one, not a hypoxic one. When adverse features including persistently absent short-term variability and small variable decelerations with overshoot or intermittent sinusoidal pattern (Figure 176.6 – bottom half) are associated with absence of accelerations the potential for adverse neurologic outcome increases considerably, especially if the preceding antepartum or intrapartum tracing was reactive.[102,120,122,129] This 'pattern of injury' may be recoverable under certain circumstances, e.g. when there is severe metabolic ketoacidosis in the mother.[130,131] The pattern of injury appears in about 0.2% of all patients undergoing monitoring, but in about 50% of fetuses who subsequently develop neurologic disability in the form of cerebral palsy.[120,122,123] The overwhelming majority of patients with this pattern will have normal pH values. Only those whose patterns show obvious decelerations also show acidosis.[123] Thus, when one encounters this pattern under the circumstances described above it seems reasonable to anticipate a significant problem with the baby and to understand that even the most aggressive and timely management may not change the outcome.

In other, rare circumstances, the decelerations disappear and the baseline rate returns to normal, but the variability remains persistently exaggerated as the marker of the neurological injury; but normal behavioral cycles are usually not maintained.[132]

On occasion the transition from a normal to a pathologic pattern is obvious and dramatic, as in the sudden development of ischemic or hemorrhagic injury – a pattern we have referred to as the 'conversion pattern'.[102,103] Figure 176.6 illustrates the dramatic conversion of a previously normal tracing to one of absent variability in a fetus who suffered a stroke during labor. These events, which may be far more common than realized, are compatible only with a regional, ischemic event, not one of progressive, systemic asphyxia. The appearance of such tracings further underscores the limitations of trying to identify neurologic problems in the fetus using a nosology of decelerations designed only to demonstrate systemic hypoxia.

While the 'conversion' pattern shows an extraordinary correlation with subsequent adverse neurologic outcome, it cannot be used in any way to ascertain the severity of that involvement[122] or that its continuation necessarily represents ongoing deterioration of the fetal condition. It is important to emphasize the determination of injury is not based solely on the presence of a tracing with absent variability and other features. To define injury or the potential for it, one must either demonstrate or have reason to believe that the pattern of injury represents the conversion from a previously normal FHR pattern.[122,128] This distinction is important because this pattern of injury may be emulated in all respects by the administration of atropine to the mother or fetus.[51,133,134] It may also appear in the non-injured fetus as a result of prematurity, extreme tachycardia from any cause, and in anomalous fetuses.[135] Abnormalities of variability in the heart rate pattern may also be seen in older children with cerebral palsy and brain damaged adults.[136–138]

Effects on the cesarean rate

Most studies suggest that the use of EFM, because of the high incidence of abnormal FHR patterns that do not reflect severe asphyxia, increases the cesarean section rate, without apparent benefit for fetal outcome. As a result, there has been considerable interest in techniques that will increase the sensitivity of the 'non-reassuring' pattern for identifying significant oxygen deprivation or acidosis. Fetal capillary blood sampling has some potential benefits in this regard, but is no longer widely used, owing primarily to its technical challenges and intrinsic measurement errors.[139,140]

The U.S. Food and Drug Administration recently approved the marketing of the Nellcor N-400 fetal pulse oximeter to be used as an adjunct to FHR monitoring to monitor fetal intrapartum oxygen saturation continuously in a singleton vertex fetus with a gestational age of at least 36 weeks in the presence of a non-reassuring heart rate pattern after fetal membranes have ruptured. The stated and the implied benefits of the technique include: (1) reduced cesarean section rate for so-called 'non-reassuring FHR patterns' (NRFHRP); (2) simplicity – ostensibly only a single reading of more than 30% between contractions is assurance that the fetus is adequately oxygenated.[15,141] This notion eliminates the requirement for understanding the periodic changes in fetal oxygen saturation associated with contractions and prevents any misunderstanding about the meaning of various FHR decelerations and their impact on the baseline heart rate and variability. It would also seem to attenuate the risk of any medicolegal challenge relative to the interpretation of FHR patterns.[142]

When the device was used in conjunction with FHR monitoring in a randomized clinical trial there was indeed a reduction in cesarean delivery rates for 'non-reassuring FHR patterns'; but there was no difference in the immediate neonatal outcomes or the overall cesarean delivery rates (the latter as a result of an increase in abdominal delivery for dystocia in the pulse oximetry group).[15] Given these data, along with data suggesting that the correlation with scalp or umbilical pH is poor and that pulse oximetry may fail to recognize FHR changes associated with neurologic injury, the net value of the device for its stated purpose is unobvious.[142–144]

According to the rationale for using adjunctive techniques such as capillary pH measurements or pulse oximetry, overreaction to abnormalities in the FHR tracing will prompt unnecessary intervention if the FHR monitor is used alone, while intervention, if ultimately necessary, can be safely delayed as long as the oxygen saturation or pH is normal.[15] There would seem to be no obvious advantage for pulse oximetry to reduce somewhat the cesarean section rate, but increase the risk of urgent interventions or more difficult operative deliveries.

Precepts of monitoring

Perhaps a broader perspective is necessary. The original incentive for implementing fetal monitoring was the notion that the unique decelerations produced in relationship to contractions would allow early detection of fetal hypoxia and early intervention, in other words, *rescue* the fetus from impending decompensation. This oft repeated precept of EFM about intervention may indeed be the major impediment to realizing its benefits. To optimize the timing of intervention, there must be knowledge about the types of FHR patterns and mechanisms that produce injury, the speed of deterioration and the options for recoverability. Clearly some patterns develop slowly with ample, non-critical, opportunities for intervention with the expectation of normal outcome. Other patterns progress more rapidly and the timing of intervention becomes critical if the fetus is to be rescued. Still other patterns develop so rapidly and unpredictably that timely intervention is improbable and, irrespective of the speed of intervention, the fetus may not escape injury or death. In other circumstances, the opportunity for timely intervention has long passed and intervention, required by the standard of care, may not change the inevitable handicap or death. There has been little meaningful discussion of these issues.

Perhaps a better understanding of the benefits of EFM will be realized if the perspective of its role is changed from rescue to prevention. To begin to realize this role for EFM requires that the medical personnel attending the parturient continuously answer three questions: 'Does anything have to be done for the mother?' 'Does anything have to be done for the fetus?' And thirdly, 'What is the feasibility of safe vaginal delivery, given the circumstances of the labor, the fetal condition and the maternal condition?' Focusing on the FHR pattern for a moment, it seems axiomatic that irrespective of any abnormality of the FHR pattern, labor can only be permitted as long as there is reasonable expectation of the feasibility of safe vaginal delivery. That is, the decelerations that can be tolerated at full dilatation of the cervix with a head ready to deliver would not reasonably be tolerated in early labor before descent of the head, rupture of the membranes and the potential for cord compression, factors likely to further increase the severity of decelerations. Indeed, the lower the feasibility of safe vaginal delivery, the lower should be the threshold for intervention for abnormal FHR patterns irrespective of the severity of the FHR pattern, or the amount of acidosis.

For example, in the patient with an arrest of dilatation with the FHR demonstrating a rising baseline with decreasing variability and recurrent decelerations, what can be the benefit of waiting for an abnormal fetal oxygen saturation or critically low pH? Abnormal FHR

patterns, in fact, anticipate difficulty in labor and the need for cesarean section for dystocia.[21] Perhaps, decelerations occur for a reason. The increased frequency of decelerations, operative intervention, and subsequent adverse neurologic outcome with fetuses in occiput posterior positions have been known for some time.[89,145–148] It stands to reason that the longer and more difficult the labor the greater are the options for decelerations from fetal head or cord compression and for subsequent harm and the less likely is safe vaginal delivery from the OP position.[103,146–149]

Continued, unproductive labor may be associated with increased cranial molding and deeper lodgement of the fetal head into the pelvis. It may provoke protracted fetal bradycardia or make ultimate operative delivery by either vaginal or abdominal routes that much more difficult. The question then arises, what is the value of delaying delivery in the face of progressive abnormalities in the FHR pattern, even if one knew the scalp blood pH or transcutaneous oxygen saturation were normal? Delaying intervention – waiting until the fetal condition deteriorates or becomes critical before intervention – seems to be a violation of one of the fundamental tenets of obstetric care – keeping the mother and fetus out of harm's way.

When the FHR pattern is reactive, there is reasonable diagnostic certainty that there is no *fetal* indication for intervention. It does not exclude intervention on the basis of fetal size or presentation or position, pelvic size or a maternal condition. Thus, the determination of the timing of intervention will depend as much on the heart rate pattern as it does on the estimated feasibility and timing of safe vaginal delivery. The strength of such evaluations is modified by the reliability and predictability of the information, the skill of the interpreter, and the clinical context. The approach we have recommended here emphasizes the need to examine and codify trends in FHR patterns in an effort to identify the boundaries that separate the normally oxygenated and normally behaving fetus from the hypoxemic one and to distinguish pure hypoxia from that likely to be associated with ischemia.

We have tried to avoid here discussing tracings as a 'snapshot' of various patterns without discussion of their evolution.[150] Such limited perspective cannot permit an accurate assessment of the fetal condition or thoughtful deliberation about the urgency and route of delivery. Assessing 'non-reassuring patterns' would seem to require less attention to specific features of the types and timing of decelerations or variability, than to changes in these values over time – we need to use the fetus as its own control. The normal tracing with a stable baseline, cyclic accelerations and variability, and absent decelerations defines absent hypoxia and normal fetal behavior. Fetuses appear not to deteriorate without first modifying their FHR baseline and variability, even in the presence of decelerations. If patterns thought to represent fetal compromise were present at the outset of labor, then any adverse outcome likely represents antepartum insult. If such patterns evolve over time during labor after an initially normal FHR, however, then less severe signs of 'distress' were likely present. Irrespective, 'rescue' at this time may not allow a normal outcome.

We believe that much more is known about the determinants of FHR patterns than is currently used clinically in their analysis or classification. Perinatal asphyxia does not mean that the fetus was injured. Perinatal injury does not mean that the fetus was asphyxiated or that it was preventable. The evaluation of these tracings, therefore, requires that testing must be performed properly and in a timely way; the results must be interpreted and communicated correctly using an agreed upon, widely understood classification, and the interpretation must provoke an appropriate response in the larger clinical context relating to the condition of the mother and the feasibility of safe vaginal delivery. To a greater or lesser extent all these components must be included in any evaluation of the reproducibility of EFM, to its comparison with alternatives, and finally to the evaluation of its role in the allegation of obstetric negligence.

As much insight as tracings are able to provide, however, they cannot be used to explain all adverse outcomes. Indeed, they provide limited affirmative evidence of adverse outcomes associated with maladroit resuscitation, congenital anomaly, traumatic or difficult delivery, sepsis, or medication. The majority of infants depressed at birth have a normal blood pH and the majority of infants with low pH have normal outcome. There is, however, no reported example of sudden, unexpected fetal death on a monitor.

Thus, all of these modalities (EFM, fetal pulse oximetry, pH) should at least anticipate, if not prevent, fetal death in labor because this outcome, unlike neurologic injury, is universally associated with either progressive hypoxia and acidosis or an acute, catastrophic event, e.g. massive abruption. But whether any of these techniques, by a single value or feature or even a combination thereof, can dictate the critical time for delivery of the fetus with a problematic FHR pattern and a abnormal labor, is unresolved. There yet seems to be a place for skilled interpretation of FHR patterns, for understanding the expected course of labor and for the Art of Obstetrics in dealing with the parturient in labor. Rescuing the fetus is not good obstetrics; preventing injury is. It should not be concluded that universal cesarean would be the obvious solution to preventing all hypoxic and ischemic injury; rather, informed and insightful management of labor, including intelligent fetal surveillance would seem to be the best route to that end. For the acceptance and benefit of monitoring to improve, we will have to learn from the mistakes of

the past and learn to ask the right questions about both immediate and long-term outcomes. We will have to broaden the understanding of both fetal and physician behavior and let the fetus act as its own control. We need to pay more attention to understanding the mechanism of fetal injury while abandoning the myths and fear of malpractice. We will need to value more both the responses of the fetus before and during labor and the potential benefits of skilled human intervention.

177 Pain relief during labor

D. J. Birnbach and E. M. Davidson

Introduction

The numerous challenges presented by the parturient requesting analgesia makes the job of the anesthesiologist working in labor and delivery both demanding and rewarding. Those providing analgesia to the obstetric patient must be familiar with the unique physiology of the parturient and the effects of many medications and techniques on the parturient and fetus, and on the labor.

Continuous improvements in drugs and techniques have led to a significant decrease in anesthetic-related deaths in the delivery suite.[1] The maternal mortality rate in the United States is estimated at 7.5 per 100,000 live births[2]; however, under-reporting makes this probably a minimum estimate.[3] A recent retrospective analysis of maternal mortality during hospital admission by Panchal *et al.* indicated that anesthesia-related complications accounted for 5.2% of maternal deaths.[4]

The American College of Obstetricians and Gynecologists (ACOG) and the American Academy of Pediatrics (AAP) have made several recommendations concerning anesthetic management in the labor and delivery suite. These include the availability of 24-h coverage in larger facilities with complicated patients, the ability to perform an emergency cesarean section within all facilities with delivery suites, and the availability of properly trained personnel to manage anesthetic complications. They further suggest that, in the event of fetal compromise, the team should be capable of starting an operative delivery within 30 min.[5] Immediate availability of anesthesiologists remains a major problem in many parts of the world, and even when available, communication between the obstetrician and anesthesiologist may be suboptimal. To provide optimal better care for the pregnant patient, obstetricians and anesthesiologists must understand the physiologic changes that exist in these patients. Maternal changes in pregnancy occur as a result of hormonal alterations, mechanical effects of the gravid uterus, increased metabolic and oxygen requirements, metabolic demands of the fetoplacental unit, and hemodynamic alterations associated with the placental circulation. Such changes become more significant as pregnancy progresses and have major implications for anesthetic management. In the section on deaths related to anesthesia in a most recent triennial report of the United Kingdom, it was noted that poor communication between obstetric and anesthetic teams remained a problem, with anesthesiologists often being presented with difficult cases as emergencies, with no prior warning.[6]

Appreciation of the roles of the obstetrician, anesthesiologist, pediatrician, and other personnel in the care of the mother and child will facilitate the highest level of care. This chapter will provide an overview of the principles and techniques utilized by the anesthesiologist in the labor and delivery suite.

Physiologic changes of pregnancy

The cardiovascular system is impacted by pregnancy and may place the parturient with preexisting cardiac disease at great risk of morbidity and mortality.[7,8] Cardiovascular changes throughout pregnancy (Table 177.1) include an increased total blood volume of up to 40%, the consequence of increases in both plasma volume and red blood cell mass, the latter increasing relatively less than the plasma. This leads to 'physiologic anemia' of pregnancy with average hemoglobin and hemocrit of 11.6 g/dl and 35.5%, respectively.[9] Increased cardiac output (30–50%) due to increased heart rate, increased stroke volume and decreased systemic vascular resistance is also present.[10] Obstruction of the inferior vena cava occurs in many term parturients in the supine position and may produce hypotension in at least 5% of patients near term.[11] Kerr *et al.* reported that 10 out of 12 pregnant patients whom they studied had signs of complete obstruction of the inferior vena cava.[12] Aortocaval compression causes an obstruction to venous return and also an increased uterine venous pressure, thus further decreasing uterine blood flow (Figure 177.1).[13] Drugs causing vasodilatation or regional anesthetic techniques causing a sympathetic blockade may further decrease venous return and worsen this supine hypotension. Left uterine displacement has been found to reverse some of these effects and to improve cardiac output.[14]

Table 177.1 Cardiovascular changes in pregnancy

Parameter	Change	Amount
Heart rate	Increased	20–30%
Stroke volume	Increased	20–50%
Cardiac output	Increased	30–50%
Contractility	Variable	~10%
Central venous pressure	Unchanged	—
Pulmonary capillary wedge pressure	Unchanged	—
Systemic vascular resistance	Decreased	20%
Systemic blood pressure	Slight decrease	Mid-trimester 10–15 mmHg, then rises
Pulmonary vascular resistance	Decreased	30%
Pulmonary artery pressure	Slight decrease	—

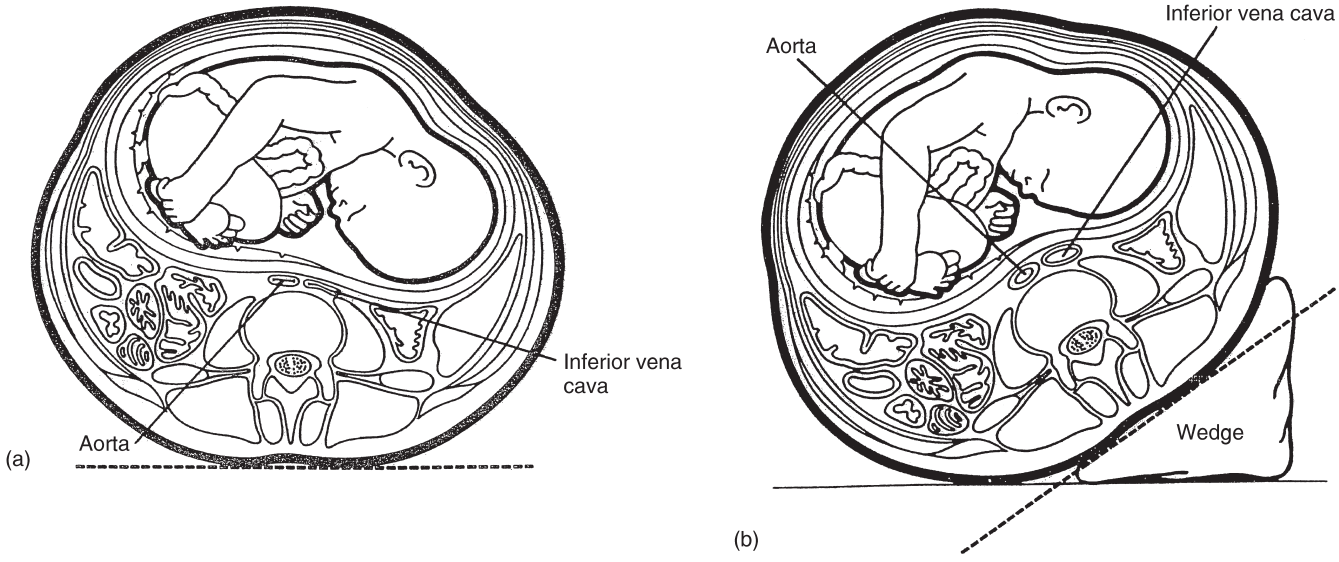

Figure 177.1 In (a) the patient is in the supine position, and the uterus compresses the aorta and inferior vena cava. A wedge under the hip (b) displaces the uterus and relieves aortocaval compression. From Fisher S, Ostheimer G, Warren TM. Obstetric analgesia and anesthesia. In Cohen WR, Acker DB, Friedman EA, eds. *Management of Labor*, 2nd edn. Rockville, MD: Aspen Publishers, 1989:80–81, with permission.

A state of hypercoaguability, which is thought to be a protective adaptation to lessen the risks of acute hemorrhage, exists in pregnancy with increased levels of most coagulation factors (Table 177.2). This hypercoaguable state may, however, lead to thromboembolism, one of the leading causes of maternal mortality.

Respiratory changes (Tables 177.3 and 177.4) include increased oxygen consumption, decreased functional residual capacity, increased minute and alveolar ventilation, increased tidal volume, and a decreased arterial carbon dioxide pressure.[15,16] The decreased functional residual capacity, in combination with the increased minute ventilation, causes lowered oxygen reserve and a risk of hypoxia developing more rapidly during attempted intubation as part of general endotracheal anesthesia.[17]

Other pregnancy-related changes of the respiratory tract and oropharynx may have important anesthetic implications. Capillary engorgement of the mucosa and edema of the oropharynx, larynx, and trachea may result in difficult intubation. Any manipulation of the upper airway such as suctioning, insertion of airways, or laryngoscopy may cause edema, bleeding, and upper airway trauma. Because of the particularly friable mucosa of the nasopharynx, instrumentation of the nose should be avoided. When performing intubation of the pregnant patient, a smaller endotracheal tube (size 6.0–7.0) should be used, and repeated attempts at laryngoscopy minimized. Every member of the medical team taking care of the parturient should be able to assess the patient's airway[18] (Mallampati classification), and should be able to recognize features that may cause difficulty in managing the airway.

Table 177.2 Coagulation factors in pregnancy

Factor	Change
II	Unchanged
VII	Increased+++
VIII, IX, X, XII	Increased
XI	Reduced
Fibrinogen	Increased+++
Platelets	Unchanged

Table 177.3 Changes in respiratory physiology at term gestation

Parameter	Change
Lung volumes	
Inspiratory reserve volume	+5%
Tidal volume	+45%
Expiratory reserve volume	−25%
Residual volume	−15%
Lung capacities	
Inspiratory capacity	+15%
Functional residual capacity	−20%
Vital capacity	No change
Total lung capacity	−5%
Dead space	+45%
Respiratory rate	*No change*
Ventilation	
Minute ventilation	+45%
Alveolar ventilation	+45%

Table 177.4 Effects of pregnancy on respiratory mechanics (adapted from Conklin[9])

Parameter	Change*
Diaphragm excursion	Increased
Chest wall excursion	Decreased
Pulmonary resistance	Decreased 50%
FEV_1	No change
FEV_1/FVC	No change
Flow volume loop	No change
Closing capacity	No change

FEV_1: Forced expiratory volume in 1 s
*Relative to non-pregnant women

Gastrointestinal changes in the pregnant patient increase the risk associated with the administration of anesthesia, by increasing the aspiration risk. The stomach and intestines are displaced in pregnancy, gastrointestinal motility is decreased, gastric acid secretion is increased, gastric volume is increased, and pH is decreased.[19,20] Because of these physiologic changes, many authors have suggested the routine administration of an antacid prior to initiation of anesthesia in the pregnant patient.[21] The use of a non-particulate antacid, such as sodium citrate, has many advantages, no major disadvantages and has become standard practice in the United States prior to cesarean delivery.[22]

The renal system undergoes major changes in the pregnant patient, mainly because of the effects of progesterone and the mechanical effects of compression by the enlarging uterus. Urea, creatinine, and uric acid clearance all rise in pregnancy. The renal plasma flow and glomerular filtration rate (GFR) increase rapidly and relate to the increase in cardiac output. GFR rises by almost 50%; this, accompanied by the dilutional effect of plasma volume expansion, accounts for the fall in plasma creatinine and urea. Hence, 'normal' renal indices in pregnancy are lower than in the non-pregnant state. Therefore, BUN and creatinine levels that would be considered marginally elevated in the non-pregnant patient are usually indicative of severe renal impairment in the parturient. The increase in GFR usually precedes the expansion of blood volume and is generally considered to be a marker of pregnancy-induced vasodilation.[23] Glycosuria is a common finding due to the increase in GFR and reduced renal tubular resorption capacity.

Analgesia for labor

Before deciding on one of the various analgesic options available to the parturient, it is important to understand the mechanisms and pain pathways of labor. Pain perception by the parturient is a dynamic process that involves both peripheral and central mechanisms.

Many factors impact on the degree of pain experienced by a woman during labor. These include psychological preparation, quality of emotional support during labor, previous experiences, patient's expectations regarding the birthing process, and whether or not the labor is augmented. An abnormal fetal presentation (such as occiput posterior) may also cause labor pain to be more intense. For most women childbirth is associated with very severe pain, which often exceeds expectations.[24] In fact, as reported on the McGill pain questionnaire, labor pain is one of the most intense pains a woman can experience, and it is typically worse than a toothache, back pain, and pain associated with deep laceration.[25] A study of women in the first stage of labor reported that 60% of primiparous women described the pain of uterine contractions as being 'unbearable, intolerable, extremely severe, or excruciating'.[25]

During the first stage of labor, pain impulses arise primarily from the uterus. Uterine contractions may result in myometrial ischemia, which ultimately

causes the release of bradykinin, histamine, and serotonin. In addition, stretching and distension of the lower uterine segment and cervix may stimulate mechanoreceptors. These noxious impulses follow sensory nerve fibers that accompany sympathetic nerve endings; they travel through the paracervical region and the hypogastric plexus to enter the lumbar sympathetic chain.[26] These stimuli enter the spinal cord at the T10, 11, 12, and L1 spinal segments. Parturients describe this pain as dull in nature and often poorly localized. With the onset of the second stage of labor and stretching of the perineum, somatic afferent nerve fibers transmit impulses via the pudendal nerve to the spinal cord at S2, 3, and 4 levels.

Labor causes increased maternal levels of adrenocorticotropic hormone (ACTH) and cortisol, epinephrine, norepinephrine and β-endorphins.[27,28] Animal studies suggest that these substances may decrease uterine blood flow and cause fetal hypoxia.[29] In addition to the obvious immediate problems associated with pain, it has also been reported that increased pain in labor was associated with a higher incidence of postpartum depression.[30]

Pain impulses may be blocked at the level of the peripheral nerves (local anesthetic, peripheral nerve blocks), the spinal cord (spinal, epidural, or combined spinal–epidural anesthesia) or centrally (systemic medications, such as opioids, general anesthesia).

The following section of this chapter will give an overview of the various methods and techniques of analgesia currently utilized.

Systemic medication

When systemic medications are chosen for labor analgesia, opioids are the most commonly used class of drugs. All opioids are associated with certain side effects including respiratory depression, nausea and vomiting, and mental status changes (ranging from euphoria to excessive sedation). All opioids cross the placenta because of their physicochemical characteristics, and they may cause respiratory depression in the newborn. However, when used in appropriate doses, systemic narcotics can be somewhat effective in alleviating labor pain for short periods of time. Other systemic drugs used in the treatment of labor pain include sedative tranquilizers and ketamine.

Meperidine (demerol, pethidine)

Meperidine is the most commonly used parenteral opioid for labor analgesia. A recent American survey examined the use of parenteral opioids in obstetric units and reported their use at 39–56%. In units with over 1500 deliveries per year, parenteral opioids were administered to 39% of women; that percentage increased as the number of deliveries decreased.[31] The intramuscular dose ranges from 50 to 100 mg, with peak effect at 40–50 min; intravenous doses of 25–50 mg act within 5–10 min. The analgesic effect lasts approximately 3–4 h. This drug may cause loss of beat-to-beat variability in fetal heart rate (FHR) tracings. Fetal exposure to meperidine is highest between 2 and 3 h following maternal administration.[32] Meperidine is felt to cause less respiratory depression in the neonate than morphine; therefore, it is more commonly used.[33]

Despite the known problems associated with meperidine, a recent meta-analysis suggested that other opioids (tramadol, meptazinol, diamorphine, pentazocine, nalbuphine, and butanorphanol) were not superior to meperidine for labor analgesia.[34] Several authors, however, have proposed that fentanyl and remifentanil are better choices.[35,36]

Fentanyl

Intravenous fentanyl is an alternative analgesic option for patients in whom regional anesthesia is contraindicated. Its short half-life makes it suitable for prolonged use in labor, either as an IV bolus or administered using a patient-controlled analgesia delivery system.[37] It provides adequate analgesia with minimal neonatal depression.[38] Although it provides strong analgesia, its use in labor has been limited by side effects and short duration of action. One study that evaluated intravenous fentanyl for labor reported that 4 of the 11 newborns whose mothers received fentanyl for analgesia during labor required naloxone treatment.[39] The usual dose of IV fentanyl for labor analgesia is 25–50 μg when given as a bolus. The peak effect occurs within 3–5 min and it has a duration of 30–60 min. A prospective evaluation of fentanyl for labor concluded that an intravenous dose during early labor was associated with temporary depressant effects on fetal biophysical parameters without apparent harm noted at time of delivery.[40] A study evaluating intravenous fentanyl in labor reported that mild sedation and a transient decrease in FHR variability were also noted.[41] Several investigators, however, have determined that intravenous fentanyl is preferable to meperidine as a labor analgesic.[42] Fentanyl offers another advantage in that it can be administered in non-parenteral modalities including orally and via a patch. These uses, however, have not been evaluated for use in the laboring patient.

Remifentanil

Remifentanil is a potent, short-acting mu-opioid receptor agonist which has been approved for clinical use. It is a piperidine derivative with a normal opioid configuration, but it contains an ester linkage that allows metabolism by non-specific esterases throughout the plasma and muscle tissue. This gives it a unique pharmacologic profile in comparison to other opioids. Remifentanil has an extremely rapid plasma clearance and offset of action. Its estimated half-life is 1.3 min and prolonged administration does not appear to cause accumulation of this drug. Studies have demonstrated an umbilical vein-to-maternal artery

ratio of 0.88.[35] Thus, fetal exposure to the drug is minimized due to its rapid metabolism or redistribution. These properties make it an attractive alternative systemic analgesic in those parturients in whom regional anesthesia is contraindicated. There are growing data in the literature regarding the use of this drug for labor analgesia.[36,43] Dose–response studies using intravenous remifentanil in patient-controlled analgesia suggest a median effective bolus dose of 0.4 μg/kg with a lockout time of 1 min[44] or a continuous infusion of remifentanil at 0.05 μg/kg/min and a bolus of 25 μg with a lockout time of 5 min provides satisfactory analgesia.[36] There is also a report of its prolonged use for 34 h in a complex parturient in whom regional techniques were contraindicated; there were no adverse effects.[45] Studies using remifentanil in labor have not fully answered whether or not it is a superior systemic opioid analgesic for parturients.[46] While preliminary reports have been promising, it is still somewhat premature to advocate the use of remifentanil until larger studies have fully evaluated its use.

Butorphanol and nalbuphine

Butophanol and nalbuphine are opioid agonist-antagonists that are structurally related to oxymorphone and naloxone. They have the potential advantages of producing less nausea and vomiting as compared with other opioids. Butorphanol is a kappa-agonist, a mu-antagonist, and has minimal affinity for sigma-receptors. Its dose is 1–2 mg IM or IV, and it has a duration of action up to 4 h. Nalbuphine is a partial kappa-agonist and a potent mu-antagonist with minimal sigma-receptor activity. A dose of 10 mg IV or IM is equivalent to 10 mg morphine with an onset of 2–3 min for IV or 10–15 min for the IM route. It provides analgesia for up to 6 h.

One advantage of these agents as compared to mu-agonists is that they demonstrate a 'ceiling effect' so that increasing doses do not produce further respiratory depression.[47] Unfortunately, the use of these drugs is limited in clinical practice because they are rapidly transferred across the placenta and have produced sinusoidal FHR patterns.[48,49] While it appears that this FHR pattern is benign and does not signify life-threatening fetal jeopardy as usually associated with such a pattern, many obstetricians do not wish to administer a drug that might mimic this ominous FHR tracing. In addition, the use of antagonists or agonist–antagonists may precipitate acute withdrawal syndrome in the mother and the newborn of an opioid-dependent parturient. This has been reported following both parenteral and neuraxial administration.[50]

Sedative tranquilizers

Sedative tranquilizers, including barbiturates, phenothiazines, hydroxyzine, and benzodiazepines, have been used during labor. While barbiturates such as secobarbitol were once popular, especially during early labor, they are currently unfashionable due to potential anti-analgesic effects in the mother and prolonged depressant effects on the neonate. Even with small doses of barbiturates that result in no depression of the Apgar score, the newborn's attention span may be depressed for upwards of 4 days.[51]

Promethazine is a phenothiazine occasionally used in the obstetric patient. Administered together with meperidine, it can be given in doses of 25–50 mg to reduce the risk of emesis. Its ability to potentiate the analgesic effects of opioids, however, has been challenged.[52] Promethazine appears in the fetal blood within 1–2 min following intravenous injection in the mother and reaches equilibrium within 15 min.[53]

Ketamine is an *N*-methyl D-aspartate (NMDA) receptor antagonist that produces dissociative anesthesia and has been used in pregnant patients. As a phenylcyclidine derivative, its mechanism of action may be mediated by an interaction with phencyclidine receptors located in the limbic and corticothalamic areas of the brain. There is evidence, however, suggesting that NMDA antagonism is central to the effects of ketamine. Ketamine has been used in subanesthetic doses (0.5–1 mg/kg or 10 mg every 2–5 min to a total of 1 mg/kg over 30 min) during labor.[54] Its main disadvantages are the potential for hypertension and emergence reactions. High doses (greater than 2 mg/kg) can cause psychomimetic effects and increased uterine tone; causing lower Apgar scores and abnormalities in neonatal muscle tone.[55]

Benzodiazepines such as diazepam (valium), lorazepam (ativan), and midazolam (versed) can be used as sedatives and anxiolytics in labor. When administered intravenously, these drugs readily cross the placenta with elimination half-lives as long as 48 h for diazepam and upwards of 120 h for its main metabolite *N*-desmethyldiazepam.[56] There is anecdotal evidence suggesting that exposure to the benzodiazepines (valium) early *in utero* may result in malformations such as cleft lip.[57] Closer analysis involving first trimester administration of benzodiazepines, however, demonstrates that the majority of infants were normal at birth and had normal postnatal development.[56] The use of these drugs during labor will obviously have no effect on fetal malformations, but they may be associated with other problems in the neonate including sedation, hypotonia, cyanosis, and impaired metabolic responses to stress. In addition, since these drugs are potent amnestic agents, a parturient may not be able to remember her birthing experience.[58] Many of the adverse effects can be reversed by the administration of flumazenil, which is a competitive benzodiazepine-receptor antagonist.

Recently, a study evaluating the use of intrathecal midazolam has suggested that this may be advantageous. This study, however, which was performed in Australia, used a non-preservative-containing formulation of midazolam which is not available in the United States and many other countries.[59]

Inhalation analgesia

Inhalation analgesia consists of the administration of subanesthetic concentrations of inhalational anesthetic agents to relieve pain during labor. This pain relief technique should not be confused with inhalation anesthesia (during general anesthesia), which produces unconsciousness and loss of protective laryngeal reflexes. Although inhalation analgesia provides some degree of pain relief, it is not associated with an adequate level of analgesia to provide sufficient pain relief for most mothers. It may, however, have a place as an adjunct to neuraxial techniques or in parturients for whom regional anesthesia is contraindicated. Inhaled analgesics can be administered either intermittently (e.g., during contractions) or continuously. They can be self-administered, but the patient should have a healthcare provider present in order to ensure an adequate level of consciousness and proper use of the equipment. Although inhalational agents continue to be used in parts of Europe as well as in some developing countries, they are seldom used for labor analgesia in the United States.

Entonox (50:50 N_2O/O_2 mixture) has been used for many years both as a sole analgesic and adjuvant to systemic and regional techniques for labor. Associated side effects include dizziness, nausea, dysphoria, and inability of the parturient to cooperate. The maximum analgesic effect occurs after 45–60 s of inhalation, and it is therefore important that the parturient uses entonox at the early onset of her contractions and discontinues its use after the peak of the contraction. The lack of scavenging systems in labor rooms may theoretically put staff at risk of exposure to excessive levels of this agent over a prolonged period. The administration of nitrous oxide and oxygen in a 50:50 combination appears to have no effect on hepatic, renal, cardiac, or pulmonary functions. While safe and economic, it is unfortunate that analgesia with 50% nitrous oxide has not been demonstrated to be reliable.[60]

Desflurane (0.2%), enflurane, and isoflurane (0.2–0.25%) have also been used successfully to provide labor analgesia, but their effectiveness appears to be comparable to nitrous oxide. While Abboud and coworkers found that enflurane and nitrous oxide were equipotent, others have found that enflurane 1% provided better pain relief.[61–63] The use of these volatile agents, however, is limited by drowsiness, an unpleasant smell, and high cost. The major risk when using volatile agents is accidental overdose resulting in unconsciousness and loss of protective reflexes. In addition, proper scavenging of gases in a labor room remains problematic.

Local and regional anesthesia for labor

Local anesthesia can provide differing degrees of sensory and motor block over specific regions of the body. Advantages over intravenous analgesia include lack of maternal central nervous system depression and low maternal-to-fetal transfer of drugs. It may be produced with peripheral nerve blocks (pudendal and paracervical blocks) or central nerve blocks at the level of the spinal cord or spinal nerve roots (caudal, epidural, spinal, combined spinal–epidural). Currently, the most commonly performed regional techniques for labor are epidural, and combined spinal–epidural. Less frequently, lumbar sympathetic blocks are performed.[64] Paracervical, pudendal, and local perineal infiltration are occasionally used by the obstetrician, but use is limited by side effects.

Patient evaluation and preparation

It is important to evaluate all patients prior to placement of a regional block by obtaining a focused medical and obstetric history, performing a clinical examination, and an airway evaluation. Use of herbal medications by the general population is gaining in popularity,[65] and obstetric patients are no different. It has recently been reported that there is a 7.1% incidence of herbal remedy use by parturients after 20 weeks' gestation.[66] Preparations containing garlic, ginkgo, ginseng, ginger, and feverfew may have anesthetic implications.

The obstetric plan and fetal well-being should be noted during this preoperative assessment. Patients should be evaluated and screened for contraindications for neuraxial blocks. Certain medical conditions require lab testing prior to performance of a neuraxial blockade. Informed consent must be obtained, and the anesthesiologist should explain the procedure and the potential complications of the technique. A retrospective study of patients' attitudes toward labor analgesia satisfaction and the consent process revealed that pain and distress during labor did not interfere with the women's ability to understand the information associated with the consent process prior to epidural placement. Furthermore, patients felt that the most valuable information received was either from the anesthesiologist who placed the epidural or from an antenatal course. A full check of emergency equipment must be performed to ensure the immediate availability of resuscitative drugs and equipment. In addition, an intravenous infusion should be started and appropriate maternal and fetal monitoring should in place before starting the procedure.

Epidural analgesia

The epidural space is a potential space containing blood vessels, fat, and lymphatics. This space extends from the end of the sacrum to the foramen ovale. For analgesia during labor it is usually entered via the lumbar intervertebral space (usually L3–L4 or L4–L5). There is no physical end-point to guide epidural catheter placement, such as free-flow of cerebrospinal fluid (CSF) when initiating spinal anesthesia. Therefore, identification of the epidural space is made

using either the 'loss of resistance' or 'hanging drop' techniques to allow verification of needle placement. The epidural needle is relatively large (usually 17 or 18 gauge) so as to allow passage of a 19- or 20-gauge catheter, which is threaded into the epidural space.

Before dosing with local anesthetic, proper placement of the epidural catheter should be assured. Accidental intravenous or subarachnoid placement may prove disastrous if unrecognized. The volume of local anesthetics necessary to achieve anesthesia are much larger than the required spinal doses, and if an epidural volume is injected into the spinal space it may cause a 'total spinal' with resultant hypotension, respiratory paralysis, and unconsciousness. Epidural doses of local anesthetics given intravascularly may cause symptoms ranging from mild central nervous system effects (tinnitus, lightheadedness) to total circulatory collapse, depending on agent, dose and rate of injection. For this reason a 'test dose', often consisting of a local anesthetic with a small amount of epinephrine, is sometimes given, especially before the use of the catheter for cesarean delivery. Evidence of significant sensory and/or motor block indicates an intrathecal placement of the catheter, while a sudden increase in heart rate shortly after injection may indicate intravascular placement of the epidural catheter. Intravascular infusions of ultradilute local anesthetics (e.g., 0.0625% bupivacaine) do not pose a serious threat unless given for prolonged periods. However, if the concentrated local anesthetic is administered for operative delivery, intravascular injection remains a real hazard.

Once the proper placement of the epidural catheter is assured, a dilute solution of local anesthetic may be given to provide labor analgesia. To achieve analgesia during the first and second stages of labor, a segmental block from the lower thoracic to the sacral dermatomes is needed. The dermatomal segments blocked depend on the location of the catheter as well as the dose, concentration and volume of the anesthetic agent used.

It has been suggested that epidural analgesia for labor may influence the outcome of labor.[67] Studies that have examined the effect of an epidural on the length of labor, incidence of malposition, and incidence of operative delivery, however, have been conflicting in their conclusions, with some finding no effect.[68–70] and others finding an increased risk of operative delivery.[71,72] Unfortunately, the majority of studies which have attempted to answer this question have been non-blinded, non-randomized, or retrospective. More recent studies suggest that there is no increased risk for cesarean delivery with epidurals as currently administered[73] although there is still controversy as to the possible increase of instrumental deliveries and possible prolongation of labor that may occur. Despite the controversy surrounding the influence of epidural analgesia on labor progress, this technique remains the most effective method of providing pain relief during parturition.[71]

Bupivacaine, in concentrations ranging from 0.0625% to 0.125%, is often used to provide epidural analgesia in the laboring patient. Initially, 8–12 ml of local anesthetic is administered via the epidural catheter (often in divided doses) to initiate analgesia. The dilute local anesthetic concentrations provide a solid sensory block with only minimal motor block. Because hypotension may occur, ephedrine and phenylephrine should be available to treat hypotension if it occurs.

Because of concerns about cardiotoxicity with inadvertent intravascular injection of bupivacaine,[74] levo isomers, thought to be less cardiotoxic, are being used by some anesthesiologists. Ropivacaine, with a similar phamacodynamic profile as bupivacaine but with less cardiotoxicity,[75] may replace bupivacaine as the local anesthetic of choice for epidural anesthesia. Santos *et al.*[76] reported that intravenous ropivacaine did not lead to any decrease in uterine artery blood flow in pregnant sheep. Levobupivacaine is also being studied and may provide an improved safety profile as compared with racemic bupivacaine.

Continuous epidural infusions

Most obstetric anesthesiologists now advocate the use of continuous infusions of dilute local anesthetic solutions for labor. Local anesthetics are used either alone or, more commonly, in combination with an opioid. The addition of epinephrine may enhance the quality of the analgesia by reducing vascular uptake, systemic absorption of local anesthetic, and by a direct agonist effect on alpha-2 spinal receptors.[77,78] From a parturient's perspective, a continuous infusion offers numerous benefits because it allows for a continuous level of comfort rather than waiting for intermittent epidural top-ups, but may be associated with higher incidence of anesthetic interventions as compared to patient-controlled techniques.[79]

Patient-controlled epidural analgesia

Patient-controlled epidural analgesia (PCEA) is a safe and effective technique.[80] This method of delivery offers effective labor analgesia and excellent patient satisfaction. It reduces the total amount of local anesthetic used; consequently, it lessens unwanted effects such as motor block. It also reduces the demands on the labor floor staff, and it gives many patients a feeling of self-control. Typically, after analgesia is established (either via spinal or epidural) the catheter is connected to the PCEA device, and the patient can then self-administer further boluses as required. Some authors advocate a continuous infusion with patient controlled top-ups; others suggest only boluses be used.[81]

Spinal analgesia

Opioids with or without small doses of local anesthetics introduced into the intrathecal space may be used to provide analgesia for labor vaginal

delivery. The block produced by spinal agents may produce anything from a little to complete sensory and motor block, depending on the agent used and its concentration. Intrathecal opioids have the advantage of providing satisfactory analgesia without causing a motor block. Commonly used intrathecal opioids which may provide labor analgesia include sufentanil and fentanyl. While meperidine and morphine have been used, they have side effect profiles that make them suboptimal as sole agents.[82,83] Combinations of opioids plus local anesthetics have also been described.[84] The addition of 2.5 mg bupivacaine to a spinal opioid has been shown to prolong the sensory block without significantly increasing motor block.[85]

A sensory block to T10 is considered adequate for controlling the pain of the first stage of labor. In situations where analgesia or anesthesia is only needed in the sacral dermatomes (as in the provision of anesthesia for a forceps delivery), a 'saddle block' may be performed. With this technique, spinal anesthesia is performed using small amounts of hyperbaric local anesthetics with the patient in the sitting position. Because the solution given is heavier than cerebrospinal fluid and the patient is sitting while the local anesthetic is administered, only the lowest dermatomes are blocked.[86]

Spinal blocks for labor may be associated with the complications that may occur with any central nerve block, including hypotension and dural puncture. The risk of postdural puncture headache can be greatly reduced, however, through the use of atraumatic spinal needles. These newer needles (including Sprotte, Gertie Marx, Whitacre, and Pencan needles) are pencil-point in shape and do not cut the dural fibers to the same extent as conventional (Quincke) spinal needles.[87]

A major disadvantage of single-injection spinal analgesia for labor is the inability to administer more medication should labor last longer than the duration of the spinal medication, or should cesarean section become necessary. Continuous spinal analgesia via a spinal microcatheter is no longer used in the United States due to Food and Drug Administration (FDA) sanctions, which arose as a result of several reports of cauda equina syndrome after use of intrathecal microcatheters.[88] The use of macrocatheters (placing an epidural needle subarachnoid and advancing a standard epidural catheter into the spinal space) has been advocated, especially in very high risk parturients or following accidental dural puncture ('wet-tap').

Combined spinal–epidural analgesia

The combined spinal–epidural (CSE) technique is widely used in obstetric practice to provide analgesia for parturients. It offers effective, rapid onset of spinal analgesia along with the ability to prolong the duration of analgesia, as required, via an epidural catheter. In addition, should an operative delivery become necessary, that same catheter can be used to provide operative anesthesia. Onset of spinal analgesia is almost immediate, and the duration is between 2 and 3 h depending on whether fentanyl or sufentanil is chosen.

In addition to the advantage of the rapid onset of pain relief, the CSE technique may reduce the incidence of several potential problems associated with the conventional epidural, including incomplete blockade, motor block, and poor sacral spread. Another potential advantage of the CSE technique is that some preliminary evidence suggests that it may be associated with a significantly reduced duration of the first stage of labor in nulliparous parturients.[89]

Side effects of intrathecal opioids include pruritis, nausea and vomiting, and urinary retention. Respiratory depression (due to cephalad spread of opioid) is rare when using lipid soluble opioids.

Use of a dilute concentration of a continuous epidural infusion (0.0625–0.1% bupivacaine) provides sensory analgesia without motor block; consequently, it permits many parturients to ambulate during labor. Prior to ambulation, however, women should be observed for approximately 30 min to ensure maternal and fetal well-being, and be assessed for adequate motor function.

Paracervical block

The paracervical block utilizes local anesthetic placed via transvaginal injection in the lateral fornix on each side of the cervix. This produces anesthesia to the nerves of the uterus (T10–L1), which is helpful in relieving pain of the first-stage labor. Currently, this block is infrequently used because of a high incidence of potentially severe and life-threatening complications. These include the possibility of local anesthetic-induced maternal seizures from intravascular injection, hematoma formation, and a high incidence of fetal bradycardia, which has been reported in 10–70% of patients who receive these blocks. Fishburne *et al.*[90] suggested that the fetal bradycardia results from decreased placental perfusion due to drug-induced uterine artery vasoconstriction, although other theories include high blood concentrations of local anesthetic in the fetus, and an increase in uterine activity.[91] Because of these risks, paracervical block is considered to be a suboptimal choice when fetal compromise exists or is anticipated.[92]

Pudendal block

A pudendal block may be performed to reduce the pain of the second stage of labor, facilitate forceps delivery, or allow the performance of a painless episiotomy. The pudendal nerve (S2–S4) innervates the vagina and the perineum, but does not affect the pain felt from uterine contractions, so its block is ineffective for the first stage of labor. In addition, perineal analgesia is incomplete, so discomfort may be felt if the episiotomy is extended or the vaginal

delivery is difficult. This block is performed by anesthetizing the pudendal nerves as they travel just posterior to the junction of the ischial spine and the sacrospinous ligament. Aspiration prior to injection of the local anesthetic is essential in order to decrease the risks associated with paracervical block. This block has a low incidence of maternal hypotension and fetal bradycardia when properly performed. Rare complications of paracervical block, however, include infection, puncture of the rectum, hematoma formation, toxic reactions of the local anesthetic, and sciatic nerve block if the needle is inserted too deeply.[93]

Lumbar sympathetic blocks

Another nerve block that can be considered an alternative to central neuraxial block is the paravertebral lumbar sympathetic technique. This block can be used to block transmission of pain from the uterus during the first stage of labor.[94] Although it is a technically difficult block to perform, it appears to be associated with far fewer complications when compared to paracervical blockade.

Local anesthetic agents

Bupivacaine

Bupivacaine is an amide local anesthetic commonly used for spinal and epidural anesthesia and analgesia in obstetric practice. Its long duration of action, differential sensory to motor block,[95] and relative lack of tachyphylaxis makes it a popular choice.

The placental transfer of bupivacaine, as with other amide local anesthetics, is governed by two factors: the degree of ionization at physiologic pH, and the extent of protein binding. Bupivacaine has a pK_a of 8.05 (highly ionized at physiologic pH) and is 95% protein-bound; thus, it has limited transfer to the placenta when compared to other local anesthetics. In the 1980s, safety concerns were raised following reports of several deaths related to cardiovascular or cardiac toxicity of bupivacaine.[96,97] Following these reports, the FDA prohibited the use of 0.75% concentration epidural solution in obstetric practice. Bupivacaine consists of two stereoisomers *S*(–) and *R*(+) and is marketed as a racemic mixture of these. When separated, the R component was found to predominantly contribute to bupivacaine's toxicity.[98,99] This led researchers to develop the use of *S*(–) isomers for clinical practice, and it resulted in the introduction of ropivacaine (the *S*-isomer of the propyl homologue of bupivacaine) and levobupivacaine (the *S*-isomer of bupivacaine).

Lidocaine

Lidocaine has been used for many years in obstetric anesthesia. It has a quick onset with an intermediate duration of action. Umbilical venous/maternal venous ratios reported in the literature are approximately 0.4–0.6.[100] Although lidocaine is very popular for use as an epidural local anesthetic for operative delivery (especially 2% with epinephrine), it is not popular for providing labor analgesia. While early reports suggested that lidocaine compromised neonatal neurobehavioral function,[101] numerous follow-up studies have not confirmed this.[102] Controversy has developed regarding the use of 5% hyperbaric lidocaine for spinal anesthesia because of reports of transient neurologic symptoms. In 1994, the FDA issued a letter concerning 5% hyperbaric lidocaine; it urged physicians to dilute the lidocaine with saline or CSF prior to injection. These precautions were subsequently incorporated into the package insert for this drug. More recent data indicate, however, that the 2.5% and 2% solutions may still cause transient radicular irritation (TRI).[103] As a result, and despite many years of use without clinical evidence of neurotoxicity, many anesthesiologists have abandoned the use of 5% hyperbaric lidocaine for cesarean section.

2-Chloroprocaine

2-Chloroprocaine is an ester local anesthetic with a rapid onset time and short-lived duration of action. Its rapid metabolism by ester hydrolysis ($t_{1/2}$=45 s) makes it a very safe agent for use in obstetrics since almost no drug crosses the placenta.[104] Because of this and its speed of onset, its primary role in obstetric anesthesia is for establishment of epidural anesthesia for emergency cesarean (when an epidural catheter is already in place). In addition to its short duration of action, a potential disadvantage of chloroprocaine is that it may interfere with the action of epidurally administered opioids.[105] This interaction may be due to antagonism at the mu and kappa receptors.[106] Furthermore, it has been reported that chloroprocaine may also interfere with the action of epidurally administered bupivacaine.[107] Previous preparations of 2-chloroprocaine were considered to be potentially neurotoxic because of reports of arachnoiditis following unintentional subarachnoid injection of this anesthetic.[108] Subsequent reports incriminated the low pH of the anesthetic along with the preservatives used for stabilization.[109] Removal of metabisulfite and methylparaben have decreased the risk of neurotoxicity. However, caution is advised because despite the availability of preservative-free preparations (marketed as MPF or methylparaben free), older formulations containing preservatives are still commercially available.[110]

Levobupivacaine

Based on the evidence that the cardiotoxicity of bupivacaine was more pronounced with the *R*(+) enantiomer, the *S*(–) enantiomer of bupivacaine (levobupivacaine), was developed for clinical use. Levobupivacaine is a long-acting local anesthetic with a similar clinical profile to bupivacaine. Both animal and human volunteer studies have demonstrated its greater safety profile compared to racemic bupivacaine.

Assessment of sensory block between 0.5% bupivacaine and 0.5% levobupivacaine demonstrated no difference in adequacy of block or time taken to reach a surgically adequate block. Similarly, other authors have recently reported that there was no difference with regard to onset or duration of sensory block when patients received either levobupivacaine 0.5% or bupivacaine 0.5% for cesarean section. In addition, the onset and regression of sensory and motor blockade, quality of anesthesia, and muscle relaxation were comparable between the two groups.[111] Levobupivacaine has also been used to provide epidural analgesia for labor. A recent multicenter study comparing levobupivacaine and bupivacaine reported these drugs have equivalent analgesic efficacy. In addition, motor blockade was similar between the groups.[112] As with other local anesthetics, recent evidence suggests that fentanyl significantly reduces levobupivacaine requirements for epidural analgesia in labor.[113]

Ropivacaine

Ropivacaine is a homolog of mepivacaine and bupivacaine, and was the first *S*-levo isomer local anesthetic to be marketed. Ropivacaine is less soluble than bupivacaine and therefore may be less potent. While clinical evidence suggests that the two drugs might be similar in potency,[114] Minimum Local Anesthetic Concentration (MLAC) studies have suggested that the analgesic potency of ropivacaine was 0.60 (0.47–0.75) relative to bupivacaine. Claims for reduced toxicity and motor block must be considered with differences in analgesic potency kept in mind,[115] because, in theory, more drug would need to be administered and any safety advantage might be minimized.

Psychoprophylaxis – non-pharmacological methods

'Natural childbirth' stems from a phrase coined by Grantley Dick-Read in 1933; he believed that childbirth was a painless process that did not need medical intervention if the mother was adequately prepared.[116] The Pavlovian methods of controlling childbirth pain used in Russia were adapted by the French obstetrician Fernand Lamaze in the late 1950s, and his work popularized natural childbirth as an option for parturients. This method focuses on teaching the mother conditioned reflexes to overcome the pain as well as the fear of childbirth. It also employs an education program, human support during labor, breathing techniques, relaxation techniques, a strong focus of attention, and specific activities to assist concentrate during contractions. Indeed, even the effect of the presence of another woman during labor to support the expectant mother has been shown to have a positive effect on outcomes, including duration of labor.[117]

Transcutanaeous electrical nerve stimulation

Transcutanaeous electrical nerve stimulation (TENS) is thought to reduce pain by nociceptive inhibition at a presynaptic level in the dorsal horn by limiting central transmission. Electrical stimulation preferentially activates low threshold myelinated nerves. Afferent inhibition effects inhibit propagation of nociception along unmyelinated small 'c' fibers by blocking impulses to target cells in the substantia gelatinosa of the dorsal horn. TENS is also thought to enhance release of endorphins and dynorphins centrally.[118] Placement of electrode pads over the lower back in the distribution of T10–L1 has been shown to provide some degree of analgesia for some patients in early labor.[119] However, other reports have failed to demonstrate its effectiveness for labor analgesia or as an adjunct to epidural analgesia.[120,121]

Anesthetic drugs and the fetus

After drug uptake into the maternal circulation, a portion of the drug will cross the placenta and enter the fetal circulation. The amount of drug that ultimately is delivered to the fetus will depend on numerous factors, including uterine blood flow, the characteristics of the drug itself, and the characteristics of the placenta.

Placental transfer of drugs

Since the placenta has the properties of a lipid membrane, the physiochemical factors related to transfer may be described by the Fick law, which states that:

$$Q/T = KA\,(C_m - C_f)/D$$

where Q/T is the rate of diffusion, A is area of placenta involved in diffusion, C_m is the maternal blood concentration, C_f is the fetal blood concentration, D is the thickness of the membrane, and K is the diffusion constant which is unique to each drug and is dependent on the properties of the drug itself including its degree of ionization, lipid solubility, protein binding, and molecular weight.

Factors that favor transfer across the placenta include low molecular weight, low degree of ionization, high lipid solubility, and low protein binding.[122] Since most anesthetic drugs are weak bases, a decrease in pH of the blood (acidemia) will increase the percentage of drug that will be in the ionized form. This will decrease the amount of drug transferred across the placenta.

The increasing ionization of most drugs with decreasing pH may cause high levels of drugs to accumulate in the fetus. For example, if lidocaine is transferred from the blood of the mother to an acidemic fetus, the lower pH of the fetal blood will increase ionization of the lidocaine. This additional ionization may make the lidocaine less able to diffuse back across the placental membrane to the mother. Thus, the ratio of lidocaine level in the fetus compared to the lidocaine level in the mother's blood

will be higher. This phenomenon is known as *fetal ion trapping*, and explains why increased blood levels of anesthetic drugs may be seen in the compromised (acidemic) fetus.[123]

Fetal circulation and anesthetic drugs

During general anesthesia for cesarean section, the mother is unconscious and her muscles paralyzed. The newborn child, however, is removed from the uterus fully awake and moving. This is explained by maternal circulation and the physiochemical processes of drug transfer across the placenta from mother to fetus.[124] An additional factor is the unique physiology of the fetal circulation.[125] The lack of muscle paralysis in the newborn is explained by the highly ionized nature of muscle relaxants, which permits minimal drug to cross the placental membrane to enter the fetal circulation. However, induction drugs (such as thiopental) freely pass through the placental membrane. The lack of rapid fetal effect of these drugs is explained by the fetal circulation. Drugs crossing the placenta are directed to the liver which will act as a reservoir for a portion of the drug. Some of the drug reaching the fetal circulation, however, will bypass the liver via the ductus venosus and proceed to the right atrium via the inferior vena cava. From the right atrium, a portion of the drug will be shunted via the foramen ovale to the left-sided circulation from which eventually it will reach the fetal brain, where the greatest effect will occur. However, a majority of the drug that enters the right ventricle passes through the ductus arteriosus into the lower systemic circulation, with very little drug reaching the brain.

Regional anesthesia and drug effects in the newborn

A well-conducted regional anesthetic given for pain control in labor will have no long-term neurobehavioral effects in the newborn. Local anesthetics injected into the intrathecal or epidural space have very limited uptake into the maternal circulation. Opioids injected into the intrathecal space for labor require only small doses compared to those needed for analgesia via the intravenous route. This results in low maternal blood levels and distribution to the fetus. The acid–base status of infants whose mothers receive epidural anesthesia during the first stage of labor is more favorable than when mothers do not receive regional anesthesia. Apgar scores are not affected in mothers receiving epidural analgesia, even when continuous epidural infusions of low-dose bupivacaine and fentanyl are maintained for many hours.[126]

Uterine activity and anesthesia

In the uterus there are α_1- and β_2-adrenergic receptors. Stimulation of α-receptors increases uterine tone, while β-stimulation produces uterine relaxation. The pain and stress of labor causes the adrenal gland to release epinephrine, which has primarily β_2-stimulating properties. This may reduce uterine contractility and slow the progress of labor. However, labor analgesia and anesthesia, because they decrease maternal pain and the stress response, may decrease adrenal epinephrine secretion.

The effect of neuraxial anesthesia on the progress of labor depends on when it is administered. If given during the active phase of labor, epidural analgesia will have little effect on the progress of labor and may even increase uterine activity. This is presumed to be due to a decreased release of epinephrine from the maternal adrenal gland in response to a decrease in pain. Systemic narcotics may also have a negative impact on labor. When given during the latent phase of labor they generally reduce uterine contractility, but when given after labor is well established they generally have no effect or increase uterine contractility.

Uterine blood flow and anesthesia

Uterine blood flow is directly proportional to uterine perfusion pressure and inversely proportional to uterine vascular resistance. Uterine perfusion pressure is the difference between uterine arterial pressure and uterine venous pressure. Since uterine arterial pressure is proportional to maternal mean blood pressure, anything that decreases maternal blood pressure will ultimately decrease transfer of respiratory gases across the placenta. This may result in a compromised, acidotic fetus. Anything that increases uterine vascular resistance may also have a negative effect on the fetus because it decreases uterine blood flow.

Anesthetic agents may both directly and indirectly change uterine blood flow. Regional anesthesia may decrease maternal blood pressure and thus indirectly impact on uterine blood flow. This may be due to the sympathectomy caused by local anesthetics, particularly if the patient is hypovolemic. Deep general anesthesia with volatile agents may also decrease maternal blood pressure due to decreases in systemic venous resistance and/or cardiac output. These unwanted effects of both regional and general anesthesia may be exaggerated if aortocaval compression is present.

Very high concentrations of local anesthetics in the uterine circulation may cause an increase in uterine vascular resistance. This may occur when large doses of local anesthetics are accidentally given intravenously. In animal studies, vasopressor agents that directly stimulate α_1-adrenergic receptors, such as phenylephrine, norepinephrine and epinephrine, have been associated with increased intrinsic vascular resistance in the uterine vasculature. Ephedrine has been considered the vasopressor of choice in obstetric anesthesia because it does not decrease uterine blood flow. This is because ephedrine has primarily direct β_1-adrenergic agonist activity. It has

some α-stimulating effects, but this is by an indirect mechanism (release of catecholamines from sympathetic terminals instead of directly stimulating the α_1-receptors). Recently, many anesthesiologists have begun using phenylephrine or a combination of phenylephrine and ephedrine to treat hypotension in the parturient following administration of neuraxial analgesia or anesthesia.[127]

Increased uterine tone may also decrease uterine vascular resistance. This occurs with physiologic contractions associated with labor and may be especially pronounced with oxytocin infusions, resulting in tetanic contractions. Accidental intravascular injections of large amounts of local anesthetics can also cause increased uterine tone, which may result in fetal compromise.

Anesthesia for cesarean section

Cesarean birth has become the most common hospital-based operative procedure in the United States and accounts for more than 25% of all live births.[128] The increased use of the procedure has been attributed to the liberalization of indications for fetal 'distress' as well as elective repeat cesarean sections.[129] The most common indications for cesarean delivery include 'failure to progress', non-reassuring fetal status, cephalopelvic disproportion, malpresentation, prematurity, and prior uterine surgery. The choice of anesthesia for cesarean section depends on the indications for the surgery, degree of urgency, maternal status, and the desires of the patient.

Regional anesthesia for cesarean section

The use of regional anesthesia has dramatically increased, and since 1997 that of general anesthesia for cesarean section has been steadily decreasing in the United States.[130] Regional anesthesia techniques have several advantages, including a decreased risk of failed intubation, and aspiration of gastric contents, avoidance of depressant agents, and the ability of the mother to remain awake and participate in the birthing experience. In addition, it has been suggested that blood loss is reduced under regional anesthesia for cesarean delivery.[131]

Although epidural, spinal, continuous spinal, and CSE techniques have all been advocated, most straightforward cesarean sections are now performed under single-shot spinal anesthesia which has been found to be faster, provide a superior block, and is more cost effective than alternative techniques.[132]

Spinal anesthesia

Spinal anesthesia offers many advantages for cesarean delivery. It has a rapid onset and provides a dense sensory block. Because of the small doses used, there is little risk of local anesthetic toxicity, and there is minimal transfer of drug to the fetus. In addition, failure rates including incomplete or patchy blocks are very infrequent with spinal anesthesia. Disadvantages of this technique include the finite duration of anesthesia and a higher incidence of hypotension, associated with the very fast onset and associated sympathetic blockade.

Spinal anesthesia can be initiated with the patient either in the sitting or the lateral position and using either plain or hyperbaric solutions. Each method has its advantages and disadvantages. The sitting position, however, appears to be optimal for placement of a neuraxial block in the obese parturient.[133] Hyperbaric solutions have an advantage of greater predictability of block height than plain solutions, and they allow the anesthesiologist the ability to adjust block height by adjusting table position.[134]

Despite achieving an adequate (T4) block, some women under spinal anesthesia will experience some degree of visceral discomfort during cesarean section. This is particularly true in situations in which the obstetrician exteriorizes the uterus. Quality of the spinal anesthesia has been reported to be improved by the addition of epinephrine,[135] morphine,[136] fentanyl,[137] or sufentanil.[138]

Epidural anesthesia

When flexibility is necessary (e.g., for a potentially prolonged cesarean section or need to bring up a block slowly), a catheter technique is optimal, and an epidural approach is often chosen. In addition, women with an indwelling epidural catheter for labor who require cesarean section usually receive medication via that catheter. In high-risk parturients, such as women with 'difficult airways', epidurals are often placed early so they will be available in the event that emergency cesarean section becomes necessary. This illustrates the importance of continuous assessment of epidural catheters and their effectiveness during labor.

The ideal local anesthetic agent for cesarean section should provide rapid onset of dense sensory or motor block with an appropriate duration of action. Commonly used agents include 2-chloroprocaine, lidocaine, and bupivacaine. As compared to spinal anesthesia, very large doses of local anesthetic are used to achieve adequate levels for cesarean section. Epidural catheters can migrate and even a negative aspiration of the catheter does not absolutely rule out intrathecal or intravascular placement. Since large volumes of potentially toxic local anesthetics are administered via an epidural catheter, several measures can be utilized to reduce the risks of local anesthetic toxicity. First, the catheter should be aspirated before use and an appropriate test dose administered. Second, the anesthetic should be administered in fractionated doses. Last, safer drugs (such as chloroprocaine and lidocaine) or the newer amide local anesthetics (such as ropivacaine and levobupivacaine) should be considered.

Intraoperative analgesia under epidural anesthesia may be improved if fentanyl (50–100 μg)[139] or sufentanil (10–20 μg)[141] are added to the local anesthetic. Clonidine has also been used as an additive to epidural local anesthetics, but it has been associated with sedation, bradycardia, and hypotension.[141]

Combined spinal–epidural technique

The combined spinal–epidural (CSE) technique has recently increased in popularity.[143] The advantage of this technique is that it provides rapid onset of dense surgical anesthesia while allowing the ability to prolong the block with an epidural catheter. In addition, because the block can be supplemented at any time, the CSE technique allows the use of smaller doses of spinal local anesthetics which may, in turn, reduce the incidence of high spinal block and hypotension.[143]

Continuous spinal anesthesia

Continuous spinal anesthesia has many potential advantages as compared to single-shot spinal or continuous epidural techniques. The classic technique required the use of large bore epidural needles or a 32-gauge microcatheter inserted through a 26-gauge spinal needle.[144] The technique rapidly gained in popularity despite technical difficulties, but, as previously described, it was abandoned following withdrawal of these catheters by the FDA. The advantages of continuous spinal anesthesia, however, remain and macrocatheters (e.g., placing an epidural catheter intrathecally) can still be used in high-risk parturients. In order to perform a continuous spinal anesthetic, the anesthesiologist intentionally pierces the dura with an epidural needle and then threads the epidural catheter 3 cm within the intrathecal space. Catheter placement can be tested by aspiration of CSF. Since a catheter is being used, smaller doses can be given in an incremental fashion. This is particularly advantageous in high-risk parturients such as those with cardiac disease, respiratory disease, morbid obesity, and those with neuromuscular disease. In order to reduce the risk of headache following this technique, the epidural needle should be turned so that it is parallel to the dural fibers at the time of insertion. In addition, to reduce further the risk of headache, it has been suggested that several steps be taken, including leaving the epidural catheter *in situ* for more than 12 h and injecting a bolus of preservative-free normal saline prior to its removal.[145]

General anesthesia

Although the use of general anesthesia for cesarean delivery has dramatically declined during recent decades, it is still necessary for the management of several situations, including maternal hemorrhage, overt coagulopathy, life-threatening fetal compromise, or in cases in which patients refuse regional anesthesia. A recent study found that anesthesia-related maternal mortality associated with regional anesthesia has declined, but the number of deaths involving general anesthesia has remained relatively constant. This has led to an increase in the relative risk of fatality during general anesthesia to more than 16 times that for regional.[146] Despite these problems, general anesthesia has the advantages of speed of induction, control of the airway, and superior hemodynamics. The frequency of the use of general anesthesia is dependant on many factors including the number of patients at that institution who receive epidural analgesia for labor, the percentage of high-risk parturients, and the skills of the anesthesiologist. Although there are no absolute contraindications to general anesthesia, certain conditions such as malignant hyperthermia or the patient with a difficult airway may require a modified anesthetic technique. Potential problems associated with general anesthesia for cesarean section include failed intubation, pulmonary aspiration of gastric contents, neonatal depression, and maternal awareness.

Steps to provide anesthesia in the healthy parturient for cesarean section include the following:

(1) Administer a non-particulate antacid. Additional agents such as metoclopramide or an H2-blocker should be considered in the patient at high risk for aspiration or failed intubation.
(2) Apply routine monitors including EKG, pulse oximetry, and capnography. Ensure that suction is functioning and that failed intubation equipment is readily available.
(3) Position patient with left uterine displacement and optimize airway position.
(4) Denitrogenate with high flow of oxygen for 3–5 minutes or four vital capacity breaths.
(5) After the drapes are applied and the surgeon is ready, initiate a rapid sequence induction. Apply cricoid pressure and continue this pressure until correct position of the endotracheal tube is verified and cuff is inflated. In hypotensive crises, ketamine 1–1.5 mg/kg should be substituted for thiopenthal. A defasiculating dose of muscle relaxant is not necessary.
(6) Ventilate with 50% oxygen and 50% nitrous oxide and volatile agent as necessary. Maintain normocarbia and use muscle relaxation as necessary with either a non-depolarizing muscle relaxant or succinylcholine infusion. Administer 0.5–0.75 MAC of volatile agent until delivery.
(7) After delivery, increase nitrous oxide to 70%, discontinue or reduce volatile agent, administer opioid and benzodiazepine. Add oxytocin to intravenous fluids.
(8) Insert orogastric tube prior to completion of surgery.
(9) Reverse neuromuscular blockade, as necessary, at completion of surgery.
(10) Extubate when patient is awake, adequately reversed, and following commands.

Failed endotracheal intubation

A study of anesthesia-related deaths in the United States between 1979 and 1990 revealed that the case fatality rate with general anesthesia was 16.7 times greater than with regional anesthesia.[146] Most anesthesia-related deaths were due to hypoxemia when difficulties securing the airway were encountered. The most commonly occurring adverse respiratory events have been failure to intubate, failure to recognize esophageal intubation, and failure to ventilate. It has been recently reported that airway evaluation can often identify the parturient with a difficult airway, but it was not performed in upwards of 10% of cases in which maternal mortality occurred.[147] Others have evaluated the risk factors associated with difficult intubation, and it appears that the greatest risks are associated with a Mallampatti 4 airway, short neck, protruding maxillary incisors, and mandibular recession.[148] From these data, an estimated prediction of a difficult airway has been calculated. Regardless of the initial assessment, all patients must have a repeat airway examination performed before initiation of anesthesia for cesarean section because it has been demonstrated that pregnancy and labor may be associated with changes in the maternal airway.[149,150]

Complications of regional anesthesia in the pregnant patient

Hypotension

Hypotension is defined as a fall of systolic blood pressure to less than 100 mmHg or > 20% from baseline values. The reported incidence of hypotension in the parturient receiving a conduction anesthetic varies depending on the type of anesthetic, the extent of the block, the type of prophylaxis, the site and frequency of blood pressure monitoring, and the definition of hypotension.[151] Ralston and Shnider[152] reported that the incidence of hypotension was reduced from 82% to 14% by conservative measures, including administration of lactated Ringer's solution and left uterine displacement. Hypotension following induction or regional anesthesia occurs primarily as a result of the sympathetic blockade, since a block of sympathetic fibers will alter the blood vessel tone and cause vasodilatation. When hypotension is recognized and immediately treated, no negative sequelae occur. However, if hypotension is not adequately treated, it may have profound effects on fetal well-being.[153] These fetal effects are primarily due to a decrease in uterine blood flow. If maternal hypotension is not treated, the uterine blood flow may decrease to the point where fetal hypoxia and acidosis occur. This is because, at term, the placental vasculature is usually completely dilated. Any untoward fetal effects of regional anesthesia are due to the ensuing hypotension and are not secondary to the anesthesia *per se*.

Treatment of hypotension should start in the preanesthetic period with appropriate prophylaxis. An intravenous catheter must be inserted prior to initiation of the block and 500–1000 ml crystalloid should be administered in order to avoid hypotension associated with vasodilatation.[154] Since glucose easily crosses the placenta, the rapid administration of glucose-containing solutions may actually cause newborn hypoglycemia and are generally best avoided.[155] Left uterine displacement is also vital in order to avoid hypotension due to compression of the aorta and inferior vena cava.

If recognized and treated promptly, transient maternal hypotension should not be associated with maternal or neonatal morbidity.[156] As previously discussed, while intravenous ephedrine in 5–10 mg increments remains a first-line treatment, recent evidence supports the use of phenylephrine.[157] There appears to be no benefit in the prophylactic administration of commonly used doses of ephedrine.[158,159]

Accidental dural puncture

A relatively common and problematic complication of epidural placement is accidental puncture of the dura ('wet tap'), with an incidence of up to 3%.[160] This complication can lead to the development of a postdural puncture headache (PDPH) in the majority of cases.[161] The traditional management of accidental dural puncture has been to remove the epidural needle and reinsert it at a different interspace. In more recent years, however, many anesthesiologists have advocated that the epidural catheter should be placed into the CSF; providing intrathecal delivery of local anesthetic as a continuous spinal technique. This establishes rapid and effective pain relief that can be very carefully titrated. In addition, analysis of aggregate data from limited retrospective trials demonstrated a significant reduction in the incidence of PDPH and the need for epidural blood patch in those patients who received continuous spinal analgesia after unintentional dural puncture.[162] In addition, the catheter provides excellent labor analgesia and a route toward almost instant onset of blockade for cesarean section. Furthermore, a recent review suggested that spinal headache could be reduced if five steps were followed. They include: (1) injection of the cerebrospinal fluid from the epidural syringe back into the subarachnoid space through the epidural needle; (2) insertion of an epidural catheter into the subarachnoid space; (3) injection of preservative-free normal saline through the intrathecal catheter before its removal; (4) administration of continuous intrathecal labor analgesia; and (5) leaving the intrathecal catheter in-situ for a total of 12–20 h.[163]

Not all postpartum headaches occur as a result of a dural puncture. A large analysis reported that headaches occurred in 15% of parturients who did not receive an epidural, and 12% of parturients who had an epidural but did not show evidence of dural puncture.[164] Other causes of headache in the

postpartum period include non-specific headache, migraine, hypertension, pneumocephalus, infection including sinusitis and meningitis, cortical vein thrombosis, and intracerebral pathology. A recent report also suggested that neurocysticercosis should be considered in the differential.[165] In addition, since coffee and tea intake is so prevalent, one should also consider caffeine withdrawal in the differential diagnosis. A PDPH has a typical presentation of a postural headache that is worsened by standing or straining and relieved by lying down. Generally, PDPH is initially treated conservatively with increased intake of both oral and intravenous fluid administration of caffeine and analgesics. There is no evidence, however, that increasing the fluid intake will cause a greater production of CSF; recently, the use of intravenous fluid has been questioned.

Drugs that have been used to treat PDPH include caffeine, vasopressin, theophyline, sumatriptan, and ACTH. Caffeine, a cerebral vasoconstrictor, has been successfully used, but the effects appear to be transient.[166] Caffeine treatment is more effective when headaches are the result of smaller rather than larger needles. A negative aspect of the caffeine treatment is that patients may feel anxious and unable to sleep. In addition, there are reports of seizures and cardiac arrhythmias following caffeine administration.[167] While some of the caffeine is present in breast milk, it has not been shown to have a deleterious effect on the newborn.[168]

If symptoms are severe enough to limit a mother's activity, or if evidence of cranial nerve involvement appears, an epidural blood patch (EBP) should be considered. The epidural blood patch was first described more than 40 years ago and it still appears to be the most effective treatment for PDPH. Although early reports suggested immediate and permanent cure of PDPH, it has recently been suggested that complete success rates are approximately 75% and that the effectiveness of EBP is decreased if the dural puncture is caused by a large-bore needle.[169] One study reported that although immediate relief occurred in almost all patients, a permanent cure following EBP was achieved in only 61%.[170] The success of an epidural blood patch is probably not as simple as the clotted blood obstructing the dural tear. CSF volume replacement is not rapid, yet the symptoms resolve almost immediately. Other explanations for the effectiveness of EBP include the increase in CSF pressure and cerebral vasoconstriction.[171] There is some controversy regarding the optimal volume of blood to be injected; however, most practitioners use 15–25 ml and stop injection of the blood if severe pain occurs. While the incidence of complications (especially back pain) increases with increased volume of blood injected, it appears that increased volume also increases the success rate.[172]

Total spinal

This rare complication occurs when the level of anesthesia rises higher than C4 and thus prevents movement of the diaphragm and effective spontaneous ventilation. It may occur from an excessive spread of local anesthesia after intrathecal injection of a correct dose, from injection of a miscalculated dose of a spinal drug, or more commonly, from an inadvertent intrathecal injection of an epidural dose. This complication may occur initially or during the course of a previously uneventful epidural anesthetic.[173] Treatment consists of immediate establishment of an airway and initiation of adequate ventilation. Since these patients cannot protect their airway, endotracheal intubation will allow for ventilation while providing protection against aspiration. Severe bradycardia progressing to cardiac asystole has been reported and therefore bradycardia should be treated early.[174] If cardiac arrest occurs, a full resuscitation dose of epinephrine should be immediately administered.[175]

Table 177.5 Maximum recommended doses of local anesthetics commonly used in obstetrics*

	Dosage (mg/kg) LA without epinephrine	LA with epinephrine
Lidocaine	4–5	7
Mepivacaine	5–6	8–9
Bupivacaine, ropivacaine	2.5–3	2.5–3
Chloroprocaine	8–10	15

*Caution note – the recommended maximum safe dose is influenced by many factors and should be adjusted to the site of injection

Local anesthetic toxicity

Local anesthetic toxicity occurs when high blood concentrations of local anesthetics occur. This can occur following accidental intravascular injection of therapeutic amounts of epidural local anesthetic or by administration of massive doses of local anesthetic into the proper space. Accidental intravascular injection can occur with any regional anesthetic technique. Table 177.5 lists the maximal recommended doses of the local anesthetics commonly used in obstetrics.

Local anesthetic toxicity is usually recognizable by prodromal symptoms of central nervous system toxicity, including ringing in the ears, perioral numbness, disorientation, and excitation. These symptoms, if unchecked, may progress to frank convulsions. Cardiovascular toxicity often begins with hypertension but quickly progresses to hypotension, arrhythmias, and cardiac arrest. Because it generally takes a higher blood level of local anesthetic to induce cardiovascular symptoms, the central nervous system and cardiovascular reactions may be usually temporally separated. Of all the local anesthetics commonly used in obstetrics, bupivacaine represents the greatest

Table 177.6 Resuscitative equipment and medications that should be immediately available*

Emergency medications	Hemodynamic support – atropine, ephedrine, phenylephrine, epinephrine
	Muscle relaxation – succinylcholine
	Hypnotics – propofol, thiopental, brevital
Equipment for emergency airway management	Laryngoscope and assorted blades
	Endotracheal tubes, with stylets
	Laryngeal mask airways of assorted sizes
	Device for emergency non-surgical airway ventilation-jet ventilator, combitube
	Device for emergency surgical airway
	Oxygen source
	Self-inflating bag and mask for positive pressure ventilation
	Suction source with tubing and catheters

*The items listed represent suggestions and should be customized to preferences and skills of the practitioner and health care facility

risk due to its potential for cardiotoxicity and the difficulty associated with resuscitation of these patients.[176] Morishima *et al.* demonstrated that bupivacaine is more cardiotoxic than other local anesthetics.[177] Because of these risks, the manufacturers of bupivacaine have suggested that 0.75% bupivacaine not be used for obstetric patients. To minimize the risks associated with this drug, it has become standard practice to administer local anesthetics by incremental injection. As noted previously, newer local anesthetics, including levobupivacaine and ropivacaine, may prove to offer improved qualities while being less cardiotoxic.[178–180]

Treatment of local anesthetic toxicity involves preventive measures (such as aspiration of the catheter and fractionated doses), early recognition and prompt response. Adequate oxygenation is of paramount importance and endotracheal intubation usually needs to be immediately performed. Benzodiazepines may be used to stop the convulsions. If cardiac arrest occurs, the patient should be treated with cardiac massage, defibrillation and cardiotonic drugs, as necessary. Emergency cesarean delivery should be considered, as early delivery following cardiac arrest has been demonstrated to increase the chances of maternal as well as infant survival.[181] Table 177.6 outlines the resuscitative medications and equipment that should be immediately available.

Allergic reactions to local anesthetics

True allergy to local anesthetics is rare.[182] Currently used local anesthetics are either amino esters or amides. Allergic reactions to amide local anesthetics (e.g., lidocaine, bupivacaine) are extremely rare. However, allergic reactions to esters (procaine, tetracaine) occur more commonly. Since allergy to *p*-aminobenzoic acid might suggest a potential for allergic reaction to an ester (which gets broken down to PABA), patients with a possible history of local anesthetic allergy should be asked about allergies to cosmetics and sunscreens. If a patient states that she has had an allergic reaction to a local anesthetic, she should be referred for an antepartum evaluation. Should a patient arrive on labor and delivery with a question of local anesthetic allergy, a thorough and detailed clinical history (including the exact symptoms and timing of the supposed allergic reaction) may reveal a history of 'adverse reaction' and exclude true hypersensitivity.[183] Recent evidence suggests that latex allergy is increasing and may be the cause of anaphylaxis in the parturient. Physicians should be aware of this growing problem and be prepared to manage the patient with a known or suspected latex allergy.[184] Management of an allergic reaction to a local anesthetic will depend on the severity of reaction. Despite the potential for alterations of uterine blood flow, epinephrine is the drug of choice in severe reactions.

Neurological complications

Direct nerve injury from spinal or epidural needles is extremely rare. Pressure on the cord or intraneural injection causes severe pain. While neuraxial blockade may cause neurologic sequelae, it is important to note that not all neurologic complications after labor and delivery are due to administration of a regional anesthetic. The process of childbirth may itself cause neurologic sympotoms. In fact, the first documented case of maternal postpartum palsy was reported in 1838, prior to the introduction of either regional or general anesthesia.[185] Obstetric causes for neurologic injury include poor patient positioning, incorrectly positioned stirrups, prolonged application of retractors and difficult forceps application.[186] Potential neurologic complications of spinal and epidural anesthesia include epidural hematoma, epidural abscess, or meningitis. Chemical contaminants have also been reported as a cause of neurologic injury, but with the

use of disposable epidural and spinal kits and commercially prepared drug ampoules, chemical meningitis is exceedingly rare. Unfortunately, there continue to be case reports describing the neurologic sequelae of accidental administration of intravenous drugs into an epidural catheter.[187–189] These accidents can be prevented by vigilance, careful handling, and inspection of drug ampoules, and the use of portless epidural tubing.

Compression of the spinal cord by a spinal or epidural hematoma is a potentially devastating complication which, if diagnosed early, does not necessarily cause permanent neurologic sequelae. The incidence of neurologic injury resulting from hematoma associated with neuraxial anesthesia is very low, with estimates of 1 in 150,000 and 1 in 220,000 for epidural and spinal anesthesia, respectively.[190] A review of 61 cases of spinal hematoma associated with spinal or epidural anesthesia reported evidence of hemostatic abnormality in 68% of patients and difficult or bloody placements of needles and catheters in 25% of cases. A new risk factor for development of spinal hematoma is the high-risk parturient who is receiving low molecular weight heparin (LMWH). Recent guidelines by the American Society of Regional Anesthesia (ASRA) suggest that neuraxial techniques should be deferred for 10–12 h in the parturient who has received preoperative LMWH or 24 h for those parturients on higher doses of LMWH (e.g., enoxaparin 1 mg/kg twice daily).[192]

Backache

Low back pain is common following delivery. Many patients believe that back pain is linked in some way to epidural analgesia administered for labor; and the alleged relationship between labor epidurals and postpartum backache has been suggested by several retrospective studies.[192,193] Recently, however, prospective studies evaluating labor epidural analgesia and postpartum back pain failed to find a significant link between epidural placement and pain. One study reported that the incidence of postpartum backache in women who received epidural anesthesia was equivalent to those who did not (44% vs. 45%).[194] Further data analysis in that study demonstrated an association between new-onset postpartum back pain with greater weight and shorter stature; postpartum back pain was also associated with a previous history of back pain, greater weight, and younger age. Similarly, another recent study found no difference in the incidence of long-term low back pain in patients who received epidurals for labor compared to controls.[195]

Anesthesia for the high-risk parturient

Parturients are considered to be 'high risk' from an anesthesiology perspective if they have a preexisting medical condition, obstetric complication, a problem that can potentially necessitate an emergency cesarean section, or a potential uncertainty regarding anesthetic management.

Pre-eclampsia–eclampsia

Analgesia for vaginal delivery

Although in the past it had been suggested that epidural analgesia should not be performed in the pre-eclamptic patient, there is a growing body of opinion among anesthesiologists and obstetricians that epidural analgesia (if there is no coagulation abnormality) is the preferred method of providing analgesia to the pre-eclamptic.[196] Epidural analgesia offers several advantages, including:

(1) It may facilitate blood pressure management;
(2) It potentially increases uteroplacental perfusion by decreasing endogenous catecholamines;
(3) It allows a fast route for cesarean section, if necessary, without the use of general anesthesia.

Anesthesia for cesarean section

General anesthesia. If general anesthesia is necessary, one should consider the following:

(1) Laryngeal edema and other airway changes may make endotracheal intubation difficult.
(2) Hypertension may be worsened by laryngoscopy and therefore elevated blood pressure should be treated prior to induction of anesthesia. Drugs that have been suggested include: labetalol, hydralazine, nitroglycerin, trimethophan and nitroprusside.
(3) Magnesium sulfate may potentiate the effects of neuromuscular blocking agents.

Regional anesthesia. Although spinal anesthesia has recently been advocated by some authors,[197,198] others suggest that epidural anesthesia causes fewer changes in blood pressure and should be used when regional anesthesia is chosen for severely pre-eclamptic women undergoing cesarean section. Points to consider include:

(1) Epinephrine-containing local anesthetics[199] may exacerbate hypertension.
(2) Consider central venous line, or pulmonary artery catheter prior to initiation of epidural, if volume status is in question.
(3) Ephedrine (and phenylephrine) should be used in small incremental doses to treat hypotension.

Assessment of platelet function in pre-eclamptic women

It is generally accepted that if the platelet count in pre-eclampsia is greater than 100,000/mm^3, it is likely that the other indices of coagulation will be normal.

However, rarely, pre-eclamptic women may have a normal platelet count with abnormal platelet function. While in the past the bleeding time had been suggested as a good test to determine platelet function, it is no longer performed by most obstetric anesthesiologists since it has not been shown to predict the risk of hematoma formation. Rogers and Levin[200] stated that 'our analysis of bleeding time data from 640 publications reveals that the value of the test in diagnosis remains unclear'. Thromboelastography can be used as a bedside measure of viscoelastic changes but has not yet been shown to be predictive in pre-eclamptic women.

Regional anesthesia can be safely performed on the pre-eclamptic patient if:

(1) A recent platelet count is normal;
(2) The recent platelet count is not dramatically lower than the previous value;
(3) There is no clinical evidence of coagulopathy.

Antepartum hemorrhage

Placenta previa

Actively bleeding/major blood loss (general endotracheal anesthesia). The following steps should be taken:

(1) Get help; second intravenous placement;
(2) Intravenous fluid administration (via rapid infusion device with warmer, if available); and
(3) Rapid sequence induction; consider ketamine 1 mg/kg.

No active hemorrhage; hemodynamic stability. If there is no hypovolemia, epidural or spinal anesthesia may be used.

Placenta accreta

Since placenta previa in a patient for a repeat cesarean delivery may be associated with placenta accreta,[201] these patients should be treated as though major blood loss will occur. Two intravenous lines should be inserted, blood should be available, and the patient should be made aware that a cesarean hysterectomy may become necessary and that general anesthesia may be required to provide appropriate operating conditions and to protect her airway in the event of massive hemorrhage and cesarean hysterectomy. In an elective repeat cesarean delivery in a patient with a placenta previa, regional anesthesia may be used and if hemodynamics remain stable, and may be continued even if a hysterectomy following delivery is performed. In a recent multi-institutional study, 12 patients received epidural anesthesia for elective or emergency cesarean hysterectomy and none required intraoperative induction of general anesthesia.[202] Should the patient become unstable, however, general anesthesia should be considered.

Fetal distress

The American College of Obstetricians and Gynecologists has issued a Committee Opinion entitled *Anesthesia for Emergency Deliveries*.[203] They suggest:

(1) Failed intubation and pulmonary aspiration remain prominent causes of maternal morbidity and mortality from anesthesia.
(2) The obstetric care team should be alert to the presence of risk factors that place the parturient at increased risk for complications from emergency general or regional anesthesia.
(3) When risk factors are identified, the obstetrician should obtain an antepartum anesthesia consultation.
(4) Strategies should be developed to help minimize the need for emergency induction of general anesthesia. Such strategies might include early placement of an epidural or spinal catheter.

Regional anesthesia for fetal distress

(1) Consider placement of epidural catheters in patients who are at increased risk for operative delivery [non-reassuring fetal heart rate tracing, intrauterine growth restriction, pre-eclampsia, preterm labor, vaginal birth after cesarean section (VBAC), multiple gestations, breech presentation, diabetes].
(2) If an epidural is functioning at the time of cesarean section, administer 15–20 ml of 3% chloroprocaine in 5 ml increments. Onset of block is within 3–5 min. Chloroprocaine is rapidly metabolized in the mother and fetus and placental transfer is not increased in the presence of fetal acidosis.
(3) The use of spinal anesthesia for emergency cesarean section remains controversial, but is routinely practiced at many institutions. Several authors have reported excellent results with spinal anesthesia in the presence of fetal distress. If the patient is not hypovolemic or acutely bleeding and if anesthesia can be achieved quickly (i.e., the patient is not morbidly obese), spinal anesthesia is an attractive alternative to general anesthesia for emergency cesarean section. If early attempts at dural puncture are unsuccessful, the anesthesiologist must have the discipline to abandon further attempts and proceed with an alternative plan (such as general anesthesia).
(4) Intravenous fluid should be administered prior to initiation of a spinal anesthetic, but there is evidence that the anesthetic need not be delayed until the total amount of fluid is administered. Consider having pressure infusion bags available so that fluid can be administered quickly in the scenario in which a patient without prior intravenous fluid administration needs an emergency cesarean section.

(5) If possible, continue to monitor the fetal heart rate in the operating room while placing the regional anesthetic.
(6) In the absence of an ongoing epidural or continuous spinal anesthetic in a case of profound 'fetal distress' (e.g., profound acidosis or fetal bradycardia, not resolving) in a patient with a normal airway, general anesthesia (with a rapid sequence induction) should be considered.
(7) In the event of a history of a failed or difficult intubation, the anesthesiologist should consider an awake fiberoptic intubation or regional anesthetic.
(8) A large bore atraumatic needle (such as a 22-gauge Sprotte needle) may speed the initiation of a spinal while still minimizing the risk of postdural puncture headache.

Summary

Obstetric anesthesia and the anesthesiologist play an important role on the labor and delivery suite. To optimize patient care and to offer the best care to our patients, cooperation and open lines of communication between all health care personnel are required.

178 Instrumental delivery

H. Hopp and P. Husslein

Vaginal operative delivery involves the extraction of the fetus by traction on its head. In some cases, this may also involve correcting the fetal attitude and position. Whether an operative delivery is appropriate depends on the circumstances of the labor, the informed consent of the mother, and the relevant experience and ability of the obstetrician. Because vaginal operative births can cause severe trauma to mother and child, it is generally accepted that they should be avoided when possible. The option of completely eliminating assisted vaginal delivery is, however, unreasonable, as there are situations in obstetrics in which such deliveries would be less traumatic and safer for a mother and child than a cesarean section or allowing the labor to continue.

In general, the degree of risk that accrues to mother and child is directly proportional to how high the head of the fetus lies in the birth canal when the delivery has begun, and to how much the sagittal suture deviates from the antero-posterior axis of the pelvis at that time. Operative delivery should be resorted to only when necessary, and midcavity deliveries should be carried out only by qualified and experienced obstetricians.

Frequency and indications

In the state of Berlin, the number of vaginal operative births decreased from 10% to 8.6% during the 1990s and has been 8.1% since 2000. The proportion of forceps deliveries, in comparison to vacuum extraction, is about 20%. In Austria, the figure for vacuum extraction deliveries during the 1990s was just below 4%, and forceps deliveries just over 1%; in 2003, the frequencies of these were 4.7% and only 0.3%, respectively (Figure 178.1). In the United States, approximately 9% of births are assisted vaginal births, of which 3% are forceps and 6% vacuum assisted deliveries, with the proportion clearly shifting toward vacuum extraction in recent years.[1]

Vaginal operative delivery can be indicated for maternal or fetal reasons. Sometimes emergencies arise in response to evidence of fetal oxygen deprivation derived from fetal heart rate monitoring or blood gas analysis. In these urgent situations, judgment is required to determine what the safest and most expeditious mode of delivery should be.

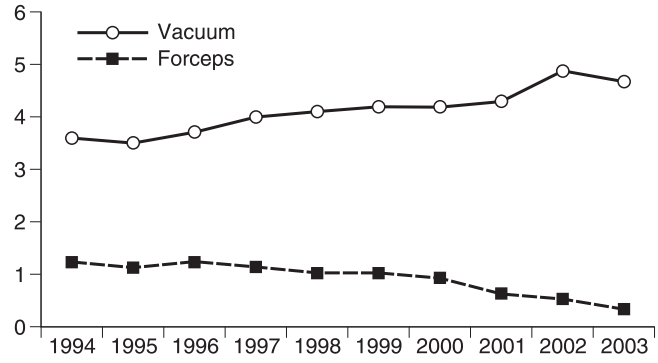

Figure 178.1 Instrumental delivery in Austria, 1994–2003.

In the event of contraction-induced acute fetal endangerment, intrauterine resuscitation measures should be used, including tocolysis when necessary, even if operative delivery is planned. This can serve to minimize further deterioration, and reduce the need for unnecessary emergency operations. If the infant's head is positioned suitably for forceps and there is a highly abnormal fetal heart rate pattern, the shortening of the bearing-down period in the second stage by operative delivery can reduce the risk of severe fetal acidosis. The heart rate pattern alone is not always adequate to make a reliable prediction of the fetal blood gas status; fetal capillary blood sampling can be an important correlative technique.

Maternal indications (sometimes combined with those related to the fetus) occur. An example would be severe pre-eclampsia, or abnormalities of fetal descent, particularly arrest of descent. If the fetus is in good health and the mother has sufficient energy reserves, the American College of Obstetricians and Gynecologists (2000) set the following maximum time limits for the expulsion phase of labor:[2] for nulliparas, 3 h with and 2 h without regional anesthesia; for multiparas, 2 h with and 1 h without regional anesthesia.

It is not uncommon for the birth to be delayed due to abnormalities of fetal position (e.g. occiput posterior) and attitude (e.g. marked deflexion). In such cases, the circumference of the head that must be accommodated by the birth canal is larger than if the head were well

flexed and anterior. Exhaustion of the mother can sometimes be an indication for operative delivery, as can the existence of various maternal diseases that would mitigate against excessive bearing-down efforts (e.g. cardiopulmonary and cerebrovascular diseases). For psychological reasons, vaginal operative deliveries should be subject to relatively strict indications and should not be carried out as prophylactic measures, which were, at one time, promoted.[3]

Conditions for operative delivery

A skillful operator working in the context of an appropriate indication ensures that the operative procedure will be as gentle as possible for the mother and fetus. Prior to the operation an accurate diagnosis must be established and documented in the record. This should include assessment or assurance of the following:

- The cervix is completely dilated
- Station of the fetal head
- Fetal presentation, position, and attitude
- Membranes must have ruptured
- Description of fetal pelvic relationships, and comment on the likelihood of disproportion
- Fetal condition
- Maternal condition.

Station of the fetal head

The precise determination of fetal station and the assessment of whether operative correction of any positional abnormalities is appropriate or possible are of utmost importance for the assisted vaginal delivery. The determination of station is based on the definition of the pelvic planes. In order to understand this concept, the pelvic inlet, the narrowest region of the pelvis, should be considered as one plane. The midpelvic region consists of a large curved cavity with anterior and posterior walls of different lengths; it reaches from the terminal plane of the pelvic inlet to the pelvic outlet plane.[4] The pelvic floor is anatomically equivalent to the pelvic diaphragm, which restricts the pelvic outlet surrounded by the bony pelvis. While the plane of passage cannot be determined accurately by vaginal examination, the level of the presenting part within the birth canal can be situated by indicating the number of centimeters below (negative values) or above (positive values) the midcavity plane. This division, according to DeLee,[3] considers the midcavity at the level of the ischial spines as the zero plane and allows the station of the presenting part to be determined in relation to it. Thus, the assessment of fetal descent is based on the station of the presenting part in relation to the station of the plane of passage at the pelvic inlet or midcavity (Figure 178.2). The exact station of the fetal head is assessed by clinical examination and must be documented prior to the operative procedure. The vaginal operative delivery should be carried out only if the station has been documented as being in the midcavity region or, preferably, on the pelvic floor.

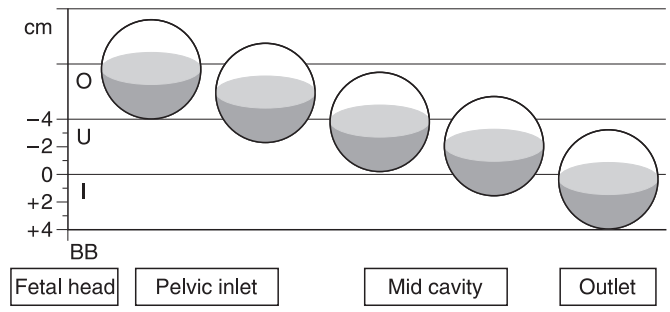

Figure 178.2 The determination of station of the presenting part and plane of passage, according to Hodge – parallel levels and according to De Lee – zero plane. BE Beckeneingang (Pelvic inlet), BM Beckenmitte (Mid cavity), BB Beckenboden (Pelvic floor), O Obere Schossfugenrandebene (Superior edge of the symphysis), U Untere Schossfugenrandebene (Inferior edge of the symphysis) I Interspinalebene (Level of the ischial spines), BB Beckenbodenebene (Pelvic floor plane)

With a vertex presentation, the midcavity position is reached when the occiput has completely engaged into the pelvis. The head has passed the pelvic inlet with its narrowest part at the level of the ischial spines and extends approximately 4 cm above the midcavity line. The leading edge of the head in the axis of the birth canal has reached the midcavity plane (station 0). The midpelvic position ends as soon as the presenting part has descended to the pelvic floor (+4). It follows that the fetal head, in a flexed position and with a palpable bony presenting part at 0 to +3 is in the midcavity.

When the station is in the midpelvic cavity, rotation has generally not been completed and instrumental deliveries from this area require a great deal of operative expertise. The degree of difficulty and danger for the operative delivery increases if the presenting part is at a station above +2, or if the sagittal suture deviates from the antero-posterior position by more than 45 degrees. If the obstetrician does not have the necessary expertise to perform such deliveries, cesarean section is generally preferred.

Operative delivery from the midcavity generally requires stricter indications than those done when the head has reached the pelvic floor, and should be carried out only in exceptional circumstances. Due to the fact that in most departments of obstetrics (at least in German-speaking countries) the proportion of births per trainee and junior level physicians has decreased quite considerably over recent years, it has become increasingly difficult to teach assisted vaginal deliveries. It is therefore anticipated that cesarean section will largely replace midpelvic operative deliveries in the near future.

When the presenting part has reached the pelvic floor (+4) the plane of passage (the biparietal

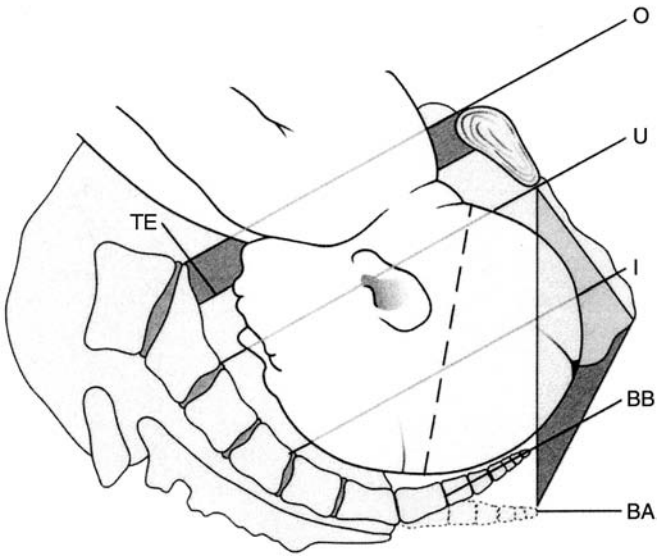

Figure 178.3 Head on the pelvic floor O Obere Schossfugenrandebene (Superior edge of the symphysis), U Untere Schossfugenrandebene (Inferior edge of the symphysis) I Interspinalebene (Level of the ischial spines), BB Beckenbodenebene (Pelvic floor plane), BA Beckenausgangsebene (Pelvic outlet level)

diameter of the head in a vertex presentation) is located parallel to the pelvic floor at the level of the ischial spines (Figure 178.3). At this time the spines and the sacral hollow are no longer readily palpable on vaginal examination. The head is visible in the vagina, and the sagittal suture has completed internal rotation, or deviates only slightly from the antero-posterior diameter of the pelvis (exceptions occur depending on the architecture of the pelvis). The majority of instrumental deliveries are performed with the presenting part at the pelvic floor. If the fetal head has descended to the introitus and remains visible between contractions, the plane of passage reaches the final phase of the birth mechanism and soon crowns at the pelvic outlet. If the baby's head does not progress naturally in this situation, operative delivery is referred to as outlet forceps or outlet vacuum extraction. In most situations, operative delivery in this situation serves primarily in a supporting role to help the mother cope with her physical exhaustion.

Contraindications

Assisted vaginal delivery of a flexed vertex presentation with the presenting part above 0 station is contraindicated; with a deflexed head the station must be at least +2. Because of the considerable distance between the plane of passage and the leading edge of the presenting part, when the head is deflexed it has generally not passed the pelvic inlet, despite the fact that the presenting part can be palpated at station 0. Operative vaginal delivery should never be attempted without clear evidence that the head has engaged.

With the station of the presenting part at or below +2, operative delivery should generally be attempted only when the sagittal suture is within 45 degrees of the antero-posterior position. Even so, it should be performed only by an experienced and qualified obstetrician. With a marked delay in progress during the second stage and clinical or sonographic evidence of fetal macrosomia, the decision to perform vaginal operative delivery is problematic, even if the fetal head has already reached the midcavity. If in doubt, a cesarean section is generally preferred. Incorrect assessments that disregard deflexed attitudes or marked molding that deforms the head are the most common contributors to failed vaginal operative delivery.

The above considerations must be taken into account independent of the choice of delivery instrument. The fact that a vacuum cup can be easily placed does not justify its use in an unengaged head. It is particularly important in situations in which there are alternative treatment methods being considered (vaginal operative delivery or cesarean delivery) to inform the patient of these options and to explain the relevant benefits and risks. In most situations, it is necessary to respect the mother's wishes. It cannot be stressed enough that these discussions should be started at the first sign of abnormalities during the pregnancy or labor that could necessitate vaginal operative delivery. That is the best way to guarantee that the mother has had sufficient opportunity to participate in the decision-making process.

Contraindications for vaginal operative delivery may be summarized as follows:

- Station of the presenting part above 0 with well-flexed vertex presentation
- Presenting part above +2 with a diagonal or transverse sagittal suture
- Station above +2 with deflexion of the head
- Cephalopelvic disproportion
- Abnormal progress in descent with fetal macrosomia

Forceps delivery technique

Instruments

Forceps consist of two blades, which are locked together in a crossed (e.g. Naegele, Simpson, Kielland) or in a parallel fashion (e.g. Shute, Bamberger Divergence forceps). Each blade consists of the headpiece, the shank, and the handle. The headpiece is curved to secure an application to the curvature of the contour of the fetal head. The conformation of the forceps to the axis of the pelvis is accomplished by the pelvic curvature of the shank, one of the factors that differentiate each forceps model.

Procedure

After it has been determined that forceps delivery will be done, the patient is placed in the dorsal lithotomy

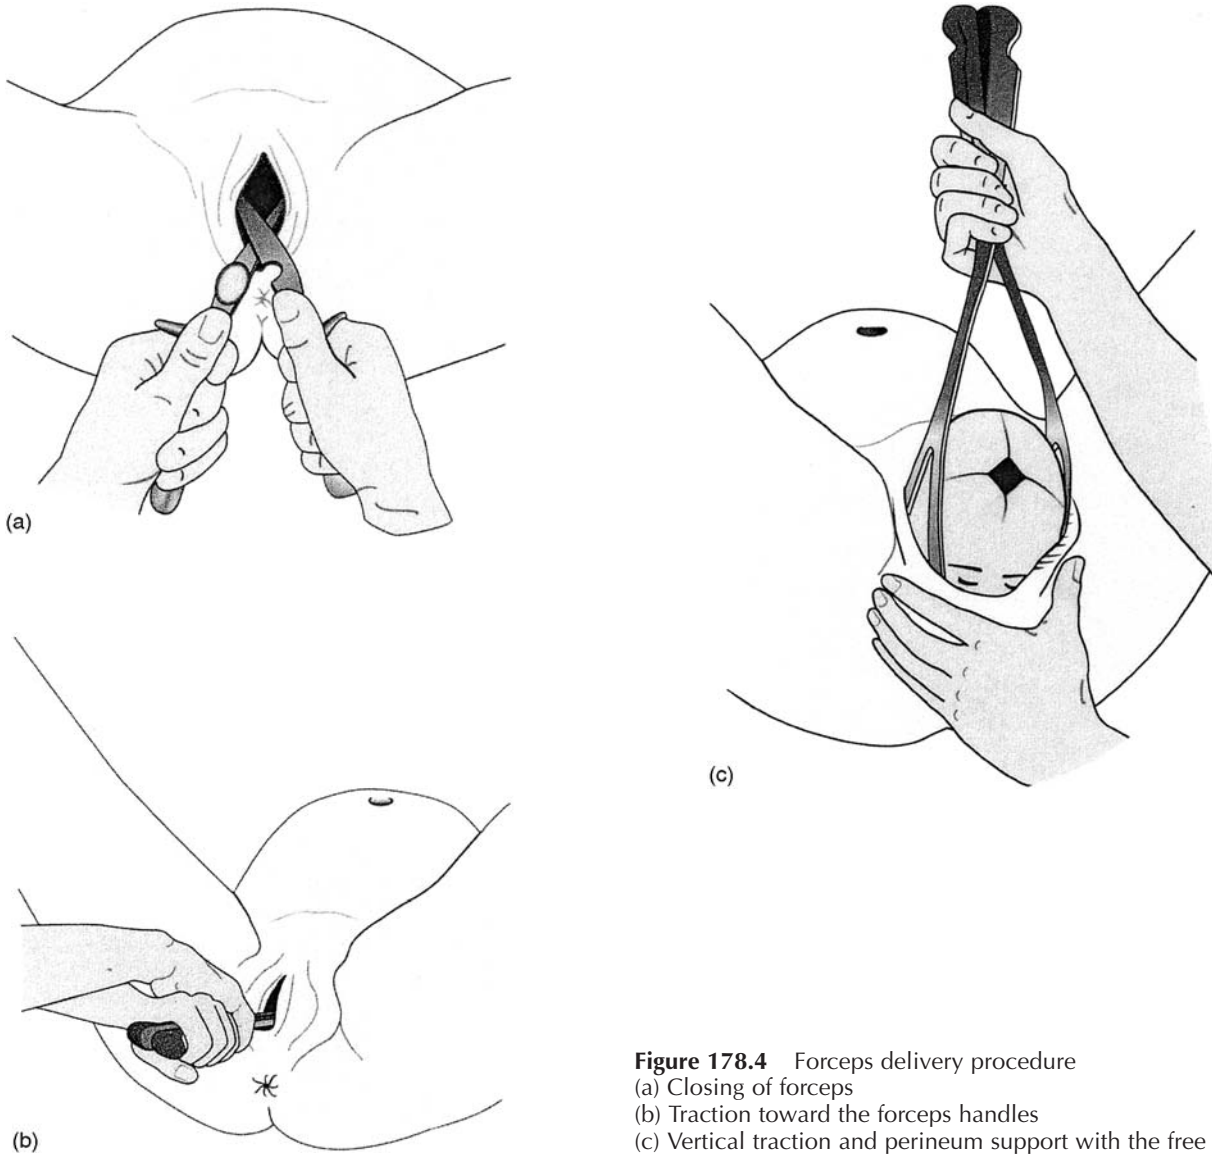

Figure 178.4 Forceps delivery procedure
(a) Closing of forceps
(b) Traction toward the forceps handles
(c) Vertical traction and perineum support with the free hand

position. It is useful to hold the closed forceps in front of the introitus in what will be their final orientation once they are inserted. It is helpful to judge the correctness of placement by observing the orientation of the handles after insertion. In order to achieve a biparietal application to a head in an anterior position using forceps with a crossed lock, the left hand takes the handle of the left blade, the convex side of the headpiece of which is on the left of the mother. The left hand positions the left blade so that it is initially vertical and hanging in front of the vulva. After the index and middle finger of the right hand have been placed between the vaginal wall and the fetal head, the blade should initially slide toward the sacrum and then, after lowering the handle along the inserted fingers, should slide into the birth canal. The right blade should be held with the right hand in the same manner, and must slide along the inserted fingers of the left hand between the vaginal wall and the fetal head after lowering the handle. If the head has not internally rotated completely, one blade must be made to wander, i.e. it must be guided gently from its initial position at insertion across the head toward the symphysis in order to be able to position the inserted blades biparietally in the first or second diameter of the lesser pelvis. The blades of the instrument can be locked by appropriate action of the relevant hand (Figure 178.4a).

The obstetrician's hand is placed in the vagina to ensure that the forceps are correctly positioned on the baby's head and that no soft tissue is trapped between them. A trial of traction is then carried out by the left hand, which grasps the lock of the upper handle and carries out a short tentative traction. The right hand checks the progression of the head during this maneuver. The progression of the head during the contraction combined with the trial of traction ensures that a gentle and successful delivery is likely to occur.

Both hands are then used to hold the handles of the forceps. The right hand grasps the instrument from

above at the level of the lock. The left hand has a firm grip on the handles and controls the instrument. With classical types of forceps, the right hand is clasped over the Busch–Drawhook. Never use excessive traction and ensure that the direction of traction is only in the midline of the pelvis and not laterally.

With an occiput anterior vertex presentation from low in the pelvis, the extraction from the curved position is slowly corrected into a flexion. Following the biparietal application, the forceps are pulled initially horizontally (toward the handles) until the hypomochlion (hairline at the nape of the neck) has reached the lower border of the symphysis pubis (Figure 178.4b). The deeper the head descends into the pelvis, the higher the handles of the forceps should be held. The delivery of the head is completed with the forceps handles being almost vertical. The obstetrician then turns either to the left or right side of the patient (to the side of the hand that is clasping the forceps above the lock) and, ideally, supports the perineum with his or her free hand (Figure 178.4c).

If the head has not internally rotated completely, the forceps extraction requires that flexion and rotation of the head be completed before traction is applied. The forceps blades are placed in a biparietal application. This requires the drifting of the anterior blade across the face of the fetus toward the symphysis. With the first attempt at traction, flexion is completed and the head is carefully rotated into the occiput anterior position. The minimum necessary force should be applied to ensure gentle progression of the fetus down the birth canal.

The forceps delivery of occiput posterior presentations must be appropriate to the relevant mechanical birthing procedures. The traction vector is more downward (posterior) than with an anterior vertex presentation; the head is flexed by raising the forceps handles after the fetal brow has stemmed under the symphysis. In other words, the exit mechanism of a fetal attitude abnormality is to be emulated during the extraction. Due to the risk of severe trauma to the fetus, vaginal operative delivery should not be carried out if the brow or face is presenting.

Vacuum extraction

To achieve sufficient traction with the vacuum cup, designed initially by Mälmstrom in 1954 (Figure 178.5), the area of the cup above the opening is expanded.[5] The various modifications of the original metal cup have retained this basic principle, which, with increasing vacuum, allows the soft tissues of the fetal scalp to be drawn into the cup. The artificially created caput succedaneum helps fix the cup to the fetal head, which allows the extraction. In addition to the metal cup, silicone vacuum cups have been developed that attach to the head by adhesion and do not cause the caput succedaneum (Figure 178.6). The advantage of this cup is the rapid accumulation of pressure. The vacuum strength, however, is relatively less, so this tool is recommended primarily for outlet deliveries.

Figure 178.5

Figure 178.6

In a 2001 review of nine studies on the effect of soft and rigid vacuum extractor cups, Johanson and Menon concluded that metal cups are more suitable for occiput posterior, transverse, and difficult occiput anterior positions.[7] The success rate of soft cups for vaginal deliveries is lower, but their use is associated with fewer scalp injuries to the baby. The technique of application involves choosing the largest cup possible that will fit in the available space. The cup is placed in the vagina, rotated 90 degrees, and placed on the fetal scalp. The cup is placed on the presenting part of an occiput anterior vertex presentation over the small (posterior) fontanel. With occiput posterior presentations it is placed over the anterior fontanel. The development of the vacuum should occur in several steps over a period of about 2 min. After the first step,

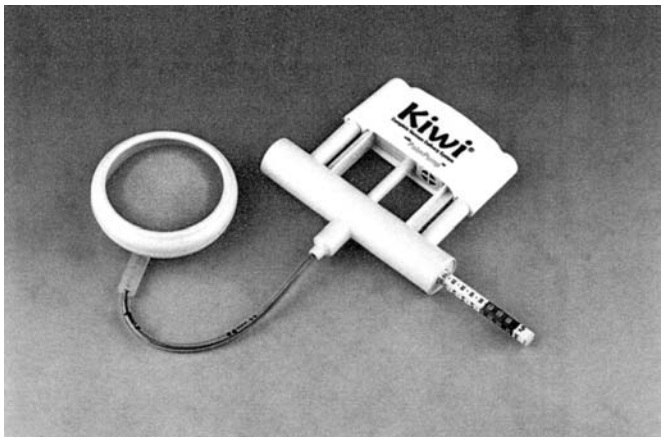

Figure 178.7

the position of the cup is rechecked to ensure that there is no maternal tissue between the fetal head and the vacuum cup. After the cup has been attached with low pressure of about 0.8 kg/cm^2 (600 mmHg) the trial traction confirms whether the head is descending appropriately during traction. Various manufacturers recommend different optimal vacuum pressures for their instrument, and physicians who use vacuum extraction instruments should be familiar with the recommendations and the specifications of the particular unit they employ.

In recent years, easy to use disposable rigid plastic vacuum cups (e.g. the Kiwi Omnicup) have been developed.[8] They allow the buildup of adequate pressure through an attachable hand pump (Figure 178.7). Maximum strength of the suction is more likely to be severely restricted by this method; however, the preparation for this form of operative delivery is much less complicated, which can have a positive psychological effect on the parents.

Traction on the vacuum device should occur coincident with maternal contractions, with increasing and decreasing traction forces paralleling those of the contraction. Using Kristeller pressure on the fundus can be helpful for the extraction if done gently.

When the fetus presents as occiput, anterior traction should occur in the axis of the birth canal and change according to the anatomic curve of the canal. The right hand is placed on the cross-handle of the cup; the left hand, or contact hand, confirms whether the fetal head is descending and whether its attitude is being maintained and rotation is proceeding as anticipated. As the head crowns, the perineum is supported to control the speed of the delivery. The obstetrician can step to the patient's left and support the perineum with the right hand. An episiotomy is not necessarily required, but can sometimes make it easier for the head to pass the terminal portions of the birth canal. After the head has been delivered, the vacuum pump is switched off. Following depressurization, the cup can be lifted easily from the head as soon as the shoulders and trunk are visible. The caput will usually resolve spontaneously after 12–24 h. The risk of cephalohematoma depends on the duration of traction, which should therefore be minimized.[9] Severe abrasions of fetal skin related to long periods of extraction, excessive pulling, and popping off of the metal or even the silicone vacuum cup can occur.

If fetal attitude is abnormal or internal rotation has not been completed, the vacuum cup should be placed over the portion of the head that will need to be flexed and rotated. Following careful reexamination of the situation, the eccentric application of the vacuum cup and the required direction of travel are established. With this kind of application, correction of fetal attitude can be attained. In most cases, the outstanding rotation is achieved by correction of the attitude and descent of the head.

Choice of instrument

Whether the attendant chooses to use obstetric forceps or the vacuum extractor depends on several factors. These include the condition of the fetus prior to attempts at delivery, and, of utmost importance, the expertise of the obstetrician with a particular instrument. Although in German-speaking countries the vacuum cup is the dominant instrument, for most of the last century forceps delivery was favored in the United States. Recently, however, increasing numbers of obstetric centers there have changed, and now emphasize vacuum extraction as the preferred approach in most situations. Although the American College of Obstetricians and Gynecologists recommended in 2000[2] that an experienced obstetrician should master both methods and use them depending on the given situation, this seems unrealistic, especially because the number of operative deliveries has been decreasing over recent decades, and as a consequence the opportunity to achieve and maintain expertise with two instruments is diminished.

With regard to the risk of trauma for full-term babies, there is no documented difference between the two methods. The listed advantages and disadvantages take into account the results of prospective studies[10–12] and were included in the recommendations of the German Institute for Gynecology and Obstetrics regarding vaginal operative delivery from the midcavity.[13]

Decisions favoring vacuum over forceps may have been influenced by the recent technical advances in vacuum cups ('soft cups', 'M-cup') and higher rate of injuries to the mother caused by forceps, with their potential for long-term effects on pelvic floor function. As a consequence, the frequency of vacuum extractions has been increasing progressively, even in countries that previously preferred the use of forceps.[14,15]

The conclusion of a *Cochrane Review* of the issue is that vacuum extraction is the preferred instrument to

minimize maternal morbidity. There is a counterbalancing benefit of forceps delivery, in the reduction of cephalohematomas and retinal hemorrhage.[16]

Midcavity delivery

Instrumental delivery from the midcavity is indicated to manage acute fetal distress or arrest of descent during the expulsion phase of labor. When there is a persistent fetal bradycardia during the terminal portion of labor, an experienced obstetrician will usually prefer vaginal operative delivery to cesarean section because of the ability to deliver the baby more expeditiously. Complex midcavity deliveries should, however, be avoided. Forced vacuum extractions should under no circumstances be carried out because of the risk of injury to the fetus. A rapid buildup of pressure, followed by popping off of the cup and related intracranial pressure fluctuations can contribute to a high risk of intracranial hemorrhage. The general guideline to initially attempt vaginal operative delivery rather than opting directly for cesarean section is no longer accepted universally. Under the premise that severe trauma for mother and child cannot always be avoided following vaginal operative deliveries and because of the increased danger of floor damage and permanent impairment of urinary and anal incontinence, instrumental delivery is questionable.

The significance of the patient's psychological well-being associated with the delivery experience has been highlighted as an important consideration in obstetric decision making. Recently, vaginal operative delivery was shown to be undesirable in this regard.[17] However, after long second stages of labor, cesarean section may be considered equally undesirable.[18] Certain changes in the anterior pelvic floor compartment (paravaginal defect) have already occurred in a high proportion of cases and the morbidity and mortality during a secondary cesarean section as compared to vaginal birth is still significantly increased. With a vaginal operative delivery, the risk of injury to mother and child is greater the higher the head lies and the more the sagittal suture deviates from the antero-posterior dimension of the pelvis. This type of operation should, therefore, be kept to a minimum or, preferably, avoided altogether. The midcavity delivery, especially with the station of the presenting part above +2, should be carried out by an experienced and qualified obstetrician. The decision to opt for an instrumental midcavity delivery is greatly influenced by the personal experience of the physician. In borderline situations, such as the station of a presenting part above +2 or a deviation of the sagittal suture more than 45° from the vertical with acute fetal distress, a cesarean section must be carried out immediately, especially in the presence of fetal growth restriction.

If it becomes apparent during the operation that the assessment of the station or the position of the head was incorrect, or if excessive force appears to be required, vaginal operative delivery must be abandoned. Therefore, the preparations for a possible emergency cesarean section must be made as soon as the decision for a vaginal operative delivery has been made. In some cases, the trial of forceps or vacuum extraction may require the presence of an anesthesiologist and surgical staff in the operating room. However, due to the severe psychological stress it creates for the mother a trial of operative delivery should remain an exception. The exceptional circumstances of these situations should always be discussed clearly with the patient and her partner. The neonatal morbidity associated with these deliveries should be stressed. The risk of intracranial bleeding in newborns is highest if cesarean section must be carried out after the failure of instrumental vaginal delivery.[19] This high risk of injury applies as well when delivery is attempted with both instruments in sequence, most commonly vacuum followed by forceps. We may conclude that a vaginal operative delivery should not generally be attempted if the success rate is considered to be low. Moreover, persistent attempts to complete the delivery vaginally when difficulties are encountered are fraught with danger. Keen judgment is necessary to avoid trauma in these situations, and abandoning attempts at forceps or vacuum in favor of cesarean should by no means be considered a failure; in fact it may signal good medical judgment.

Outlet instrumental delivery

Vaginal operative delivery when the head has reached the pelvic floor is considered safe and presents minimal risk to mother and fetus when performed properly. This is true when the head is in a direct anterior position, or with the sagittal suture no more than 45 degrees from the midline. When the head has assumed a transverse position the risks of forceps delivery are considerably greater, and the obstetrician must have expert knowledge of the mechanisms of labor and of the expertise required to correct abnormalities in fetal position and attitude. Often a persistent transverse position with the head relatively low in the pelvis results from the head failing to flex. The fontanelles are consequently palpated at the same level of the pelvis. Flexion of the head with the forceps or vacuum is necessary in order to allow internal rotation, descent, and delivery.

To accomplish this flexion using the vacuum extractor, the vacuum cup is positioned eccentrically over the small fontanelle, primary traction to the opposite side and dorsally is carried out until the head is in a direct anterior position. The increasing flexion of the head produces the passive rotation and

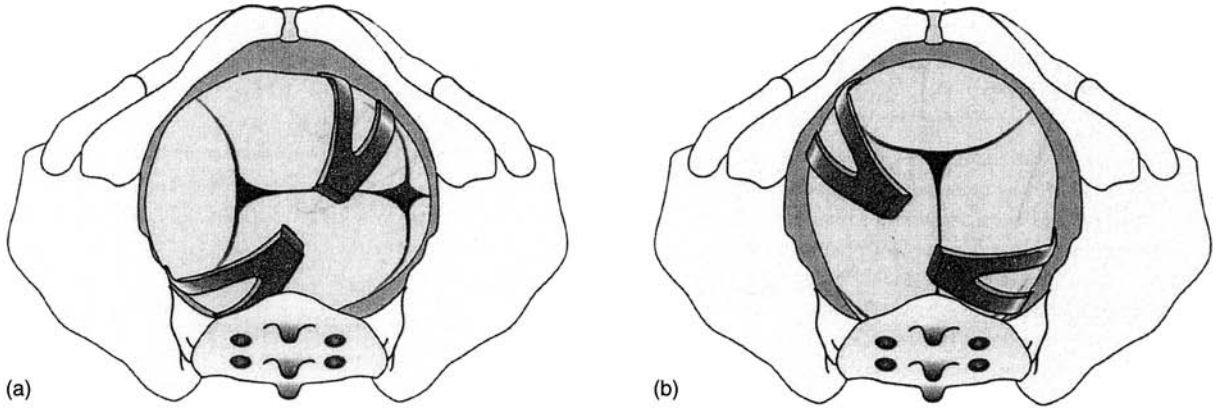

Figure 178.8 Forceps delivery of a fetus in low transverse position
a. With right low transverse position the forceps are positioned in the first diameter of the lesser pelvis
b. After rotation into vertical position, the progression of the occiput anterior vertex presentation follows

no further assistance is required in this regard. The subsequent traction follows the axis of the birth canal with appropriate changes in the direction.

Forceps may also be used to effect delivery of a fetus in a low transverse position. In a right occiput transverse, the left blade of the forceps is inserted first between the head and the sacrum. It is then moved carefully across the fetal face to achieve a diagonal application. The right blade is then inserted in the first diameter of the lesser pelvis (Figure 178.8a). During the extraction, the forceps must be initially rotated so that the small fontanelle is directed underneath the symphysis pubis. The resulting occiput anterior vertex presentation thereby progresses along the axis of the birth canal with no need to alter the application of the forceps before applying traction (Figure 178.8b).

Kielland forceps, a special instrument that lacks a pelvic curve, were designed especially for the rotation of the head in a transverse or posterior position. Some operators remove them after the rotation and apply classical forceps for the traction.

Complications

The risk of fetal and maternal injury related to forceps or vacuum use is increased in proportion to the complexity of the vaginal operative delivery. With fetal stations above +2, correct positioning of the forceps is difficult to achieve and often results in hematomas and abrasions of the fetal skin. When instrumental rotation of the head is necessary, rotational shearing forces can cause severe maternal injuries.

Technical conditions concerning vacuum extraction influence risk. Proper application of the cup is important, as is applying sufficient traction in the correct direction. The potentially lower tractive force generated when the cup is positioned eccentrically and the prolonged extraction time when it is necessary to correct fetal attitude and position increase the danger of the cup popping off, which can cause intracranial pressure fluctuations of up to 50 mmHg as well as injury to the scalp. Subgaleal hemorrhage may occur and be severe enough to be life-threatening. Excessive force or inappropriately long durations of traction should be avoided irrespective of the choice of instrument. The easy placement of the vacuum cup cannot *per se* justify attempting delivery from above the midpelvis.

Fetal injuries

Excessive force should under no circumstances be used during vacuum extraction because of substantial risks of injury to the fetus. The rapid development of pressure from excessively forceful traction followed by popping off of the cup can lead to considerable intracranial pressure fluctuations and a risk of intracranial hemorrhage.[20]

The most common external fetal trauma from vaginal operative delivery is cephalohematoma, which occurred in 3% of 1672 forceps deliveries and in 12% of 371 vacuum extractions.[21] The indication 'impending asphyxia' during vacuum extractions resulted in the frequency of cephalohematomas increasing 10-fold, presumably related to the perceived need for rapid development of the vacuum. In a review of 10 randomized studies of instrumental delivery, Johanson and Menon[16] concluded that cephalohematomas and retinal bleeding occurred more often during vacuum extractions than forceps delivery. The pathogenesis of retinal bleeding that is the consequence of instrumental delivery is uncertain, as are its long-term effects.

Skin injuries from the vacuum extractor can result in long-term alopecia, caused by scarring. Fetal injuries following forceps deliveries include abrasions of the skin, hematomas, and transient (rarely,

permanent) paresis of the facial nerves. Skull fractures and intracranial bleeding occur rarely with both methods if the operative technique is applied correctly.

Neonatal morbidity (5-min Apgar score less than 7 and umbilical artery pH below 7.20) following vaginal operative deliveries from the midcavity did not differ from instrumental delivery from the pelvic floor, despite the higher operative pressure and manipulation suffered by a head that has not yet descended or completed its flexion and rotation.[21] In comparing the results of midcavity forceps to cesarean delivery, one study showed no difference regarding the neonatal adjustment responses for the frequency of linguistic and neuromotor development delays.[22] There is, however, controversy about this area (see Chapter 187).

Maternal injuries

Maternal injuries, such as lacerations of the perineum, vagina, or cervix, are a function of the choice of instrument as well as the degree of expertise of the obstetrician. There is evidence[16] that vacuum extraction causes significantly fewer maternal injuries than does forceps delivery. Vacuum delivery is also associated with less use of regional and general anesthesia and less pain during delivery and in the 24 h after birth.

Cheong *et al.*[23] demonstrated that an approach to teaching precision in vaginal operative delivery did not necessarily increase the success rate but clearly reduced the number of complications to mother and child. Weitzel and Hopp[21] found little difference between instruments in the frequency of vaginal lacerations (25% during forceps deliveries and 23% during vacuum extractions). However, forceps deliveries resulted in significantly more third- and fourth-degree perineal tears than vacuum extraction (7.4% vs. 1.7%), particularly when performed from the midcavity. Similar results were found by Johanson *et al.*[11] and Sultan *et al.*[24] who reported that the number of hidden anal sphincter injuries (35% with spontaneous births) doubled following forceps deliveries. In a recent inquiry, their group[25] discovered that vaginal delivery, particularly after forceps or vacuum, was associated with a reduction of anal pressure and increase in sphincter trauma, independent of the choice of instrument.

The risk of injury to the mother and child is greater the higher the head lies and the more the sagittal suture deviates from the antero-posterior diameter of the pelvis at the time the instrumental delivery is begun.[2] Because injuries are relatively frequent, it is necessary to inspect the vagina and cervix thoroughly after each vaginal operative delivery to make an early diagnosis of these injuries and to repair them surgically.

Questionnaires received from patients showed that 18% of mothers who had vacuum deliveries and 27% who had forceps delivery reported unbearable pain during the delivery, and 7% and 18%, respectively, reported similarly of severe pain in the perineal region on the fourth day after delivery.[11,14] Garcia *et al.*[26] made the following statement: 'Compared to forceps delivery, women who deliver by vacuum extraction suffer less pain, but have more trouble with their babies'. This was confirmed in a study[27] in which a total of 31,000 vacuum and 19,000 forceps deliveries between 1991 and 1996 were examined. It was established that there was a relative risk of 0.48 of perineal trauma during vacuum extraction. The risk of subarachnoid bleeding was, however, 5.4 times greater and the risk of cephalohematoma was twofold higher compared to that of a forceps delivery.

For vaginal operative delivery, in addition to the benefit of pain relief, relaxation of the pelvic muscles by pudendal block analgesia (when the head is at the pelvic floor) or epidural anesthesia (when the head is in the midcavity) is beneficial. Pudendal block analgesia is easy to carry out transvaginally. It allows the active participation of the parturient during the delivery process. Vacuum delivery from the pelvic floor, however, is often carried out relatively easily and does not always require anesthesia.

Guidelines for operative vaginal delivery

Guidelines for the physician regarding the indications and contraindications for vaginal operative delivery are based on clinical experience as well as on recommendations of expert committees.[2,13,28] In terms of choice of instrument, convincing evidence is available based on meta-analyses.[7,16] These indicate that both forceps and the vacuum extractor are acceptable and safe instruments for vaginal operative delivery. The expertise of the operator is imperative for the choice of instrument in a particular situation. The meta-analyses indicate that vacuum extraction is associated with a higher rate of failed operations as well as more cephalohematomas, retinal bleeding, and neonatal jaundice. Forceps are associated with higher associated rates of regional or general anesthesia and maternal trauma. There is no apparent difference between the two instrument types with regard to cesarean section rates, Apgar scores, and 5-year follow-up of maternal and child condition. With regard to the choice of cup material, metal cups have a higher rate of scalp injuries than do silicone cups. The latter, however, are associated with more failed operations, especially with malpositions of the occiput and delivery from the midcavity.

Other recommendations are based on more limited or inconsistent scientific evidence.[10,19,29] It can be concluded that vaginal operative delivery from the midcavity with a station of +2 should be carried out if the clinically estimated likelihood of success is high

and if the obstetrician is qualified and trained in the method. The length of the vacuum application is related to the frequency of cephalohematoma formation and other forms of head trauma; therefore, this time should be minimized. The incidence of intracranial bleeding is highest in newborns delivered by cesarean section following a failed operative delivery. This risk is high as well when the combination of vacuum extraction and forceps is used. One can conclude that vaginal operative delivery should not be attempted if the *a priori* success rate is considered to be low.

Forensic viewpoint

The law in many countries is becoming increasingly strict with regard to the physician's requirement to inform the patient of the risks, benefits, and alternatives of medical procedures. As soon as there is any indication that the birth may require an operative procedure, the obstetrician must discuss this with the patient and request her authorization. The earlier this is carried out the more likely is the patient to be still fit enough to agree, i.e. still able to follow the conversation and weigh the advantages and risks of the recommended procedure.

If treatment alternatives can result in different levels of pain and suffering for the mother or fetus, or have different success rates, the doctor is required to inform the patient of these. It is important, especially with midcavity positioning of the baby's head, that the patient be aware of the different delivery options: vacuum extraction, forceps, and cesarean. Because the dangers to the mother and fetus are different in each of these methods, according to German and Austrian law, the mother has the option of either making her own interests a priority or choosing according to the best interests of her baby. There is great discrepancy between the legal requirement and the reality of birth, however, which results in the patient sometimes being completely overwhelmed with the decision process. Moreover, the need to process objectively information that may be complex and unfamiliar during a time of great stress is at best challenging, and at worst impossible. It is the physician's duty to respect the patient's autonomy and to assist her as best as possible to comprehend the situation and its potential harm and benefits.

This basic principle applies: the more urgent the situation, the shorter the time to inform the patient. If adequate information can still be conveyed in an emergency, but would delay an urgent operation, the doctor will be held liable in the case of damage.[11] With expected complications during a vaginal operative delivery (delivery with a possible requirement for a cesarean section), the patient must be informed of the increased fetal risk. The patient should ideally have already received basic information about vaginal and abdominal surgical procedures during her prenatal care, so that further information can be given in abbreviated form during an emergency.

179 Cesarean delivery

M. Pajntar

Cesarean delivery is defined as the delivery of the fetus through an incision in the abdominal wall (laparotomy) and the uterine wall (hysterotomy). This definition does not include the removal of the fetus from the abdominal cavity in the case of a rupture of the uterus or an abdominal pregnancy.[1]

Frequency

Monitoring of cesarean delivery rates is one way to take the pulse of obstetric practice and is a key factor in any form of obstetric audit and in international comparisons.[2] Over the last three to four decades, a substantial increase in cesarean delivery rates has been registered almost everywhere in the developed world. The incidence of cesarean delivery has increased from 4–5% to 15–25% on average; however, some countries report much higher rates (e.g. 40% in South Korea in 2000,[3] 52% in Italy, especially in Campania[4] in 2000, and in some hospitals in Brazil as high as 72%[5]). This increasing incidence has been observed despite the recommendation of the World Health Organization to keep it below 10–15%.[6]

Comparative studies of cesarean delivery rates in industrialized countries in the mid- to late 1980s showed a wide variation.[7–9] Almost a quarter of births in the USA and one-fifth in Canada were by cesarean delivery, compared with 6–7% in the Netherlands, Japan, Slovenia, and the former Czech Republic. The rates for other developed countries, for which data are available, ranged from 10% to 15%.[2] A further increase in almost all countries has been observed since the late 1990s: in 2002 it was 26.1% in the USA[10] and 13% in Slovenia.

Fear of litigation is widely held to have played a key part in the rise in the cesarean delivery rates in the USA and the UK.[11–13] In Canada, however, where litigation is not nearly so widespread as in the USA, the rate is nearly as high and well above that for most European countries.[12,13] One factor may be that doctors rather than midwives supervise most of the deliveries in the USA, and the countries in which midwife deliveries predominate generally have lower cesarean rates. Methods of payment may also be important: high rates have been observed among private patients, in private hospitals and in other settings where fee-for-service payments are involved.[14,15] In Sao Paolo, Brazil, the cesarean section rate in the private sector is 80%, and in the public health system, 32.1%.[16] Although the evidence that an elective operative delivery leads to a better outcome for term breeches[2,17,18] or for very small babies[17] is controversial, cesarean rates for these indications have also increased considerably in developed countries.[2]

Fetal distress and a previous cesarean delivery were important contributors to the growth of cesarean delivery rates in Scotland, Norway and Sweden in recent decades. Cesarean deliveries for a previous cesarean delivery and dystocia are the primary contributors to a substantially higher cesarean delivery rate in the USA.[19]

In the Netherlands, the largest increase in the cesarean delivery rate was found within the medium-risk group (singleton, at term, vertex presentation, normal birth weight, mothers aged 20–35 years and with a normal diastolic blood pressure). Although no evident pathology can be found in the data, these women no longer belonged to the low-risk group, because they had been referred to an obstetrician.[20]

Increasing cesarean delivery rates coincided with several changes in obstetric practice, including the introduction and dissemination of technology (ultrasound, cardiotocography); women becoming pregnant and delivering despite severe diseases; improved safety for women undergoing operative delivery;[9] the increased inclination of obstetricians to operative delivery, uncritically transferring the experiences of others to their own institution; and ever-less obstetrical experience in maternity hospitals with a decreasing number of deliveries, resulting in obstetricians being no longer skilled in various operative deliveries (e.g., breech delivery). Numerous articles have been published on the effects of vaginal delivery on the pelvic floor, urinary incontinence, pelvic organ prolapse, and, especially, fecal incontinence. All these publications conclude that cesarean section has a protective effect.[21] An association exists between pelvic floor damage and childbirth, but this cannot be attributed entirely to vaginal delivery and occurs after a cesarean delivery as well.[22]

The incidence of cesarean delivery performed on request without a medical indication is rising too. The reasons for this are not only a perceived medical

benefit but also social, cultural, and psychological factors. The legal and ethical issues of cesarean deliveries on request are complex. In dealing with requests for a cesarean section, obstetricians should establish the reasons for the request and provide clear, unbiased information based on the best available evidence.[22]

Although some claim that over the last 20 years the decrease in the perinatal mortality rate from 20–30 per 1000 to 10 per 1000 is mainly due to the increased cesarean delivery rate, there are others who disagree this. For example, while data show a close relationship between mortality and cesarean rate in the USA, the same fall in mortality was observed in Ireland without a significant change in its cesarean rate.[23] The decrease in perinatal mortality has occurred for various reasons, such as higher patient educational and socioeconomic levels and generally improved perinatal care, but primarily, it has been due to better neonatal intensive care and therapy.

Many studies have found no relationship between the frequency of cesarean delivery and the level of perinatal mortality. The comparison among different countries has also shown that in some populations, low levels of early infant mortality can be achieved despite a low cesarean delivery rate.[17,24] On the contrary, it has been found that in many instances, cesarean delivery increases the risk to the mother, fetus, and neonate. Different authors have demonstrated that the overall cesarean delivery rate can be safely lowered without increasing the maternal, fetal, or neonatal morbidity and mortality (from 17.5% to 7.8% and from 31.1% to 15.4%).[26–28]

A stated USA national goal by the year 2000 was to reduce the cesarean delivery rate from 25% to 15%. It was estimated that this 10% reduction in the national cesarean rate could save more than 1 billion US health care expenditure dollars annually.[29] This goal was, however, not achieved.

In our opinion, and that of many others,[20,30,31] the cesarean delivery rate could be decreased by decreasing the number of repeat cesareans, active management of dystocia, efforts to increase the vaginal breech delivery rate, improving methods of diagnosing fetal distress, and preventive and timely active management of labor (timely termination of pregnancy, augmentation of weak contractions, external cephalic version for a transverse lie and breech presentation, etc.).

Indications

There are various indications for cesarean delivery. Generally, they can be divided into fetal, maternal, and fetomaternal indications. However, they are greatly affected by the different policies of individual maternity hospitals, and by individuals; this has also been reported in a study performed in five maternity hospitals.[32] It was found that the clinical and nonclinical factors that influence the cesarean delivery rate are highly site-dependent. This implies that physicians practicing at different sites are influenced by different criteria when deciding whether a cesarean delivery should be performed.

The majority of cesareans are performed for fetal indications; a few are done solely for maternal reasons, and some for the benefit of both the fetus and the mother. The most frequent indications for a cesarean delivery found in the literature are the following: arrest of progress of labor (dystocia), fetal distress, breech presentation, and repeat cesarean delivery with various possible combinations. In different countries, the cesarean delivery rate by indications may be quite disparate.

In the early 1990s, the cesarean delivery rate was three times higher in the USA than in Slovenia, which was then known for a relatively low operative delivery rate (12% of deliveries were done by cesarean, vacuum extraction, or forceps).[24] The cesarean delivery rate for various indications in Slovenia was quite different. The relative share of repeat deliveries and dystocia was smaller, whereas for all other indications it was larger. The absolute rate for all other indications was 2.14% in Slovenia, even lower than in the USA (3.3%) (Table 179.1).

In Slovenia, with 19,108 deliveries in 1995, and an overall early neonatal mortality (over 500 g) of 2.4 per 1000 live births, the cesarean delivery rate was 9.2% in 1994 and 1995. The comparison between the time periods 1988–1991 and 1992–1995 (Table 179.1) shows an increase in cesarean deliveries with all indications, the highest being for breech presentation and the lowest for dystocia. Despite these good results, the cesarean delivery rate in Slovenia increased to 13% in 2002, while the early neonatal mortality rate remained the same (2.4 per 1000 live births).

Over the last few years, the number of cesarean deliveries done in response to patient request has been increasing. While for many women the experience of vaginal delivery is among the most fulfilling of their entire life, comparable only to sexuality-related moments of ecstasy, there are women who regard delivery as the worst thing ever to have happened to them, an experience attended by pain, fear, loneliness, and

Table 179.1 Cesarean delivery rates (per 100 deliveries) for selected indications in the United States and in Slovenia (the data for USA are adapted from Cunningham *et al.*[1])

	Rate (%)		
Indication	**USA, 1985**	**Slovenia 1988–1991**	**Slovenia 1992–1995**
Repeat section	9.0 (36)	1.25 (17.0)	1.55 (17.9)
Dystocia	7.6 (31)	1.41 (19.2)	1.56 (18.0)
Fetal distress	2.3 (9)	1.30 (17.7)	1.52 (17.6)
Breech	2.5 (10)	1.25 (17.0)	1.58 (18.3)
All others	3.3 (13)	2.14 (29.1)	2.44 (28.2)
Total	24.7 (100)	7.35 (100)	8.65 (100)

perhaps long-lasting negative consequences.[33] In some countries, the indication 'cesarean delivery on request' has been accepted and is documented in records; thus, in Norway the rate of cesarean delivery on request is known to have been 7.6% in recent years.[34] In most countries, this indication is not officially recognized. However, many believe[35] that a woman can always find an obstetrician willing to perform a cesarean section for non-medical reasons. Of course, the indications for these sections are hidden, mostly under the diagnosis of dystocia.

Many distinguish between absolute indications for a cesarean delivery, and clinical situations in which a cesarean delivery may be indicated (relative indications). However, there are many different opinions, especially concerning the clinical situations in which a cesarean delivery may be performed.

The absolute indications include the following.

(1) Placenta previa totalis (centralis)
(2) Placental abruption (with fetal distress, jeopardized mother)
(3) Cephalopelvic disproportion (evident)
(4) Umbilical cord prolapse (with incomplete cervical dilatation)
(5) Transverse lie
(6) Proven (pH) fetal distress (with incomplete cervical dilatation)
(7) Active genital herpes infection
(8) Obstructive benign and malignant tumors
(9) Impending maternal death.

The relative indications include the following.

(1) Previous classical cesarean delivery
(2) Previous uterine surgery
(3) Arrest of progress of labor (dystocia)
(4) Abnormal presentation
(5) Fetal anomalies
(6) Suspected fetal distress [fetal heart rate (FHR)]
(7) Multiple pregnancy (triplet or higher).

Decisions for cesarean for fetal distress must include thorough analysis, an interpretation of FHR pattern abnormalities, with consideration of the stage and progress of labor, and the presence of factors such as intrauterine growth restriction, thick meconium, and oligohydramnios.

Various maternal diseases are classified among the relative indications, i.e. cases in which the physician treating the basic disease fears an increased risk to the parturient, especially with prolonged and difficult labor. The risks to the fetus for various diseases, such as rhesus isoimmunization should also be taken into account.

Each relative indication provokes a higher risk if combined with another. All decisions for intrapartum cesarean should be strongly influenced by assessment of the progress of labor. The decision-making process should be influenced by evidence-based considerations when possible; but often there will be no good quality studies to bear on specific situations, and the obstetrician must use his or her own clinical wisdom and experience.

Contraindications

In modern obstetrics, with a good anesthesiology service, there are no absolute contraindications for a cesarean delivery, but there exist several relative contraindications.

The most common inappropriate reasons for cesarean include the following.

(1) Diagnosis of failed induction when the labor is still in a normal latent phase
(2) Diagnosis of inadequate uterine contractions when oxytocin stimulation has not been properly applied, or there has been exceedingly heavy sedation
(3) Diagnosis of abnormal fetal descent before complete cervical dilatation
(4) Breech presentation as the only indication
(5) Transverse lie without a previous attempt at external cephalic version
(6) Fetal distress (without a reliable cardiotocographic evaluation or pH measurement)
(7) One previous cesarean delivery
(8) Single or combined indications, such as advanced maternal age in a nullipara, infertility, high-risk pregnancy, etc.
(9) Intrauterine fetal demise.

Repeat cesarean

The attitude toward the management of labor after a previous cesarean has greatly changed over the last two decades. The policy of many maternity hospitals followed the principle of 'once a cesarean, always a cesarean' for many years. However, with the recognition that vaginal delivery can be effected safely after a cesarean, this policy has changed.

The main concerns about laboring after a prior cesarean delivery relate to the risk of uterine rupture and its consequences. These were most frequent when the cesarean was done through a vertical incision in the uterine fundus (now referred to a as a 'classical' cesarean), which was commonly performed in the past. Repeat cesarean delivery remains the leading indication in many maternity hospitals. In the USA in 1978 repeat cesarean deliveries were performed in 98.0% of cases, and represented 30% of all the indications for a cesarean delivery.[35] Repeat cesarean delivery was thus one of the main reasons for the increased cesarean delivery rate in the USA.

Once obstetricians began to do most cesareans using a low transverse uterine incision, the occurrence of uterine rupture decreased considerably, thus making the possibility of a vaginal delivery following a cesarean section more feasible. There is evidence that the mother with a previous low-segment vertical

cesarean delivery can undertake a trial of labor with relative maternal and perinatal safety. The likelihood of a successful outcome and the incidence of complications are comparable with those published for trials of labor after a previous low-segment transverse incision.[36]

A substantial reduction in the cesarean rate can be achieved safely and efficiently by using a trial of labor for appropriate cases with prior cesareans. In a study of 17,322 patients with a previous cesarean delivery, a trial of labor was used in 80% of women with one previous cesarean, 54% with two, and 30% with three and more. The success rate was significantly higher with one previous cesarean delivery (83%) than with two or more (75.3%).[37] Others report 75–81% success rates with trial of labor.[38–40] In a large retrospective analysis of trials of labor, the variables that significantly predicted success were prior vaginal delivery, malpresentation, pregnancy-induced hypertension, and Bishop score ≥ 4.[38]

The indications for a previous cesarean delivery, such as cephalopelvic disproportion or arrest in the progress of labor, are not absolute contraindications for trial of labor in a subsequent pregnancy. With these indications for a previous cesarean section, a trial of vaginal delivery was successful in 50–75% of women.[35–38] Multiple previous cesarean deliveries are not an absolute contraindication either. Comparative studies report results almost as favorable for trials of labor after two previous cesarean deliveries as after a single previous cesarean.[35] The maternal and perinatal mortality rates were not increased, but there were slightly more uterine dehiscences and lacerations of a minor degree (up to 3.8%).[35] A trial of labor for patients with more than one previous cesarean delivery is allowed under the conditions that permit prompt recognition and treatment of emergencies.

Thus, the results of many studies show the beneficial effect of trial of labor after a previous cesarean delivery, especially if there are no strict contraindications. The repeat cesarean delivery is done only if new indications for a cesarean occur.

A vertical lower uterine segment incision has been reintroduced in some maternity hospitals for preterm cesarean deliveries, because a thick undeveloped lower uterine segment may not safely accommodate a standard transverse incision. This seems to have resulted in more reports of uterine rupture. It has been found,[35] however, that they are not as frequent as with classical incisions, probably due to the preterm cesarean incision being made in the lower segment rather than in the fundus. The difference between uterine rupture following a lower transverse incision and that following a vertical incision on the uterine corpus is that the latter frequently occurs suddenly and unpredictably in pregnancy, and is thus more dangerous. According to our experience, there is usually no proper indication for a vertical incision in preterm labor. With an unripe lower uterine segment, we recommended making a transverse incision somewhat higher than in normal conditions.

Procedures with a trial of labor

The use of oxytocin for either induction or augmentation of labor in women with a prior cesarean had long been controversial. The overview of various reports shows that the use of oxytocin does not increase the incidence of rupture; therefore, it can be used for induction and augmentation of labor under the same conditions as in labor in an unscarred uterus.[42] In most Slovenian maternity hospitals, oxytocin has been successfully used in induction and augmentation of a trial of labor after a previous cesarean delivery for many years.

The use of analgesia and regional and epidural anesthesia has also been greatly discussed. In the opinion of some, analgesia could mask the pain and uterine sensitivity at the site of the scar, thus delaying identification of a rupture; others claim that the use of analgesia does not increase the risk of trial of labor after a previous cesarean delivery.[35]

In 1970, Greenhill[43] recommended that the uterus be digitally examined after every vaginal delivery. In some maternity hospitals, this recommendation is still being followed. Enkin[35] considers the question of the thinning or laceration of the uterus to be of a purely academic nature. If there is no bleeding, repair of injuries to the uterus is not necessary. Besides, no beneficial effect of a digital examination of the uterus following delivery has been reported so far. There is always a possibility of infection, or of enlarging a simple dehiscence into a greater rupture. Some recommend digital examination of the uterus only if significant bleeding persists more than 1 h after delivery. Improved techniques of cesarean delivery have almost abolished severe ruptures, and only one-half of uterine dehiscences are due to a previous cesarean delivery.

Conclusion

In the absence of an absolute contraindication to vaginal delivery, based on history and the situation in the current pregnancy, a trial of labor is highly recommended. The management of this labor follows the same principles as that of labor without a previous cesarean delivery, except that more careful monitoring is required for the development of risk factors, signs, or symptoms of uterine rupture. Should there be a threatened rupture of the uterus, the decision for cesarean delivery is made earlier than it might be in a labor without a uterine scar.

Cesarean delivery for breech presentation

Over recent decades, cesarean delivery rates for breech presentation have increased in most developed countries, thus contributing to the overall rise in the incidence of cesarean delivery (see Chapter 181). This approach is based on the experience of some obstetricians who have attempted to prevent the poor outcomes of vaginal breech delivery by recourse to

cesarean section, beginning especially after publication of the studies of Kubli and colleagues and Ingemarsson and associates pointing towards acidemia and adverse long-term sequelae for the newborn after vaginal breech delivery.[44] The rates of cesarean delivery thereafter continued to rise; thus, in many European and North American maternity hospitals, especially in small ones, breech presentation *per se* is an accepted indication for a cesarean delivery. Over the last two decades, the management of breech delivery has changed from mainly vaginal to principally abdominal delivery[45] in some maternity units, while in some others this policy has never been accepted.[46–48] In maternity units with moderate policy, the cesarean delivery rate in mature breech deliveries has in many European countries increased to 30–40%.[46,48]

Authors of numerous studies propose a policy of either routine cesarean or selective vaginal breech delivery. Some claim that the registered data on singleton-term breech deliveries imply that vaginal delivery is associated with increased morbidity and mortality.[49] The results of many other studies suggest that a routine cesarean delivery does not in itself guarantee a reduction in neonatal morbidity and mortality, and should not be promoted at the expense of maternal health.[48,50,51] Poor perinatal outcomes of breech deliveries are primarily related to factors other than breech presentation; moreover, the route of delivery in infants weighing more than 1500 g does not influence neonatal outcome.[52] Cesarean delivery solely for breech presentation in birth weights of more than 1500 g does not appear to be justified.[53] Observational data, based on the Slovenian perinatal database, suggested better outcomes in 5012 singleton breeches delivered vaginally than in those delivered by cesarean.[54]

The increased cesarean delivery rate in breech presentation has resulted in a 5- to 25-fold higher maternal mortality rate[53] and up to a 38-fold increase in maternal morbidity.[54,55] Cesarean delivery can reduce the risk of adverse childhood neurologic outcomes for those born with myelomeningocele and may reduce the rate of brachial plexus palsies, neonatal herpes virus and human immunodeficiency virus (HIV) infections. However, children born by cesarean have no reduced risk of childhood neurologic problems or cerebral palsy that can be documented.[56]

While some[57] report better outcomes of cesarean deliveries in babies weighing between 1000 and 1500 g, others are of the opinion that there are no differences between the respective modes of delivery in this weight group. In a prospective study, Weisbach *et al.*[58] found no differences in the outcome of delivery of babies of less than 1500 g according to the route of delivery. Among breeches, the route of delivery does not significantly influence the outcome among complete and frank presentations; abdominal delivery may offer some benefit for footling breeches.

An observational study using the Slovenian database[59] showed that the outcomes of 6020 singletons in breech presentation weighing more than 1000 g (excluding the babies with lethal malformations and stillbirths) delivered vaginally using the Bracht or Covianov maneuver were most favorable in terms of early neonatal mortality and some signs of neonatal morbidity. Less-favorable outcomes were achieved with abdominal deliveries, and the poorest by all kinds of vaginal extraction.

Conclusions

On the basis of recommendations by the International Federation of Gynecology and Obstetrics Committee on Perinatal Health, Eskes and Wallenburg[44] proposed a solution to the problem, i.e. external cephalic version at term, as well as the use of physicians well trained and experienced in handling vaginal breech delivery.

Complications of cesarean delivery

Maternal morbidity and mortality

Maternal morbidity following a cesarean is much higher than following a vaginal delivery, the main causes being infections, hemorrhage and injuries to the urinary tract. Infections are very common; 10–80% of women have elevated body temperature, usually due to endometritis.[60] Dehiscences and wound infections are less frequent. Infections are often associated with low socioeconomic status of the mother, frequent vaginal examinations, long duration of labor, and a long interval from rupture of membranes to cesarean delivery. In long labor, in which delivery starts more than 6 h after the rupture of the membranes, endometritis occurs in up to 85% of cases.[7]

In a meta-analysis of several prospective studies, Enkin[35] found that febrile morbidity was significantly less frequent in the vaginal (2.4–23.1%) than in the cesarean delivery group (9.8–37.7%). In addition, blood transfusion, infection of the abdominal wound, thromboembolic complications, anesthesia-associated complications, pyelonephritis, pneumonia, and septicemia were also less frequent in the vaginal delivery group. Between the two groups, no significant differences in perinatal morbidity and mortality were found.

In many cesarean deliveries blood loss is great, especially with placenta previa, placental abruption, pre-eclampsia, and multiple pregnancy. It depends on the surgical technique used; it is greater if a classical longitudinal incision is made into the uterine corpus. It is less when a transverse or a small longitudinal incision in the lower uterine segment is made. If a transverse incision is made too low in the lower uterine segment of an unripe uterus, uterine arteries may often be injured.

The incidence of injuries to the urinary bladder in a cesarean delivery is 0.3%. The incidence may be higher in a repeat cesarean.[9] Injuries to the urinary bladder are more frequent in the presence of adhesions between the bladder and the anterior abdominal

wall. Injuries to the ureter occur less frequently, mainly when attempts are made to stop the bleeding from major uterine vessels.

Late complications of cesarean delivery include intestinal obstruction from adhesions, dehiscence of the uterine scar in subsequent pregnancies, and incisional hernia in a longitudinal skin incision (laparotomia mediana inferioris). Multiple cesarean deliveries pose little risk to the mother, but may be associated with an increased neonatal risk, attributed mainly to a preterm non-elective cesarean delivery.[57]

In developed countries, maternal mortality related to cesarean delivery has decreased over the last two decades. In the USA and Great Britain, maternal mortality is less than 1 per 1000 cesarean deliveries. In other parts of the world, maternal mortality resulting from cesarean delivery is markedly higher.[61] Generally, it is 2–4 times higher than with vaginal delivery.[61] The main causes of death following a cesarean delivery are infections, hemorrhage, pulmonary embolism, and anesthesia-associated complications, the most frequent being aspiration pneumonia and cardiopulmonary arrest. Cesarean delivery was an important underlying cause of death in Norway and contributed to the increased maternal death ratio in the last decade.[62]

Neonatal morbidity

Cesarean delivery is not always atraumatic to the fetus. Although injuries are fewer than with vaginal delivery, they are also relatively frequent during cesarean section, especially in premature babies and in forceful deliveries or extractions. The fetal head in the vertex presentation is sometimes injured when the head is low in the birth canal or the operative incision is too small, resulting in difficulty extracting it. Fractures of long bones may also occur. All these injuries are more frequent with extraction by the feet. In breech deliveries, the soft tissues, bones and fetal head are most exposed to injuries.

In babies delivered by cesarean, the incidence of respiratory distress is higher, and so is the neonatal mortality due to hyaline membrane disease. The lecithin/sphyngomyelin ratio is poorer after elective cesarean than after induced labor. In babies delivered by an elective cesarean, the volume of the lungs is smaller, and the resistance of the respiratory tract is increased compared to babies delivered vaginally. The outcome of babies delivered by an emergency cesarean delivery is ranked somewhere in between.[63]

Cesarean delivery is associated with an increased risk of disorders of placentation in subsequent pregnancies. Delivery by cesarean delivery in the first pregnancy could increase the risk of an unexplained stillbirth in the second. The risk of unexplained antepartum stillbirth at or after 39 weeks' gestation is about double the risk of stillbirth or neonatal death from intrapartum uterine rupture.[64]

Unfortunately, there are few data to suggest that the liberalized indications for a cesarean delivery have reduced the incidence of cerebral palsy and other long-term disabilities. This is probably because most perinatal morbidity and mortality is caused by premature births, fetal anomalies, or antepartum events.[65,66]

Elective and emergency cesarean delivery

A delivery is designated an elective cesarean delivery when the obstetrician decides on a cesarean delivery prior to labor, for various indications. To facilitate the elective cesarean delivery, some induce labor for an hour or two before the procedure in order to achieve the thinning of the lower uterine segment and better uterine contractility, which may result in reduced blood loss and improved adaptation of the newborn to extrauterine life. Although the onset of labor is induced, the delivery is still referred to as an elective cesarean. Emergency cesarean delivery occurs when indications for delivery arise during labor, which require a cesarean.

In developed countries, the rates of elective cesarean delivery are increasing, especially in cases where cesarean is commonly performed on patient request, for breech presentation and for twins. In the USA, the cesarean delivery rate for the second twin after vaginal delivery of the first twin is approximately 9.5%.[54]

Technique of cesarean delivery

Preparation of the parturient

At emergency cesarean delivery, the preparation of the parturient is short, especially when done in haste. The parturient should be given an explanation of the procedure, of the risks involved, and she should be given the reason why the procedure is necessary. The appropriate informed consent form(s) should be signed by the woman, stating the type of procedure, the type of anesthesia, potential complications necessitating further procedures (blood transfusion, hysterectomy, if necessary), and any special requests of the parturient. The blood group should be verified and pubic hair shaved.

Prior to elective cesarean delivery there is enough time to discuss the reasons for the procedure, the procedure itself, and the postoperative course with the woman in greater detail. The obstetrician enquires about the possibility of sterilization. The woman is advised to do respiratory exercises, and if a smoker, she is advised not to smoke for some time before the procedure. She has to have her blood group determined, if this has not been already done, and some basic blood tests are performed as well. The woman is examined by an anesthesiologist, and additional tests are carried out if she suffers from any disease (heart or kidney diseases, diabetes mellitus, etc.).

Prophylactic amnioinfusion in women with thick meconium decreases the incidence of meconium below the fetal vocal cords and the impact on the incidence of meconium aspiration syndrome may be apparent in future in larger series.[67]

Anesthesia

Considerable data support the presumption that the fetal condition worsens as the time of exposure to general anesthesia lengthens. Progressive fetal depression as the induction-to-delivery time is prolonged makes it important to avoid unnecessary delay during the operative procedure. The abdomen should be fully prepared, draped, and ready for the incision before general anesthesia is induced.[40]

Just before surgery, the woman should be given antacid to neutralize the acids in the stomach contents to prevent pulmonary complications in case of vomiting and aspiration. It is not yet clear which agent best achieves this effect.

In Slovenia, a cesarean delivery is performed under general endotracheal anesthesia. In some countries, regional anesthesia is increasing in popularity as the mother feels more involved in the birth of her baby and there is less likelihood of neonatal respiratory depression.[68] The procedure of anesthesia is described in detail elsewhere.

Usually 1–2 l of fluid containing electrolytes is infused during and immediately after the operation. Throughout the procedure, and subsequently while in the recovery area, the blood pressure and urine flow are monitored closely to ascertain that the perfusion of vital organs is satisfactory.

Position of the patient and immediate preparation

At a cesarean delivery, the woman is at high risk of developing thrombophlebitis and thromboembolism. Therefore, proper care of the parturient's legs in the operating room is important, and spontaneous movements of the legs and early ambulation after a cesarean delivery are strongly recommended.

In Slovenia, a cesarean delivery is usually performed with the parturient on the gynecologic operating table and her legs spread on the leg supports (Figure 179.1). Thus, vaginal interventions are made possible, if necessary (e.g. pushing up the head). Immediately before the procedure, the urinary bladder is catheterized, and methylene blue injected, so that an incision of the bladder is quickly recognized.

The most convenient position for the parturient is slightly lateral (15°) and light Trendelenburg position (15°).

Skin incision

Two skin incisions are commonly used: transverse, the incisio secundum Pfannenstiel being more common, and vertical (laparotomia mediana inferior). Advocates of the former claim that the incision leaves a better cosmetic effect, as the scar is smaller, and is usually covered with pubic hair, and that incisional hernia is a less frequent consequence. The advocates of the latter consider the vertical incision to offer more rapid access and better visibility of the whole abdomen. In general, the transverse incision is reproached for slower access, especially in the case of a repeated incision, and the vertical incision for a less cosmetically desirable scar, and more frequent incisional hernias.[69]

In agreement with the enumerated advantages of the transverse incision, we are of the opinion that it should be used in the majority of the cases. The vertical incision should only be used in exceptional cases when good visibility of the upper abdominal cavity is required.

Uterine incision

Two uterine incisions are mainly used: transverse in the lower uterine segment, and a vertical incision. Some distinguish between the vertical incision of the lower uterine segment and the high vertical incision of the uterine corpus, although a combination of both is most commonly used. Frequent occurrence of serious uterine ruptures during subsequent pregnancies following a high vertical approach has made this incision nearly obsolete. In the opinion of some,[68] it is appropriate with a neglected transverse lie, when the approach to the lower uterine segment is not easy (congenital anomalies, severe adhesions following inflammations and surgeries, tumors of the lower uterine segment – primarily leiomyomas – and severe kyphoscoliosis of the parturient), and with the preterm uterus with an undeveloped lower segment. A skilled surgeon has to revert to the vertical uterine incision only rarely.

Recommended technique

We recommend a technique that, in our experience, provides relatively quick access to the uterus and results in little blood loss, minimal lacerations of the uterus and major uterine vessels, infrequent postoperative complications, and a favorable cosmetic effect.

Incision of the abdominal wall

The surgeon stands to the left of the parturient, the first assistant to the right. The second assistant, if required for expected operative complications (multifetal pregnancy, etc.), stands between the patient's legs. The skin incision (Pfannenstiel) should be made with a determined move transversely in a slightly curvilinear direction, approximately 2 cm above the symphysis pubis, preferably in the skin fold (Figure 179.2a) at the level of the pubic hairline. An incision of 12 cm is sufficient. A subcutaneous tissue incision is made somewhat higher than the skin incision, but only in the middle to provide access to the fascia. Minor bleeding veins are ignored; arterial bleeding, which occurs uncommonly with such a small incision, is managed with a small clamp, which is left in place.

Figure 179.1 Position of the patient for cesarean delivery (slightly lateral and light Trendelenburg position, legs spread on the leg supports).

A short median transverse incision in the anterior rectus fascia is made with a scalpel (Figure 179.2b). The fascia is separated from the underlying muscle with closed scissors in the direction of the intended incision; then, pushing the half-open scissors laterally, the fascia is incised curvilinearly on either side for 7–8 cm (Figure 179.2c). The surgeon and the assistant grasp the superior edges of the fascia and elevate them with strong forceps. The surgeon and the assistant hold the upper incised edge of the fascia approximately 2 cm from the midline on each side, and separate the fascial sheath from the underlying rectus muscles with the index finger (Figure 179.2d) for 2 cm on either side of the intact midline and upward almost to the umbilicus. They should be careful not to rupture the blood vessels coursing between the muscles and the fascia. Ruptures occur only rarely if we take care not to separate the fascial sheath from the muscles too laterally from the midline. In case of a rupture, the blood vessel is clamped and ligated. With semicurved scissors, the midline of the fascia is then sharply separated from the rectal muscles to near the umbilicus (Figure 179.2e).

The rectus muscles are separated with the index fingers or with the tip of the closed forceps and the separation is stretched in the direction symphysis–umbilicus; the pyramidalis muscles are detached in the midline with the scissors.

The surgeon and the assistant grasp the parietal peritoneum and incise as far cephalad as possible to avoid damage to the bladder. This incision of the peritoneum is then lengthened, first upward, and then downward. Some surgeons prefer simply to perforate the peritoneum, after which the two sides are stretched with the index fingers. This may reduce the risk of bladder injury.

The laparotomy wound may be covered with soft gauze. Only a sufficiently wide anterior hook is inserted into the abdominal cavity in a downward direction to uncover the site of the uterine incision.

Uterine incision

With smooth forceps, the surgeon grasps and lifts the serosa in the midline, approximately 1 cm above the bladder and incises with the scissors (Figure 179.2f). The scissors are inserted between the serosa and myometrium, which are then separated laterally and incised. The incision, made curvilinearly somewhat in a cranial direction, is approximately 5 cm long on either side. Varices, if any, should be avoided. Extremely unripe cervices in low gestational age or extremely dilated cervices demand the incision to be made 1 cm or more higher. It is not necessary to separate the bladder from the myometrium. The small low transverse uterine incision is begun in the middle (Figure 179.2g). To avoid incising the fetus, it is safer to perforate a thin posterior layer of the uterine wall with a finger or a handle of the scalpel. With the two index fingers the incision is extended by spreading the incision to achieve the required size of the opening. The initial incision needs only rarely to be lengthened using the scalpel or scissors. This may, however, be the case with an unripe uterus, when the uterine wall is thick and the incision is made too low. The incision should be made carefully, curving it laterally cephalad, to avoid injuries to the major uterine vessels. If the membranes are still intact, they should be ruptured, and the amniotic fluid suctioned. If the placenta is encountered in the line of incision, it must be incised. When the placenta is incised, the cord should be clamped as soon as possible to prevent fetal hemorrhage. The anterior hook is removed to enlarge the opening.

Delivery of the baby

Delivery of the fetus in the vertex presentation. The surgeon's left hand gently slips behind the symphysis and between the lower uterine wall and the head, attempting to reach as far below the fetal head as possible. The head should then be flexed gently and elevated into the incision. When the fetal head is rather tightly wedged into the birth canal, a careful

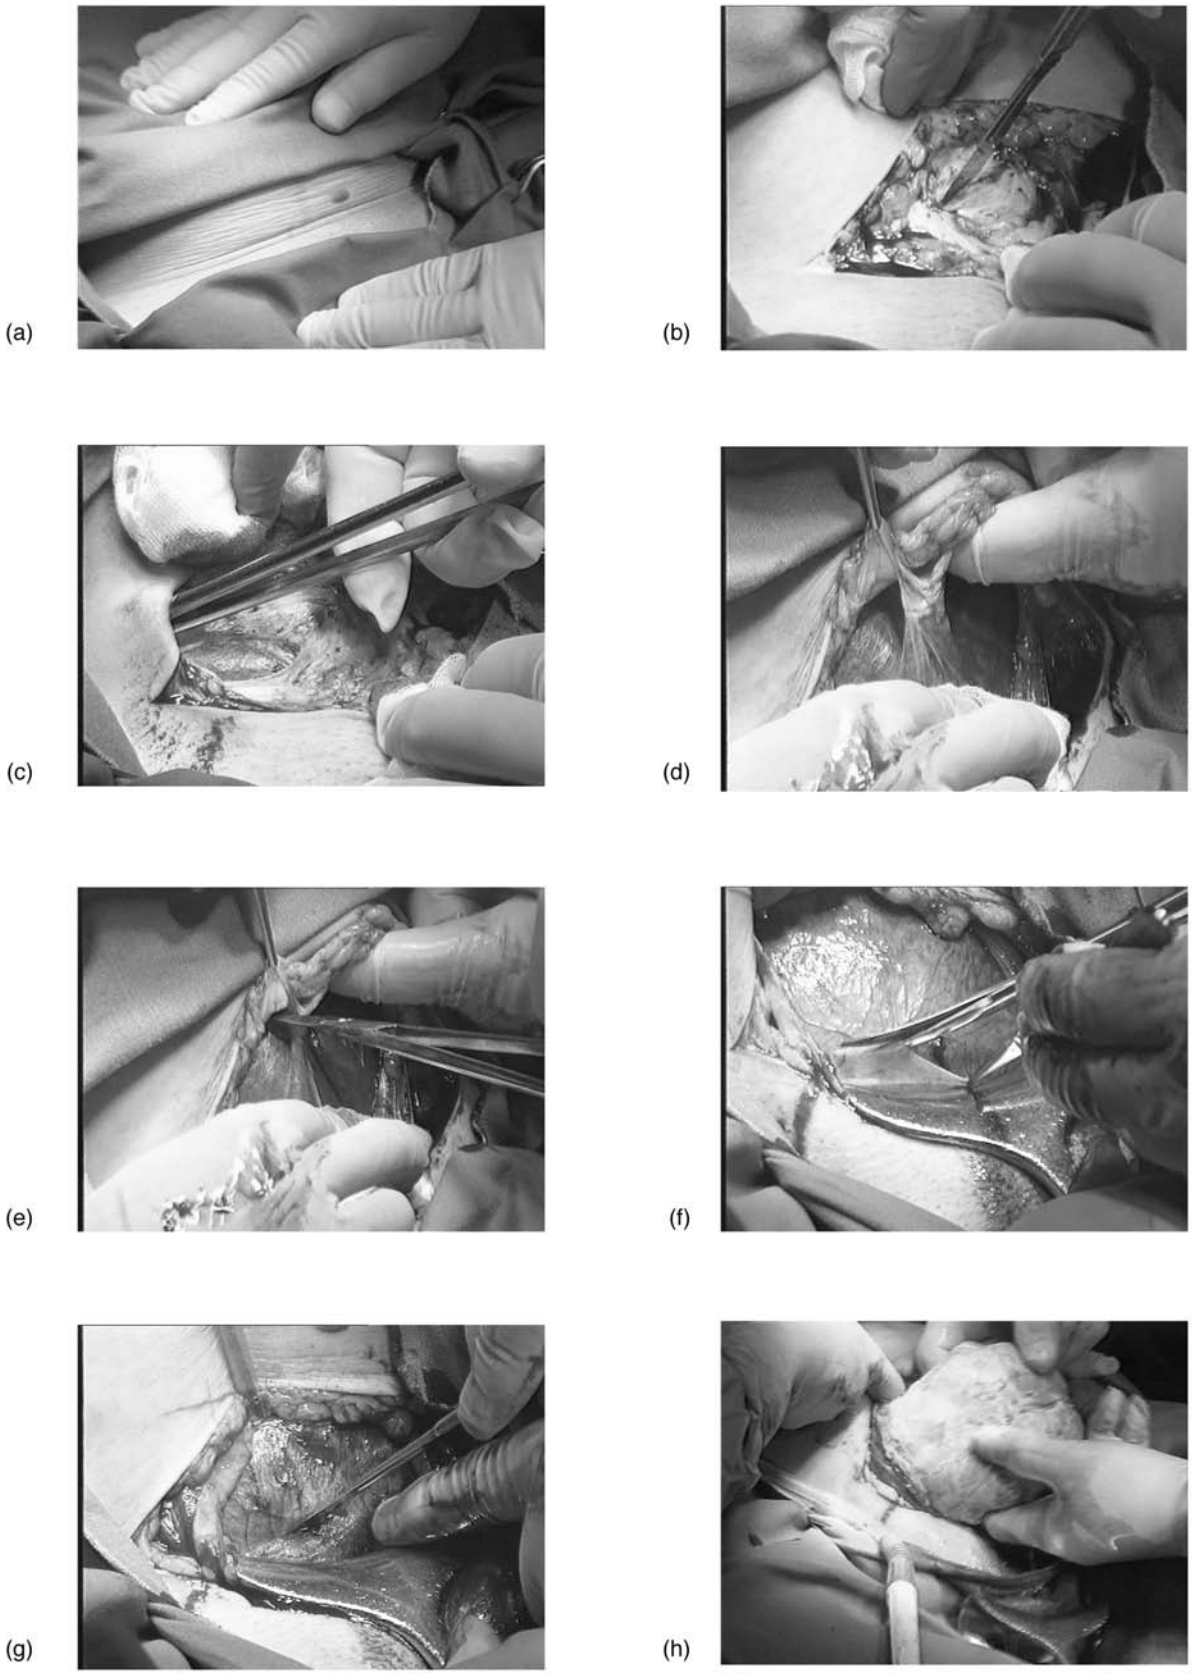

Figure 179.2 (a) Skin incision in skin fold; (b) small incision of the fascia with scalpel; (c) incision of the fascia with scissors; (d) separation of the fascia with index finger; (e) sharp separation of the fascia from rectal muscles; (f) incision of visceral peritoneum; (g) incision of the uterine wall; (h) delivery of fetal breech;

upward pressure exerted through the vagina by an assistant will help to dislodge the head. It is of the utmost importance that the surgeon's right hand presses the uterine fundus, retaining it and preventing it from moving upward. When pressing the fetal head upward, especially if it is already deep in the birth canal and thus more force is required, the surgeon may, especially if too forceful, push the entire uterus upward, resulting in an unwanted extension of the initial incision. If the fetal head and the surgeon's hand are both large, the use of the right blade of the forceps may prove helpful in flexing and directing the fetal head. Once the fetal head is directed toward the incision, the assistant helps deliver the head by pressing the uterine fundus through the abdominal wall. If necessary, the surgeon simultaneously retracts the uterine wall over the head with the fingers of his or her right hand. When the head is delivered, and the baby's mouth and nose are wiped, the head is held with both the surgeon's hands in an attempt to deliver the trunk, in similar manner to vaginal delivery. If the baby is large, the shoulders are usually delivered by pressing the baby's head toward the umbilicus. First, the inferior shoulder is delivered; then, by pressing the head against the symphysis, the superior one. The baby should not be held above the level of the uterus until the cord is clamped, otherwise the blood will tend to drain from the fetus to the placenta.

After the baby is born, the umbilical cord is clamped at three sites to obtain blood for pH measurement, which is important for evaluation of the baby's condition at birth.

Breech delivery. At a frank breech presentation, the buttocks are directed toward the incision by the surgeon's left hand in a similar manner to the fetal head at a vertex delivery. If this manipulation fails, the surgeon attempts to deliver the buttocks by hooking the fetal inguinal regions with both index fingers (Figure 179.2h). With various types of footling presentations, or with transverse and oblique lies, the delivery is started by delivering a foot, or feet, if possible. By the traction on a foot or feet, the fetal trunk is delivered. Traction limited to one foot only should be performed carefully to avoid fracturing the femur, especially when rotating the foot. At delivery of the aftercoming head, a spasm of the uterine muscles around the fetal neck sometimes occurs, especially when the traction has been hasty, or when the fetus is smaller with a relatively larger head. In the rare instance in which the extraction of the fetal head by a modified Mauriceau–Smellie–Veit maneuver fails, the uterine incision should be extended, usually by T-incision.

In either mode of delivery, an ecbolic agent (ergometrine 0.25 mg or oxytocin 5 units) is administered intravenously after the fetal head is delivered. By gentle traction on the umbilical cord, the placenta is delivered (Figure 179.2i). To avoid heavier bleeding, manual removal of the placenta is not recommended. The edges of the uterine incision should be grasped with ring forceps, first at the angles, and then in the middle of the lower edge. If heavy bleeding occurs at other sites, they are also clamped with ring forceps. When the delivered placenta is incomplete, or the membranes have been retained, the uterine cavity is explored and wiped using a swab on a stick. Manual exploration should be avoided, especially with preterm rupture of the membranes and with suspected chorionitis. Should manual exploration be absolutely necessary, surgical gloves should be changed after suturing the uterine wall.

The hysterotomy incision is then reapproximated with either continuous or interrupted sutures (Figure 179.2j), usually in one layer when the uterine wall is thin, and in two layers when the uterine wall is thick. The endometrium should be directed toward the uterine cavity. Sutures are applied as far apart as possible (1.5–2 cm), not tightly tied, or not sutured with a running-lock, to avoid ischemia.

When the second layer is being sutured, the stitches are put between the stitches of the first layer. After each layer has been sutured, massage of the uterus is necessary. If after the suturing there is still bleeding, additional hemostatic sutures are introduced.

Serosal edges are usually approximated with continuous sutures (Figure 179.2k). Many do not close the visceral peritoneum. Nagele *et al.*[70] reported that nonclosure of the visceral peritoneum was associated with lower febrile and infectious morbidity.

After the suturing, the uterus is massaged again, the adnexa are examined, and the abdominal cavity above the uterus manually explored to verify the possible presence of adhesions. Blood is also removed, usually by hand. If a gauze pack is used for the purpose, forceful wiping should be avoided, as it may cause postoperative atony of the bowels or lead to injuries of the serosa. The injured serosa presents a higher risk of subsequent adhesion formation than the retained blood.

Continuous sutures, avoiding forceful traction of the suture, can be used to close the parietal peritoneum (Figure 179.2l). Some do not approximate the peritoneum; its non-closure does not cause increased postoperative complications.[71,72]

After delivery, the suturing of the rectus abdominus muscles is not necessary, or just one suture is made at the top of the pyramidalis muscles.

The fascial edges may be reapproximated with either a continuous suture (Figure 179.2m) or interrupted sutures about 1 cm apart, mostly with synthetic resorbable sutures. Care must be taken not to wipe off the blood clots, which are hemostatic; therefore, only gentle blotting is applied. The clamps, if used, are removed, and ligation is used only if bleeding occurs. A few interrupted sutures may be made to obliterate the dead space and reduce the tension on the skin edges. If there is abundant adipose tissue, these sutures should not be too tightly tied either. The skin is usually sutured with interrupted sutures (Figure 179.2n), which should not be too close together or tied too tightly. Alternatively, we can use staples.

Cesarean delivery performed in the manner described usually takes 15–17 min. The most common operative errors are the following.

(1) Making the skin incision too long
(2) Making the transverse skin incision too high
(3) Excessive coagulation or ligation of the bleeding sites, leading to necrosis and development of favorable conditions for infections
(4) Making the rectus fascia incision shorter than the skin incision
(5) Separating the anterior rectus fascia from the rectal muscles too laterally
(6) Not separating the fascia from the rectal muscles up to the umbilicus
(7) Separation of the bladder from the myometrium in the case of a low transverse uterine incision
(8) Making a transverse uterine incision too low, especially when the cervix is unripe or fully dilated
(9) Failing to curve the lateral portions of the uterine incision upward, with consequent rupture of uterine vessels
(10) Forceful extraction of the fetus, leading to risks of uterine laceration and damage to the fetus
(11) Tying the sutures too closely and too tightly, resulting in ischemia and greater risk of infections
(12) Forceful wiping of the uterus and abdominal cavity

(13) Suture of the anterior fascia too laterally, resulting in the entrapment of the cutaneous nerves (genitofemoralis) consequent pain after the operation.

Hemorrhage

Parturients undergoing a cesarean delivery, in whom factors for an increased risk of hemorrhage exist, can be identified prospectively. These women will benefit greatly from extended preoperative counseling when possible, effective utilization of blood bank technology through the type and cross-match requests, and preventive measures during abdominal delivery to minimize blood loss.[73]

The woman of average size with a hematocrit of 30% or more, and a normally expanded blood volume and extracellular fluid volume, most often tolerates blood loss up to 1500 ml without difficulty.[1,5] The average reported blood loss during a cesarean delivery is 800–1100 ml.[74] In the Ljubljana maternity hospital, the mean blood loss is 500 ml. In only 5% of women is the blood loss greater than 1000 ml.

Antibiotic prophylaxis

The advantages and disadvantages of antibiotic prophylaxis of the parturient at a cesarean delivery have been discussed for years. In our opinion, antibiotic prophylaxis (treatment) should be used at every cesarean delivery after a preterm rupture of the membranes, with suspected chorioamnionitis, with prolonged labor and thus numerous vaginal examinations, and in maternity hospitals with frequent postpartum infections. In all such cases, after the umbilical cord is clamped, intravenous antibiotic (ampicillin or preferably a cephalosporin) should be injected. The administration is usually repeated twice.

Postoperative procedure

The basics of the postoperative course are the following.

(1) Regular monitoring of uterine contraction and hemorrhage (at least twice on the day of surgery, and once daily afterward)
(2) Monitoring of the operative wound (once daily)
(3) Infusion: 1500–2000 ml of fluid, usually Ringer lactate in a 5% glucose solution, on the day of surgery and the following day
(4) Analgesia: intravenously when access is available; afterward oral or intramuscularly, if required
(5) Getting up: 3–6 h after surgery
(6) Breast-feeding: almost immediately after recovery from anesthesia
(7) Nutrition: fluids and light food as soon as bowel sounds reappear and nausea disappears
(8) Active physical exercises immediately after surgery: arms, legs, breathing, pelvic floor
(9) Removal of sutures: 4–6 days after surgery

Discharge from hospital is becoming dictated by the economic and insurance conditions, rather than an ideal management. In the opinion of some authors, the mother may be safely discharged from hospital on the third or fourth postpartum day, unless there are complications in the puerperium.[1] In Slovenia, the mother is usually discharged from hospital on the seventh or eighth day.

180 Transverse lie, brow and face presentations

Ž. Novak-Antolic

The lie and presentation assumed by the fetus have considerable influence on perinatal and maternal morbidity and mortality. These influences relate in part to the factors that cause abnormal lies or presentations and in larger measure to the complications that accrue to pregnancies with these abnormalities during the process of labor and delivery. In this regard, abnormal lies and presentations have an increased risk of cesarean delivery (CD), as well as of fetal injury during labor and vaginal birth. The early diagnosis of these abnormalities is important for optimal management.

Maternal and fetal factors are involved in the term fetus assuming the most commonly encountered longitudinal cephalic–occiput presentation. At the end of gestation the fetus probably adjusts to the position in which it best fits: generally its podalic pole is where there is more space and, because of the piriform shape of the uterus, the fundus is more spacious. When the normal tonus of the uterus, the abdominal wall or the fetus is absent or other factors are present, an abnormal lie or presentation ensues. Other factors are fetal and uterine anomalies, polyhydramnios, uterine leiomyomas or other pelvic tumors, and placenta previa. Hydrocephalic and anencephalic fetuses are often in breech presentations; those with nuchal teratomas or goiter are likely to be in face presentation.

Transverse lie

Face and brow presentations

Definition

The lie of the fetus is determined with regard to the relation between the longitudinal axis of the fetal spine and that of the maternal spine. Longitudinal axes are usually parallel; when they are not, the lie is transverse or oblique. The latter is sometimes referred to as an unstable or transitory lie. When labor starts, most transverse lies change into longitudinal ones. We do not know when or whether this is about to occur, and at the end of pregnancy, interventions to convert the fetus to a more favorable lie before labor starts may prevent complications and perinatal and maternal morbidity and mortality.[1]

Diagnosis

The diagnosis can sometimes be made solely by inspection, and suspected with palpation and vaginal examination. Ultrasound should be used to confirm the lie and to rule out placenta previa. With early diagnosis, complications can be reduced.[2]

Labor and delivery

The presenting part is the fetal shoulder. The fetal back can be superiorly, inferiorly, anteriorly, or posteriorly positioned. A full-term fetus in a transverse lie cannot be delivered without serious injury. (If, however, the fetus is previable or dead it can be delivered.) If the regular strong contractions have fixed the fetus in the transverse lie, a CD should be performed immediately. The technique of CD itself may need to be modified, because the lower uterine segment has not generally softened and thinned. Sometimes the vertical cervico-isthmic incision is the proper solution. When possible, intraoperative version just before the uterus is incised may be performed.

If the labor proceeds, the most serious complication, the so-called neglected transverse lie, results: after rupture of the membranes and when uterine contractions push a fetal shoulder into the pelvis, the lower uterine segment becomes very thin. A fetal arm may prolapse through the cervix (Figure 180.1). With further contractions, the risk of uterine rupture is substantial. It can occur spontaneously, or be provoked by any vaginal manipulation at this stage.

Epidemiology and predisposing factors

Among more than 52,000 deliveries in 3 years (1997–1999) in Slovenia, the overall occurrence of transverse lie was 0.24%. With placenta previa, transverse lie occurred in 13.6%; in babies weighing less than 1500 g, in 3.3%; and with uterine anomalies, in 4.5%. The percentages are quite similar to those in the period from 1987 to 1995, calculated for more than 204,000 deliveries.[3] The percentage was the

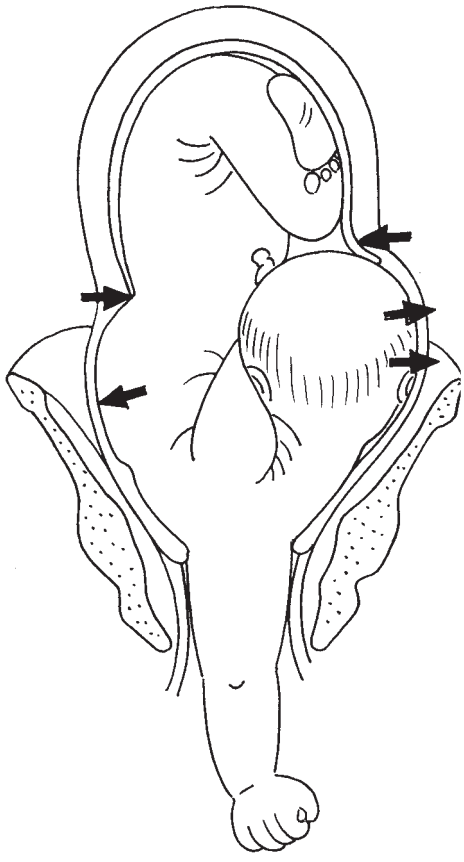

Figure 180.1 Neglected transverse lie.

highest at 27 weeks (11.5%), and dropped to 0.1% at term. With polyhydramnios there were 1.7%, with a lethal malformation 1.4%, and with myomas present there were 1.2% of transverse lies. The occurrence of transverse lie was 0.5% if the maternal age was over 35 years. Transverse lie occurred in 0.13% of nulliparas and in 0.9% of those with a parity of four or more, which is significantly different from brow, breech, and vertex presentations.

Therefore, the factors predisposing to transverse lie are as follows: placenta previa, uterine anomalies, low birth weight, prematurity, polyhydramnios, lethal malformations, myomas, maternal age over 35 years, and multiparity.

Complications

The complications of transverse lie are cord prolapse, obstructed labor, rupture of the uterus, and infection. As these complications are rare, the numbers calculated for the larger of the above-mentioned populations[3] are presented: in the transverse lie, cord prolapse occurred 17 times more often (1.7% vs. 0.1%), perinatal mortality was 12 times higher (8.4% vs. 0.7%), and rupture of the uterus occurred 10 times more often (0.3% vs. 0.03%) than in cephalic presentations. Also, blood transfusion was given six times more often, as placenta previa is a frequent cause of transverse lie. Postpartum infections were four times more common.

Conclusions

Whenever the presenting part cannot be felt in the pelvic inlet in late pregnancy, ultrasound should be performed to diagnose a possible transverse lie and also to rule out placenta previa, pelvic tumors, and fetal anomalies. When fetal maturity is reached, the cervix is ripe, and there are no contraindications, external cephalic version (ECV) could be performed, followed by amniotomy and oxytocin infusion. In a randomized trial, ECV with epidural analgesia was more successful[4] than without. ECV was also described in a woman with ruptured membranes; however, prolapse of the cord ensued.[5] It should be noted that pregnancies after successful version should not be considered the same as normal pregnancies.[6] For breech presentation at term it appears that ECV reduces the chance of non-cephalic birth and cesarean section; there is not enough evidence to quantify most risks of ECV at term.[7] There are no useful data for other malpresentations. During labor, or when the membranes have ruptured, one cannot wait and a CD should be performed as promptly as possible. Internal podalic version (IPV) is contraindicated because of its associated high perinatal mortality.[8] Even in resource-poor countries, safe cesarean section is regarded as a technology that should be employed to help reduce maternal mortality.[9]

Transverse lie of the second twin

Epidemiology

Among 2226 pairs of twins (Slovenia, 1987–1995),[3] 55.2% were both in cephalic presentation, and the CD rate was 16.8%. There were 17.2% of cases that presented as cephalic (first twin)/breech (second twin), of which 24.3% were delivered by cesarean; 10.8% were breech/breech (CD 63%); and 7.5% were breech/cephalic (CD 58.5%). Transverse lies were not uncommon: 4.7% presented as cephalic/transverse (CD 55.9%), 3.3% as breech/transverse (CD 91.7%), and in 0.7% both were in a transverse lie (CD 100.0%); 0.3% were transverse/breech and the same percentage were transverse/cephalic. The percentages of various combinations were similar for the population of 780 pairs of twins born during 1997–1999; the CD rate, however, being higher for all combinations in the more recent period. In roughly 1% of cases, CD was performed for the second twin only.

Combined delivery

The indications for the so-called combined delivery, in which the first twin is delivered vaginally and the second by cesarean, are most often prolapse of the cord, transverse lie, brow, face and compound presentations, cephalopelvic disproportion, fetal distress, placental abruption, contracted cervix, extreme discordance, and failed versions.[10–12] The setting must be such that the interval between births

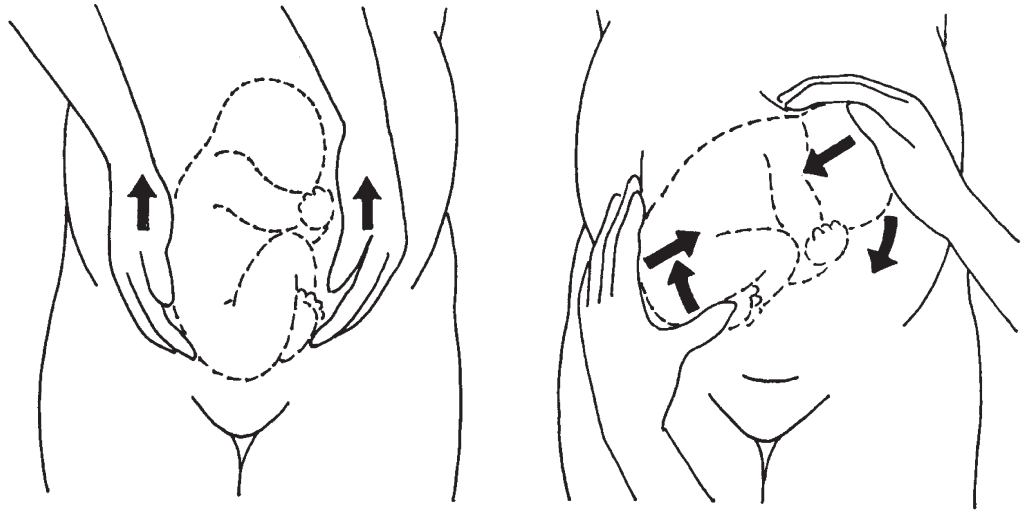

Figure 180.2 Intrapartum external cephalic version.

is not too long; otherwise, the outcomes are not good.[13] A Cochrane review indicated that caesarean section for the birth of a second twin not presenting cephalically is associated with increased maternal febrile morbidity with, as yet, no identified improvement in neonatal outcome; this policy should not be adopted except within the context of further controlled trials.[14] The occurrence of combined deliveries is directly proportional to the increased use of CD for twin pregnancy.[11] One of the causes of an increasing occurrence of cesarean births in twins is the fact that obstetric experience in the cases of vaginal delivery in these circumstances is not easily acquired; the other is the threat of litigation.

External cephalic version

Intrapartum ECV (Figure 180.2) of the second twin, whether in transverse lie or breech presentation, is most successful in gestations over 35 weeks, with intact membranes of the second diamniotic twin, no oligohydramnios, and no nuchal cord.[15]

The complication rate of ECV (cord prolapse, persistent abnormal fetal heart rate tracings, abruptio placentae, and compound presentation) is 10 times higher[16] for the second twin compared to ECV in singletons before labor. Possible explanations for the high complication rate are more premature deliveries, advanced cervical dilatation, and less experience of the operator in twin deliveries, in which ECV occurs in the context of labor, whereas in singletons it is planned.

Internal podalic version

IPV with unruptured membranes using nitroglycerin as a uterine relaxant was performed under epidural anesthesia successfully in 20 of 22 second twins found in transverse lie.[17] In their report, the authors stated that IPV is superior to ECV.[18,19] The numbers reported in most studies were small, and the studies were neither prospective nor randomized.

The attitude of a group of doctors toward the mode of delivery of twins was surveyed; it is interesting to note that 64% of respondents on twin births were interested in a randomized controlled trial to compare planned caesarean section with planned vaginal birth for twin pregnancies.[20] In a cohort study it was found that, at comparable gestational ages, the neonatal morbidity of second twins was comparable to that of a low-risk population. It should be remembered that because immediate management of the vaginally delivered second twins often needs to be more intensive than that of vaginally delivered singletons in the cephalic presentation, appropriate obstetric and neonatal care must be available to ensure optimal outcome.[21]

Deflexion attitudes

Brow presentation

Definition

The fetal head is extended more in the face presentation and less in the brow presentation (Figure 180.3), the presenting part being the part of the fetal head from the anterior fontanelle to the root of the nose (Figure 180.4). Reported incidences differ because of the different times when the diagnosis was made.

Diagnosis

Twenty-four percent are not diagnosed before the second stage.[22] The root of the nose, the upper part of the orbits, frontal sutures, and the anterior fontanelle

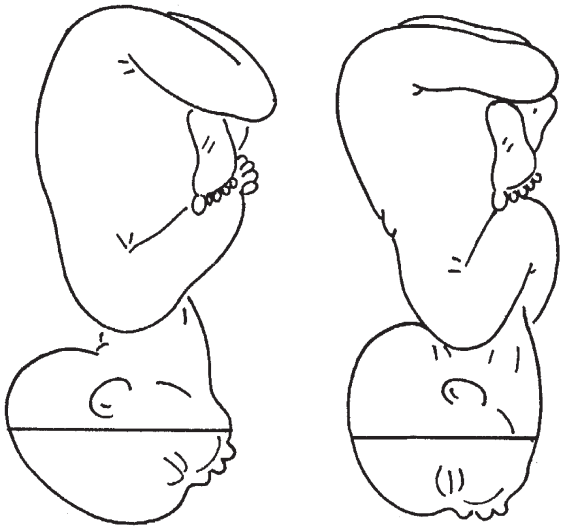

Figure 180.3 Brow (left) and face (right) presentation.

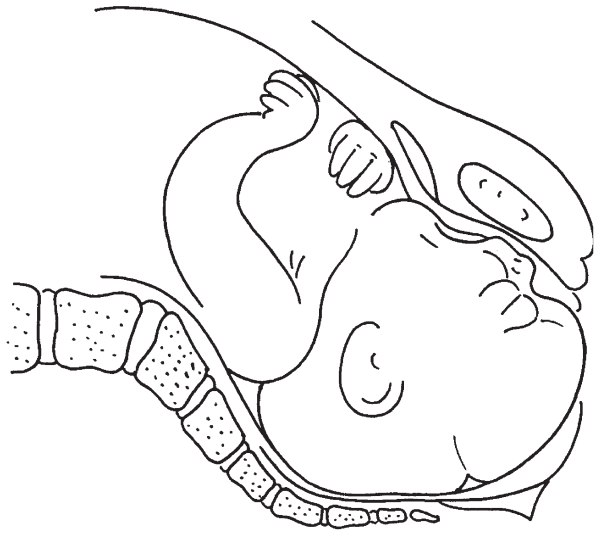

Figure 180.4 Brow presentation. Small fetus.

are felt on vaginal examination. The anterior fontanelle is the point of orientation.

Labor and delivery

Brow presentation is transient in most cases: it is delivered as a vertex if the head flexes, or as a face presentation if the head further extends. As long as labor progresses without signs of fetal distress, one can wait. Very small babies can be delivered vaginally even without further flexion or extension.

With the electrodes for internal fetal heart rate monitoring, damage may be done to the fetus if the electrode is attached to the face or over the anterior fontanelle; therefore, the external mode is preferred. Likewise, one must be very careful with the sites chosen for fetal blood sampling.

In persistent brow presentation, delivery is only possible with a very small baby when the fetal back is posterior or when the pelvis is extremely large. Extensive molding of the head occurs so that the occipitomental diameter is diminished, and usually there is a large caput succedaneum over the forehead. Swelling might be such that it feels to the examiner as if the head is descending. Delivering over the perineum, the fetal head first flexes so that the brow, the sinciput, and the occiput are delivered, and then it extends so that the face is delivered. In most cases, when brow persists and the labor is dysfunctional, a CD should be performed, as vaginal manipulations increase perinatal mortality dramatically.

Epidemiology and predisposing factors

At the time of delivery, brow presentations were present in 0.09% of more than 204,000 deliveries over 9 years (1987–1995) in Slovenia.[3] During the second period analyzed (1997–1999) there were also 0.096% of brow presentations. With polyhydramnios, the occurrence of brow presentation was 0.4%, and in babies weighing less than 1500 g it was 0.19%. The percentage was the highest before 34 weeks (0.16%), dropped to 0.08% at term, and rose slightly after 42 weeks to 0.10%. Brow presentation occurred in 0.1% of nulliparas, and in 0.04% of those whose parity was four or more, which is significantly different from the face presentation and transverse lie. The predisposing factors, listed in decreasing order of appearance, were polyhydramnios, low birth weight, prematurity, and postmaturity. Uterine leiomyomas were not predisposing factors, nor were uterine anomalies, lethal malformations, maternal age over 35 years, or birth weight over 4000 g.

Mode of delivery and complications

In the above-mentioned population of brow presentations,[3] 69% were delivered by cesarean and 5.9% by vacuum extraction. Compared to vertex presentations, cord prolapse occurred five times more often, and rupture of the uterus 17 times more often (0.5% vs. 0.03%); blood transfusion was three times more likely, and postpartum infections occurred four to five times more often than in vertex presentations. The perinatal mortality was 1.6% compared to 0.7% in vertex presentations.

Conclusions

When a brow presentation is diagnosed early in labor, a policy of watchful waiting is usually appropriate. Oxytocin should be used cautiously if uterine contractions are weak, but should be avoided when the descent is absent, or abnormal, or cephalopelvic disproportion is suspected. If a brow presentation persists, a full-term fetus should be delivered by cesarean.

Face presentation

Definition

The fetal head is completely extended. The position during labor is designated by the mentum, which can be on the left or on the right and anterior or posterior, as felt on vaginal examination.

Diagnosis

Forty-nine percent are not diagnosed before the second stage.[22] Sometimes, by abdominal palpation, parts of the fetal head are palpated better on the side of the fetal back. The nose, eyes, mouth, and chin are felt on vaginal examination. The chin is the point of orientation. If the face is swollen, which is common, it can be mistaken for a breech.

Labor and delivery

A direct electrode should not be applied (or, if absolutely necessary, with extreme caution on the fetal chin; it must be removed carefully to avoid injury to the skin), but external fetal heart rate monitoring should be used. For the same reason, fetal blood sampling cannot be performed. Stimulation of the face is sometimes used as an indicator of good fetal condition. Very careful oxytocin stimulation may be used. Labor should proceed as in vertex presentation: arrest of labor and fetal distress are indications for CD.

The mentum anterior position with the fetal back posterior may be delivered vaginally (Figure 180.5). The neck is relatively short and can flex around the pubic symphysis; but because it cannot flex around the sacrum, term fetuses in the mentum posterior position cannot safely deliver vaginally. A persistent mentoposterior (Figure 180.6) is therefore accepted as an absolute indication for CD. In the anterior position, the head delivers by flexing, so first the face emerges, then the brow, the sinciput, and the occiput. An episiotomy should be performed.

The mento-occipital diameter might be somewhat elongated because of molding. The baby's face is often quite swollen, and difficulties may sometimes arise because of laryngeal edema.

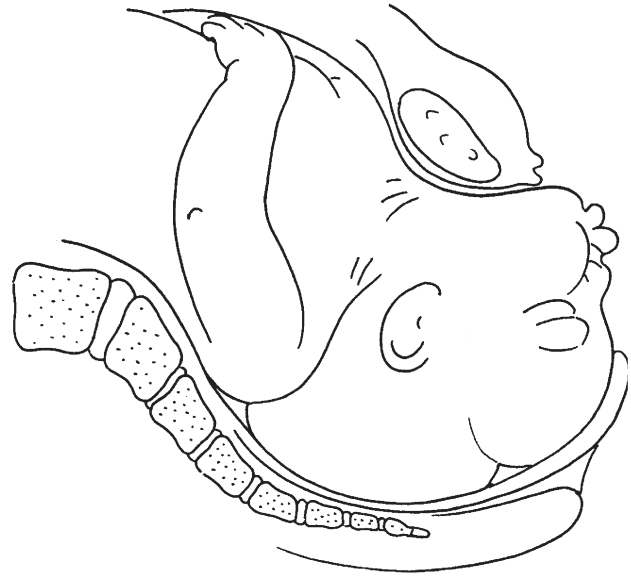

Figure 180.5 Face presentation, mentum anterior.

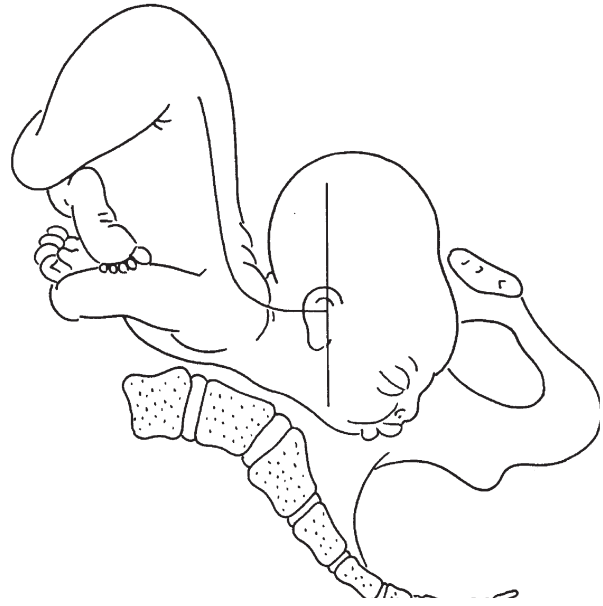

Figure 180.6 Face presentation, mentum posterior: indication for cesarean delivery.

Epidemiology and predisposing factors

Face presentations constituted 0.11% among more than 204,000 deliveries over 9 years in Slovenia,[3] an incidence similar to that reported by other authors.[22] Face presentation occurred in 0.9% of babies with a lethal malformation; in babies weighing less than 1500 g, 0.71% were face presentations. In association with polyhydramnios, 0.63% of the presentations were face, and with placenta previa, 0.46%. The percentage was the highest before 34 weeks (0.51%), dropped to 0.09% at term, and rose after 42 weeks to 0.18%. In primiparas there were 0.08%, in secundiparas 0.12%, in terciparas 0.16% and in those who delivered for the fourth time or more 0.18%, which is significantly different from brow presentation. The predisposing factors, listed in decreasing order of appearance, were the following: lethal malformations, low birth weight, polyhydramnios, prematurity, postmaturity, multiparity.

Myomas were not predisposing factors, nor were uterine anomalies, maternal age over 35 years, or birth weight over 4000 g.

Mode of delivery and complications

In the above-mentioned Slovenian sample, cesarean deliveries were performed in 44% of cases. Cord prolapse occurred nine times more often, rupture of the uterus 30 times more often (0.9% vs. 0.03%), and blood transfusion was given twice as often as in vertex presentations. The perinatal mortality was 5.8% compared to 0.7% in vertex presentations.

Conclusions

When labor starts, one can wait as long as there is no fetal distress and labor proceeds normally. Fetal anomalies should be ruled out. Very often, the face presentation does not undergo internal rotation until the face has encountered the pelvic floor. A persistent mentum posterior position is indication for a CD.

181 Breech presentation

M. Foley and M. Alarab

Introduction

The incidence of breech presentation is relatively low at term, but because cesarean birth is the mode of delivery in at least 50% of cases, maternal mortality and morbidity are increased. Perinatal mortality and morbidity rates are increased for a number of reasons, of which prematurity is the most significant. The incidence of breech presentation is about 20% at 28 weeks' gestation and 3% at term, indicating that most fetuses that are in a breech presentation early in gestation undergo spontaneous cephalic version. In countries with high rates of premature birth, the incidence of breech delivery is therefore proportionately higher.

The major controversy regarding the management of breech presentation concerns the question of what method should be used for delivery at term: is a trial of labor and vaginal delivery in selected cases as safe as universal cesarean section? This question took on particular importance following publication of the Term Breech Trial in 2000,[1] which concluded that elective cesarean birth was best for breech presentations at term. Interestingly, at the same time this approach was being recommended as the standard of care, individual centers were reporting the safety of vaginal breech birth.[2–4] Of great concern with regard to setting policy is that vaginal breech delivery requires a degree of skill acquired by practice and experience. Even if vaginal delivery by an experienced attendant were appropriate, one may reasonably ask how today's obstetricians in training can acquire that skill in the context of shorter work hours and fewer vaginal breech deliveries available to allow the requisite acquisition of skill and clinical judgment? Of course, those skills will be necessary under any circumstances because a proportion of planned cesarean births will labor and may present in advanced labor when the expertise for a safe vaginal delivery is needed; also, some mothers may opt to have a trial of vaginal breech birth.

External cephalic version (ECV) would seem an obvious answer for the breech problem, but suffers from variable popularity in different countries and within institutions, possibly because the procedure is not without risk (albeit small), requires a measure of skill and experience, and has a relatively high failure rate – an unpopular combination with many obstetricians. There is a danger that this expertise may also be lost as part of the breech controversy, because some obstetricians now feel that cesarean section is the only solution for breech presentation in general. Moreover, a greater proportion of women are declining the offer of ECV than in the past and are opting for cesarean birth. Perhaps, critical to the current controversies is the question of informed consent based on objective evidence for both trial of vaginal breech delivery and ECV, balancing short- and long-term risks of cesarean delivery for the mother and baby.

Cesarean delivery for breech birth has been shown to increase both short- and long-term maternal morbidity and mortality in both observational and randomized controlled studies,[5–8] not least because it predisposes to further cesareans in subsequent pregnancies. A change to cesarean delivery for all breech presentations in institutions currently offering a trial of vaginal delivery (with a 50% vaginal delivery rate) would double the cesarean rate attributable to breech presentation from 2% to 4% of all term deliveries, with an inevitable incremental effect on the repeat cesarean rate.

Etiology

Premature delivery is the commonest reason for breech presentation, just because there will have been insufficient opportunity for spontaneous version. The fetus may be a factor: the majority of breech presentations at term have extended legs, suggesting that this posture prevents spontaneous version. Version is less likely to occur spontaneously in nulliparas compared with multiparas, probably because of increased uterine tone or abdominal wall tone or both and is also less likely to occur in a patient who has had a previous breech delivery, presumably because of some uterine factor[9] (Table 181.1; Figure 181.1). A fetal malformation may be a factor. For example, hydrocephalus may prevent version, as may a neurologic deficit in which poor muscular activity does not promote spontaneous version. Seemingly high rates of long-term handicap have been reported

Table 181.1 Likelihood of spontaneous turning during pregnancy in two groups of mothers (from Westgren *et al.*,[9] with permission)

Ultrasound findings	Persistent breech ($n=133$)	Spontaneous cephalic version ($n=177$)
Fetal size		
Biparietal diameter, mm (SD)	82.2 (4.4)	82.6 (3.9)

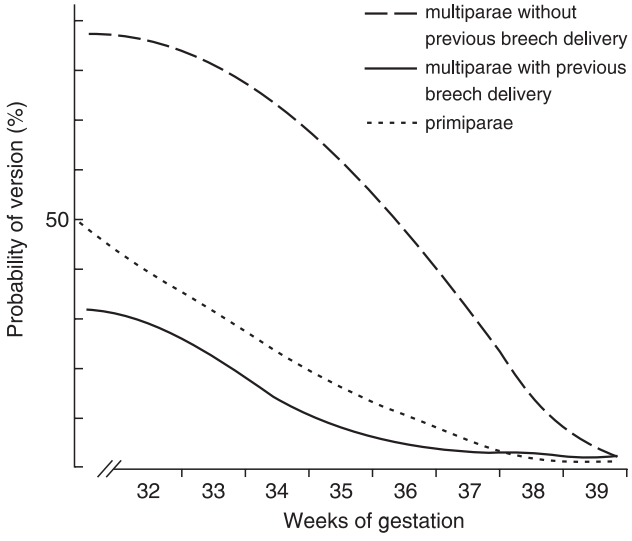

Figure 181.1 Probability of spontaneous version of breech to cephalic presentation according to parity, gestational age, and prior breech delivery

in term breech fetuses independent of the method of delivery – cesarean or vaginal – but data on outcome of cephalic births were not always available for comparison.[10] While there has always been the anecdotal suggestion of an 'inherent' breech problem, this may not be true when corrected for prematurity and intrauterine growth restriction.[11] Excessive or reduced amniotic fluid volume are risk factors, as is placenta previa, the management of which takes priority over the presentation. Uterine malformations are obvious causes, and occasionally a pelvic tumor, e.g. a leiomyoma or ovarian cyst, may prevent spontaneous cephalic version.

Techniques of breech delivery and their attendant risks are related in part to the type of breech presentation that exists (Figure 181.2). The commonest type of breech presentation is the extended or frank breech, in which both legs are extended at the knee (60%). The flexed or complete breech (15%) has both legs flexed at the knee. The footling breech (25 %) has one or both feet presenting.

Perinatal mortality and morbidity

Prematurity and its consequences are the major contributors to mortality and morbidity: extreme prematurity incompatible with survival, intraventricular hemorrhage, respiratory distress syndrome, infection, necrotizing enterocolitis, jaundice, feeding difficulties, and the psychosocial effects of being in a neonatal intensive care unit all affect outcome. Neonatal respiratory morbidity is also increased up to fivefold following elective cesarean delivery,[12] and while delaying delivery until after 39 weeks' gestation can minimize this, the chance of having to deal with a breech in spontaneous labor increases.

Perinatal mortality specific to vaginal breech delivery includes cord prolapse, anoxia caused by delay in the actual delivery of the breech, and traumatic intracranial hemorrhage. The latter can be related to difficulty delivering the head, or in the opposite case, to a rapid uncontrolled delivery associated with sudden compression and then decompression of the unmolded head. Both situations can result in tearing of the falx cerebri and associated catastrophic intracranial hemorrhage. Intrapartum and early neonatal hypoxic deaths are highest when intrauterine growth restriction has been undiagnosed[13], and when there exist fetal heart rate abnormalities in labor.[14] Skeletal trauma can include fracture of the femur during vaginal delivery and can also be a problem at cesarean delivery when the legs are extended. The clavicle or humerus may be fractured during delivery of the shoulders. Skeletal injuries generally heal quickly with no long-term sequelae. Cranial nerve or nerve root injury can occur but seem to be less common than with shoulder dystocia;[1] recovery depends on the degree of the initial trauma.

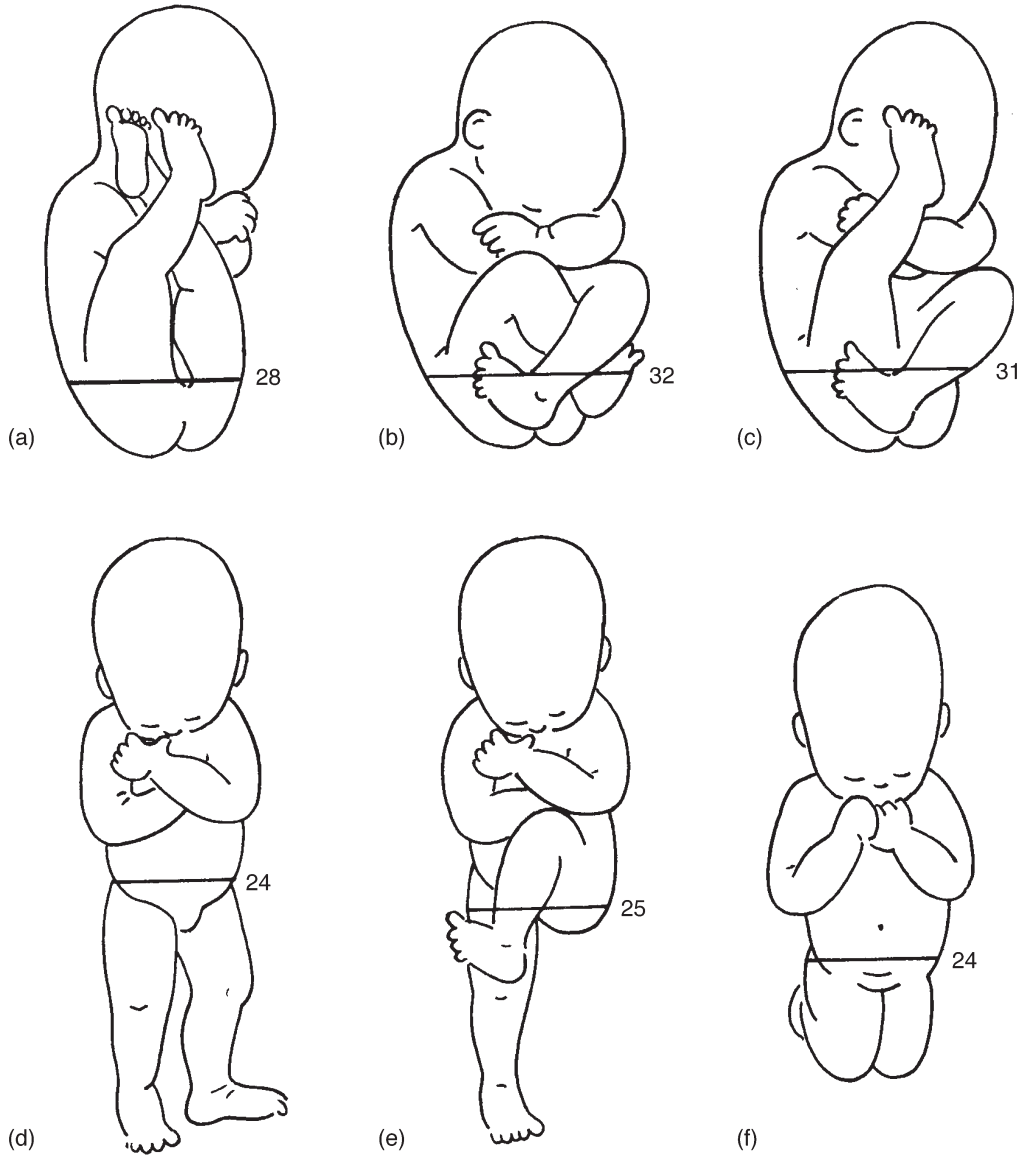

Figure 181.2 Types of breech presentations: (a) frank breech; (b) complete breech/footling; (c) incomplete breech/footling; (d) complete footling; (e) incomplete footling; (f) knee. Numbers indicate largest circumference of the presenting part (cm) in an average size fetus. From Pajntar, M. Breech presentation. In Kurjak A. *Textbook of Perinatal Medicine,* 1st edn. London: Parthenon Publishing, 1998.

The genitalia, facial structures, and even intra-abdominal viscera may be injured, but these injuries area not exclusive to vaginal breech delivery; they can also occur at cesarean section. The 2-year neurologic follow-up of babies in the Term Breech Trial[15] showed no differences between the planned vaginal breech delivery and the planned cesarean section groups, and similar results have been reported at 7 years comparing breech and cephalic deliveries.[16]

Diagnosis

The diagnosis is made by abdominal palpation, and while not really relevant until 34 weeks' gestation, it is worth noting at earlier visits to serve as an *aide memoire* for 34 weeks when the option of ECV should first be considered. Difficulty palpating a fetal head above the pelvic brim, or the sense that there is a deeply engaged head should raise the possibility of malpresentation. With increasing use of imaging in antenatal care, the incidence of undiagnosed breech presentation should be minimal, and while a cephalic presentation can revert to a breech at any time in multiparas, this probably almost never happens in late pregnancy in nulliparas.

Occasionally, a patient will present in labor with an indeterminable presentation on vaginal examination. The differential diagnosis generally includes breech presentation, face presentation, compound presentation, shoulder presentation, fetal malformation (e.g. anencephaly), and, rarely, a pelvic tumor

(e.g. a cervical fibroid or an ovarian cyst in the Pouch of Douglas), or even a congenital uterine abnormality (e.g. a prolapsed uterine horn). The diagnosis is made by palpation but should be confirmed by ultrasound. The management of most of these cases, with the exception of anencephaly, often is cesarean section. A plain film of the abdomen might be helpful in some circumstances when neither palpation nor ultrasound can confirm the diagnosis.

External cephalic version

With the decline in enthusiasm for vaginal breech delivery the main opportunity for reducing the rate of cesarean section for breech presentation is to increase the use of ECV, and the availability of this procedure to all patients is recommended by both the American and the Royal Colleges of Obstetricians and Gynecologists.[17,18] Since the Term Breech Trial, however, there has been a decline in enthusiasm for ECV as well as for vaginal breech delivery.[19]

There is good evidence that ECV reduces the incidence of non-cephalic births by nearly 60%,[20] although the risk of intrapartum cesarean is still higher after successful ECV than for spontaneous cephalic presentations.[21] One study calculated that four attempted version procedures were required to prevent one cesarean section, reducing to two attempts if applying current practice of cesarean section for all term breech presentations.[22] Despite this, the technique is not part of routine clinical service in many centers;[23,24] and in general the uptake of ECV is low, partly because of patient refusal.[22,25] The success rate is greater in multiparas (60%) compared with nulliparas (40%), presumably because uterine and abdominal wall tone is greater in nulliparas, which is a strong argument for analyzing all data separately by parity. A disproportionately higher number of nulliparas presented in our series[4] with a breech presentation, which may have reflected the higher success rate of ECV in multiparas. Although the success rate of ECV declines with advancing gestational age, it is generally recommended that it be carried out at 37 weeks' gestation, to allow for spontaneous version in some cases, reduce the incidence of spontaneous reversion of the fetus, and minimize potential neonatal problems in the event of an emergency delivery being required.

Comparing ECV at 34–36 weeks' gestation with 37–38 weeks' gestation, the rates of breech presentation at birth were lower in the early ECV group, but not significantly so,[26] and a recent Cochrane review[27] concluded that early ECV was not effective in lowering non-cephalic presentation or the rate of cesarean section. A survey of practice in Australia and New Zealand[24] (74% response rate) found, nevertheless, that almost 40% of obstetricians attempted ECV before 37 weeks. While neither of the authors of this chapter has experience in the use of tocolytics to facilitate ECV, analysis of a variety of interventions, including use of tocolytics, fetal acoustic stimulation, epidural or spinal regional analgesia vs. none, showed that only the use of routine tocolysis with beta-stimulants was associated with fewer failures of ECV.[28]

Therefore, the major decisions concerning the use of ECV relate to the gestational age at which the procedure is attempted, particularly in relation to parity, and the use of tocolytic drugs. Despite all the evidence, our experience is that the best chance of ECV in nulliparas is between 34 and 36 weeks. It is extremely rare for a cephalic presentation to convert to breech in nulliparas and for this to occur after a 'successful' ECV would suggest that the ECV was not successful in the first place. The same is not true of multiparas and for them ECV at 37–38 weeks is reasonable, but has to be balanced against parity. A multipara with one previous pregnancy is not the same as one with five, who might almost be regarded as having an unstable lie. On this basis, if tocolytics are to be used they should certainly be offered to nulliparas. It is our understanding that many of these questions will be answered by ongoing randomized trials.

Complications of ECV are well documented. Antepartum hemorrhage complicating the procedure must be interpreted as being due to placental separation and therefore requiring delivery, usually by cesarean. Factors predisposing to placental separation (hypertension, a previous antepartum hemorrhage) are therefore relative contraindications to ECV. Feto-maternal transfusion is an issue in two respects: in the rhesus-negative patient immunoprophylaxis is recommended, which may deter patients from undergoing ECV; also, a major fatal fetomaternal transfusion may rarely occur during the procedure. The potential complication of cord entanglement unfortunately captures the imagination (particularly of the patient), but should not be any more common than with spontaneous version. Certainly, the fetal heart slows down if pressure is applied to the fetal head and a bradycardia is common after an attempted or successful ECV. The wise option is to perform fetal heart rate monitoring as well as an ultrasound scan prior to the procedure, because in some cases breech presentation is associated with preexisting fetal compromise (abnormal fetal heart rate pattern, fetal growth restriction, reduced amniotic fluid) and this should be excluded as far as possible before embarking on ECV. The fetal heart rate should be monitored after the procedure, but it must be borne in mind that temporary fetal heart rate abnormalities are common after ECV and should be anticipated. The risk of emergency cesarean section for fetal distress following ECV is small, at less than 1%.[29,30] Both Royal and American Colleges recommend that the procedure be performed in a hospital setting with emergency facilities available; whether it should be

performed in the operating theatre with the patient fasting is questionable. Relative contraindications to ECV include previous cesarean section and other previous uterine surgery (e.g. myomectomy) and an estimated birth weight at term of greater than 3800 g, as the failure rate is higher with larger babies.

The management of ECV

Ideally, cases should be referred to a dedicated breech clinic. The question of consent, balancing the risks of ECV, vaginal breech delivery, and cesarean birth should be initiated by the referring doctor; but if presented in a negative fashion it is probably not worth referring the patient. A good service, well organized and with good results, would obviously help to dispel any negative preconceptions. Every attempt should be made to diagnose breech presentation at 34 weeks' gestation, to allow plenty of time to formulate a plan of management. The initial assessment includes a structured ultrasound examination documenting placental site, estimated fetal weight, amniotic fluid estimation, type of breech, fetal attitude, and fetal morphology. ECV is offered with informed consent if the estimated fetal weight, amniotic fluid volume, placental site, and fetal morphology are normal. A non-stress test is performed before and after the procedure.

A useful technique is as follows: The presenting breech is first disengaged from the pelvis and directed laterally at least 90 degrees; generally, the head would have passed 90° in the other direction. Then, both poles can be manipulated in tandem to complete the ECV. Manipulation of the head as a first step is less likely to be successful except perhaps in a multiparous patient. When a tocolytic is to be prescribed, and provided there are no medical contraindications, the drug is administered 30 min before the procedure. Most recommend no more than two attempts at ECV in any one session, but ECV can be repeated later in the pregnancy; this decision is determined by how early the initial attempt is made.

The premature breech

The management of the premature breech in labor has clearer established guidelines, mainly favoring cesarean delivery, although this approach has not been subjected to large clinical trials. The evidence suggests that cesarean birth reduces neonatal mortality in babies less than 32 weeks and weighing less than 1500 g,[31,32] with no differences in the incidence of handicap between the two methods of delivery.

Condition at birth is a major determinant of early neonatal progress, and while neonatologists would probably favor cesarean delivery for the premature baby, abdominal delivery does not guarantee an easy birth. When the lower uterine segment is poorly developed, a high transverse incision is preferable to an inadequate low incision, which may necessitate extending the incision into the upper uterine segment or making a T-incision in order to deliver the baby. Anecdotal evidence suggests that a high transverse incision through the upper segment of the uterus is less likely to rupture in a subsequent pregnancy than a vertical incision in that area. Prior preterm cesarean section is, however, a risk factor for uterine rupture in a subsequent labor[33] and this should be a consideration when deciding to perform a preterm cesarean delivery, particularly if subsequent deliveries are likely to be poorly supervised. When the birth weight is between 1500 and 2500 g the concern is that the cervix may entrap the aftercoming head and for that reason cesarean section is recommended. This is an unpredictable and unpreventable emergency and the treatment options include using traction and making relieving incisions in the cervix. The main complications are trauma and asphyxia secondary to delayed delivery, often with a catastrophic outcome for the neonate.

Vaginal breech delivery at term

Case selection and management in labor are most important when considering a trial of vaginal delivery, and the old maxim of 'breech and any other problem – cesarean section' still holds true. General non-specific obstetric indications for elective prelabor cesarean delivery include maternal age, infertility, maternal disease likely to put the fetus at risk (e.g. diabetes), and significant preeclampsia. In our center, prelabor cesarean delivery is offered at 41 weeks as an alternative to induction because oxytocin to induce or augment labor is more likely to be required following induction of labor and for prolonged pregnancy, particularly in nulliparas; oxytocin is not used either to augment or to induce labor with a breech presentation.

It is generally felt that an estimated birth weight of 3800 g at term should be the cutoff for a trial of vaginal delivery, but there are difficulties in predicting birth weight on palpation and by ultrasound. To be a candidate for a vaginal delivery, the fetus should be in the extended or flexed position, i.e. not footling. Hyperextension of the fetal head – an angle of extension of greater than 90° – is rare, but must be excluded because hyperextension makes vaginal delivery of the head very difficult. If the problem is not recognized in labor until delivery of the head, it may be, unfortunately, too late to prevent spinal cord injury. Any evidence of fetal compromise such as suspected intrauterine growth restriction or oligohydramnios is an indication for cesarean section.

Although the selection criteria for elective cesarean section from various centers are similar, the reported percentage considered suitable for a trial of vaginal delivery varies from less than 20% in some hospitals

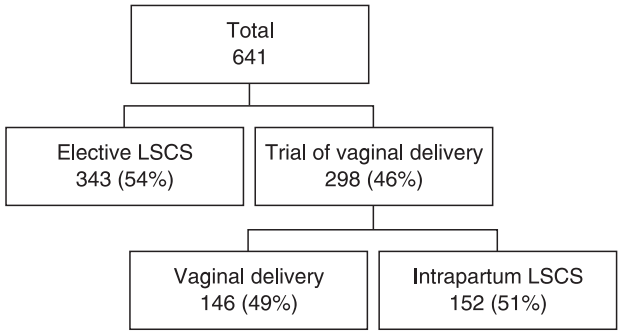

Figure 181.3 Obstetric outcome in 641 consecutive vaginal breech presentations at term, analyzed according to intended and actual route of delivery. Adapted from Alarab *et al.*,[4] with permission.

in the USA[34,35] to around 70% in some European centers;[3,36] 56% were considered suitable for a trial of labor in the Term Breech Trial. Less clearly defined in most series are the criteria for management of breech labor, particularly in relation to the timing of the onset of labor, and hence the diagnosis of prolonged labor, time limits for the duration of the first and second stages of labor both for nulliparas and multiparas, the use of oxytocin to augment labor, the question of induction of labor, and the expertise of the obstetrician conducting or supervising a vaginal breech delivery.

In our unit, patients are offered a trial of vaginal delivery if the following criteria are fulfilled: (1) estimated fetal weight 2500–3800 g; (2) deepest amniotic fluid pool 30 mm or more; (3) normal fetal morphology and normal placental location; (4) absence of hyperextension of the fetal head (an angle exceeding 90°); and (5) flexed (complete) or extended (frank) breech presentation. Management of fetal anomalies depends on the type of malformation identified. Elective prelabor cesarean section is advised based on the following indications: estimated fetal weight more than 3800 g, footling breech, hyperextension of the fetal head, or when fetal compromise is suspected. Maternal indications for elective cesarean section include maternal preference, previous cesarean section, significant preeclampsia, and placenta previa. Induction of labor is not practiced with breech presentation. Elective prelabor cesareans are scheduled for 39 weeks' gestation or, if a trial of labor has been planned, at 41 weeks if labor has not ensued.

On admission in spontaneous labor, a vaginal examination is carried out early in labor to confirm the type of presentation, to exclude cord presentation, and to rupture the membranes in order to inspect the amniotic fluid. Oxytocin is not used to augment labor in the first or second stage. Time constraints for the first and second stages are based on the average duration of the first and second stages of labor in this hospital for nulliparas and multiparas.[37] The average first-stage durations are 6 and 2 h, and the active second stages 1 h and 30 min, respectively; up to 1 h may be allowed for descent of the presenting part at full dilatation but not associated with active pushing. We have a very low threshold for intervention and cesarean section in both the first and second stages of labor if there is delay or if fetal distress is noted. The presence of meconium with a breech presentation does not necessarily indicate fetal distress; nevertheless, its presence should not be altogether ignored if detected in early labor. All should have continuous external monitoring in labor, and cesarean section should be performed for suspected fetal distress with a breech presentation. Epidural administration is based on maternal request. An experienced obstetrician (senior resident with at least 4 years' experience or a consultant) conducts all vaginal breech deliveries, and a pediatrician is also in attendance.

In our institution, during a 42-month study period[4] up to the year 2000, 641 patients presented with singleton breech presentation at term, of whom 374 (58%) were nulliparas and 267 (42%) were multiparas. They were managed according to the guidelines outlined above. Applying our selection criteria, 343 patients (54%) underwent elective prelabor cesarean section, and 298 (46%) progressed to a trial of vaginal delivery (Figure 181.3). Specific obstetric indications for elective prelabor cesarean delivery were present in 56% of cases; these included birth weight more than 3800 g, gestation more than 41 weeks, previous cesarean section, pre-eclampsia, oligohydramnios, suspected intrauterine growth restriction, hemolytic disease, and placenta prevail. Non-specific indications, such as maternal or obstetrician's preference pertained in 151 cases (44%).

Of 298 patients who progressed to a trial of vaginal delivery, 146 (49% of the total) delivered vaginally and 152 (51%) were delivered by intrapartum cesarean section (Figure 181.2); 13 (8.6%) intrapartum cesareans were performed in the second stage of labor. One hundred and forty-three of the intrapartum cesarean sections (94%) were performed for failure to progress in labor and seven (4.6%) for suspected fetal distress; all seven babies had Apgar scores of 9 at 1 min. The vaginal delivery rate in multiparas (63%) was significantly higher than the rate in nulliparas (37%) ($P < 0.001$) (Figures 181.4 and 181.5). Nine patients (6%), two nulliparas and seven multiparas, were ready to deliver on admission to the delivery ward. There were two intrapartum cesarean sections for cord prolapse: one was detected on admission in labor and one 2 h after admission. Epidural analgesia was used in 53% of labors (nulliparas 61% and multiparas 45%); 82 (56%) women with epidural analgesia delivered vaginally.

Mean birth weight and the frequency of birth weight exceeding 3800 g were significantly greater in

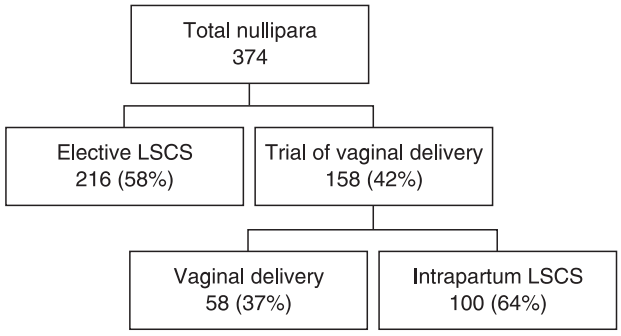

Figure 181.4 Outcome of labor in nulliparas. Adapted from Alarab *et al*.[4] with permission.

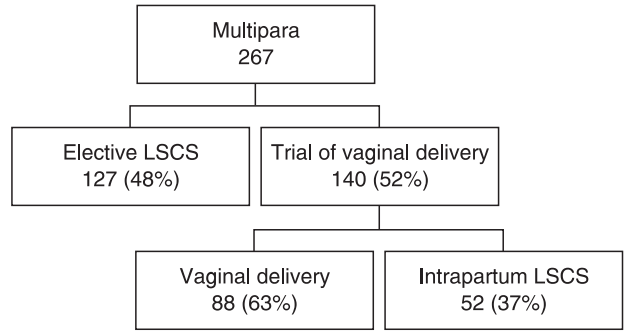

Figure 181.5 Outcome of labor in multiparas. Adapted from Alarab *et al*.[4] with permission.

women delivered by elective or intrapartum cesarean section compared with those delivered vaginally, particularly among nulliparas. The mean durations of the first and second stages of labor for nulliparas who delivered vaginally were 4.4 h (range 0.5–11), and 24 min (5–75), respectively, and for multiparas they were 3.0 h (0.2–11), and 13 min (10–45), respectively, indicating that our criteria for management of labor, including avoiding oxytocin and applying strict time limits for the first and second stages of labor, select out the larger babies for cesarean delivery. There was no significant neonatal morbidity and no intrapartum or neonatal deaths in normally formed infants in either the vaginally or cesarean delivered cohorts.

This study, in keeping with other well-organized retrospective studies[2,3,34,38,39] showed that vaginal delivery is still a safe option provided strict criteria for selection for a trial of labor and for the management of labor are applied, with a low threshold for cesarean delivery in either the first or the second stage of labor, and an experienced obstetrician to conduct the delivery.

The Term Breech Trial showed that cesarean delivery was safer than vaginal delivery for a breech birth and that perinatal morbidity and mortality were increased by a factor of 3 in the planned vaginal breech delivery group. These findings have been criticized for a number of reasons.[34,40] Intrauterine growth restriction, one of the exclusion criteria for vaginal breech delivery, was underdiagnosed; fetal monitoring in labor was inadequate; induction and oxytocin augmentation of labor were freely used; the definitions of prolonged first and second stages of labor would be questionable in most centers with a cephalic presentation; the study was conducted in 26 different centers with a range of approaches and possibly experience, and some of the centers had very few vaginal breech deliveries. An unexpected finding was that a composite of adverse perinatal outcomes was worse in countries with low background perinatal mortality rates; but analysis of perinatal deaths only showed no difference and revealed that some were unrelated to the method of delivery. The definition of perinatal morbidity used in the study has been questioned, and the normal outcome at 2 years for both arms of the trial supports that criticism.[15]

The study was, however, unique because of its size and organization and will probably never be repeated. While the Term Breech Trial was randomized and prospective, a large retrospective study[36] of over 33,000 breech deliveries from the Netherlands in Northern Europe reported results similar to those of the Term Breech Trial. This report from a country in which practices have been fairly standard and stable over years, and where vaginal breech delivery is widely practiced, probably carries more weight on this side of the Atlantic, because of their strong background experience of vaginal breech delivery and also because of a presumption in that country that vaginal breech delivery was perfectly safe with careful selection (at least until the publication of their recent trends[19]). The Dutch study also addressed one important question by showing that cesarean section was safer even in a group managed without induction or augmentation of labor with oxytocin, thus addressing a potential weakness in the interpretation of the Term Breech Trial. They did report that the highest neonatal morbidity and mortality occurred with delivery of the aftercoming head and was related to the duration of the second stage (a 20% complication rate with the aftercoming head after 90 min in the second stage).[36] This is a complication that we advise could be minimized with stricter guidelines for the duration of the second stage for nulliparas and multiparas. Although the question of the presence of an experienced obstetrician for the delivery was not addressed, we would assume that this was the case in the Netherlands. The authors suggested that obstetricians had rushed with 'unseemly haste' (*Macbeth*) to abandon vaginal breech delivery and perhaps should show more consideration for the long-term consequences of cesarean delivery.[36]

A study from Finland that compared breech cesarean delivery, breech vaginal delivery, and vertex vaginal delivery interestingly found no significant differences in perinatal mortality between the vertex and breech vaginal deliveries and less trauma in the

vaginal breech delivery group, although the Apgar scores were lower in the breech vaginal group. All adverse events were lowest in the planned cesarean section group. The breech vaginal group required fewer admissions to the outpatient department and the cumulative incidence of long-term morbidity in the breech vaginal delivery group was smaller to the age of 7 years than in the breech planned cesarean group. Age at going to school and school performance showed no dependence on the mode of delivery. They asked the question, 'Are our expectations of term breech infants unrealistically high?'.[16] A neonatal follow-up of babies born in the Term Breech Trial showed no significant differences at 2 years between the various groups.[15] Our study showed that with careful selection, careful management in labor, and the mandatory presence of an experienced obstetrician (arguably the most important factor), safe vaginal delivery could be achieved. With fewer vaginal breech deliveries, and shorter working hours for physicians (at least in Europe), the need for an experienced attendant at a breech delivery is fast becoming the weak link in the chain.

Studies[1,8] comparing morbidity in elective vs. emergency cesarean section for breech presentation showed no difference, although it has been argued[41] that the increased morbidity associated with emergency cesarean section in general outweighs the gain in vaginal breech delivery once the number of vaginal breech deliveries falls below a critical level. With our criteria for the management of breech labor, emergency cesareans are performed relatively early in labor (average 3.8 h, range 0.5–9 h in nulliparas and 2.4 h, range 0.5–8 h in multiparas) and because the lower segment has thinned out and the breech is usually not deeply engaged in the pelvis they are arguably the easiest cesareans from a technical point of view. Emergency cesareans after prolonged labor with a cephalic presentation are as difficult as an elective cesarean section with a poorly formed vascular lower segment, whatever be the presentation. We are not recommending a trial of vaginal breech delivery to facilitate a subsequent cesarean section, but feel strongly that the argument regarding an increased morbidity with emergency cesarean section is irrelevant within the guidelines for the duration of labor in our reported series.

Conduct of vaginal breech delivery

The breech is allowed to descend spontaneously to the maternal perineum; the fetal anus should be visible with a contraction. When delivery appears imminent, timing is critical to ensure that the delivery commences at the start of a contraction, holding back the presenting part if necessary. As the contraction begins, an episiotomy is timed to coincide with a concentrated maternal effort, the objective being to deliver the trunk of the baby with a single contraction. If the trunk delivers only up to halfway, we do not advise delivering the legs at this stage because the extended legs of the frank breech act as a splint to protect the cord, and may also provide a better stimulus for the next contraction than the soft fetal abdomen. If difficulty is experienced with delivery of the shoulders with the next contraction, traction should be applied to the fetal pelvis, keeping in mind the potential risk of damaging intra-abdominal viscera. Lovsett's maneuver should be used to deliver the shoulders. In general, traction should only be required as a last resort and the breech should be allowed to deliver by maternal effort. The breech should now be suspended from the mother, as this facilitates passage of the fetal head into the pelvis. Delivery of the head is controlled by either the Mauriceau–Smellie–Veit maneuver or with obstetric forceps. Some obstetricians find it easier to control the descent and delivery of the head using forceps and employ them routinely; in this case, the forceps are not used for traction. The most important principle is to deliver the head slowly, as rapid compression and decompression of a fetal head that has not undergone gradual molding can result in a tentorial tear or other injury. The same principles hold for cesarean breech delivery.

If the head does not descend into the pelvis on its own and delivery is not imminent with the next contraction, either of the above procedures can be used to deliver the head into the pelvis. In most centers, operative deliveries are performed in the lithotomy position, but delivery in the left lateral position should be considered because access is easier, and the baby can be suspended over the side of the bed when the trunk has been delivered.

Alternative approaches

Alternative methods to encouraging cephalic version and for vaginal breech delivery are described as part of an excellent and balanced review of the whole question of breech birth[42] but we have no personal experience with these.

The aftermath of the Term Breech Trial

The experience in the aftermath of publication of the Term Breech Trial was an almost immediate, dramatic change in practice, amplifying an already existing trend of rising cesarean sections rates for term singleton breech presentation. This trend had been first reported from the Netherlands,[18] with similar experience in the USA,[43] Canada,[44] and Australia/New Zealand.[19,45] The incidence of term breech has increased significantly in the periods studied, which may reflect a degree of indifference to the practice of ECV, which has been proposed as a viable solution for the rising cesarean section rate for breech presentation.[23] What was most surprising in some of the centers was the rapidity with which vaginal breech delivery was dropped in favor of cesarean section. It seemed almost as if a generation of obstetricians,

secretly terrified of vaginal breech delivery, could hardly wait for the 'permission' to abandon the practice that the Trial seemed to provide.[19] Nevertheless, the experience from the randomized trial (10%) and from our study (6%) showed that a proportion of women scheduled for planned cesarean breech delivery presented in an advanced stage of labor and required a vaginal delivery. In some cases, the diagnosis of a breech presentation will first be made in labor; in a comparison of such cases with antenatally diagnosed breeches, a higher vaginal delivery rate with no increase in neonatal morbidity among the cases diagnosed in labor was reported.[46]

In an editorial[43] titled 'Teaching Infrequently Used Skills: Vaginal Breech Delivery', the editor of the *American Journal of Obstetrics and Gynecology* argued that given two opposing views (vaginal vs. cesarean breech delivery), the one appearing to minimize professional liability risk will prevail in this litigious age. This view makes more compelling the question: How will we teach vaginal breech delivery? Perhaps we need to learn from educational approaches used for other infrequently used skills such as cardiopulmonary resuscitation (CPR) and management of shoulder dystocia. Teaching films, hands-on sessions, and mannequins have been shown to be of value in teaching CPR. Such approaches should be brought to bear for breech delivery. It is also important to remember that the technique of breech delivery during a cesarean section is similar to a vaginal breech delivery. All the common maneuvers – Lovsett, Mauriceau–Smellie–Veit, and application of forceps to the aftercoming head – are routinely employed, and a formal teaching approach could be used at this time.

In conclusion, the evidence suggests that most obstetricians feel that cesarean section is the preferred method of delivery for breech presentation, and this is already the prevalent approach in the developed world. There is evidence that ECV can reduce the incidence of breech presentation at term. Numerous studies from individual institutions have reported the safety of vaginal breech delivery at term, but whether this expertise can be maintained with fewer vaginal breech deliveries requires careful monitoring. Developing countries will have to balance a practice of prelabor cesarean for breech presentation against the long-term maternal risk of cesarean delivery, particularly where subsequent labor is likely to be poorly supervised, and also with the immediate complications and cost implications. It is an interesting irony that when the expertise for vaginal breech delivery exists and where vaginal breech delivery is widely practiced, there are arguably better results for this presentation compared with the developed world.[1]

182 Shoulder dystocia

F. Goffinet and D. Cabrol

Definition and mechanism

During normal labor and delivery, the fetal shoulder width (the bisacromial diameter) advances through one of the oblique diameters of the pelvic inlet: the posterior shoulder moves into the concavity of the sacrum or the sacrosciatic notch, while the anterior shoulder glides behind the symphysis. Then, as they descend, the shoulders turn into the anteroposterior diameter of the midpelvis. Shoulder width usually ranges between 12 and 13 cm; compressed, it passes easily through the pelvic inlet.

Shoulder dystocia (SD) can be categorized into three degrees of increasing severity:[1]

(1) Slight dystocia, in which the shoulders rotate normally, but the large size of the baby requires considerable compression of the shoulders in order to deliver.
(2) Unilateral dystocia, in which the posterior shoulder enters the pelvis, but the anterior shoulder remains above the symphysis.
(3) Bilateral dystocia, in which both shoulders remain above the pelvic inlet.

In the latter two types, downward traction on the fetal head when it has delivered serves only to aggravate the impaction of the shoulders in the pelvis. As the brachial plexus is already stretched once the head is delivered and one or both shoulders remains impacted, any further stretching through traction risks lacerations of the C5-T1 nerve roots. Prolonged forcible traction can lead to delivery only at the cost of injury to the mother and the child.

Because this anatomical classification is difficult to use in practice, more pragmatic definitions have been proposed and are sometimes used in the literature. These include: (1) a condition in which special maneuvers, in addition to downward traction and episiotomy, are required to deliver the shoulders; (2) the arrest of spontaneous delivery due to impaction of the anterior shoulder against the symphysis pubis; or (3) a time between the delivery of head and body longer than 60 s.[2]

Frequency

The variety of different definitions used in published series results in a great variability in the reported frequency of SD. If we consider only the third, most severe, stage, this accident occurs in 1 of every 4000 deliveries.[1] With more pragmatic definitions, the frequencies reported range from 0.2% to 2.1% of all vaginal deliveries.[3] The frequency also varies according to the population considered, and, in particular, according to the distribution of the principal risk factors, such as fetal macrosomia.

Maternal and neonatal consequences

Neonatal complications included mortality, asphyxial, neurologic, and orthopedic damage. Perinatal mortality may increase as much as ninefold among babies with SD,[4] although the perinatal mortality rate associated with it in a recent series was reported to be below 1%.[3] In a British study of 1,400,000 deliveries and 56 deaths directly associated with SD, the incidence of fatal SD was reported to be 0.04 per 1000 births and 0.025 per 1000 births when the definition of 'true SD' was used.[5] In this registry, the perinatal loss rate was 0.57 per 100 cases of SD, with a vaginal delivery rate of 70% and the SD incidence 1% of all vaginal deliveries. In their literature review, Rouse *et al.* reported two to four SD-associated deaths with SD per 100,000 births.[6]

Neonatal morbidity has been reported to complicate 24.9% of births with SD.[3] In addition to nerve injury and fractures, neonatal asphyxia, due to the long and difficult delivery, is a common causal mechanism. Hope *et al.* reported that in their series, the median interval between delivery of the head and the body for the 56 deaths caused by SD was only 5 min.[5] A 5-min Apgar score < 3 was found with a frequency 6–11 times greater in births with SD than in controls.[4]

The most common fractures are those of the clavicle and the humerus, associated with SD in 9.5% and 4.2% of cases, respectively.[3] The incidence of clavicle fractures in the general population is estimated as 2.7%;

among infants with a birth weight of 4000–4500 g it reaches 14%, and among those weighing more than 4500 g it reaches 38%.[1]

Gherman *et al.* reported brachial plexus injury (BPI) in 16.8% of SD cases and Rouse in 6–35%.[3,6] Most are temporary, persisting at 1 year among about 5–8% of babies.[3,6] The most common injury affects the C5 and C6 nerve roots and causes Duchenne–Erb paralysis. Paralysis of the C7 to T1 roots below the plexus (Klumpke paralysis) is quite rare, but has a worse prognosis, with a recovery rate of only 40% in 1 year.

Permanent brachial plexus palsy is not always associated with SD, or even with vaginal delivery: one study found that no perinatal risk factors could be identified in one-third of the cases of brachial plexus palsies identified in newborns.[7] Numerous other studies confirm that brachial palsies cannot be accurately predicted before delivery, either by risk factor scoring or by partographic analysis.[8,9] Finally, infants with transient brachial plexus neuropathies do not differ from those with permanent injuries with respect to most antepartum or intrapartum characteristics.[10] Birth weight is the only reproducibly identified risk factor; but a minority of large babies have brachial plexus injuries. In a series of 210,947 births, the overall incidence of BPI was 50 per 100,000.[11] This risk was 2.5-fold higher in neonates weighing 4000–4500 g and 10-fold higher in those > 4500 g.

Adverse maternal consequences of shoulder dysticia may include cervicovaginal injuries, third-stage hemorrhage, and infection.[3] The frequency of these complications is not well documented in the literature.

Table 182.1 Distribution of complications according to birth weight categories (from Gonen *et al.*[14])

	n (%)		
Birth weight	SD (*n* = 92)	BPI (*n* = 9)	Clavicle fracture (*n* = 39)
< 4000	46 (50)	5 (56)	32 (82)
4000–4500	40 (43.5)	3 (33)	7 (18)
> 4500	6 (6.5)	1 (11)	0

Risk factors and predictability

Risk factors

Fetal macrosomia is the principal risk factor of SD. Two recent series found the risk of SD to be 11.4% for babies weighing 4200 g or more and 22% for babies weighing 4500 g or more.[12,13] Table 182.1 summarizes the distribution of birth weights in the series by Gonen *et al.*, according to the three most common traumatic injuries.[14] The clear relationship between birth weight and the risk of SD and BPI notwithstanding, predicting SD from the presence of estimated fetal weight (EFW) is associated with numerous false-positive and false-negative predictions. The vast majority of macrosomic babies delivered vaginally do not present with SD. Moreover, half the cases of SD and BPI occur in children with a birth weight less than 4000 g. A recent review reports that 26–58% of the cases of SD and 24–44% of the BPIs occur among babies weighing less than 4000 g, even though the risk of SD among infants with macrosomia is multiplied by nine [OR = 9.1, 95% CI (8.3–10.0)].[15]

Maternal diabetes mellitus is an important factor that, because of its common association with fetal macrosomia, increases the chance of delivery trauma. The incidence of SD among children of non-diabetic mothers varies by birth weight category as follows: 4000–4250 g, 5.2%; 4250–4500 g, 9.1%; 4500–4750 g, 14.6%; and 4750–5000 g, 21.1%; for those with mothers with diabetes, the frequencies in the same birth weight groups are 12.2%, 16.7%, 27.3%, and 34.8%, respectively.[16] In a large series of children with birth weights > 4000 g, Langer *et al.* found that the risk of SD was multiplied 3.6-fold when the mother had diabetes.[4]

Other risk factors that have been implicated include a history of SD in a prior pregnancy (risk multiplied by 17), high maternal weight gain during pregnancy, multiparity, long labor, and the need for forceps-assisted delivery.[17] Table 182.2 summarizes the principal risk factors of macrosomia and SD. Because so many of these criteria are cross-correlated, it is difficult to identify their independent contributions to risk. The use of these criteria for predicting macrosomia and SD is thus disappointing. While their sensitivity is good, their specificity is very mediocre, because most women with at least one of these risk factors give birth to a child weighing less than 4000 g and without SD.

Prediction of fetal macrosomia: Evaluation of the available diagnostic methods

Prenatal assessment of the risk of SD is often limited to an assessment of the risk of macrosomia. Unfortunately, prenatal diagnosis of macrosomia is also difficult. Screening during standard prenatal monitoring generally involves abdominal palpation and measurement of fundal height, but this technique is quite imprecise. One study found the precision of EFW by clinical examination to be ±500 g in 82.5% of all cases but in only 35.3% of those with a birth weight > 4500 g.[18]

With the introduction of ultrasound in the late 1970s, it was hoped that the problem of this imprecision would be solved. Numerous formulas and indices for predicting fetal macrosomia have been reported; they used various combinations of biparietal diameter, head circumference, transverse abdominal diameter, abdominal circumference, and femur length.[19–21] These

Table 182.2 Risk factors for fetal macrosomia and SD

History	Current pregnancy	Intrapartum events
High maternal birth weight	Gestational diabetes	Abnormal labor, especially
SD	Excessive weight gain	during second stage
Macrosomia	Suspected fetal	Instrumental delivery for
Preexisting diabetes	macrosomia	failure to progress
Gestational diabetes	Post-term	at mid pelvis
Obesity		
Multiparity		
Maternal age >35 years		

formulas for EFW differ little in precision, and none is clearly superior to any other. The mean error is significantly higher in cases of macrosomia, reaching approximately 15%,[21,22] while 50–70% of the estimates have a mean error less than 10%.[22–25] For example, McLaren *et al.* showed that for an EFW of 4000 g, there was a 95% chance that the birth weight would range between 3288 and 4798 g and for an EFW of 4500 g, between 3750 and 5269 g.[26] These data confirm the imprecision of the EFW calculated by ultrasound, which thus yields many false-positive and false-negative predictions.

Several studies have compared the relative utility of clinical and ultrasound estimates for predicting birth weight at term, and most have not found ultrasound to be clearly superior.[27,28] In an earlier study, predicted birth weight was similar for ultrasound, clinical examination, and the woman's own estimate at the onset of labor.[29] Similarly, Gonen *et al.* found diagnostic value to be better with clinical examination alone than with clinical examination and ultrasound for predicting newborns ≥ 4500 g.[14]

In view of the imprecision of ultrasound in predicting fetal macrosomia, most teams do not systematically use it to estimate birth weight at the end of pregnancy. Generally, screening involves standard prenatal monitoring with ultrasound then performed only if macrosomia is suspected.

Prediction of the risk of SD

Since the principal goal is to predict SD (or, better, BPI) and not fetal macrosomia, several authors have sought to identify criteria specifically predictive of SD. Some risk factors have been identified, but their extremely low sensitivity and specificity make them essentially useless for practical decision making. This applies as well to radiographic pelvimetry for which there exist no data to justify its use to predict SD.

Among the most predictive factors, we find the sequence dubbed 'DOPE' (diabetes, obesity, postdatism, excessive fetal weight or maternal weight gain). Although the concurrence of these factors does not justify systematic cesarean, it signals the need for extreme prudence during labor.

Shoulder width is thought to be greater in newborns with SD than in those who had uncomplicated deliveries [30]. The factors associated with increased shoulder width are the same as those linked to SD and are often interdependent, as Verspyck *et al.* showed in a prospective study.[17] In addition to greater shoulder width, newborns with SD have other biometric characteristics different from those with the same birth weight but without SD.[31] These findings have led some authors to seek antenatal ultrasound criteria to predict SD. Some data suggest that differences between ratios of measurements (e.g. thoracic diameter to biparietal diameter, as well as between abdominal diameter or thoracic circumference and the biparietal diameter)[19,32,33] can identify fetuses at increased risk of SD. Riska *et al.* found the ultrasound measurement of the distance between the humeral heads to be significantly correlated with the measurement of shoulder width.[34] Others showed that shoulder width can be measured by magnetic resonance imaging (MRI) and suggest that the comparison of its measurement by MRI and radiopelvimetry might be a decision criterion.[35] Their studies are generally preliminary and isolated: prospective confirmation of these results will require considerable supplementary data. Moreover, only one report assessed the predictive value of these different parameters for the risk of SD: Verspyck *et al.* measured shoulder width in 2222 consecutive births.[17] The prevalence of SD in that study was 1.2%, and the mean shoulder width was significantly higher in the cases of SD than among those without it (130.1 ± 9.6 mm vs. 122.1 ± 10.5 mm, $P < 0.001$). Table 182.3 summarizes the predictive values for SD of the various significant parameters, especially the shoulder width. Although the predictive values of some criteria appear interesting, specificity must be very high if they are to serve as a basis for decision making in a general population. The overall conclusion of these authors was that regardless of the criterion or shoulder width threshold chosen, predictive value is insufficient to justify the use of these indicators in daily practice. Thus, even if shoulder width could be measured perfectly, that is, with no false-positives or false-negatives before labor (the measurements in the study discussed were made at birth), its predictive value for SD would be inadequate.[17]

Table 182.3 Predictive value of maternal and neonatal criteria significantly associated with SD (from Verspyck *et al.*[17])

Predictive factors	Sen	Spe	PPV	NPV
Shoulder width (mm)				
≥130	68.2	69.3	2.7	99.4
≥140	27.3	91.8	4.0	99.0
≥145	9.1	98.5	7.1	98.9
Maternal weight gain (kg)				
≥15	72.1	64.3	2.5	99.5
≥20	31.8	92.6	5.2	92.6
Gestational age at delivery (weeks)				
≥41	36.4	85.7	3.1	99.1
≥42	9.1	96.7	3.4	98.8
Birth weight (g)				
≥4000	36.3	95.3	8.7	99.2
≥4250	22.7	98.8	19.2	99.0
≥4500	13.6	99.5	25.0	99.5
≥5000	4.5	99.9	50.0	98.8

Prevalence of SD = 1.2% (n = 22)
Sen, sensitivity; spe, specificity; PPV, positive predictive value; NPV, negative predictive value

Prevention of SD

Efforts proposed to prevent SD generally entail an attempt to identify cases of fetal macrosomia so that a cesarean delivery can be performed, or labor induced before the fetus gains even more weight. Two assumptions underlie this approach. The first is that the estimation of SD risk is clinically meaningful, and the second is that some effective preventive management would be possible once the risk is identified.

To be clinically useful, a method to predict SD would need to be associated with only a small percentage of false-positives and false-negatives. In practice, diagnostic resources are directed toward fetal macrosomia rather than its complications. Accordingly, even if the diagnosis of macrosomia were always correct, the number of false-positive diagnoses of complications would be very high (approximately 90% of cases of macrosomia are not accompanied by SD). Moreover, it is not clear that intervention to prevent SD could be rationalized. For example, cesareans for 10% of the total population based on estimated excess fetal weight would result in a rise in maternal morbidity (or even mortality), an increase in the number of uterine scars, and changes in the organization and cost of care. These changes must be assessed according to the number of complications avoided.

Cesarean in cases of suspected fetal macrosomia

Some physicians consider that an EFW > 4000 g or > 4500 g indicates the need for cesarean delivery, although no policy of that type has yet been subjected to systematic evaluation. We can, nevertheless, study the risks and benefits of such approaches using theoretical decision models, such as those employed by Rouse *et al.*[6] Table 182.4 summarizes the consequences of three intervention strategies on the rates of cesarean delivery, SD, and BPI per million pregnancies without diabetes after 39 weeks' gestation.

A policy of systematic cesarean for EFW > 4000 g would result in a cesarean rate of 27.6% for the total population, and 3695 cesareans would be performed to prevent one Erb palsy; systematic cesarean for EFW > 4500 g would reduce the cesareans required to prevent one BPI to 2345. The authors conclude that such a policy is indefensible, given the number of unnecessary cesareans that would be performed. This low 'yield' is due to the low frequency of SD (1%) and the low predictive value of EFW for macrosomia and SD. If the mother also has diabetes, 489 cesareans would be necessary to avoid one case of permanent BPI at a threshold of 4000 g and 443 cesareans at a threshold of 4500 g.

Weeks *et al.* reviewed their 6-year experience with 504 consecutive cases of infants born weighing more that 4200 g.[36] Macrosomia had been diagnosed prenatally for 102 of these. The principal findings of the study (Table 182.5) were a significant increase in the number of cesareans before labor, more inductions of labor, and more failed inductions in the group with 'diagnosed fetal macrosomia' compared with the 'undiagnosed fetal macrosomia' group. The two groups did not, however, differ in their rates of SD or

Table 182.4 Obstetrical results and cost according to three different management policies for 1 million pregnant women with diabetes after 39 weeks (USA) (from Rouse *et al.*[6])

Management policy	CS (%)	SD (%)	BPI (n)	n of CS to avoid one BPI	Cost ($)**
Classic management	19.1	1.00	157*		9.0
Systematic ultrasound and cesarean if EFW > 4500 g	27.6	0.84	134	3695	18.0
Systematic ultrasound and cesarean if EFW > 4000 g	30.6	0.64	108	2345	26.0

CS, overall rate of cesarean deliveries in the population; n, number
*Or 0.0157%. **Millions of US dollars

BPI. The authors concluded that ultrasonography and induction of labor for patients at risk of fetal macrosomia should be discouraged.[36] These results are similar to those found in a prospective study in 15 maternity hospitals in Paris and the Ile-de-France area.[37] Although these findings must be interpreted prudently (the most high-risk cases may have been screened and delivered by cesarean), they nonetheless show the limits of decisions based on EFW. In another retrospective study, similar results were found: the policy of elective cesarean section for diagnosed fetal macrosomia (EFW > 4500 g) did not have a significant effect on the incidence of brachial plexus palsy.[38]

The problem seems different, however, in cases in which macrosomia is associated with another important risk factor, such as maternal diabetes. In a historical study of 1200 pregnancies of mothers with diabetes, the authors compared a period during which fetal weight was not estimated and a second period where a cesarean was performed when the EFW was ≥4250 g.[39] They found a significant reduction of nearly 50% (2.8% vs. 1.5%) in the SD rate, with only a moderate increase in the number of cesareans (21.7% vs. 25.1%). Accordingly, most authors consider that when the mother has diabetes, an EFW of about 4250 or 4500 g requires cesarean delivery; there are, however, no data precisely on point, probably because of the difficulty of recruiting enough subjects to reach a conclusion.

Should labor be induced when fetal macrosomia is suspected?

Many obstetricians think it is reasonable to induce labor before the weight of the fetus becomes excessive and increases the risk of complications associated with macrosomia. A systematic review of observational studies found, however, that labor induction for suspected fetal macrosomia increased the cesarean delivery rate without improving perinatal outcome.[40] Table 182.6 reports the results of a meta-analysis based on the two published trials:[42,43] their combined results show that induction of labor does not reduce the risk of cesarean or instrumental delivery. Birth weight and gestational age were comparable in both groups. Neonatal morbidity was similar in both but their statistical power to demonstrate differences with this regard was weak. Based on what we now know, inducing labor for suspected macrosomia is not recommended.

Management at delivery

Our ability to predict SD is unfortunately very limited, as pointed out above. The audit by Hope *et al.* of 56 cases of fatal SD showed that its occurrence was most often unpredictable.[5] SD occurs and will continue to occur in numerous cases with no known predictive factors. In view of this unpredictability, the only real solution is to prevent its complications (nerve palsies, fractures) by appropriate management at delivery. Obstetricians and midwives must know the appropriate maneuvers thoroughly. Each department should have a written protocol, which lists the order in which the different maneuvers should be performed, and these should be regularly explained and reviewed.

General rules

In all cases of suspected macrosomia, the entire team must be informed at the woman's arrival in the delivery room. A case–control study in the Paris metropolitan area of 384 deliveries of babies with macrosomia found that the midwife was alone for 53.4% of the spontaneous vaginal deliveries with suspected macrosomia.[37] At delivery, an obstetrician, anesthetist, and pediatrician should be in the delivery room with the midwife. Prophylactic use of the McRoberts maneuver and suprapubic pressure is not recommended in a population of patients at increased risk of SD, since it appears to be ineffective. Delivery time did not differ in a randomized trial between the prophylactic and control patients (24 ± 18 s vs. 27 ± 20 s, $P = 0.38$).[44]

The first step in management is the rapid recognition of SD, so as to avoid inappropriate procedures with potentially irreversible adverse consequences. The accoucheur must remain calm and act rapidly, but neither precipitately nor impulsively. A large episiotomy should be performed. Analgesia must be

Table 182.5 Obstetrical results and risks of SD according to whether macrosomia was predicted before birth (from Weeks *et al.*[36])

	Macrosomia predicted (n D 102) (%)	Macrosomia not predicted (n D 402) (%)	*P*
Cesarean (rate)	52.0	30.0	< 0.01
Cesarean before labor	14.7	10.2	NS
Cesarean before 4 cm (among attempted vaginal deliveries)	49.0	16.5	< 0.01
Induction	42.5	26.6	< 0.01
Failure of induction	59.5	33.4	0.01
SD	11.8	11.7	NS

Table 182.6 Induction of labor in cases of suspected fetal macrosomia: meta-analysis of results of two clinical trials (from Irion and Boulvain[49])

	Induction of labor (n=153)	Expectant (n=160)	Relative risk (95% CI)
Cesarean	32	38	0.88 (0.59–1.34)
Instrumental interventions	17	18	0.98 (0.53–1.82)
SD	9	9	1.06 (0.44–2.56)
BPI	0	2	0.21 (0.01–4.28)
Birth weight (g)	4086	4149	NS

perfect; peridural anesthesia is often sufficient, but in case of agitation or pain, general anesthesia may be administered.

The '3 Ps' summarize what absolutely must not be done:[1] Panic-pulling, Pushing, or Pivoting.[45] That is, do not exert traction, which might rupture the brachial plexus of the anterior shoulder; do not exert fundal pressure; and do not pivot the head by twisting the neck.

Several maneuvers have been described that are potentially useful for the resolution of impacted shoulders. Operators must not only know them perfectly, at least in theory, but also must know the order in which they will employ them. The protocol in our department calls for beginning with McRoberts maneuver, because it is the least invasive and the least difficult, and then, if it fails, attempting a Jacquemier maneuver (delivery of the posterior arm). The advantage of having two principal preferred maneuvers is that they are explained regularly to the staff at the morning meetings when interns, midwives, and the senior obstetrician describe in detail to the rest of the team any maneuvers they performed during the night. If the Jacquemier maneuver fails, a careful Woods maneuver will be attempted. If these fail, we recommend beginning them over, in the same order.

The McRoberts maneuver[1,46]

This is a simple method with a high success rate and should be attempted first. In a retrospective study of 236 cases of SD, use of the McRoberts position alone successfully alleviated SD in 98 cases (42%).[47] The woman's feet should be removed from the stirrups and her legs hyperflexed at both the hip and the knee joints, so that her thighs rest on her abdomen, while her buttocks remain in complete contact with the delivery table. This maneuver elevates the pubic symphysis and thus brings the axis of descent closer to the umbilical–coccygeal axis of the pelvic inlet.

Oblique suprapubic pressure by an assistant on the median line above the symphysis is used in association with the thigh hyperflexion and is part of the maneuver. It pushes the posterior face of the anterior shoulder toward the ventral surface of the fetus, thereby reducing shoulder width. The operator applies downward traction in an attempt to accomplish delivery. Fundal pressure is expressly contraindicated.

The Jacquemier maneuver

This maneuver is designed to deliver the posterior arm of the fetus. The accoucheur, kneeling, introduces a lubricated hand into the vagina. The palm of the hand should face the fetal abdomen (left hand if the back is to the left, right hand if the back is to the right) and enter the uterus along the umbilical–coccygeal axis. The posterior shoulder is identified at the level of the sacral promontory; the arm is followed distally past the elbow and forearm (often flexed), and the hand grasped firmly. If the hand cannot be grasped initially, the humerus should be brought in front of the fetal thorax with the operator's fingers placed to support the humerus, to reduce the risk of its fracture.

Once the hand is grasped, the arm is withdrawn gently, by sweeping it across the front of the chest and face of the fetus. This maneuver transforms the bisacromial diameter (shoulder width) into an axillo–acromial diameter and may be sufficient to deliver the fetus. If delivery of the posterior arm is not sufficient, the body should be rotated 180° to transfer the anterior shoulder into the posterior shoulder and then repeat the Jacquemier maneuver.

Other maneuvers

The Woods maneuver

This approach involves transforming the posterior shoulder into the anterior shoulder. It is important to exert the rotational force on the shoulders, and not the head. To do this, the accoucheur places a palm behind the posterior shoulder and exerts pressure on it to force a 180° rotation of the shoulder axis. Exerting pressure in the opposite direction on the front of the anterior shoulder can facilitate rotation. This maneuver allows the engagement beneath the sacral promontory of the anterior shoulder, which becomes posterior at the end of the rotation.

The Zavanelli maneuver (replacement of the fetal head)

This method is used for dystocia considered intractable. It involves flexion of the fetal head, after tocolysis, in order to reintroduce it into the vagina, and then the uterus in order to perform a cesarean. In nearly 70 published cases, this maneuver has often been presented as easy to accomplish.[48] In a retrospective study, O'Leary *et al.* reported 59 women who underwent replacement of the fetal head after unsuccessful attempts at vaginal delivery.[49] All but six infants were successfully replaced and delivered by cesarean. Three neonates died and five had permanent brachial plexus palsy. Hysterectomy was required for two women. The authors conclude that cephalic replacement is a useful technique that need not be used as a last resort, but may be considered if any undue difficulty is encountered. It may have a place as an initial technique for those who are inexperienced with management of SD. It is difficult to interpret the results of this study because we know neither the severity of the cases of SD nor what maneuvers were attempted before the cesarean. The role of this maneuver must still be defined. We think that it is preferable to attempt the maneuvers described above rather than resort early to this technique. We have never had to use this extreme method in our hospital and have had no deaths associated with SD over the past 10 years.

Conclusion

The occurrence of SD in the delivery room, because it is so often unable to be predicted, cannot be attributed simply to poor medical practice. Even careful screening for macrosomia cannot eliminate this catastrophic complication. SD occurs and will continue to occur in numerous cases that have no known predictive factors. In view of this unpredictability, the only real solution is to prevent its complications (primarily BPI, fractures, and hypoxia) by optimizing management at delivery. Obstetricians and midwives must know the appropriate maneuvers thoroughly, and each department should have a written protocol, which lists the order in which they should be attempted. Moreover, these maneuvers must be regularly explained and their procedures repeated. It is also necessary that the entire obstetrical team – including the midwife, senior obstetrician, anesthetist, and pediatrician – be in the delivery room for cases of suspected fetal macrosomia.

183 The third stage of labor and the puerperium

G. Sylvestre and Y. S. Thornton

The third stage of labor is defined as the time between delivery of the infant (or infants) and that of the placenta. The puerperium, also referred to as the postpartum period, is broadly defined as the interval between placental delivery and 6–12 weeks after delivery. While a wealth of literature is available on prenatal care and on the first and second stages of labor, relatively little attention has been devoted to advance our understanding of the third stage of labor and the puerperium.

The puerperium is remarkable in that many of the physiologic changes that evolved gradually over the course of pregnancy in virtually every organ system revert to the non-pregnant state at an astonishing pace. These rapid changes are well tolerated by most women, but those with certain underlying pathologic conditions may not withstand them very well, and may suffer serious complications. For example, the sudden blood loss and fluctuations in the cardiovascular indices in the immediate postpartum period can cause acute decompensation in patients with cardiovascular conditions such as pulmonary hypertension or aortic stenosis. Not surprisingly, more women die from anomalies of the third stage of labor than during the two other stages combined.[1,2]

The third stage of labor

Normal third-stage physiology

The delivery of the infant at the end of the second stage causes a dramatic reduction in uterine volume. This rapid uterine involution leads to a proportional decrease in the decidual surface where the placenta is inserted, leading to the shearing of the placenta off its uterine attachment. Myometrial contractions then effectively compress the large blood vessels and venous sinuses lying in the placental bed, thereby minimizing excessive bleeding and assisting expulsion of the placenta and membranes. Uterine massage during that moment is uncomfortable for the mother, and is unlikely to hasten the process of placental expulsion. For most parturients, spontaneous placental separation occurs within two contractions after vaginal delivery of the neonate and placental expulsion is usually completed after a few more contractions. Although the length of the third stage does not vary significantly across gestational ages, with median durations of 8 and 5 min, at 26 and 40 weeks, respectively, many studies have noted an association between preterm delivery and prolonged third stage of labor.[3]

Minimizing blood loss in the third stage

Under normal circumstances, in the interval between delivery of the infant and effective compression of the placental bed vasculature by myometrial contractions, a substantial amount of blood loss normally takes place. Given the physiologic increase in blood volume associated with pregnancy, this blood loss is usually well tolerated and intervention to minimize it is probably unnecessary for most parturients. However, in some cases, such as patients with significant anemia or those with a history of postpartum hemorrhage, pharmacologic and non-pharmacologic interventions may be warranted to minimize puerperal blood loss. The association between prolonged third stage and postpartum hemorrhage is well documented, so most interventions are aimed at decreasing the duration of the third stage.

Controlled cord traction (Brandt–Andrews technique)

After delivery of the infant, many clinicians apply controlled cord traction (CCT) to the umbilical cord at the level of the introitus. At the same time, cephaloposterior pressure on the uterus or direct grasping of its fundus is used to prevent uterine inversion. The CCT method, widely used in Canada and elsewhere, is less popular in the United States, where expectant management and maternal pushing efforts are more commonly used to achieve placental delivery.

Khan *et al.* compared CCT to no intervention and found CCT was associated with significantly decreased incidences of postpartum hemorrhage, prolonged third stage, and the need for surgical

intervention.[4] Another well-designed randomized controlled trial comparing CCT to expectant management failed to detect a difference in the need for surgical removal of the placenta, but confirmed reduced blood loss and shorter duration of the third stage[5] in the intervention group.

Oxytocin/oxytocin and ergotamine

The efficacy of oxytocin administered after delivery in reducing the risks of postpartum hemorrhage, the need for secondary uterotonic drugs, and postpartum anemia has been well established.[6,7] In theory, its administration prior to placental delivery could lead to contraction of the cervix and of the lower uterine segment, thus interfering with placental expulsion; but one study comparing administration of oxytocin pre- to postplacental delivery failed to show any difference in the incidence of placental retention and the need for surgical placental removal.[8]

Oxytocin is most commonly administered intravenously as a dilute solution after placental delivery, but can also be given intramuscularly and as a direct injection in the myometrium. Intravenous injection of an undiluted oxytocin bolus is best avoided, as sudden hypotension can occur with this route. The addition of the ergot derivative ergometrine to oxytocin substantially increases the rate of hypertensive episodes, nausea and vomiting after its administration and offers, at best, marginal superiority over oxytocin alone.[9,10]

Misoprostol

In the last decade, misoprostol, a prostaglandin E_1 analog, has been used more frequently in obstetrics and its use has been introduced for the prevention and treatment of postpartum hemorrhage. Oral, vaginal, and rectal routes of administration have been described, with varying degrees of success. Its greatest advantages over other drugs used to prevent postpartum hemorrhage are its low cost, ease of storage, and non-intravenous route of administration. One randomized controlled trial suggested superiority of rectal misoprostol over placebo,[11] so in countries where oxytocin is unavailable, misoprostol is a welcome alternative. Oxytocin is, however, superior to rectally or orally administered misoprostol, and is, therefore, the drug of choice for this purpose. The addition of oral misoprostol to intravenous oxytocin may be slightly superior to oxytocin alone in preventing postpartum hemorrhage.[12,13]

Retained placenta/abnormal placentation

Traditionally, a prolonged third stage is diagnosed when the placenta has been retained for more than 30 min. Irrespective of elapsed time, in the presence of heavy vaginal bleeding, manual removal of the retained placenta should be undertaken immediately. In a cohort study of third-stage duration, Dombrowski *et al.*[3] noted that 11.5%, 3.5%, and 2.1% of patients required surgical removal of the placenta at 26, 34, and 40 weeks' gestation, respectively. In addition to preterm birth, other factors that have been associated with a prolonged third stage include fetal anomalies, pre-eclampsia, nulliparity, and labor induction.[14]

Surgical removal of the placenta usually involves introducing a hand through the vagina, finding the plane between the uterus and placenta, and then separating the placenta from its uterine attachment. Regional or general anesthesia is usually appropriate for this procedure, although intravenous sedation can also be used. If cotyledons or pieces of membrane appear to be missing from the removed specimen, or if the specimen is extensively fragmented, the procedure should be completed with curettage of the uterine cavity, using a large curette. If difficulty is encountered in finding the plane between the uterus and placenta when attempting to extract the placenta, or if fragments are resistant to removal, or if bleeding becomes brisk, one should suspect placenta accreta. Excessive traction on the uterus or overaggressive curettage places the patient at risk of uterine inversion, perforation, and can contribute to severe hemorrhage. In such cases, it is usually wiser to proceed promptly to hysterectomy. The following factors place patients at particularly high risk for placenta accreta and percreta:

- Prior uterine incision (e.g. cesarean or myomectomy)
- Multiple previous curettages or intrauterine manipulations (such as hysteroscopic myomectomy or polypectomy)
- Abnormal placental location (e.g. placenta previa or low-lying placenta)
- Grand multiparity.

Before attempting manual removal of a placenta in a situation in which there is a high risk of placenta accreta, good intravenous access is important, and blood for transfusion should be available when possible.

Uterine inversion

This uncommon but serious complication occurs with an incidence of 1 in 3000–6000 deliveries. It is encountered more frequently with a fundal placenta, and may be more common with excessive traction on the umbilical cord between uterine contractions. Typically, partial delivery of the placenta is noted, and is followed rapidly by severe blood loss and hypotension. Uterine inversion is graded as incomplete, complete, or prolapsed. Incomplete inversion is limited to the fundus and does not reach the cervix. Complete uterine inversion refers to the delivery of the uterine fundus and corpus through the cervix. If the inverted uterus extends beyond the introitus, it is referred to as a prolapsed inversion. Uterine inversion is an obstetric emergency and, unless corrected rapidly, the cervix and lower uterine segment create a constricting band around the inverted fundus. The constriction causes edema of the uterus, reduction of

its blood supply and, eventually, necrosis. The following sequence of steps should be followed to manage uterine inversion:

(1) If recognized early, before substantial edema is present, the uterus can be replaced without anesthesia through the constricting band, with transvaginal pressure over the inverted fundus.
(2) When the constricting band is too tight and the uterus too edematous, the maneuver described above should be tried using a combination of general anesthesia and uterine relaxants, which may assist in releasing the constriction.
(3) If still unsuccessful, laparotomy should be performed. A combination of traction on the round ligaments from above and upward pressure on the uterine fundus from below are applied.
(4) A posterior vertical incision can be made on the posterior wall of the uterus and is useful in many ways.[15,16] It allows the surgeon to visualize directly and to reverse the inversion; it makes upward traction easier; and it relieves the constricting band.

It is of utmost importance to replace the blood lost aggressively, as hemodynamic shock is a frequent complication. Intravenous access through two large-bore catheters is recommended. Unless it has already separated from the uterine wall, the placenta should not be detached during the above manipulation, as profuse bleeding may result. It should be removed only once the uterus is restored to its normal position and the patient is hemodynamically stable. Once the uterus is successfully repositioned, there is a great risk of atony. Therefore, all uterine relaxants should be discontinued and uterotonics administered.

The puerperium

Postpartum hospital stay

From the beginning of humanity until the 20th century, the vast majority of deliveries occurred at home, either unsupervised or monitored by lay attendants. In the early 1900s, a new trend began, and childbirth became a more 'medicalized' event in the industrialized world, taking place increasingly in hospitals (often referred to as 'lying-in hospitals') and supervised by medical personnel. There were many perceived advantages to hospital birth:

- Hospital births were safer. With more births taking place in hospital, a significant reduction in both perinatal and maternal morbidity was observed, attributable to some extent to hospital-based childbirth.
- Some interventions, such as analgesia, cesarean birth, antibiotics, and transfusions, were accessible only in a hospital setting.
- It allowed the opportunity for medical personnel to be trained in obstetrics.
- Women could rest more comfortably away from their home.

Until a few decades ago, hospital bed rest was recommended for the postpartum woman, often for an extended period of time. Since the 1980s, however, this trend changed, with more and more women wishing to return home as soon as possible after the delivery. The cause for this shift probably is a combination of the desire of women to 'demedicalize' childbirth and, in some countries, a desire to decrease the costs associated with childbirth and the puerperium.

In the United States, the law in most states requires hospitals to allow a minimum of 48 and 96 h postpartum stay after an uncomplicated vaginal birth and cesarean delivery, respectively. Discharge within 24–48 h after an uncomplicated birth, has proven safe in most contexts.[17] Prior to discharge, the following minimum conditions should be met:

- Common maternal and neonatal problems such as infection, bleeding, severe anemia, and hyperbilirubinemia have been ruled out.
- Neonatal screening has been completed, in accordance with local regulations. For example, neonatal screening for phenylketonuria is required by many states. This test must be performed after 24 h of life, and unless it has been arranged for testing as an outpatient, this precludes neonatal discharge before 24 h of life.
- The mother must be familiar with breast-feeding or, if applicable, other forms of infant nutrition. Frequently, optimal 'hands-on' education about breast-feeding cannot take place immediately postpartum, a period during which the breast milk cycle has not yet been established. This must be taken into consideration before discharge. Sometimes formal home visits during the days after early discharge are used for follow-up and patient education.
- The mother is properly educated about normal and abnormal postpartum and neonatal findings.
- Appropriate resources are available to ensure efficient and rapid assessment of the mother or newborn, should any acute problem occur at home, or should the parents have any questions or concerns.
- Potential social problems that could compromise care for the newborn have been addressed, such as financial difficulties or limited intellect.

In a Canadian study, Liu *et al.* reported a higher readmission rate in children discharged within 48 h, most commonly for neonatal hyperbilirubinemia, feeding problems, and suspected infection.[18] In another study, maternal readmission rates were found to have been similarly affected by early discharge. When compared to a 5-day postpartum stay after a cesarean delivery, women who were discharged at 2, 3, and 4 days

postcesarean have a readmission rate increased by 21%, 18%, and 10%, respectively.[19] Ideally, preparation for short postpartum stays should take place early in prenatal care so that patients deemed suitable for early discharge, and, where it is optional, willing to participate, can be identified. Multiparas with proper home support are often good candidates.

Physiologic changes

From conception until delivery, many maternal organ systems have undergone some degree of physiologic or anatomic changes to adapt to the pregnant state. The return to prepregnant status is not immediate, and in some cases, the changes induced by the pregnancy are permanent (e.g. the cervix and the breast).

Postpartum weight loss

The rate of obesity in the Western hemisphere is increasing, particularly so in the United States, where over 50% of women have a body mass index of over 25 kg/m^2,[20] and where 18% of women are frankly obese, defined by a body mass index over 29 kg/m^2.[21] One event that most pregnant women look forward to is the dramatic weight loss that occurs during the puerperium. Although considerable weight is shed immediately through delivery of the fetus, amniotic fluid, and placenta, the remainder of the weight gained during pregnancy – increased fat stores and expanded intravascular and extracellular fluid – is lost more slowly. Rooney and Schauberger studied the postpartum weight pattern in a cohort of 795 women from Wisconsin.[22] At 2 weeks, 6 weeks, and 6 months postpartum, the average weight lost was 9.7, 10, and 11 kg, respectively. Twenty-two percent of patients had returned to their prepregnancy weight by 6 weeks and 37% by 6 months. Most women were still above their prepregnancy weight at 6 months postpartum, with an average net weight gain of 1.4 ± 4.8 kg. The persistence of net weight gain after pregnancy was confirmed by a large study from Smith *et al.* During a 5-year period, they studied the effects of pregnancy on weight in a racially diverse cohort of 2788 women. When compared to women who remain nulligravid throughout the study period, black and white women who experienced a first pregnancy gained an extra 4.3 and 2.3 kg, respectively. The findings did not differ significantly when corrected for behavioral factors such as baseline fitness, smoking status, and education.[23]

Although women who gain weight excessively during pregnancy lose more weight postpartum than those who gain more modestly, many authors have also noted that these women also retain more weight at 6 months postpartum and are at increased risk for long-term obesity.[24] Less weight is retained postpartum in smokers and in women who return to work promptly. In a large cohort of women studied during more than one pregnancy, Green *et al.* found that there was a direct correlation between weight gain during the first pregnancy and the weight at the onset of a subsequent pregnancy.[25] Cesarean delivery is also associated with delayed postpartum weight loss, but at 6 months that difference is no longer significant. Breast-feeding has not consistently been associated with more effective postpartum weight loss but, reassuringly, aggressive maternal weight loss through diet and exercise has no deleterious effect on the growth of breast-fed infants.[26]

It is important to note that although there are clear associations between pregnancy and postpartum weight patterns and long-term development of obesity, it has not been established whether or not interventions for weight control during pregnancy or the puerperium have any impact on enduring obesity.

Uterus

At term, the uterus weighs nearly 1 kg and its fundus reaches the level of the xyphoid process. Its cavity is large enough to accommodate one (or more) fetus(es). Immediately after delivery of its content, the uterus contracts and involutes down to the dimensions it had at 20 gestational weeks. The uterus then continues to decrease in size through a diminution in cell size and through dissolution of the connective tissue framework. Two weeks later, it usually has returned to its pelvic location. Uterine involution plateaus at 12 weeks postpartum and, for primiparas, the organ rarely returns to its original nulligravid size.

Endometrium

Within days following the delivery, the superficial decidual layer necroses and sloughs off in the form of lochia, a term used to describe the vaginal discharge during the puerperium. New endometrium is regenerated from the underlying basal layer and within 7–10 days after delivery, the endometrial surface has been completely regenerated with the exception of the area of placental implantation. The placental site is slowly resurfaced from the adjacent growth of new endometrium.

Lochial discharge is divided into three phases. Immediately postpartum, it consists of *lochia rubra*, a bloody discharge that lasts until the third or fourth day postpartum. It is then replaced by *lochia serosa*, a mucopurulent discharge with a more watery consistency that lasts up to a few weeks. Eventually, the blood and water content of the discharge decrease and its inflammatory cell content increases, forming the *lochia alba*, a yellowish-white discharge that lasts a few weeks further postpartum. Although it is often thought that lochial discharge stops after 2 weeks postpartum, more recent research suggests that many women experience a longer duration than previously thought. The duration of the lochia varies, and averages approximately 5 weeks, with a frequent waxing and waning amount of flow and color. In a cohort of 477 Filipina multiparous women, Visness *et al.* reported that postpartum vaginal discharge persisted

beyond 6 weeks after delivery in nearly 10% of women.[27]

Cervix

Immediately after delivery of the uterine contents, the cervix retracts, looks edematous, loses much of its elasticity, and frequently bears minor lacerations, especially on its lateral edges. Although the cervix regresses back to its prepregnancy appearance and consistency after approximately 1 week, the external os never reachieves its pinpoint nulligravid appearance; it is wider, flat, or stellate in appearance.[28]

Perineum, perineal lacerations, and episiotomy

Some degree of perineal pain is almost universal during the immediate puerperal period, and is usually proportional to the severity of the lacerations or episiotomy. Ibuprofen is the analgesic of choice as it usually provides sufficient perineal analgesia, relieves the pain from postpartum uterine contractions, and, being present in very low levels in breast milk, is safe for the breast-fed newborn.[29] Further relief can be obtained by cold Sitz baths, where ice cubes are added to the water in which the perineum is immersed. The cold temperature provides immediate relief by decreased excitability of severed nerve endings.[30]

Perineal infections are surprisingly uncommon, given the high bacterial colonization of the lower genital tract and high frequency of perineal lacerations. This is probably explained, at least to some extent, by the dense vascularity of the perineal tissues. Perineal injury dehiscence usually presents within a few days or weeks postpartum, and is almost always associated with infection of the involved tissues.[31] For this reason, immediate reapproximation of episiotomy or laceration breakdown has been traditionally discouraged, with a period of 3 or 4 months usually allowed until secondary repair is contemplated. This period allows the tissue to revascularize, the infection to clear, and, in most cases, the injury to heal spontaneously by primary intent. Some authors advocate early repair of episiotomy or laceration breakdown, i.e. within a few days after the dehiscence.[32] If performed early, the repair must be preceded by meticulous debridement of necrotic tissue, diligent cleaning of the wound edges (using Sitz baths and local wound care) and clearance of infection, with systemic or local antibiotics. Once the wound edges are well granulated and show no evidence of necrosis or infection, usually after a few days, they are reapproximated using usual postpartum laceration repair techniques.

Bladder

There has recently been an extensive burst of new data concerning the effects of pregnancy and delivery on the urinary tract. Both hormonal and mechanical factors account for these changes. Vaginal delivery leads to marked distension of the lower genital tract and may cause some degree of trauma to the urethra, bladder, and pelvic floor. The most commonly observed postpartum urinary dysfunctions are urinary retention, usually a short-term, self-limited problem, and genuine urinary stress incontinence, which can be more of a chronic issue. Some authors have found increased rates of postpartum bladder dysfunction in the second stage complicated by macrosomia, use of forceps or vacuum, and perineal lacerations. Other authors suggest that vaginal delivery in itself is a risk factor for the subsequent onset of urinary dysfunction, such as genuine stress incontinence,[33,34] and go even further in suggesting that there may be, in selected cases, a role for elective cesarean delivery in preventing incontinence. Urinary incontinence is an underestimated and under-reported problem and some degree of urinary incontinence has been described in at least 12% of women following delivery. Factors associated with a more severe degree of incontinence include development of symptoms during pregnancy and anteceding pregnancy. It is unclear whether the use of Kegel exercises during pregnancy and the puerperium ameliorates the risk and course of urinary stress incontinence.[35]

Lactation and breast feeding

A full description of lactogenesis and breast feeding is beyond the scope of this chapter. Nevertheless, important considerations about breast-feeding are introduced here, and should be known by any clinician dealing with women in the puerperal period. After a period of relative unpopularity in the United States, breast feeding is regaining ground with over 60% women now having done some breast feeding by the time they leave the hospital. Breast feeding offers many advantages to both mother and newborn: transfer of immunoglobulins (IgA) to the newborn with consequent decrease in the incidence of gastroenteritis, colic, and other infections; decreased admission to the hospital during infancy; improved maternal–infant bonding; low cost; and reduced long-term development of diabetes and obesity. Maternal advantages include a reduced incidence of breast and ovarian cancer, a degree of contraception, and reduced anemia, from the delayed return of menses. Successful lactation relies on many factors: motivation of the mother; physicians and nurses who understand breast feeding and can provide assistance and advice; and a hospital or birthing center hospitable to breast feeding and able to provide adequate education on the topic.

Breast feeding relies on milk production (lactogenesis) and the ejection (let-down) reflex. Progesterone exerts an inhibitory effect on lactogenesis. The dramatic decrease in its concentration immediately after delivery allows lactogenesis to begin, a process that is mediated by prolactin. Milk production gradually

increases from as little as 50 ml in the first 24 h to 750 ml/day by the eighth day.[36] Milk ejection is mediated through the release of oxytocin, which contracts the myoepithelial cells within the milk sinuses. Suckling of the infant stimulates both milk production from the lactotrophs and milk ejection from the milk sinuses and ducts, via the release of prolactin and oxytocin, respectively.

It is important that mothers (and their attendants) understand that the relatively limited production of milk in the first few days is a normal event, and that the infant can safely lose up to 5–10% of its body weight during that period. That weight is usually regained by days 7–10. The breast-fed infant should void and stool at least once, twice, and three times during the first, second, and third days of life, respectively. After this, at least six voids and three stools should be expected. Voids and stooling less than this or weight loss beyond 7% warrant reviewing breast feeding techniques with the mother. Breast feeding is not contraindicated in women who previously underwent breast surgery, such as reduction mammoplasty and breast augmentation, providing that the lactiferous ducts were not substantially disturbed. Patients who had mammoplasty via periareolar incisions, and those who had very little breast tissue prior to breast augmentation are more at risk for insufficient milk quantity.[37–39] Patients who had a breast cyst removal or a lumpectomy can usually breast feed without problems.[40] Adequate caloric intake in the newborn is confirmed by monitoring proper weight gain and frequency of voiding and stooling episodes as described above.

Table 183.1 Symptoms of major postpartum depression with postpartum onset (from American Psychiatric Association:[41] postpartum depression is defined in the DSM-IV as that which begins within 4 weeks after delivery)

Major depression is defined by the presence of five of the following symptoms, one of which must be either depressed mood or decreased interest or pleasure*

- Depressed mood, often accompanied or overshadowed by severe anxiety
- Markedly diminished interest or pleasure in activities
- Appetite disturbance – usually loss of appetite with weight loss
- Sleep disturbance – most often insomnia and fragmented sleep, even when the baby sleeps
- Physical agitation (most commonly) or psychomotor slowing
- Fatigue, decreased energy
- Feelings of worthlessness or excessive or inappropriate guilt
- Decreased concentration or ability to make decisions
- Recurrent thoughts of death or suicidal ideation

*Symptoms must be present most of the day nearly every day for 2 weeks. A diagnosis of major depression also requires a decline from the woman's previous level of functioning and substantial impairment

Postpartum cognitive issues, postpartum depression (PPD), and postpartum psychosis

Even in the most uneventful pregnancy, significant physical, biochemical, and important psychosocial changes take place, at a relatively rapid pace. Consequently, pregnancy, delivery, and the puerperium bring about unique and complex stresses. The psychological changes noted during pregnancy are well documented but not fully understood and are probably the result of interactions among social, biological, and cultural factors. Forgetfulness, confusion, and inability to concentrate are often reported during the puerperal period. In addition, 'postpartum baby blues' are common, and manifested by anxiety, sadness, irritability, and some degree of confusion. Unlike PPD, the baby blues usually do not significantly interfere with daily functioning and resolve by the 10th postpartum day. These minor mood and cognitive changes are almost universal – and most likely benign in nature; but 10–15% of women suffer from more clinically concerning psychiatric disorders.

PPD is a well-recognized entity and has been reported in at least 10–12% of women in the postpartum period. The clinical findings associated with PPD are similar to non-puerperal depression, and its diagnostic criteria are identical,[41] except that they must be present within 4 weeks after birth (Table 183.1). The diagnosis is often delayed or the condition simply missed because mood changes, weight loss, or change in appetite – classical signs of depression – can easily be considered normal postpartum symptoms by the inexperienced clinician. As in non-puerperal depression, management usually consists of a combination of psychotherapy and pharmacotherapy. Although some antidepressants must be used cautiously in the breast feeding mother, most have little effect on the breast-fed infants. The agents of choice are the secondary amines and the selective serotonin reuptake inhibitors, which have gained increasing popularity in the last decade.

Risk factors for PPD include pregestational psychiatric conditions, antepartum pregnancy complications, especially those requiring hospitalization, complications during parturition, and poor social support. Women who experience PPD are at risk for a recurrence in a subsequent pregnancy as well as for non-puerperal depression.

Postpartum psychosis is a rarer, but serious condition. There is significant risk for both newborn and mother and it therefore should be considered a psychiatric emergency. Suicide or infanticide has been reported to occur in 5–10% of cases. Its onset is usually within the first 2 weeks postpartum and is characterized by marked disorganization, delusions, and

hallucinations. Compared to non-puerperal psychotic episodes, postpartum psychosis is often more akin to psychosis caused by an organic syndrome. Neuroleptics, lithium carbonate, electro-convulsive therapy, and antidepressant drugs have all been used in the treatment of postpartum psychosis with some degree of success. However, the optimal management of PPD remains unclear, as there are limited numbers of comparative trials looking at the efficacy of the various pharmacologic agents. Given the lack of data at this point, the therapeutic approach is similar to the non-pregnant state. Compared to non-puerperal psychosis, recovery from postpartum psychosis is faster, and its overall long-term prognosis is better. The recurrence rate in subsequent pregnancies is 20%. Interestingly, some authors have described the use of sublingual estrogen, and reported significant efficacy, for the treatment of both postpartum psychosis[42] and PPD.[43]

Sexuality and the puerperium

Resumption of sexual activity

Physicians frequently recommend an arbitrary period of abstinence after delivery, usually between 2 and 6 weeks. There is little evidence that it is medically necessary but, obviously, there are many non-medical reasons that women choose to abstain from sexual activity during the postpartum period, including sleep deprivation, concerns about the newborn, sudden change in the family dynamics, lochia, perineal pain and tenderness, and fear of pregnancy. For many women who have had a vaginal birth and for all women who have had an abdominal delivery, intercourse shortly following delivery would be painful, as a certain period of time is needed for proper perineal and abdominal healing. Furthermore, the hypoestrogenism associated with breast feeding frequently contributes to vaginal dryness and consequent dyspareunia. After the vagina has healed properly, this problem is easily managed with a simple vaginal lubricant. If the problem is recalcitrant, local estrogen cream can also be used. Although a small amount of hormone is absorbed systemically with the local use of estrogen, breast feeding should not be affected.

Resumption of fertility and menstruation

The return of menstruation is highly variable during the postpartum period, and is significantly influenced by breast feeding. Campbell and Gray[44] and Gray *et al.*[45] extensively studied the relationships among lactation, ovulation, and menstruation. In their cohort of 22 non-lactating and 66 lactating mothers, first ovulation occurred on average 45 days after delivery among non-breast feeding mothers and 189 days among breast-feeding mothers. The initial menstruation is frequently anovulatory or its luteal phase is inadequate; but resumption of the normal ovulatory cycle is observed rapidly thereafter. All non-breast feeding mothers menstruated within the first 12 weeks postpartum, compared with just 20% of nursing mothers. Factors directly proportional to the risk of ovulation include duration of suckling per feed and the daily number of nursing episodes. Up to 6 months postpartum, exclusive breast feeding reduces the risk of pregnancy by 98–99% during amenorrhea and by 94–97% after anovulatory menstruation. Only amenorrheic women practicing exclusive breast feeding during the first 6 postpartum months can achieve a pregnancy rate below 2%, suggesting that contraceptive use is recommended among all other lactating women who resume menstruating before 6 postpartum months or who continue to breast feed beyond 6 months.

Birth control

The lactational amenorrhea associated with exclusive breast feeding provides effective contraception (98% effectiveness) for some time, but the failure rate is much higher if more than 10% of the caloric intake is not provided by breast milk. In a cohort study of 319 women who initiated breast feeding, Halderman and Nelson found that only 24% provided at least 90% of their child's caloric intake through breast feeding at 6 weeks postpartum.[46] This indicates that, as noted previously, effective contraception is frequently needed even among breast feeding women.

The most popular contraceptive methods used in the postpartum period are the barrier methods (condoms, diaphragm) and hormonal contraception. Because of their lack of influence on breast milk production, progestin-based contraceptive methods such as levonorgestrel pills and intramuscular medroxyprogesterone acetate are ideal choices. Compared to progestin-based oral contraception, estrogen–progestin combination oral contraception offers more effective contraception and more cycle regularity but has been discouraged in the breast feeding mother mainly because of its effect of decreasing milk production. This effect is less clinically significant when such contraceptives are initiated after 6 weeks postpartum. In women who have a well-established breast feeding pattern and who would be able to detect a clinically important decrease in milk supply, combination oral contraception can be considered after 6 weeks postpartum. Another reason to delay its use is the pregnancy-associated thrombogenic state, which could be worsened by estrogen. There are at this time insufficient data on the transdermal estrogen–progestin patch or on the transvaginal estrogen-releasing ring to consider their use in the breast feeding mother.

The timing of initiation of hormonal contraception in the postpartum period has been the object of much debate. Since ovulation rarely occurs prior to 45 days after delivery, and is even more delayed in the breast

feeding mother, and since many couples wait a few weeks prior to resuming sexual activity, contraception can safely be withheld in most couples until 2–3 weeks postpartum. The United States Food and Drug Administration recommends waiting 6 weeks in the breast-feeding mother and 3 weeks in the non-breast feeding mother prior to initiation of progestin-based oral contraceptives, but practical reasons (e.g. questionable compliance with postpartum visit or medical insurance coverage issues) may call for earlier initiation of such contraception. This practice has not been shown to be deleterious to successful breast feeding or newborn growth. In many clinical settings, progestins are administered intramuscularly at 2–3 days postpartum, immediately before discharge from the hospital, and no adverse effects have been found.[47]

184 Postpartum hemorrhage

J. Herczeg

At the beginning of the 20th century, parturient mothers were fearful for their own lives during childbirth. Beginning some 40 years ago, an unprecedented and rapid development of the management of childbirth occurred, especially in the field of electronic surveillance and in the care of the critically ill obstetric patient.

Throughout recent decades in the developed world, fetal health has been the primary focus of prenatal and intrapartum care. Obstetrics in the 21st century will pose new challenges, many of which will be directed at the maintenance of maternal well-being. One contributor to this shift in emphasis relates to the change in maternal demographics that has occurred in many parts of the world. Some women are prepared to undertake high medical risks to their own lives by having a child close to or 'beyond' the extremes of their reproductive lives.

The peripartal period is one of the most dangerous times of life. Family expectations are very high, and the responsibilities of the obstetrician are expanding. It is very difficult to draw a line between good and substandard care, and practitioners of obstetrics are well aware of the fact that modern reproductive research does not eliminate all the risks and hazards associated with childbirth.

Direct causes of maternal mortality in modern obstetrics include:

(1) Postpartum hemorrhage (PPH)
(2) Infections during labor and delivery
(3) Puerperal sepsis
(4) Complications arising from the second stage of labor
(5) Pregnancy-induced hypertension
(6) Obstructed labor
(7) Abortion-related causes
(8) Uterine inversion.

Although modern medicine has made considerable progress in reducing the mortality from all these causes, PPH remains one of the most frequent causes of maternal mortality, arising most often from uterine hypotonia or atony. Ironically, with the availability of appropriate modern techniques of prevention and treatment, many of these deaths are avoidable.

Maternal death rates from infection and sepsis have shown a steady decrease over the last several decades, while hemorrhage-related maternal deaths have declined more slowly, pointing to the fact that they are more difficult to prevent.[1] PPH is still a leading cause of maternal mortality in some areas of the world. The incidence of PPH is 3–5% of all deliveries, and its incidence is doubled after induced labors.[2] It is the greatest single cause of maternal deaths in the majority of mortality surveys, and is directly responsible for 12–60% of maternal mortality in developing countries.

Postpartum hemorrhage can also be indirectly responsible, as an associated factor, for a further proportion of maternal deaths attributed directly to other causes, such as infection and obstructed labor. About one-third of all maternal mortality is related to obstetric hemorrhage. In sharp contrast to antepartum hemorrhages, which usually claim life after 10 h if left untreated, PPH kills swiftly, often in less than 2 h if not properly treated. In the overwhelming majority of cases, the PPH occurs unexpectedly, exploding into a drama in the labor room, where blood is seen everywhere. The mother's face and lips are pale and her skin is covered with a cold sweat. Her calm suggests that she thinks she is going to die. In such a severe clinical emergency, successful management requires immediate access to special expertise and facilities, and the outcome is dependent on instant availability of blood replacement facilities, and swift expert decisions on the steps necessary to bring the bleeding under control.

Clinical definitions

The widely accepted clinical definition of PPH is blood loss greater than 500 ml during the first 24 h after delivery. The excessive bleeding is usually evident within 5 min following birth. It should be pointed out that blood loss after spontaneous vaginal delivery may be up to 600 ml and can amount to 1000 ml or even as much as 1500 ml, following instrumental or operative delivery. Extensive obstetric experience is necessary to determine if bleeding is occurring too rapidly, and if it is responsive to conventional treatment. Excessive blood loss is especially

dangerous in cases where the physiologic expansion of blood volume during pregnancy has not occurred, such as in cases with preeclampsia.

Bleeding during the third stage of labor occurring before delivery of the placenta (third stage of labor defined here as the period from delivery of the fetus to expulsion of the placenta and its membranes and establishment of satisfactory uterine tone) is also categorized not as intrapartum but as PPH.

Primary PPH

Primary PPH has been defined internationally as more than 500 ml of blood loss during the first 24 h following delivery. The main argument for this threshold rests on the fact that postpartum blood loss is notoriously and significantly underestimated. In addition, there are clinical cases in which the mother does not undergo the normal physiologic blood volume adaptation during pregnancy, or in which the mother is anemic (small stature women, pregnancy blood expansion not yet developed, or restricted, such as in preeclamptic patients). In such cases, a lower level of blood loss should prompt therapeutic measures.

Primary PPH is a frequent, unpredictable and potentially lethal complication of childbirth. In the vast majority of cases, primary PPH is caused by hypotonia or atony of the uterus. The most common causes of primary PPH are listed in Table 184.1.

Secondary (late) PPH

Secondary PPH is defined as serious bleeding from the genital tract after the first 24 h and during the first 6 weeks of the postpartum period. Its most frequent causes are the subinvolution of the attachment site of the placenta, puerperal infection (endometritis), and retained placental fragments. Its prevention resides in awareness of the dangers and avoidance of mismanagement of the third stage of labor. Treatment includes oxytocic administration. In severe cases, administration of third-generation prostaglandin analogs may become necessary. In the author's experience these have proved to be extremely useful. It should also be noted that in rare cases a primary PPH (e.g. postcesarean hemorrhage) may be followed 10–15 days later by a secondary 'attack' necessitating the reintroduction of the original treatment. In late hemorrhage cases, gentle curettage and antibiotics are also in the mainstream of management.

Causes of PPH

Uterine atony

Uterine atony is defined as a loss of blood that is not arising from trauma to the birth canal or from placental tissue left in the uterine cavity. In modern obstetric practice, the increased use of labor induction carries an increased risk of postpartum atonic hemorrhage (PPAH).

Table 184.1 Common causes of primary postpartum hemorrhage

(1)	Uterine hypotonia/atonia
(2)	Retained placenta, placental fragments (succenturiate lobe or cotyledon)
(3)	Subtle myometrial trophoblastic invasion (focal placenta accreta)
(4)	Obvious myometrial trophoblastic invasion (placenta accreta, increta, percreta)
(5)	Lacerations of the lower genital tract
(6)	Intravascular coagulation
(7)	Rupture of the uterus
(8)	Uterine inversion

The incidence of PPH due to uterine exhaustion or hypotonia (arrhythmia) is very high. Uterine atony is responsible for 90% of all PPHs (trauma is responsible for about 7% and coagulation failure for 3%).[3] Severe hemorrhage from uterine atony can be defined as a > 30 mmHg drop in blood pressure, a decrease of hemoglobin by 3g/dl or more, and an estimated blood loss > 1000 ml.

If routine oxytocics are not administered following delivery, the frequency of PPAH is between 10% and 20%.[4] Clinical investigations have proved that programmed routine use of oxytocics significantly reduces the incidence of PPH.[5]

Postpartum atonic hemorrhage is a dramatic clinical situation putting the life of the mother into immediate danger, because it may lead to circulatory collapse within a few minutes, and it is often accompanied by coagulation dysfunction, which can perpetuate severe bleeding. It is imperative to be aware of (1) predisposing factors, because postpartum uterine atony can sometimes be anticipated, and (2) the fact that PPAH often does not respond to conventional therapy.

Retained placental fragments

In the natural course of the third stage of labor, the placenta generally separates in about 10–15 min, then gradually descends to the lower part of the genital tract. In cases with a history of previous radical intrauterine instrumentation or infection, an unsuspected focal placenta accreta can develop, and part or all of the placenta remains in the uterine cavity. Retained placental fragments are the most common cause of delayed PPH.

Placenta accreta

The rising cesarean delivery rate has increased the incidence of placenta accreta. In these cases, the basal decidual layer is defective, and the trophoblast invades the myometrium. Manual removal of the placenta is

difficult even in mild, focal cases, because there is no clear cleavage plane for placental separation. In most cases with significant placental invasion, manual removal of the placenta is impossible, and hysterectomy is usually required to control hemorrhage.

Bleeding from lacerations

Lower birth canal lacerations should be suspected if the uterus is firmly contracted but the bleeding is profuse. Adequate exploration with good exposure is necessary; lacerations must be repaired promptly and with careful attention to good hemostasis.

Uterine rupture

The most severe obstetric catastrophe is uterine rupture. Damage to this upper region of the genital tract is serious because this region is supplied by large vessels; therefore, any vascular tear in this region can result in immediate and catastrophic loss of blood. Its incidence is about 1 in 2000 deliveries (there is great variation among different places, ranging from 1:100 to 1:11,000). The dehiscence of a previous cesarean section scar is less dangerous than the rupture of an unscarred uterus, and in modern obstetrical institutions the use of the partogram has proved to be helpful in avoiding this serious complication.

Careful management of labor inductions, with close supervision of uterine stimulation with oxytocin infusion is an important preventive measure. The rate of the oxytocin infusion must be decreased when the partogram shows that the acceleration phase of labor has been reached. Preinduction ripening of the uterine cervix with a prostaglandin E_2 gel preparation should also be carefully supervised, because the prostaglandin might initiate strong contractility with the potential to rupture the uterus. Clinical management requires considerable surgical skills, because the uterus in most cases should be removed, and large hematomas may be present in the operative field.

Acute inversion of the uterus

Fortunately this problem is rare, if mismanagement of the third stage of labor is avoided. Its incomplete forms should also be recognized. Management sometimes requires uterine relaxation with betamimetics, manual repositioning, and administration of a prostaglandin analog to keep the uterus well contracted.

Coagulopathy

Bleeding from venous puncture sites or the sutured cesarean section wound suggests coagulopathy. A platelet count and D-dimer (a fibrin degradation product) level can be quickly obtained before any sophisticated tests; a low platelet count or the presence of elevated D-dimer concentrations raises the possibility of disseminated intravascular coagulation (DIC). DIC is often triggered by a sudden episode of blood loss, and the generated fibrin degradation products from the transient DIC episode further impair myometrial contractility.

To correct the coagulation disturbance, fresh whole blood (very difficult to obtain nowadays), fresh frozen plasma, and, if possible, thrombocyte preparations, should be administered.

Basic studies: exhaustion of cellular mechanisms of contractility

The human uterus has a highly sophisticated, multilayered bleeding control system. The first line of defense is the hemostatic contractions of the different myometrial layers, twisting and compressing the vessel tree. This myometrial contractile action is supplemented by constriction of the torn maternal vessels at the placental site.

The level of excitability and the condition of electrical coupling between myometrial cells determine the ability of the uterine muscle to contract. Hormonal, nervous and immune intrinsic factors, and many extrinsic pharmacologic factors, can modulate membrane potential, ionic exchange and electrical propagation. Between myometrial cells electrical coupling is possible via gap junctions; postdelivery disappearance of gap junctions is accompanied by a nearly total inability of the muscle to contract and respond to stimulation.[6] The exhaustion of cellular mechanisms (ionic exchange and electrical propagation) after delivery can be an explanation for uterine atony.[7] Exogenous prostaglandins in pharmacologic doses can sometimes restart the 'burned out' system.

Contractility of uterine muscle is regulated by calcium. Prostaglandins facilitate the entry of calcium into the cell through specific calcium channels or receptor-operated channels.[8]

The intracellular adenosine triphosphate-dependent Ca^{2+} transport pump is an important regulator of cytoplasmic calcium levels, and thus of the contractile state of the muscle.[8] Ca^{2+} is essential for myosin light-chain kinase activation, and is carried by the calmodulin–Ca^{2+} complex. An unknown calcium regulatory system may play a role, allowing uterine muscle to remain contracted at less than maximum levels of cellular calcium.[9] Subthreshold doses of prostaglandins potentiate the spasmogenic Ca^{2+}, even after removal of the prostaglandins.[10] Synergistic effects of Ca^{2+} and prostaglandins are utilized to enhance mid-trimester uterine activity.[11] Therefore Ca^{2+} entry blockers (nifedipine) should not be used close to delivery because of the high risk of postpartum atony, resistant to oxytocics.[12–14]

There is no anatomically demonstrable specific pacemaker and propagation system in the human uterus. There appears to be a physiologic pacemaker area. Contractions begin high in the lateral side of the

fundus, and the speed of stimulus propagation downward is 2 cm/s. When the whole uterus is covered, the stimulus travels back.[15,16] Contractions are strongest near the pacemaker and have the longest duration there (high power area, HPA).[17] In the synchronous pattern, HPA is monofocal and is high in the fundus. The HPA propagates all over the uterus. HPA is of multifocal origin in false labor, proceeding in an asynchronous pattern leading to uterine arrhythmia.[17]

Disorders of HPA will be manifest as an inverted triple descending gradient, in terms of propagation, intensity, duration, and are called wandering HPA, resulting in impaired contractions. Asynchronous tocograms predict complicated labor, and may forecast uterine atonia.[17]

Risk factors for atonic PPH

Widely-known risk factors include previous PPH, manual removal of the placenta, abruptio placentae, placenta previa, prolonged labor with prolonged administration of oxytocin, precipitate labor, difficult vacuum extraction or forceps delivery, and breech extraction.

Following uterine inertia during labor, for which correction has been attempted by supportive administration of oxytocin, or following a short, precipitate labor, or following labor induction, the uterine muscle often fails to contract in the third stage. The failure of the normal hemostatic contraction and retraction of the myometrium is due to exhaustion of the cellular contractile system.

Postpartum uterine activity is also impaired under anesthesia. The resting tone remains unchanged, but contractility is inhibited, recovering with time.[18,19]

The predisposing conditions for uterine atony are listed in Table 184.2. However, the predictive values of antenatal factors is disturbingly low. Previous third-stage bleeding in the case history increases the likelihood of PPH twofold. Pregnant women with unfavorable characteristics, such as age over 35 years, infection, diabetes mellitus and cardiac disease, are not necessarily at increased risk for PPH, but these underlying conditions worsen the serious sequelae of PPH.

Table 184.2 Conditions predisposing to postpartum hemorrhage[4]

Case history	Prenatal factors	Labor factors
Primigravida	Placenta previa	Labor induction
Multigravida (5+)	Placental abruption	Prolonged/ obstructed labor
Myoma	Hydramnios	Short labor
Von Willebrand's disease	Multiple pregnancy	Cesarean section
Anemia	Intrauterine death	Epidural anesthesia
Purpura	Pre-eclampsia	Disseminated intravascular coagulation
Unknown	Placenta accreta	Chorioamnionitis

Maternal response to massive blood loss

Normal pregnant patients expand their original 5000 ml blood volume by at least 1500 ml, a hematologic adaptation that reduces the risk from hemorrhage at delivery. Some fraction of this extra volume can be lost without obvious signs of hypovolemic shock.

If an obstetric patient with a normally expanded blood volume bleeds profusely, symptoms of shock will usually appear following a loss of more than 1500 ml. Loss of 25% of intravascular volume may be fatal, but in the early stages of shock arterial blood pressure remains unaltered.[3]

Coagulation failure often accompanies severe postpartum bleeding.[20] Disseminated intravascular coagulopathy may be triggered by obstetric events such as release of thromboplastic substances during placental abruption, or may develop as a consequence of hypovolemic shock. When there has been massive blood replacement, an element of dilutional coagulopathy may also exist. Diagnosis may not await the results of sophisticated tests; observing the operative field and a tube of freshly drawn blood for the presence of clots and a thrombocyte count can aid prompt diagnosis.

Good myometrial contractions generally prevent fatal hemorrhage from the placental site, even when the maternal blood is incoagulable, but fatal bleeding can occur in the presence of uterine atony.

Prevention of PPAH

Nowadays, there are new aspects to the prevention of PPAH. Patients are concerned about receiving blood transfusions, because of the small HIV and hepatitis risk. Autologous blood can be taken and retransfused when needed, but this is not a simple method, and requires that excessive blood loss is anticipated.

Planning of labor inductions so that patients deliver during the daytime, when access to life-supporting facilities are optimal, can help, but induction itself is a predisposing factor to uterine exhaustion and atonic bleeding.[21] The introduction of active third-stage management, controlled cord traction, and use of oxytocics were major improvements, but these measures are not without risks. Oxytocin can cause a drop of blood pressure, and can lead to arrhythmias. Ergot derivatives can precipitate hypertension in one-third of cases and cause nausea or vomiting in a quarter of cases. Prostaglandins offer a better and more efficient choice to prevent and correct uterine hypotonia.

Prostaglandins in postpartum uterine hemostasis

Prostaglandins play a fundamental role in the maintenance of continued contractions, myometrial retraction, vasoconstriction and platelet activation. Prostaglandin metabolites rapidly increase in the peripheral circulation at the time of placental separation, pointing to a dramatic increase of myometrial prostaglandin synthesis, which is responsible for maintaining uterine tonicity and controlling postpartum hemostasis.[22,23]

Prostaglandins offer a logical choice to fight against uterine hypotonia, because endogenous prostaglandins are involved in maintaining postpartum resting uterine tone and stimulating myometrial contractions, which continue after delivery of the baby and the placenta.[24,25] Their usefulness has been demonstrated in many clinical studies during the last two decades.

When uterine activity and blood flow were studied, it was shown that intravenous sulprostone (16-phenoxy-prostaglandin E_2) infusion resulted in a uterine contracture (sustained contraction) response, which was obvious on photographs taken intraoperatively; a change of color of the uterine surface indicated reduction of perfusion.[26]

Early observations with prostaglandin $F_{2\alpha}$ in the third stage proved that intramyometrial injections cause myometrial ischemia and sustained contracture, with rapid spread over the uterine surface providing good hemostasis.[27] These early observations provided the basis for use of prostaglandins in atonic hemorrhage.

The pioneering clinical use of first-generation prostaglandins more than 15 years ago was not without problems. Takagi *et al.* injected prostaglandin $F_{2\alpha}$ intramyometrially.[28] Later, 15-methyl-prostaglandin $F_{2\alpha}$ was used,[29] but maternal arterial oxygen desaturation, secondary to increased intrapulmonary shunting, was reported after this prostaglandin was given for arresting postpartum atonic bleeding.[30] Continuing research has resulted in the development of second-generation prostaglandin analogs, with significant improvement in utero-selectivity and clinical acceptability.

A multisubstituted third-generation prostaglandin analog, the 16-phenoxy-E_2 molecule (sulprostone), has a highly selective effect on the uterus, since it does not influence the function of other smooth muscle tissues, as natural or first-generation prostaglandins do. From this observation, a significant clinical advantage originated: there is separation between the desirable, therapeutic effects and the unwanted, mainly gastrointestinal, side-effects.[31] The drug is available in Europe, but not in the United States.

Sulprostone has shown good tolerance in local and systemic routes of administration, focused action on the uterus, and an acceptably low incidence of side-effects. The use of relatively low doses is possible due to its marked biostability.[32] The main effect of the uterotopic sulprostone is induction of controllable uterine contractions, with simultaneous compression and constriction of the uterine blood vessels, especially at the placental site. Following intramuscular injection, sulprostone reaches maximal plasma levels within 5–15 min; its plasma level decreases by 50% in 1–2 h. The uterorelaxant effect and risk of atonic bleeding from tocolytics such as betamimetics, magnesium sulfate in toxemia, and prostaglandin synthetase inhibitors, can be quickly neutralized by postpartum administration of sulprostone infusion.[33–35]

Prevention and treatment of PPAH in the labor and delivery room

In cases of atonic bleeding quick action is necessary to save the life of the mother. The two simultaneous lines of treatment are: (1) control and stop the bleeding, and (2) correct hypovolemia (hematocrit is not reliable in sudden acute severe blood loss). The age-old observation should be kept in mind: 'An empty, well-contracted uterus with good myometrial contractile ability will not bleed'. The following management approach consists of 10 steps, assuming that the delivery takes place in a hospital and that active third-stage management was employed. The scheme is summarized in Table 184.3.

Step 1

React to excessive rates of bleeding even if the loss has not exceeded 500 ml. Reconsider the history and the clinical course for possible causes, remembering that more than one etiologic factor could be responsible.

Step 2

If the uterus is atonic by abdominal palpation, and the placenta has already been expelled, fundal massage should be started immediately, which helps to initiate good uterine contraction and expel accumulated clots from the uterine cavity. Do a bimanual examination and perform bimanual uterine massage and compression. Order oxytocin and intravenous ergometrine.

External fundal massage should be complemented by internal bimanual compression: with one hand in the lower birth canal the cervix and the paracervical region should be compressed, and with the other hand the uterus should be elevated. This forced anteflexion of the uterus should help to control the bleeding, and it also makes it possible to give a prostaglandin injection through the abdominal wall directly into the myometrium. For this purpose only the safest available prostaglandin analog should be used, such as sulprostone (described in step 5).

Step 3

If bleeding continues, and the uterus is still boggy and atonic, consider early intravenous administration of a

Table 184.3 Management of postpartum (atonic) hemorrhage

Step 1	React to excessive bleeding, even if it does not exceed 500 ml
Step 2	If the uterus is atonic, do fundal massage to expel clots; perform bimanual massage and compression; order oxytocin and intravenous ergometrine
Step 3	If bleeding continues with an atonic uterus, consider early intravenous prostaglandin analog; install a reliable intravenous line; ask for blood typing and cross-matching
Step 4	If the uterus is well contracted but the bleeding is continuing, prepare for manual exploration of the uterus
Step 5	Mild atonic hemorrhage will not exceed 1000 ml of lost blood; intravenous sulprostone 4.1 μg/min (40 drops/min) for 120 min, up to 16.7 μg/min
Step 6	For severe atonic bleeding exceeding 1000 ml of blood loss, immediately restore lost volume with fresh whole blood and estimate blood loss; sulprostone dose may be increased briefly up to 330 drops/min (33.3 μg/min)
Step 7	If bleeding is continuing, transfer patient to the operating room; intracervical prostaglandin analog injection might help
	Postcesarean atonic bleeding within 30 min is especially dangerous; transfer patient back to operating room; sulprostone intracervically on the operating table
	For intraoperative atonic bleeding during cesarean section give intraoperative, intramyometrial injection of sulprostone (100–300 μg)
Step 8	In cases of acute inversion of the uterus: after manual repositioning of the uterus give intravenous sulprostone infusion
Step 9	Ligation of the hypogastric artery or the uterine artery can control pelvic hemorrhage
Step 10	Hysterectomy is indicated when all attempts to control the bleeding have failed. Placenta previa with previous cesarean section and uteroplacental apoplexy are especially prone to uncontrollable bleeding, and are often hysterectomy indications

third-generation prostaglandin analog, as described in step 5. Install a reliable intravenous line, and ask for blood typing and cross-matching. Notify anesthesia and operating room personnel.

Step 4

If the uterus is well contracted and the bleeding is continuing, prepare for mandatory manual exploration of the uterus under general anesthesia, to remove possible placental fragments and rule out injury in the higher region of the genital tract. This exploration is extremely important, because it is the only defense against severe mistakes, such as overlooking cervical or high sulcus lacerations or, the most severe obstetric complication, rupture of the uterus. Lower genital tract lacerations are repaired under adequate exposure.

Step 5

Mild atonic hemorrhage will not exceed 1000 ml of lost blood. The patient is still in the labor and delivery room and the modern management list includes all of the above: massage and bimanual compression of the uterus, giving uterotonic drugs, exploring the uterus, placing an ice bag over the lower abdomen, and simultaneous establishment of an intravenous line for administering sulprostone, 500 μg in 250 ml of any isotonic crystalloid solution. The recommended dosage is 4.1 μg/min (40 drops/min) for 120 min, which can be increased up to 16.7 μg/min (120 drops/min) for 30 min as a maximum.

Step 6

For management of severe atonic bleeding exceeding 1000 ml of blood loss, immediately start restoring lost volume with an estimate of blood loss. Rapid volume replacement is crucial, even before deterioration in the patient's vital signs, because in the early stages of shock, arterial blood pressure can remain unaltered.[3]

Fresh whole blood is ideal for treatment of serious obstetric hemorrhage; but over the last 25 years, the availability of whole blood has decreased due to blood bank fractionation, and packed red blood cells are generally used, along with crystalloid solutions and fresh frozen plasma as required.

Prepare the operating room and inform the patient that surgery may become necessary. The sulprostone intravenous dose may be increased briefly to 330 drops/min (33.3 μg/min). Take a quick look at blood coagulation, looking for the presence of clots, because obstetric events often trigger a sudden, transitory episode of DIC.[20] Coagulation failure with decreased thrombocyte count suggests DIC, while fragile coagulums with normal thrombocyte count point to fibrinolysis as the main pathological event.

Rule out injury, and remove intrauterine clots. Chronic intravenous administration of sulprostone should be continued. The infused dose of sulprostone per hour should not exceed 500 μg (approximately 80 drops/min). The infusion should be continuously supervised, and the maximum total dose should be 1500 μg. With this therapy, atonic blood loss will be no more than 1000 ml, because the rapid, efficient and long-lasting myometrial contraction induced by the prostaglandin compresses the uterine vessels.

Step 7

The patient is transferred to the operating room if all the above measures fail to control the bleeding. Manual exploration has been done, and damage to the birth canal has already been ruled out in the labor and delivery room. On the operating table, while preparing for surgical intervention as a last resort, intracervical prostaglandin analog injection can be carried out under adequate exposure.

At the same time, accumulated intrauterine clots can be removed. At this stage a coagulation failure with DIC is usually present; therefore fresh frozen plasma should be administered. Even if the bleeding is decreasing, the patient is kept on the operating table, with full preparation for surgery. In such cases, usually 1–4 h are required to complete cessation of the bleeding. Intravenous prostaglandin analog treatment is continued as described above.

Postcesarean atonic bleeding is especially dangerous, and usually appears within 30 min following transfer to the recovery room. The patient should be immediately transferred back to the operating room and treatment should proceed as described in steps 5 and 6. Sulprostone can also be given intracervically under adequate exposure on the operating table. In high-risk atony-prone cases, postoperative prophylactic intravenous low-dose administration (2 μg/min) of sulprostone may be recommended.

Intraoperative atonic bleeding during cesarean section is quite common, especially if there was a preceding elective labor induction with oxytocin. In the author's experience, intraoperative, intramyometrial injection of sulprostone (100–300 mg) proves to be extremely helpful. Contraction is promptly initiated within seconds by the prostaglandin analog, given into the anterior wall of the uterus. Avoid direct intravascular injection of the prostaglandin.

Step 8

In case of acute inversion of the uterus, which is fortunately rare, a two-stage treatment is recommended: first, in some cases betamimetics are needed for relaxing the contraction ring; then, after manual repositioning of the uterus, intravenous infusion of sulprostone should be started immediately, while holding the repositioned uterus in its correct position by hand. This type of treatment has proved to be successful.

Step 9

Ligation of the hypogastric artery or the uterine artery is described in every standard textbook of obstetrics. The use of this method is advocated in cases of placenta previa, focal placenta accreta, and cervical pregnancy. However the author's experience has showed that in a real catastrophic obstetric scenario, the large uterus prevents adequate exposure of the vessels, especially if a hematoma is present. Such a case has been encountered when even a vascular surgeon was unable to locate the vessels for more than 30 min in the large pelvic hematoma. Although hypogastric artery ligation can control pelvic hemorrhage through eliminating uterine artery pulsation (the so-called 'trip-hammer effect'), it is a time-consuming approach with potential for serious operative field complications.[36]

Ligation of the ascending branch of the uterine artery on both sides requires the elevation of the uterus out of the abdominal cavity. The ureter is in close proximity, and there is a danger of ureteral ligation, because of the distorted anatomy of the postpartum uterus.

Step 10

Hysterectomy is indicated when all attempts to control the bleeding have failed. It is a striking observation that 26% of patients who require emergency hysterectomy cannot be identified before delivery by the existence of predisposing risk factors.[37]

The author's experience has shown that in cases in which severe PPH is combined with severe DIC and multiorgan failure, it is futile to try to preserve the uterus. In many such cases when the uterus was preserved, it became a focus of infection, and the patient, who already survived the bleeding and the DIC, died of sepsis.

The author had a case in which, after a placental abruption, the uterine bleeding and DIC were successfully controlled, but then multiorgan failure supervened. The patient became unconscious, and was transferred by helicopter in deep coma to a national center. There she underwent hysterectomy, and recovered after a long stay in a critical care unit.

Placenta previa with previous cesarean section is especially prone to uncontrollable bleeding and is often an indication for hysterectomy. Uteroplacental apoplexy (Couvelaire uterus) is very often accompanied by a total inability of the uterus to contract, due to intramural bleeding spots, and the fibrin degradation products (originating from the coagulopathy) further impair myometrial contractility; therefore hysterectomy is frequently needed.

In cases of uterine rupture and placenta accreta, removal of the uterus also serves the best interests of the patient. In a hemodynamically unstable patient, subtotal hysterectomy may be performed.

In the fortunately rare surgically unmanageable, case of diffuse posthysterectomy bleeding, a situation accompanied by DIC, a pelvic pressure pack can be used (Logothetopulos umbrella pack).[38]

Future clinical aspects

Obstetrics is a 'bloody arena', and in the new millennium practitioners of obstetrics are facing new challenges. The inability to predict PPH makes it necessary to be always prepared to deal with it. The main problem is the poor predictive power of screening, because

low-risk women who have delivered normally previously, without complications, do sometimes develop serious postpartum bleeding.

Avoiding transfusion in obstetric management is increasingly demanded for various reasons, and at the same time the availability of fresh whole blood is also decreasing. Some have taken extraordinary measures in this regard. A placenta percreta case in a Jehovah's Witness, diagnosed by magnetic resonance imaging, has been posted previously on the Internet. The patient donated blood for herself and in week 37 she underwent laparotomy, the aorta was clamped, hysterotomy was performed, and then bilateral hypogastric artery ligation was carried out prior to hysterectomy.

The life-threatening association of massive hemorrhage and coagulation failure, which knocks out the stability of the hemostatic system, is the most feared cascade of events frequently seen in postpartum bleeding scenarios. Clotting factors are consumed (consumption type) or removed from the bloodstream (in case of placental abruption) and the fibrinolytic system is activated. Thromboplastic materials, cytokines, and interleukin-6 may enter the bloodstream; endothelial damage and intravascular hemolysis occur, with release of procoagulants. These factors explode into DIC, resulting in a critically ill obstetric patient with uncontrollable hemorrhage.

There are no 'evidence-based' markers or clear guidelines in this dark field: we have to wait many years until such knowledge will be available. In 2004, the author participated in the EUPHRATES expert meeting (**Eu**ropean **P**roject on Obstetric **H**emorrhage **R**eduction: **A**ttitudes, **T**rial, and **E**arly warning **S**ystem) in Paris, trying to reach a multinational minimum consensus on PPH management and raising the level of awareness of professionals, health care planners and governments of the magnitude and importance of this cornerstone of obstetrics. For the coming years our own clinical experience, professional judgment, clinical research data from the literature, and expert opinion are still the prime source of our management plans.

A large number of maternal deaths could be attributed to this deadly combination of PPH and coagulation disorder. The author's experience also showed that saving the life of these patients requires a concerted team effort, often including access to emergency air transport to a state-of-the art critical care facility, where there is experience in dealing with massive hemorrhage and its consequences. The availability of all modern blood-banking equipment, including plasmapheresis, can be life-saving.

Obstetricians are continuously trying to use novel approaches in such critical treatments, and also rediscover some old options, like uterine packing. Here are some examples of newly proposed approaches to PPH:

Compression sutures, B-Lynch suture[39]: This technique is designed to try to control uterine atony by compressing the uterus with large sutures. These may cause severe complications, and require a word of caution.[40] The use of prostaglandin analogs is the more logical treatment choice in uterine atony cases. In the author's experience over the last 30 years, since the availability of synthetic prostaglandins, there was not a single case of uterine atony that was not successfully managed by a prostaglandin analog.

The author was only forced to resort to hypogastric artery ligation in a case of cervical pregnancy, but never encountered a case in his large obstetric practice, when a uterine compression suture was thought to be needed.

In such a case of cervical pregnancy with profuse bleeding the author compressed the abdominal aorta transabdominally with his left hand, and opened the abdomen, without stopping to scrub, still compressing the abdominal aorta until the bleeding was controlled. The patient recovered smoothly and quickly without any fever. So, in the author's opinion, the 'best compression' is the age-old hand compression of the abdominal aorta, until the bleeding is brought under control.

Misoprostol,[41] a prostaglandin-E_1 analog that was developed for the management of peptic ulcer disease, has found some uses in obstetrics. Its use is plagued by legitimacy issues,[41] and in case of massive bleeding – when every passing second increases the risk, its rectal use is inadequate in the author's opinion.

Pelvic arterial selective embolization[42] requires a hemodynamically stable patient, when the bleeding is not immediately life-threatening, and a special unit with an interventional radiologist. The technique is not without serious complications, but has been used with success in selected situations.

Recombinant activated factor VII (rFVIIa)[43–45] is a new and promising option to fight intractable postpartum bleeding arising from the life-threatening combination of profuse bleeding and associated destabilization of the hemostatic system (DIC, hemolysis, elevated liver enzymes, low platelet count (HELLP syndrome)), especially the rampant variety, characterized by gross depletion of coagulation factors and very high levels of fibrin degradation products (D-dimer).[20] Its place in the management of PPH is still uncertain, and it suffers from the problems of a short half-life (about 2 h) and extremely high cost. Limited experience suggests that it may have a lifesaving role when DIC cannot be controlled by more conventional means.

Over the years the author has encountered many cases of horrendous postpartum bleeding, one in which the patient was operated on five times in 30 h, and got 25,000 ml of blood; another in our national critical care center received 100,000 ml of blood until stabilization. It is hoped that in the coming years rFVIIa will give us great help, and such heroic, extremely high-volume blood transfusions will be a relic of the past. The use of rFVIIa might prove to be a quantum leap in this murky field of obstetrics. The author recently had a case with acutely successful use of rFVIIa, which stopped the postcesarean, then

posthysterectomy bleeding; however, due to its short half-life, the intra-abdominal bleeding restarted 6 h later, requiring another reoperation. The patient ultimately recovered smoothly.

Some adjunctive treatments like planned autotransfusion, erythropoietin, synthetic blood also deserve research as potential tools in the management of patients during and after severe PPH.

Summarized conclusions from clinical experience

Strategy: Try to identify high-risk cases that are prone to PPH.

Tactics: Management should be carried out according to a logical plan, which should include the early or immediate use of third-generation prostaglandin analogs when atony is present.

Be alert: Always rule out damage to the higher and lower genital tract. In cases of a reluctantly atonic uterus with non-traumatic bleeding, use prostaglandin analogs as a first choice, especially in high-risk cases of atony.

Be aware: Labor induction or augmentation increases PPAH risk by uterine exhaustion.

Think prevention: By using intravenous third-generation prostaglandin analogs, prevention can be achieved. Accompanying coagulation disturbance is dynamic and self-limiting with time if the bleeding is controlled.

Keep in mind: The intravenous route for chronic administration of prostaglandin analog is especially good if atonic hemorrhage is persistent.

Count on: Prostaglandin analog treatment decreases bleeding within 2–4 min, and will stop non-traumatic bleeding within 5–15 min.

Remember: Atony following cesarean section is especially dangerous, and in cases at high risk for atony prophylactic intravenous administration of sulprostone is advisable, using a lower dose range (approximately 2 μg/min).

185 Resuscitation and immediate care of the newborn

J. Babnik

There are few moments in life when humans are as vulnerable and as dependent on the help of others as at birth. In a few seconds the newborn must adapt from life in the warm, moist, sterile environment of the mother's womb to wholly different extrauterine surroundings. Every organ must adjust to this change over a few minutes or a few days; but the key to immediate survival of the newborn is a smooth cardiopulmonary transition. The neonate must successfully inflate his or her lungs and rearrange the fetal circulation. With modern obstetric care there are only a few newborns who do not succeed in this adaptation, primarily for reasons related to perinatal asphyxia. Immediately after delivery these infants are not vigorous, do not cry, and do not breathe regularly. Resuscitation, from the Latin *resuscitate*, 'to arouse again', implies those actions that restore life. Skillful resuscitation of the asphyxiated infant immediately after delivery can prevent brain damage and minimize subsequent neonatal disease.

Approximately 5–10% of all newborn infants require some form of resuscitation.[1] Jain and Vidyasagar[2] found that the percentage could be as high as 9.4% (excluding suctioning) and that 6% of newborn babies were intubated. Not all hospitals experience such high numbers of resuscitated infants. Our data from the Ljubljana Maternity Hospital for the 6-year period 1997–2002 include 33,357 live-born babies. Of these, 4.2% were born with a 1-min Apgar score < 7 and 0.6% with score < 3. The majority of babies (94.7%) accomplished their transition to extrauterine life without any help: 1.4% received only suctioning, 3.6% were ventilated with bag and mask, and an additional 0.4% required intubation, chest compression or medication.[3]

Causes of newborn depression

Intrapartum asphyxia cannot be easily differentiated clinically from neonatal depression caused by a variety of drugs during labor, congenital anomalies, prematurity and other diseases of the infant. Initial resuscitative measures are, nevertheless, similar in all situations and should be initiated without delay.[4] The major causes of neonatal depression at birth are shown in Table 185.1. The diagnosis of perinatal asphyxia should only be made when certain clinical criteria are met.

Table 185.1 Causes of delayed onset of regular respiration

Perinatal asphyxia
Excessive suctioning (vagal stimulation causes bradycardia and apnea)
Trauma, especially to central nervous system (tentorial tears) or cervical cord
Drugs that depress breathing (anesthetic, narcotic, alcohol, magnesium sulfate, tranquilizers)
Severe immaturity (surfactant-deficient lung, inadequate respiratory effort)
Perinatally acquired sepsis: group B streptococci, *Listeria monocytogenes*
Primary neuromuscular disease (Werdnig–Hoffmann disease, congenital myopathies, myotonic dystrophy, congenital muscular dystrophy)
Congenital malformation obstructing the airway or preventing lung expansion (choanal atresia, Pierre–Robin syndrome, laryngeal atresia, diaphragmatic hernia, pulmonary hypoplasia)

Definition of perinatal asphyxia

Perinatal asphyxia remains a concern of obstetricians, neonatologists and others involved in the care of women, infants, and children. Despite considerable advances in our knowledge of its epidemiology and pathophysiology, and despite the development of novel diagnostic tools and new treatments, a precise definition remains elusive. The American College of Obstetricians and Gynecologists' (ACOG) Committee on Maternal–Fetal Medicine and the American

Table 185.2 Essential characteristics of perinatal asphyxia[5]

Profound metabolic or mixed academia (pH < 7.00) in an umbilical cord arterial blood sample
Persistence of an Apgar score of 0–3 for > 5 min
Clinical neurological sequelae in the immediate neonatal period, including seizures, hypotonia, coma, or hypoxic–ischemic encephalopathy
Evidence of multiorgan system dysfunction in the immediate neonatal period

Academy of Pediatrics' (AAP) Committee on the Fetus and Newborn have defined certain criteria that must be met if neurologic deficits are to be attributed to perinatal asphyxia.[5] All of the characteristics listed in Table 185.2 must be present, including evidence of at least one organ dysfunction. If such evidence is lacking, it is difficult to conclude that perinatal asphyxia is the cause of later developmental disability.

Pathophysiology of asphyxia and resuscitation

In order to undertake the necessary and appropriate measures for resuscitation of the newborn, a firm understanding of pathophysiologic events that occur during asphyxia is vital. Asphyxia (which etymologically means 'without pulse') is defined as hypoxia combined with respiratory acidosis (organ gas exchange failure). When this occurs, the arterial carbon dioxide partial pressure ($PaCO_2$) rises, whereas the arterial oxygen partial pressure (PaO_2) and pH fall. During lack of oxygen the cell switches to anaerobic metabolism to meet energy requirements. Glycolysis is accelerated, but in anaerobic conditions 15 times more glucose is expended for the same amount of ATP production as occurs in aerobic conditions. Therefore, anaerobic glycolysis represents only a short-term compensation and leads to a large amount of lactic acid accumulation that is partially buffered by the bicarbonate in the blood.

The main causes of asphyxia are hypoxemia and ischemia, hence the term hypoxic–ischemic encephalopathy. Five principal mechanisms of asphyxia have been described in the human infant during labor, delivery, and the immediate postpartum period.[5] These are: (1) interruption of umbilical blood flow (cord compression, prolapse); (2) failure of gas exchange across the placenta (placental insufficiency, abruption, or previa); (3) inadequate perfusion of the maternal side of the placenta (severe maternal hypotension, hypertension from any cause, or excess uterine contractility); (4) impaired maternal oxygenation (cardiopulmonary disease, anemia); and (5) failure of adequate cardiopulmonary adaptation after birth (insufficient lung inflation and faulty rearrangement of the fetal circulation).

Classic changes of perinatal hypoxia were described in the rhesus monkey experimental model and probably imitate events in human fetuses.[6] Figure 185.1 illustrates the changes in heart rate, breathing movements, blood pressure and pH during 10 min of total asphyxia and after subsequent resuscitation. Immediately after delivery, the umbilical cord was tied, and the head of the monkey was covered with a bag of a warm saline. Within 30 s a short series of rhythmic respiratory efforts began, which was interrupted by a series of clonic movements accompanied by an abrupt and profound fall in heart rate to below 100 beats per minute (bpm), after which the animal lay inert with no muscular tone. The skin became cyanotic and during the next few minutes it gradually became pale as vasoconstriction appeared and produced asphyxia pallida. The initial period of apnea (primary apnea) lasted for 30–60 s. After primary apnea, the monkey made deep gasping efforts for 4–5 min. The gasping then weakened gradually until it ceased completely, with the last gasp about 8 min after the onset of total asphyxia. Secondary (terminal) apnea followed, during which the heart rate and blood pressure declined steadily. During the period of primary apnea, spontaneous respiration could be induced by tactile stimulation. Profound changes in pH, PCO_2, and PO_2 occurred during the 10 min of total asphyxia: pH decreased from 7.3 to 6.8; $PaCO_2$ increased from 45 to 200 mmHg; and PaO_2 decreased from the normal umbilical arterial level of 25 mmHg to nearly zero. During secondary apnea, tactile stimulation could not induce spontaneous respiration, and unless resuscitation with bag and mask ventilation began within a few minutes, death resulted. The longer is the delay in initiating resuscitation after the last gasp, the longer is the time to the beginning of spontaneous respiration (Figure 185.2).

Early in perinatal asphyxia, cardiac output is maintained, but its distribution changes radically. Blood flow to less vital organs such as gut, kidney, muscle and skin is reduced by selective regional vasoconstriction.[7] However, blood flow to brain and myocardium increases, and the delivery of oxygen to these organs is maintained despite reduced blood oxygen content.[8] If asphyxia progresses to the severe stage, oxygen delivery to the brain and heart decreases. At first, the myocardium uses its stored reserve of glycogen for energy; but when this has been consumed, the combined effect of hypoxia and acidosis impairs myocardial function.[9] The result is decreased blood flow to the brain, which can lead to brain damage.

The adaptive events described above probably reflect the responses of the human newborn to absolute asphyxia such as could occur during total placental abruption, rupture of the uterus or prolapse and compression of the umbilical cord. Such experimental knowledge is not always directly applicable to

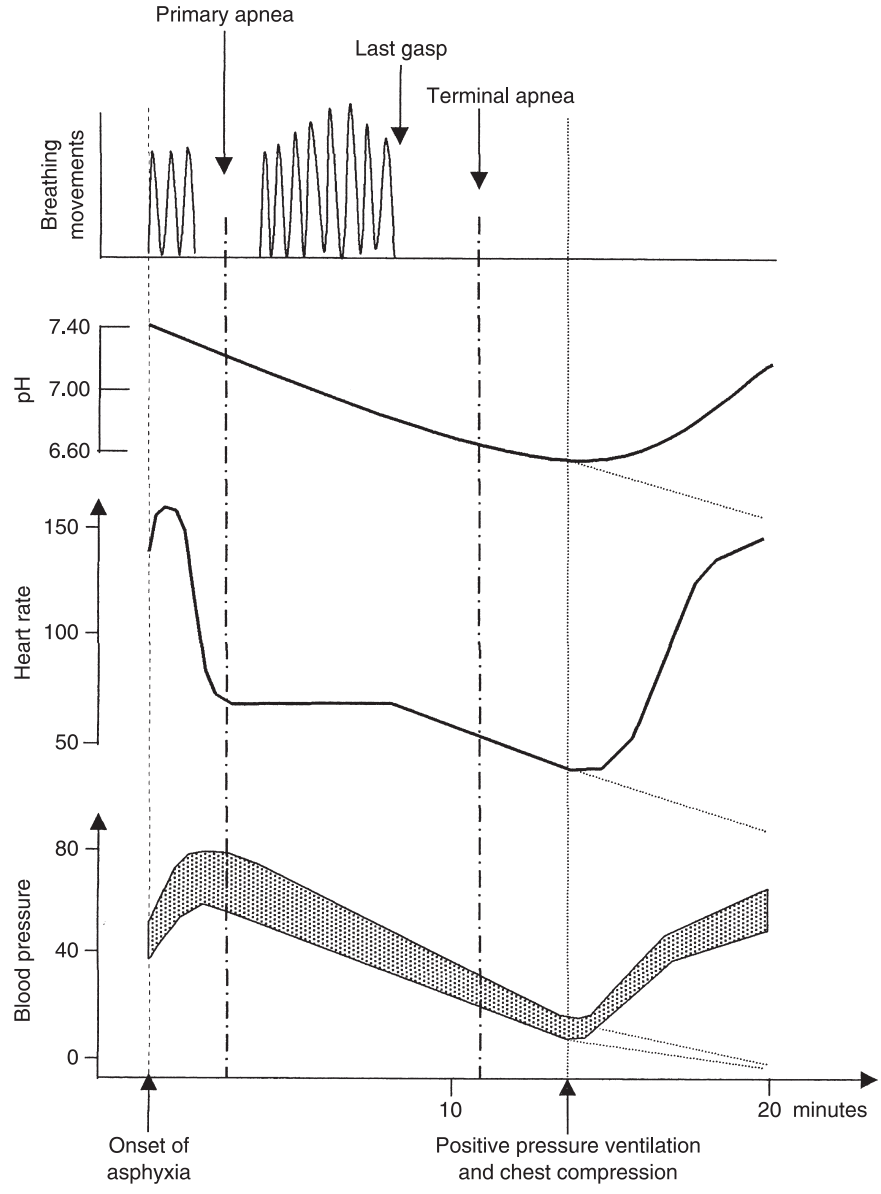

Figure 185.1 Physiological changes during asphyxia.[6]

the human fetus and newborn, because most clinically encountered asphyxia is intermittent, subacute or chronic. Nevertheless, the sequence of events in successful resuscitation is quantitatively similar in all species, including man.[10]

The apneic newborn who responds to tactile stimulation by gasping is in primary apnea. If the infant is till gasping, administration of air (oxygen) or gentle tactile stimulation is sufficient for recovery, unless the gasps are too feeble and arterial pressure too low.

If asphyxia is only moderate, the resuscitation begins when the infant is apneic but the myocardium has not yet failed. Effective ventilation with oxygen corrects acidosis by lowering PCO_2, while oxygenation of blood dilates the pulmonary vascular bed. During secondary apnea the human newborn is usually pale. The first sign of recovery once adequate ventilation is achieved is an acceleration of the heart rate. Following this, the blood pressure rises, the skin becomes pink, and gasping then reappears after an interval. The duration of this interval has some practical value in indicating the magnitude of the asphyxial insult that the infant has suffered. Rhythmic spontaneous respiratory efforts become established after a further interval and muscular tone reappears gradually over the course of the next hour or more.

If the asphyxia proceeds to myocardial failure, resuscitation must include the restoration of cardiac output as well as the establishment of effective ventilation and perfusion of the lung. Generally, myocardial failure does not occur until both pH and PaO_2 are extremely low, approximately 6.9 and 20 mmHg, respectively. Chest compression (external cardiac massage) should be performed until cardiac output is

reestablished. As soon as the pH is raised to 7.1 and PaO_2 to 50 mmHg, the myocardium responds, and heart rate and aortic pressure rise, while the central venous pressure falls. Because vasoconstriction to non-vital organs is still present, the infant becomes hypertensive. With correction of acidosis and continuous oxygenation, vasoconstriction is relieved and pressure will fall toward normal. The skin becomes pink and well perfused. The improved perfusion to all organs means that lactic acid, sequestered in these tissues, enters the circulation and makes the metabolic acidosis even greater than before. Measuring lactic acid in the umbilical cord just after delivery does not always reflect the magnitude of the asphyxia, as lactate is also produced in the placenta, and an increased quantity may result from decreased uptake by the asphyxiated fetal liver.[11]

The blood volume of the asphyxiated infant may be abnormal. Usually there is no great shift of blood between the fetus and placenta and the infant is born with an adequate blood volume. In the clinical situation of external bleeding from the feto-placental unit, in feto-maternal or feto-fetal bleeding, the infant's blood volume is reduced. The other most common causes are cord compression (venous flow is compressed more than the arterial flow), and severe maternal hypotension and asphyxia occurring at the end of labor.[12]

Clinically it may be difficult to determine if the shock is hypoxic or hypovolemic, as both can cause bradycardia, metabolic acidosis, hypotension and poor peripheral perfusion. Only changes in the central venous pressure, which is low in hypovolemic shock, may be of discriminative value. The course of events during resuscitation usually determines the adequacy of blood volume. During asphyxia the systemic and pulmonary vasoconstriction maintain normal blood pressure, even with reduced blood volume. The administration of a blood volume expander at this point would only overload the circulation. The correction of asphyxia relieves vasoconstriction, and a small blood volume becomes inadequate to support circulation. Reperfusion of the ischemic tissues leads to intravascular water loss from the capillary bed and aggravates hypovolemia.

The signs of hypovolemic shock include low aortic pressure with narrow pulse pressure, falling hematocrit, persistent metabolic acidosis, low central venous PO_2 (< 30 mmHg) after correction of arterial hypoxia, cold extremities, and delayed capillary refilling. Tachycardia is often absent, as the predominant regulator of cardiac output in the human fetus and newborn is the Frank–Starling mechanism and not the heart rate.[13] As in the adult, the fetal heart follows a Frank–Starling curve in such a manner that an increase in the filling pressure leads to an increase in stroke volume. However, the fetal heart operates, in its baseline state, high on its cardiac function curve. With increasing atrial pressure, there is diminished capacity to increase myocardial performance, as the length–tension relationship has already approached its maximal plateau.[14]

Hypovolemia should be treated promptly, lest prolonged under-perfusion of tissues leads to increased capillary permeability and pulmonary disease, which make resuscitation more difficult. Excessively rapid volume replacement can lead to myocardial failure; therefore, repeated small infusions of whole blood (5 ml/kg) or packed erythrocytes should be used.

Resuscitation

Based on extensive review of available information, neonatal resuscitation guidelines (basic and advanced life support) were revised extensively in 1999 by the International Liaison Committee on Resuscitation (ILCOR) Pediatric Working Group, with representatives from North America, Europe, Australia, New Zealand, Africa, and South America.[15] Consensus was reached on almost all aspects of neonatal resuscitation, was published,[16] and is widely accessible on the Internet (http://www.circulationaha.org, http://www.pediatrics.org/cgi/content/full/103/4/e56).

Although the guidelines focus on the newly born infant, most of the principles are applicable throughout the neonatal period (first 28 days of life) and early infancy. The term newly born refers specifically to the infant in the first minutes to hours after birth. The point at which neonatal resuscitation guidelines should be changed to a pediatrics resuscitation protocol varies for individual patients. The transition from fetal to extrauterine life involves dramatic changes in cardiopulmonary physiology (initial lung expansion, decrease in pulmonary vascular resistance, closure of intracardiac shunts), temperature regulation and metabolic adaptation. Although certain physiologic features are unique to the newly born, others pertain to infants, especially to premature infants, throughout the neonatal period. Therefore, until discharge from maternity hospital or from a neonatal intensive care unit newborn resuscitation guidelines should be followed; after readmission pediatric protocols should be used.

However useful the guidelines are it should be remembered that, much of what they proposed was based on opinions of experienced clinicians or on less than optimal studies.[17] Only two of the recommendations are Class I (based on the evidence from randomized, controlled trials that showed a large effect); therefore, areas of controversy and of high priority for additional research were delineated. Moreover, the guidelines made no distinction between the techniques used for term and very preterm infants and it is very likely that some of the proposed procedures may even hurt preterm infants instead of treating them. The current chapter includes the proposed guidelines, with special consideration devoted to areas of controversy.

Only basic resuscitation measures, discussed in this section, should be carried out in the labor ward. The aim should be to normalize the heart rate and to assure breathing, if necessary with the aid of intermittent positive-pressure ventilation and chest compression. To achieve these goals, the only medications, except for epinephrine and plasma expanders, which can be tried blindly, are naloxone, a single dose of bicarbonate, and an infusion of glucose. All other treatments are best postponed until the baby is in the neonatal intensive care unit.[4]

Anticipation of resuscitation and preparation for the delivery

A maternity hospital should be designed so that the delivery rooms and the neonatal unit are adjacent to each other. If this is not the case the labor ward should be prepared to carry out more prolonged resuscitation and for the care of the baby, until transport to the neonatal unit is accomplished.

Only about 5–10% of all newborn infants require some form of resuscitation[1] and this number increases exponentially for very low birth weight (VLBW) infants. The delivery of a baby requiring resuscitation may often be predicted, as more than 50% of such babies are born after some complications during pregnancy or labor. Whenever complications are expected, it is advisable, when possible, to transport the woman (transport *in utero*) to an institution where appropriate care can be offered and experienced personnel are available. Many of these high-risk categories, presented in Table 185.3, have been defined, and hospital practice is that such a delivery should be attended by the neonatologist/pediatrician. Optimally, the pediatrician should be present at more than 30% of all deliveries, although he or she will often not be needed. Cesarean section is the most common reason for calling the neonatologist, although an elective cesarean section is not necessarily a high-risk situation.[18,19] Usually the risk factors are combined (emergency cesarean section and fetal distress) but when considered alone, the most common reasons for skilled resuscitation are emergency cesarean section, forceps and vacuum delivery, newborn being covered with thick particulate meconium, breech delivery, prematurity, multiple birth, and fetal distress.[20,21]

Although the causes of asphyxia are numerous, review of the clinical situation and of the patient's history can help guide the physician's approach to the resuscitation. When time permits, the following information should be acquired: gestational age, fetal growth during pregnancy, findings of amniocentesis or ultrasound assessment (gastrointestinal anomaly, diaphragmatic hernia, bilateral renal anomaly), reasons for preterm delivery (chorioamnionitis), complications during pregnancy, course of labor, indications for operative intervention, drug administration, and maternal health during labor (evidence of infection).

Personnel

Although it has been suggested that around 60% of deliveries resulting in the need for neonatal

Table 185.3 Risk factors associated with the need for neonatal resuscitation (from Emergency Cardiac Care Committee and Subcommittees, American Heart Association[22] with permission)

Antepartum factors	Intrapartum factors
Maternal diabetes	Emergency cesarean section
Pregnancy-induced hypertension	Forceps- or vacuum-assisted delivery
Chronic hypertension	Breech or other abnormal presentation
Chronic maternal illness (cardiovascular, thyroid, neurological, pulmonary, renal)	Premature labor
	Precipitate labor
Anemia or isoimmunization	Long labor (> 24 h)
Previous fetal or neonatal death	Prolonged second stage of labor (> 2 h)
Bleeding in second or third trimester	Chorioamnionitis
Maternal infection	Fetal bradycardia
Polyhydramnios	Abnormal fetal heart rate patterns
Oligohydramnios	Use of general anesthesia
Prelabor rupture of membranes	Narcotic administration to mother proximate to delivery
Post-term gestation	Meconium-stained amniotic fluid
Multiple gestation	Prolapsed cord
Intrauterine growth restriction	Abruptio placentae
Drug therapy (lithium, magnesium, adrenergic blocking agents)	Placenta previa
Maternal drug abuse	
Fetal congenital anomalies	
Diminished fetal activity	
No prenatal care	
Age < 16 or > 35 years	

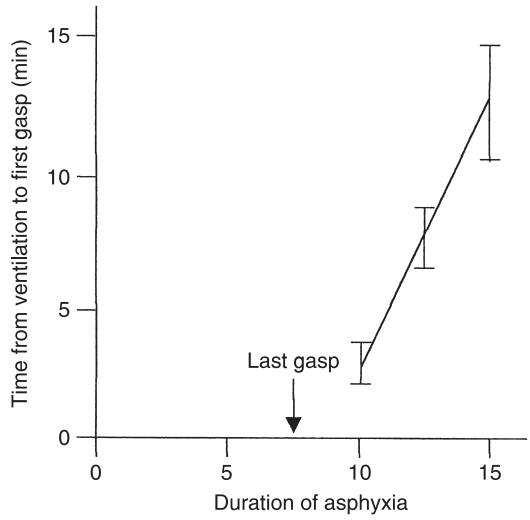

Figure 185.2 Mean time from the onset of asphyxia or anoxia to the last gasp, and mean time from the beginning of positive pressure ventilation to the first gasp in fetal monkeys asphyxiated for 10, 12.5 and 15 min.[6]

resuscitation can be anticipated,[2] many more are unpredictable events, and these usually require the most urgent and most aggressive resuscitation. The recommendation that someone who is trained in all aspects of neonatal resuscitation should be present at every delivery is impractical.[22] More reasonable is that such qualified person should be available in the hospital at all times and should attend only high-risk deliveries. Depending on the organization of the health service and the particular hospital policy, this person could be a pediatrician, an obstetrician, an anesthesiologist, an obstetric nurse or a respiratory care practitioner. It is imperative that he or she is well trained in neonatal resuscitation, which includes initial management, bag and mask ventilation, intubation, and umbilical catheter insertion. However, in cases of unpredictable events, resuscitation is given by the first person available who is skilled in basic procedures (prompt evaluation of the newborn's condition, clearing the airway, bag and mask ventilation). These goals must be achieved through carefully programmed training for all persons who could possibly be involved in resuscitation. It does not mean that every person knows all the steps; a nurse may not be expected to have the intubation skills, and a respiratory therapist may not be asked to provide medication.

Equipment

At every delivery the equipment and medication necessary for resuscitation should be prepared, and appropriate function should be checked before the anticipated need, and replenished after each use. It is recommended to have a list of the necessary equipment and medication, and every day the integrity should be guaranteed by the signature of a responsible person.

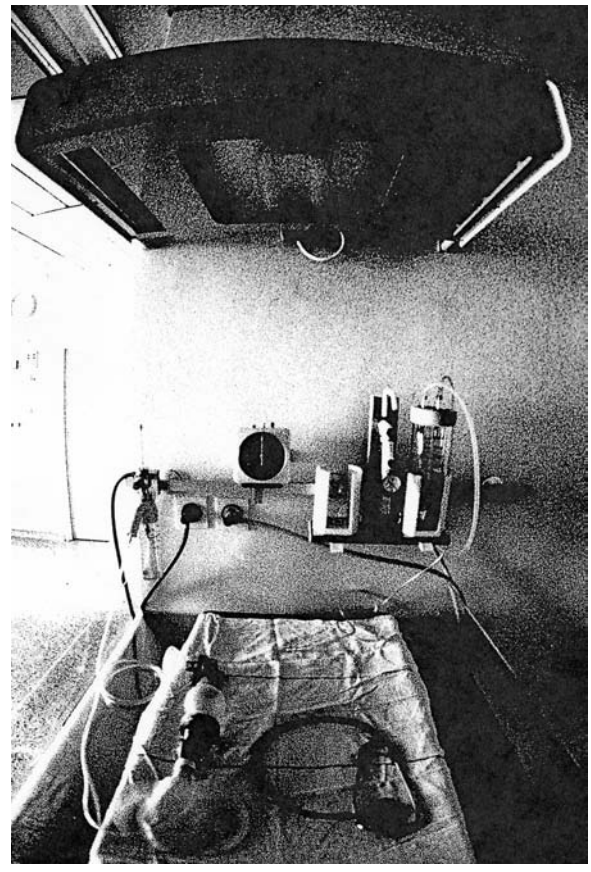

Figure 185.3 Place for resuscitation of newly born infants in the delivery room, with wall-mounted oxygen supply, suction device and radiant heater.

Most neonatal resuscitation is now carried out on resuscitation trolleys built for this purpose or in a special place in the delivery room (Figure 185.3), equipped with the essential components listed in Table 185.4 (radiant warmer, supply of oxygen, suction with manometer, large clock), and with good access from at least two sides. The shelf should be tiltable and at a comfortable height for the resuscitator. On arrival to the labor ward the resuscitator should check the equipment for resuscitation: radiant heater and room temperature, oxygen supply, adequate suctioning, functioning of self-inflating bag and laryngoscope, availability of the appropriate mask and endotracheal tubes, warm towels and linen.

Evaluation of the newborn's condition

Immediately after birth (and not after the umbilical cord is cut) the clock should be started and signs that show infant condition (meconium in the amniotic fluid or on the infant skin, cry or respiration, muscle tone, color, term or preterm gestation) should be evaluated simultaneously by visual inspection. Indications for further assessement and intervention under the radiant warmer include: meconium in the amniotic fluid

Table 185.4 Resuscitation equipment required in the delivery room[16,22]

Radiant warmer

Supply of oxygen with flowmeter (capable of delivering at least 10 l O_2/min) and tubing (including portable oxygen cylinders)

Suction with manometer: the suction should not exceed 200 mmHg, and for routine use should be set at 100 mmHg

Suction equipment
Bulb syringe
Suction catheters, 5F or 6F, 8F, and 10F or 12F
Meconium aspiration device

Bag-and-mask equipment
Face masks, newborn and preterm size (mask with cushioned rim preferred, should be easily detached from the bags and replaced with endotracheal tube connectors)
Resuscitation bags: self-inflating with pop-off valve opened at 30–35 cmH_2O or anesthesia bags

Intubation equipment
Tracheal tubes, size 2.0, 2.5, 3.0, 3.5 and 4.0 (internal diameter)
Laryngoscope with straight blades No. 0 (preterm) and 1 (term)
Endotracheal tube introducers (optional)
CO_2 detector (optional)
Magill forceps for nasotracheal intubation
Laringeal mask airway (optional)

Medication
Epinephrine ampule (1 mg/ml) (1:10,000 solution should be prepared)
Naloxone hydrochloride (1 or 0.4 mg/ml solution)
Sodium bicarbonate (0.5 mEq/ml solution)
Volume expander: normal saline (0.9% NaCl), Ringer's lactate

Umbilical vessel catheterization tray
Umbilical catheters (3.5F and 5.0F)
Three-way stopcocks

Miscellaneous
Nasogastric feeding tubes (6F and 8F) for gastric suction
A selection of syringes, needles, intravenous cannulas, specimen bottles
Scissors, adhesive tape of a type that will not damage very fragile preterm infant skin
Solution for skin disinfection, gloves
Stethoscope
Oropharyngeal airways, newborn and premature infant size
Cardiac monitor and pulse oximeter or fetal cardiac monitor are desirable

or on the infant's skin; absent or weak respiration; persistent cyanosis; and preterm birth.

In every labor ward, the Apgar score is traditionally used for the assessment of the newborn and to provide an overview of the degree of resuscitation likely to be necessary. Before and during resuscitation, however, it is enough to assess sequentially the respiratory effort, heart rate and color.

Respiratory efforts may be manifest as vigorous crying, regular breathing, gasping respiration or apnea. The assessment should be done by auscultation or inspection of breathing movements. If breathing is shallow or the infant is apneic, he or she needs physical stimulation and bag and mask ventilation. Regular respiration should be sufficient to maintain heart rate > 100 bpm.

The heart rate may be evaluated by auscultation with a stethoscope, with palpation of the pulse at the base of the umbilical cord, or with a fetal cardiac monitor (Doppler method). The palpation of femoral or brachial pulses is unreliable and even umbilical pulsation must not be relied upon if low or absent.[23] The Doppler method is most desirable, as all resuscitators can hear the heart beat and take appropriate steps in response to it. There is no need for exact counting of the pulse rate during resuscitation; a rapid estimation of whether the heart rate is above or below 100 bpm or whether it exists at all is most important. Therefore, all other resuscitation measures are discontinued for some seconds during auscultation.

Color can range from normal pink with acrocyanosis to central cyanosis or pallor. Color indirectly reflects the state of the circulation. Pallor is due to peripheral vasoconstriction and is a sign of shock (hypoxic or hypovolemic), acidosis or hypothermia, whereas cyanosis suggests normal circulation, with disturbed oxygenation. Preterm newborns are not infrequently covered with bruises, making evaluation of color difficult. A look at the lips usually suffices to evaluate cyanosis and the need for oxygenation.

Immediate newborn care: initial stabilization

Positioning

Just after delivery the face and nose should be wiped, and a healthy baby is placed on his or her side to aid drainage of the mucus from the nasopharynx and trachea. Usually, the healthy baby retains good muscle tone in the flexed position, and begins crying after initial drying. Most immediate care of the healthy newborn can be accomplished while the newborn is held on the mother's abdomen or under the radiant warmer, which may be placed near the parents so that they can see the baby. Because of reports of sudden unexpected neonatal death, the baby lying prone on the mother's abdomen should be constantly observed.[24]

The neonate requiring resuscitation should be placed supine or on his or her side with the neck in a neutral position. Overextension or flexion may produce airway obstruction and should be avoided.

Cord clamping

If time permits, umbilical cord should be clamped when pulsations cease, usually 30–60 s after birth; when resuscitation is required the umbilical cord should be clamped immediately. It is important that

as much umbilical cord blood as possible is taken for further analysis: blood gas analysis, hematocrit, blood group studies, lactate, etc. For this purpose a section of cord is clamped between the newborn infant and the placenta. The results of blood gas analysis may be available within minutes and can be helpful in further management of the asphyxiated infant.

Maintaining warmth

The first priority is to provide and maintain warmth, because cold stress can increase oxygen consumption and impede effective resuscitation.[25] The newborn is, therefore, dried immediately and all wet linen is removed. Warmth can be maintained by covering the newborn with warm blankets or by placing it in skin-to-skin contact with the mother. There is no need for bathing and removing the vernix from the infant's skin. These procedures can be safely postponed until the end of the first day when the adaptation to extra-uterine life has been well accomplished.

When placing the infant under a radiant warmer, hyperthermia should be avoided because it is associated with respiratory depression.[26,27] Moreover, recent data suggest that even mild hyperthermia during or following a hypoxic–ischemic insult may exacerbate damage.[28] The mechanism of this adverse influence is unclear but may be related to a dramatic increase in the release of excitotoxins.[29]

Some animal studies revealed that hypothermia after hypoxic–ischemic injury reduced histologic evidence of brain damage,[30,31] delayed cerebral energy failure,[32] and improved behavioral outcome.[33] Cooling was achieved with the head and neck covered with ice bags and with peritoneal cold lavage performed when the spontaneous circulation was restored. The mechanism of therapeutic hypothermia is multifaceted and includes preserving energy, stabilizing membranes, decreasing oxygen demand, excitotoxicity, free radical reactions, and deleterious enzyme reactions.[34]

Under normal conditions the brain is metabolically highly active, and produces about 70% of total body heat in the newborn.[35] The heat produced is dissipated by conductive loss through the cerebral circulation and by radiant loss from the scalp. There is a normal core-to-skin gradient in the head of more than 1°C, which is lost when the external heating under a radiant warmer begins.[36] Considering that overhead heating prevents heat dissipation and even promotes cerebral hyperthermia, mild systemic hypothermia, with or without head cooling has been proposed as a therapeutic intervention in infants who suffer perinatal hypoxic–ischemic injury.[37,38] However, because of potential adverse effects, including metabolic, cardiovascular, pulmonary, coagulation, and immunologic complications, hypothermia cannot be recommended as a routine therapeutic intervention until appropriate controlled studies in human have been performed.[15]

Tactile stimulation

Most newborn infants begin to breathe and cry during wiping with a towel. However, rubbing the back and slapping or flicking the soles are two other safe methods of tactile stimulation. Tactile stimulation may initiate spontaneous respiration in a newborn with primary apnea. If no response occurs within 10–15 s, the infant should be placed under a radiant warmer on the resuscitation desk, and positive pressure ventilation should be initiated.

Type of resuscitation after initial stabilization

After initial evaluation and stabilization, one can classify the newborn as either healthy, with good tone, regular breathing and a loud cry, or as one with shallow breathing, apnea, pallor or cyanosis.

Healthy newborn crying loudly

Such a newborn needs no additional care. No pharyngeal or tracheal aspiration is needed unless the amniotic fluid is exceedingly bloody or meconium-stained. After clamping the umbilical cord, the infant should be thoroughly dried, and put into contact with the mother. The mother should be encouraged to put it against her breast because early suckling induces more efficient breastfeeding and quicker contraction of the uterus. When still in the delivery room, the infant must be identified and must receive 1 mg of vitamin K for protection against hemorrhagic disease of the newborn. Eye infection prophylaxis should be administered with topical 1% $AgNO_3$, 0.5% erythromycin or 1% tetracycline.

Newborn not breathing and cyanotic or pale

The umbilical cord should be clamped quickly, the infant put on the resuscitative trolley, and resuscitative measures started without delay. The promptness of the response to resuscitation efforts enables a retrospective diagnosis of primary or terminal apnea.

Most depressed newborns are in a state of primary apnea, and they start breathing after sensory stimulation (wiping or rubbing the soles or back) or after short bag and mask ventilation. Once they become pink, breathe regularly or cry, they may generally be admitted to the ward for healthy newborns, regardless of the 1-min Apgar score.

The newborn in terminal apnea experiences severe asphyxia and will not start breathing spontaneously without appropriate resuscitation measures. The longer the resuscitation is postponed, the more severe the metabolic and physiologic changes and the greater the possibility of brain damage. Resuscitation should be started immediately (Figure 185.4). Some newborns are born dead (with Apgar score of 0) but are still

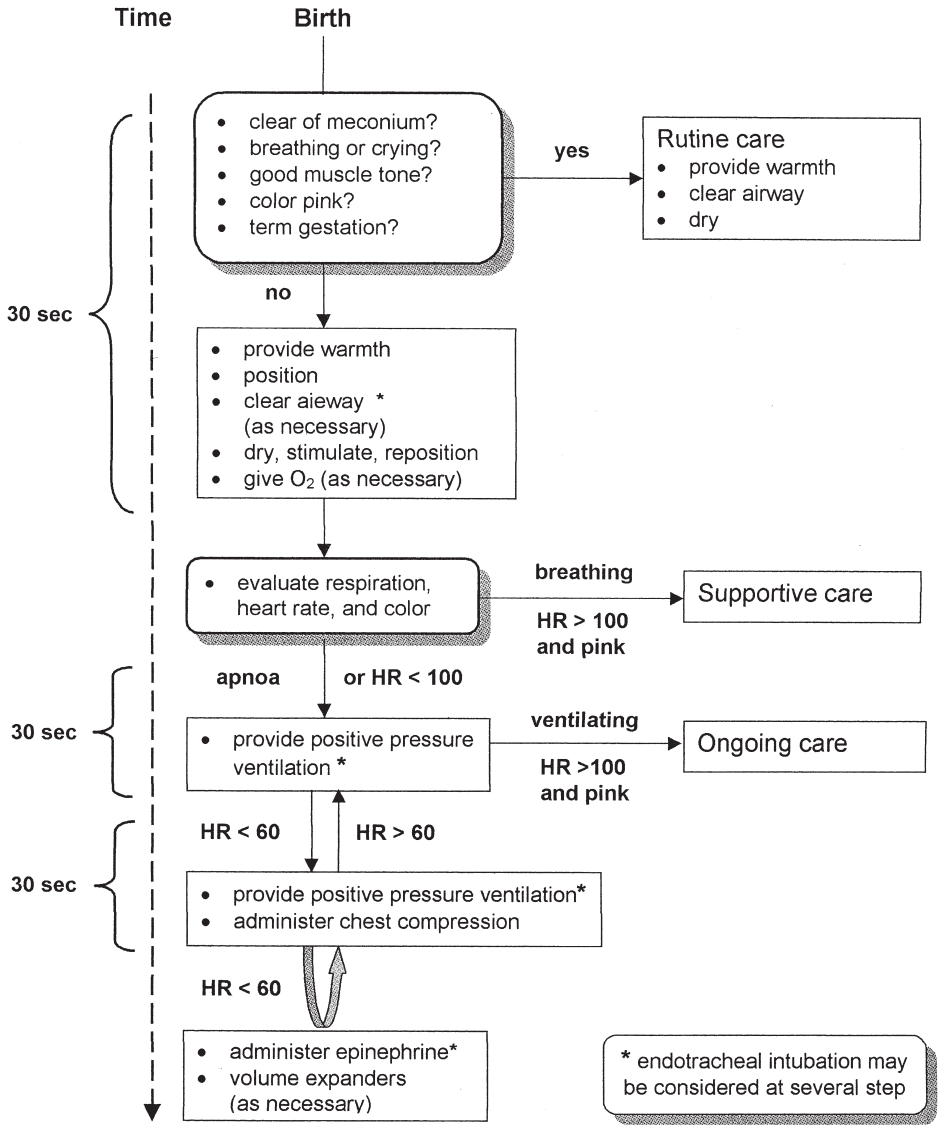

Figure 185.4 Algorithm for the resuscitation of the newly born infants.[16,22]

resuscitatable. In that situation, resuscitation is started unless the obstetrician is sure that the fetal heart ceased beating more than 10 min before delivery. If the heart rate does not appear within 10–15 min after birth, the resuscitation should be stopped.[39]

Techniques used during resuscitation

Suctioning

Guidelines for neonatal resuscitation[16] still recommend suctioning of the infant's nose and mouth with a bulb syringe after delivery of the shoulders, but before delivery of the chest. This task is often difficult to accomplish because, after delivery of the head, the rest of the body often delivers promptly. In addition, it has been shown that oropharyngeal suctioning at the perineum does not affect the rate of meconium aspiration syndrome (MAS).[40]

Immediately after the fetal head is delivered, whether vaginally or by cesarean, the newborn's face should be wiped with gauze or a towel, and, once delivered, a healthy baby should be put on its side or prone. At birth the baby has amniotic fluid and mucus in its mouth, nose and pharynx. We should remember that throughout its intrauterine life the fetus exercised respiratory movements and that the presence of amniotic fluid is indispensable for development of the fetal lungs. If the amniotic fluid is not meconium-stained and there is not much maternal blood in it, healthy, vigorous newly born infants generally do not require suctioning.[41] With the first few deep breaths the newborn expels the amniotic fluid, together with the rest of the fluid from the lungs, into the pharynx and swallows it. Some of the fluid is absorbed into the pulmonary interstitium and removed by blood or lymph. Aggressive suctioning of the pharynx may cause laryngeal spasm and vagal bradycardia.[42] Suctioning

should be carried out only when the newborn is depressed and needs bag and mask ventilation or tracheal intubation, especially when amniotic fluid is meconium-stained or is exceedingly bloody.

Clearing the airway of meconium

Approximately 8–13% of infants are born with meconium in the amniotic fluid[43,44] and 3–7% of these develop MAS.[39,45] The meconium causes chemical pneumonitis, and at the same time inhibits surfactant activity and thus leads to severe respiratory distress. The first priority after delivery is, therefore, to clean the infant's airway. As noted, although guidelines and common practice counsel[15,16] suctioning of infant's mouth, pharynx and nose just after delivery of the head with a large-bore suction catheter (12F) or bulb syringe, it is not certain that oropharyngeal suctioning at the perineum reduces the risk of meconium aspiration.[39] To remove thick meconium a higher negative pressure is needed than provided by a De Lee oral aspirator or a bulb syringe. Efficient aspiration must be carried out as soon as possible on the resuscitation table with vacuum or air aspirators.

Results of several recent studies, summarized by the Cochrane database of systematic reviews[45–48] showed that intubation and suctioning of the apparently vigorous meconium-stained infant did not result in a decreased incidence of MAS or other respiratory disorders. Therefore, intubation and suctioning should be carried out only in depressed infants.

The initial aspiration of thick meconium may require negative pressures as high as 150 mmHg.[49] The 10F or 12F suction catheter is introduced under laryngoscope-guided control; the mouth and pharynx should be aspirated first, followed by the trachea. Should meconium be found in the trachea, aspiration is continued so that as much of the meconium as possible is aspirated in the shortest possible time before the first breath. During this time all actions which could induce breathing (drying, tactile stimulation) should be postponed, until the posterior pharynx is clean of meconium.[47–49]

If the meconium is extremely thick and infant is still depressed, the trachea should be intubated. Current recommendation is that aspiration and removal of the tube are carried out simultaneously. The procedure is repeated until the tracheal tube is almost cleared.[16] Between two aspirations, which must be brief, the newborn's condition is monitored. If the infant's heart rate or respiration is severely depressed, resuscitation with positive pressure ventilation should be initiated, despite the presence of the meconium in the airway. A large amount of meconium is usually present in the stomach and should be suctioned after cleaning the respiratory tree.

Ventilation

The indications for positive pressure ventilation after birth are: apnea or gasping respiration; heart rate less than 100 bpm; and persistent central cyanosis despite the delivery of 100% free-flow O_2.

Bilateral chest wall motion and audible breath sounds are adequate signs of successful ventilation. To establish effective ventilation after birth, the neonate must generate an opening negative pressure of 20–40 cmH_2O,[50] and even higher pressures may be required to inflate the fluid-filled lung of the baby who does not breathe spontaneously after birth. Inflation should be prolonged, lasting 3–5 s to establish a functional residual capacity (FRC).[51] Less pressure and shorter inflation times are required for succeeding breaths. The observation of chest wall movement is a more reliable sign of appropriate inflation pressure than any pressure read from the manometer. If the lungs cannot be inflated, attempt the following: (1) reposition the mask to ensure a tight seal between face and mask; (2) reposition the head in a case of overextension or flexion; (3) repeat suctioning if necessary; and (4) use increased inflation pressure. If these measures are inadequate, prompt intubation is necessary. Prolonged bag and mask ventilation may insufflate the stomach; therefore, after suctioning the mouth and nose a catheter left open to air should be inserted into the stomach. Ventilation should be at the rate of 40–60 breaths per minute, and after 15–30 s the infant's response should be checked.

Most infants respond to adequate ventilation within 10–15 s with increasing heart rate to more than 100 bpm, and with improvement in color. If spontaneous respiration is present, ventilation should be slowly discontinued. Gentle tactile stimulation, such as rubbing the skin, helps to commence and maintain spontaneous respiration.

If the infant is cyanotic or pale blue despite good chest wall movement, the heart rate should be re-evaluated, even before 15–30 s as recommended. If the heart rate is more than 60 bpm and rising, ventilation is continued. If the heart rate drops below 60 bpm, chest compressions are initiated and ventilation continued.[15,16]

Face masks

Most neonates requiring respiratory support can be adequately ventilated with a bag and mask at a rate of 40–60 breaths per minute. For proper ventilation, face masks fitting term or preterm infants should be available. Cushioned, soft rims are essential for achieving a tight seal between the mask and the face.

Ventilation bags. Two types of ventilation bags are available: self-inflating bags and anesthesia bags (Figure 185.5).

Self-inflating bags are independent of the gas flow. The elasticity of the bag permits its rapid refill through the intake valve that is open to air and to the O_2 reservoir. If there is sufficient O_2 flow, keeping the reservoir full, the bag can deliver nearly 100% O_2.

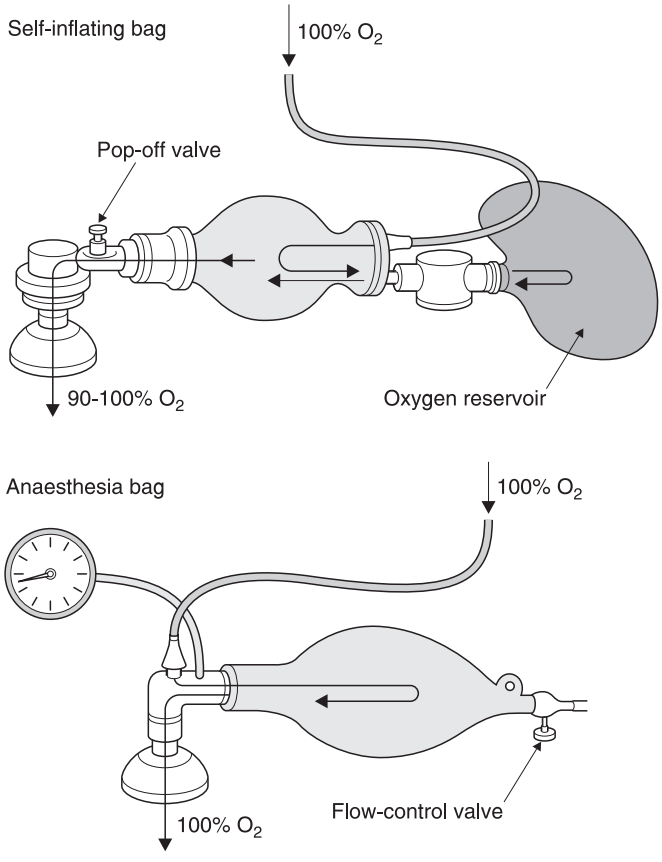

Figure 185.5 Self-inflating bag with reservoir and anesthesia bag.

Without the reservoir, O_2 is diluted with air. Many self-inflating bags are equipped with a pop-off valve that opens when the pressure exceeds 30–35 cmH_2O. If there is a leak around the face mask during bag and mask ventilation the pop-off valve can be closed to ensure a higher pressure. Bags without a pop-off valve should be used with caution, especially if the infant is intubated, because baro- or volutrauma from excessive peak inspiratory pressures is the most common complication during neonatal respiratory support. Many self-inflating resuscitators are commonly used with different characteristics in inspiratory or expiratory resistance, pressure relief valve, fraction of delivered O_2, and function at extreme temperature.[52] Bags that cannot be disassembled easily and are equipped with a reservoir to provide visual assurance of gas flow may have less margin for error and can be more easily used by resuscitators.[53]

The anesthesia bags require compressed air or O_2 flow for inflation. As they can deliver very high pressures, the pressure should be constantly monitored. Proper balance between the flow of gas and the flow control valve, and a tight seal around the face are required for effective use. Usually more training and experience is required for adequate use of anesthesia bags than for self-inflating bags.

Laryngeal mask airway

The laryngeal mask airway (LMA), developed in 1981 by Brain,[54] became available in 1988 for clinical use in anesthesiology. Initially, the LMA was designed for use in adults and has revolutionized routine airway treatment in the operating theater.[55] Later, many studies reported its successful use during newborn resuscitation,[56] and successful resuscitation of infants with Pierre–Robin syndrome when all the classical methods (bag and mask ventilation, oropharyngeal airway, tracheal intubation) failed.[57] It has been suggested that all pediatricians involved in neonatal resuscitation should become familiar with LMA use,[58] especially in the case of ineffective bag and mask ventilation and tracheal intubation. Neonatal guidelines do not recommend its routine use at this time, as the device cannot allow tracheal suctioning of thick meconium.

If the neonate requires positive pressure ventilation, the head is placed in the standard position for tracheal intubation, and a lubricated size 1 LMA, with the cuff fully deflated, is blindly inserted into the pharynx. The LMA is advanced, with the aperture facing anteriorly, until resistance is encountered. The cuff is then inflated with 2–4 ml of air to make a low pressure seal around the larynx.

The design of the LMA (Figure 185.6) prevents the distal end from entering the esophagus while it sits in the hypopharynx over the laryngeal inlet. When the cuff is inflated, a gas-tight seal exists between the larynx and the LMA which allows a peak inspiratory pressure of up to 30–40 cmH_2O; with some leaks this is around 20 cmH_2O.[59] In the hands of an experienced resuscitator it can be inserted within 8 s, nearly always at the first attempt, with successful ventilation within 20 s. The advantages over a facemask include better oxygenation, prevention of gastric distension, successful ventilation in cases of facial dysmorphism (e.g. Pierre–Robin syndrome, Treacher–Collins syndrome) and blind insertion, avoiding the need for laryngoscopy. The limiting features are that the airway is not protected from regurgitating gastric contents (not a serious problem in resuscitation of the newborn), and the low-pressure seal limiting inflation of a low-compliance lung. The size of the LMA-1 is appropriate for the newborn weighing more than 2.5 kg. Use of the LMA has not been sufficiently studied for patients who require chest compressions or who suffer from congenital anomalies (diaphragmatic hernia, abdominal wall anomalies). The LMA is not a substitute for tracheal intubation, which should be carried out when indicated.

Endotracheal intubation

Endotracheal intubation is indicated when: (1) bag and mask ventilation is ineffective; (2) tracheal suctioning of thick meconium or maternal blood is required; and (3) prolonged positive ventilation is anticipated. When chest compression is required,

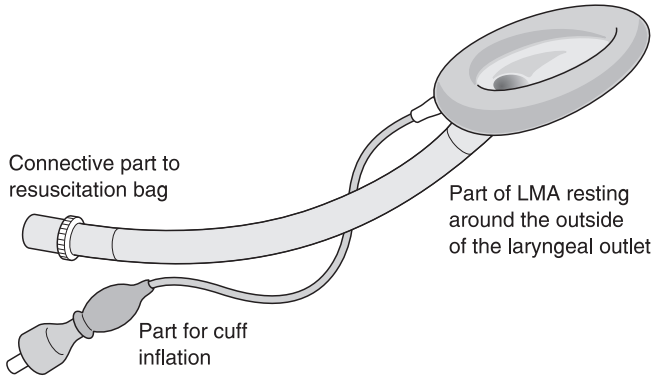

Figure 185.6 Laryngeal mask airway.

Table 185.5 Guidelines for endotracheal tube size

Tube internal diameter (mm)	Infant weight (g)	Suction catheter size
2.0	< 600	5F
2.5	600–1000	5F
3.0	1000–2000	6F
3.5	2000–3000	6F
3.5–4.0	> 3000	8F

positive pressure ventilation is much more easily accomplished if the infant is intubated.

Successful intubation should be checked by observing for: (1) symmetric chest wall motion during inflation; (2) audible and equal breath sounds bilaterally, especially at the axillae; (3) improvement in heart rate and color; and (4) absent breath sounds over the stomach. When in doubt, the position of the tube should be visualized, and the infant reintubated if necessary. If the infant is to remain intubated, a chest radiograph should confirm the proper position of the tube before its fixation. When available, an exhaled-CO_2 monitor may be used to verify tracheal tube placement. Inadequate pulmonary expansion, decreased or absent pulmonary blood flow in cases with extreme bradycardia or asystole, and small tidal volume may limit its use in the delivery room.

The common ventilation rate is that of ventilation with bags: 40–60 breaths per minute. If chest compression is required, the ratio 3:1 should be applied (three chest compressions interposed with one breath at a common rate of 120/min).

The tracheal tube should be radio-opaque, without cuff, and with the same diameter throughout.[60] The Cole tube, with a small diameter at the distal end, is no longer recommended, as visualization of the larynx is more difficult, and the narrowed diameter prevents effective suctioning.[61] The Murphy tube is now preferred, with a uniform internal diameter, centimeter markers along the length, and a default marker 2 cm above the tip. The clinician can avoid deep insertion, leaving the default marker at the level of the glottis. Another guide to the proper depth of tracheal tube placement is a distance from the tube tip to the lip of the infant of 6 cm plus the infant's weight in kilograms (for infant weighing 3 kg, the 'tip-to-lip' distance would be 9 cm).[62] The guidelines for tracheal tube size are listed in Table 185.5.

Intubation can be performed orally or nasally. Oral intubation is generally easier, faster and less traumatic, and it is generally preferred in an emergency.

Orotracheal intubation. The infant should be placed in the supine position and the chin extended slightly, but care should be taken not to hyperextend the neck. Hyperextension may impede venous return, increase intracranial pressure,[63] or kink the trachea.[64] A newborn glottis is in close proximity to the base of the tongue and visualization is easier if the neck is not extended. A laryngoscope with a Miller No. 0 or 1 straight blade, with the light close to the tip of the blade, is used to visualize the glottis. The blade No. 0 is usually sufficient for all newborns, except the largest ones. The laryngoscope is held between the thumb and the first finger of the left hand, the other fingers holding the chin. The blade is introduced from the right side between the tongue and palate and, while advancing, the tongue is pushed to the left. With the small finger of the left hand, pressure over the cricoid bone is applied to move the larynx posteriorly and visualize the glottis. The tip of the blade should advance into the vallecula epiglottis, and with a slight elevation the epiglottis is lifted anteriorly to expose the glottis (Figure 185.7). The tracheal tube, held in the right hand, is then introduced from the right corner of the mouth, along the side of the laryngoscope, through the glottis. When a properly sized tube does not pass easily into the trachea, the neck should be slightly flexed, and with rotating movement the tube should be slowly advanced. For difficult intubation in cases of dysmorphism of the upper airway a small bronchoscope should be available.[65] The bronchoscope should be inserted into the tracheal tube and then intubation can be endoscopically guided.

Nasotracheal intubation. Nasotracheal intubation is more time-consuming and technically more difficult for an inexperienced resuscitator. The tube should be lubricated with a water-base lubricant, inserted into one nostril, and with rotating movements advanced until the tip is seen in the posterior pharynx. In cases of difficult insertion a small suction catheter, pulled through the tube, should be a guide. After advancing through the nasal cavity the tube is easily passed and the catheter is then removed. The laryngoscope is placed into the mouth as described before, and the glottis visualized. With the aid of the Magill forceps

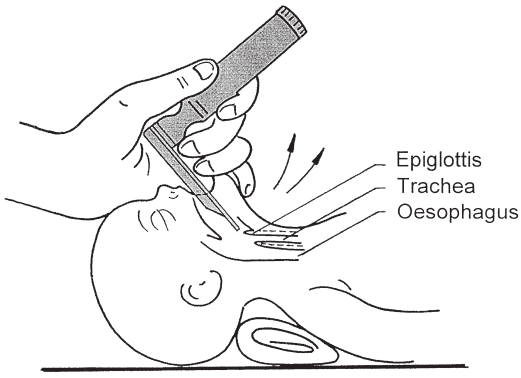

Figure 185.7 Placement of laryngoscope and landmark for intubation.

the nasotracheal tube is grasped short distance from its tip and advanced into the trachea.

Chest compression

Physiology

From the first report of cardiopulmonary resuscitation (CPR) by Kouwenhoven *et al.* in 1960,[66] it was believed that the blood flow caused by external chest compression was a result of direct squeezing of the heart between the sternum and the spinal column (cardiac pump mechanism). In 1976, Criley *et al.*[67] reported that by repeated coughing, several patients who developed ventricular fibrillation maintained a cardiac output adequate to maintain consciousness. These coughing spells were felt to increase the intrathoracic pressure, and the thoracic pump hypothesis soon followed. According to this hypothesis the external chest compression produces an increased intrathoracic pressure which translates to the lung and heart. Because of a competent venous valve at the thoracic inlet, the blood is squeezed out to the arterial system. According to this theory the heart plays no active role as a pump, but serves only as a passive conduit for the flow. It has been reported that simultaneous ventilation and external cardiac compression increase the intrathoracic vascular pressure to a greater extent than either measure alone, and enhance the cerebral and myocardial flow.[68]

Infants have a more pliable thorax, and during standard CPR a greater pressure in comparison with an adult model is generated. Secondly, a neonatal cardiac arrest differs from an adult cardiac arrest, which is usually of cardiac origin with an arrhythmia (ventricular fibrillation) as a terminal event. In infants and neonates there is generally a respiratory failure which leads to hypoxia and tissue acidosis with consequent bradycardia, decreased cardiac contractility and cardiac arrest. Therefore, establishing ventilation is of primary importance during CPR. This task is more easily accomplished with unobstructive ventilation coordinated with compression.

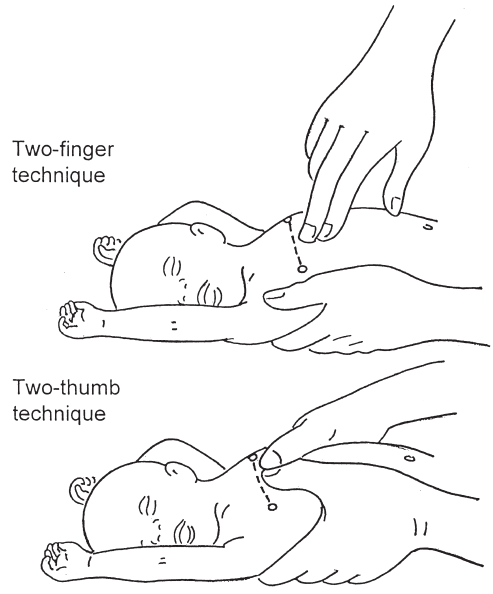

Figure 185.8 Methods of applying chest compression: two-finger technique and two-thumb technique. For a very small newborn the thumbs could overlap each other. Thumbs or fingers must be positioned on the sternum just below an imaginary line drawn between the nipples.

There are two recommended techniques for performing chest compression in the neonate (Figure 185.8).[69] In the two-thumb technique the hands are wrapped around the chest with thumbs placed on the lower third of the sternum, just below the line connecting the nipples. In the two-finger technique the index and middle fingers compress over the sternum, while the other hand supports the thorax. With the two-thumb technique the sternum is compressed and the thorax is simultaneously squeezed; therefore, cardiac and thoracic pump mechanisms are operating simultaneously. In animal studies it has been shown that with this technique higher arterial and coronary perfusion pressures are achieved.[70] For this reason, guidelines recommend two-thumb technique for chest compression in newborns whose size permits its use.[15,16]

Current recommendations

Chest compression should be started only after establishment of adequate ventilation, when a heart rate is below 60 bpm and not improving despite proper ventilation with 100% O_2 for 30 s. Both hands are placed around the thorax, with the thumb on the lower third of the sternum. Direct compression on the xiphoid or lower part of the sternum can damage abdominal organs and should be avoided. The sternum should be compressed firmly, approximately one-third of the anterior–posterior diameter of the chest, with a rate of 120 per minute (2 per second). Chest compressions should be interposed with intermittent ventilation (through bags or tracheal tube) in a 3:1 ratio.[71]

Table 185.6 Medications for neonatal resuscitation[73]

Drugs	Dose and route	Concentration	Total dose	Precautions
Epinephrine	0.01–0.03 mg/kg, IV or ET	Diluted to 1:10,000	0.1–0.3 ml/kg	Give rapidly
Volume expanders	10 ml/kg, IV			Infuse over 5 min
Sodium bicarbonate	1–2 mEq/kg, IV	0.5 mEq/ml	2–4 ml/kg	Give slowly over 2 min
Naloxone	0.1 mg/kg, IV, ET, IM or SC	0.4 or 1.0 mg/ml	0.25 or 0.1 ml/kg	Give rapidly, preferred IV or ET

IV, intravenously; ET, endotracheally; IM, intramuscularly; SC, subcutaneously

This means that the combined rate is 120 per minute: 90 chest compressions and 30 ventilations. It is recommended that the rescuer who performs chest compression counts loudly 'one-and-two-and-three-and-bag-and-one' so that synchrony is accomplished.[72] When the heart rate is greater than 60 bpm, chest compression should be discontinued.

Medications

Severe bradycardia that does not respond to adequate ventilation and chest compression is usually due to long-standing intrauterine hypoxia superimposed on acute deterioration during delivery. If after 30 s of chest compression and ventilation with 100% oxygen, bradycardia (heart rate < 60 bpm) persists, medications are indicated. This recommendation is restricted to delivery room resuscitation; therefore there is no place for medications other than epinephrine and volume expanders. Sodium bicarbonate is helpful only after prolonged resuscitation, and naloxone hydrochloride when respiratory depression secondary to maternal analgesia is suspected to exist. Medications, routes of administration, and currently recommended doses of commonly used drugs are provided in Table 185.6.[73]

Intravascular access

In the delivery room the umbilical vein can be rapidly identified and catheterized. A 3.5F or 5F single-hole radio-opaque catheter should be inserted, with the tip just below skin level, so that a free flow of blood returns on aspiration. When the catheter is inserted too deeply and without x-ray control, the tip of the catheter may be wedged in the liver, and the administration of vasoactive or hypertonic solutions may damage the liver parenchyma. A peripheral vein can be used, but can be difficult to cannulate in the presence of impaired circulation.

Tracheal access

Although this route of emergency drug administration has been widely accepted and frequently used, little scientific investigation on human subjects has been carried out. Epinephrine and naloxone can be administered by this route.[74]

Many issues concerning drug dose, route of instillation, and dilution have not been sufficiently clarified by current recommendations for resuscitation of the newborn infant. Several studies carried out on animals show that direct instillation of diluted drugs into the tube, followed by some inflation, produces the same concentration and lung distribution as other more cumbersome methods.[75] Direct instillation of epinephrine into the tube has also been found advantageous in a pediatric animal study.[76]

Drug dilution is very important for ensuring a good distribution over the largest possible surface area, providing a good pharmacological response. Redding *et al.*[77] found that 1 ml of endotracheal epinephrine was ineffective in adults unless diluted with 10 ml of water, and thereafter it has been generally accepted that endotracheal drugs should be diluted with 5–10 ml of distilled water or normal saline. Currently, there is no specific recommendation for diluting the drug in neonates, but for practical and theoretical reasons a common volume should be at least 0.5–1.0 ml.

Hypoxic neonates experience prolonged adaptation to extrauterine life. They are likely to have fluid-filled lungs and a right-to-left shunt at the level of the foramen ovale and ductus arteriosus.[78] No studies have been published on the pulmonary absorption of epinephrine in a neonatal animal model. In the first description of successful survival after the endotracheal administration of epinephrine to neonates, who did not respond to chest compression and ventilation, a standard dose (0.01 mg/kg) was used.[79]

The current recommendation states that, whether giving epinephrine intravenously or intratracheally, 0.01–0.03 mg/kg should be used. After giving the drug into the trachea, five quick insufflations are recommended before continuation of CPR.[15,16]

Intraosseous access

When a vascular line is difficult to achieve, intraosseous access can be useful for application of fluid and medication in children and adults. This is not the case in newborn infants, where the umbilical vein is easily accessible, small bones are fragile, and the intraosseous space is small, especially in premature infants.

Epinephrine. Administration of epinephrine is indicated when the heart rate is < 60 bpm after a minimum of 30 s of adequate ventilation and chest compression. The dose for neonates is 0.01–0.03 mg/kg (0.1–0.3 ml/kg of 1:10,000 solution), and the administration may be repeated every 3–5 min, if necessary. If there is no venous access, epinephrine may be administered intratracheally. Endotracheal epinephrine can be associated with low plasma levels,[80] and if there is no response the drug should be given intravenously without delay.

Epinephrine is an endogenous catecholamine with both alpha- and beta-adrenergic activity. It is released from the adrenal medulla during hypoxia and acidosis. Following intravenous administration of 0.01 mg/kg epinephrine, a further increase in plasma catecholamines is observed.[81,82] After saturation of the peripheral beta-receptors (which mediate vasodilatation) epinephrine, through the stimulation of alpha-1 receptors, decreases blood flow to the periphery (skin and skeletal muscles) and enhances myocardial and cerebral perfusion. This increase seems necessary to bring the myocardial blood flow to a sufficiently high level for restoration of spontaneous circulation (more than 20 ml/100 g/min).[83] Epinephrine also stimulates and enhances cardiac contractility, and increases heart rate.

During their early investigation, Redding and Pearson[84] found that 1 mg of epinephrine was effective in resuscitating dogs weighing approximately 10 kg, i.e. at a dose of 0.1 mg/kg. Nevertheless, the standard dose of epinephrine in adult and pediatric CPR has been for a long period considerably lower: 0.01 mg/kg. There have been reports in the pediatric and adult literature that a 10-times higher dose of epinephrine (0.1–0.2 mg/kg) is more effective than the standard dose regimen.[85,86] In the animal studies standard-dose epinephrine had a minimal effect on myocardial perfusion pressure and blood flow, whereas high-dose epinephrine (HDE) enhanced both, despite a significant reduction in cardiac output.[87] Later, randomized clinical studies revealed that HDE improved the return of spontaneous circulation, but no benefit in the discharge rates or neurological outcome was observed.[88,89]

Some of these clinical findings could be explained by a beta-1 agonist effect of epinephrine on increasing myocardial metabolism and oxygen demand, which offsets any increase in myocardial oxygen delivery during CPR. Moreover, many animal or human observational studies confirm that HDE has a detrimental effect on postresuscitation myocardial function, which includes prolonged hypertension, lactic acidemia, tachycardia, low cardiac index, low systemic oxygen delivery and consumption.[90–92] Besides, there is a substantial theoretical risk for the newly born, especially for premature infant, that rapid elevation of blood pressure may lead to intraventricular hemorrhage (IVH).[93]

Despite the existence of formal guidelines for the use of epinephrine in neonatal resuscitation, it should be emphasized that there have been no randomized controlled trials evaluating the administration of epinephrine to the apparently stillborn or extremely bradycardic newborn infant, the effect of high vs. standard doses, or the effect of intravenous vs. endotracheal administration of epinephrine.[94]

Volume expanders. Fetuses can suffer from significant blood loss into the placenta without any external evidence of acute hemorrhage. Therefore, hypovolemia should be suspected whenever a neonate is unresponsive to epinephrine, or when in spite of a normal heart rate the neonate remains pale, with a barely palpable pulse. Recommended volume expanders for such situations are normal saline (0.9% NaCl) and Ringer's lactate. Usually, a dose of 10 ml/kg is administered slowly over 5 min into the umbilical vein. Current recommendations do not support the use of albumin-containing solutions, because of risk of infectious disease and an observed association with increased mortality.[95] The use of albumin for resuscitation in acute hypovolemia in adults is still debated as well.[96,97]

A neonate in severe hypovolemic shock should receive plasma expanders at a dose of 20 ml/kg and an infusion of an inotropic agent such as dopamine at a rate of 5–20 μg/kg/min or epinephrine at a rate of 0.1–0.5 μg/kg/min. In cases of feto-fetal or feto-maternal hemorrhage, where acute blood loss is superimposed on more chronic blood loss, repeated small infusions of whole blood (5 ml/kg) or packed erythrocytes should be infused, or exchange transfusion should be carried out, if high central venous pressure already reflects myocardial failure.

Sodium bicarbonate. Perinatal hypoxia leads to lactic acidosis, which decreases myocardial contractility, lowers blood pressure, and decreases cardiac response to catecholamines. Theoretically, there are therefore many reasons for using sodium bicarbonate ($NaHCO_3$) during resuscitation.

The ability of $NaHCO_3$ to buffer an increase in H^+ depends upon the ability of the lung to exhale CO_2 produced by the buffering process: $H^+ + NaHCO_3 = Na^+ + H_2CO_3 = Na^+ + H_2O + CO_2$.

The ability of the lung to eliminate CO_2 depends on ventilation and pulmonary blood flow. At the beginning of resuscitation, in the state of low cardiac output, giving $NaHCO_3$ is counterproductive. Even with adequate ventilation, a low pulmonary blood flow does not allow CO_2 elimination, and metabolic acidosis is simply replaced by respiratory acidosis. As CO_2 easily crosses the cell membrane, it transiently lowers the intramyocardial pH and decreases myocardial contractility,[98] even if the pH in the arterial blood is normalized. After the restoration of pulmonary blood flow and ventilation, this effect can be quickly

reversed. Furthermore, $NaHCO_3$ may even contribute to IVH[99] in preterm infants. IVH is thought to be secondary to hypernatremia and hypertonicity,[100] but any preterm infant requiring CPR is at increased risk for IVH.

Recently, the role of $NaHCO_3$ has been reevaluated. In an animal model it was found that during neonatal resuscitation, with hypoxia and compromised hemodynamics, metabolic acidemia significantly attenuated the hemodynamic responses to epinephrine and oxygen, suggesting that the correction of metabolic acidosis may be warranted.[101] However, a randomized controlled trial of $NaHCO_3$ in neonatal resuscitation did not provide evidence for improved survival or immediate neurologic outcome.[102] Even more, a thorough review of the physiologic evidence for use of bicarbonate in the neonatal intensive care unit showed that, should bicarbonate be introduced today as a new drug for the treatment of acidosis, its approval could not be supported on the basis of existing experimental data.[103]

During brief resuscitation the use of bicarbonate is discouraged. It should be administered only when CPR is prolonged, adequate ventilation has been established, and there is no response to epinephrine and volume expanders. The dose of 1–2 mEq/kg of 0.5 M solution is administered intravenously, at the slow rate of 1 mEq/kg/min, to minimize the acute effect of hypertonicity.[16,104]

Naloxone hydrochloride. Naloxone hydrochloride is a narcotic antagonist that reverses the respiratory depression induced by narcotics. It is indicated when there are no clinical signs of hypoxic–ischemic injury (adequate circulation is established) and with a history of maternal narcotic administration within 4 h prior to delivery. The dose is 0.1 mg/kg,[105] and should be given every 2–3 min, as the narcotic suppression of respiration exceeds the effect of the antagonist.

The preferred route of administration is intravenous or intratracheal, but the drug can also be given intramuscularly or subcutaneously. Continuous monitoring for at least 6 h after administration is indicated. In the neonate whose mother is suspected to be addicted to narcotics, the use of naloxone hydrochloride is contraindicated because narcotic withdrawal can induce severe seizures.[106]

Oxygen. Oxygen has been traditionally used for resuscitation of the newborn. Current guidelines[15,16] recommend using 100% oxygen in a breathing newborn during stabilization, whenever he or she is cyanotic, bradycardic, or has other signs of distress. Oxygen should be delivered close to the infant's face by oxygen mask, face mask or by flow-inflating bag. Many self-inflating bags do not deliver 100% oxygen if they are not squeezed simultaneously. Obviously, 100% oxygen should be provided during positive-pressure ventilation and, even more importantly, during chest compressions. If oxygen is not available, resuscitation should be initiated with positive-pressure ventilation and room air.

Oxygen paradox

The paradox of aerobic life is that higher eukaryotic aerobic organisms cannot exist without oxygen, yet oxygen is inherently dangerous to their existence through the formation of highly toxic free radical species. These molecules are highly reactive and are capable of damaging all biological macromolecules including proteins, DNA and lipids and have been implicated in inflammatory, toxic and metabolic insults, ischemia–reperfusion injury, carcinogenesis and atherosclerosis.[107] It has recently been proposed that many diseases affecting preterm infants are only different facets of the same oxygen radical disease.[108] Furthermore, it has become evident that hypoxic tissue injury is not caused only by lack of oxygen but occurs to a large extent from events in the posthypoxic reoxygenation period, which lasts long after the primary insult.[109]

In animal experiments it was found that room air was as effective as 100% oxygen for normalizing blood pressure, heart rate, base deficit, and plasma hypoxanthine after severe neonatal hypoxia, and that the extent of hypoxic brain damage was similar. There were also no differences in cerebral blood flow (CBF) or somatosensory-evoked potentials.[110,111]

Oxygen is not universally used in many situations during resuscitation outside hospitals, and in many developing countries supplementary oxygen is rarely available. The results of several clinical studies have also shown no differences between the groups of infants resuscitated with room air or 100% oxygen in heart rate response, acid–base status, or outcome at 28 days.[112,113] Furthermore, they found that infants resuscitated with air recovered more quickly as assessed by Apgar scores and time to first cry. The air-resuscitated babies achieved a sustained pattern of respiration more quickly, and required a shorter duration of positive-pressure ventilation. A trend toward lower mortality was noticed, although it was not statistically significant. It was also found that oxidative stress measured by the ratio of reduced to oxidized glutathione in whole blood and by superoxide dismutase activity in erythrocytes, was increased in newborns resuscitated with oxygen compared with room air.[114] Biochemical findings of prolonged oxygen stress were apparent even after 4 weeks of postnatal life.[115]

Despite these growing biochemical and clinical evidence of oxygen toxicity, Niermeyer and Vento[107] concluded that further research in the way of a prospective randomized clinical trial is needed before the use of room air instead of 100% of oxygen can be recommended. While waiting for the new recommendation, the goal of oxygen supplementation should be normoxemia. A recent international survey of a sample of academic centers disclosed that approximately

50% of neonatologists reported that they already had begun to modify the percentage of oxygen used during neonatal resuscitation in their institutions.[116] Obviously, adequate ventilation seems to be more important than oxygen supplementation during resuscitation. However, some newborns with severely impaired lungs may not be adequately oxygenated with room air and on such occasions monitoring with pulse oximetry is recommended.

Problems of resuscitation

Technical errors

In spite of apparently appropriate resuscitation, some newborns remain cyanotic and bradycardic or breathe irregularly. Sometimes the cause may be a congenital anomaly, but first one should consider the possibility of the following technical errors in resuscitation:

- not enough pressure delivered with the self-inflating bag (change bag for another),
- incorrectly sized face mask or loss of tight seal around the mask,
- collapsing upper airway because of neck hyperextension or flexion (change position of the head while observing chest movements),
- disconnection of the oxygen (anesthesia bag is not inflating, oxygen reservoir on self-inflating mask is empty),
- tube not in the trachea but inserted too deep in main bronchus, or tube slipped into the esophagus (observe chest movement, auscultate, reintubate if necessary),
- improperly sized tracheal tube, which is too small for the particular infant.

Pneumothorax

Pneumothorax should always be considered in the neonate responding poorly to resuscitation. The main clinical signs are a lateral shift of the heart sounds, sometimes with muffled tones, decreased movement of the thorax and difficult inflation, distended abdomen (especially in preterm infants), and sustained or secondary bradycardia.

As there is no time for an x-ray, cold-light examination can be of assistance. If the newborn's condition deteriorates rapidly, trial punctures on both sides of the thorax in the midclavicular line in the second intercostal space, must be carried out. If air comes out and the newborn's condition improves, a thoracic drainage is performed, or a venous cannula (18–20 gauge) is inserted at the side of the pneumothorax, the stylet removed, and the neonate prepared for transport.

Congenital malformations

Some newborns are vigorous and have a normal heart rate, but have increasingly severe respiratory distress and remain cyanotic in spite of oxygenation and bag and mask ventilation. In such cases the possibility of congenital malformation should be considered.

Some malformations of the upper respiratory tract (choanal atresia, Pierre–Robin syndrome) are disclosed clinically and during laryngoscopy. A prone position, insertion of an oropharyngeal tube or intubation will usually solve the problem. Laryngeal or tracheal atresia are found during an unsuccessful trial of intubation, and only emergency tracheotomy or puncturing of the trachea with a thicker vein cannula may help the baby to survive in the delivery room.

Neonates with lung malformations (pulmonary hypoplasia due to Potter syndrome or prolonged membrane rupture, congenital anomalies of the lung itself, pleural effusion) are usually intubated at birth because of respiratory deterioration; for diagnosis and management, transport to the neonatal intensive care unit is urgent.

There are many dysmorphic syndromes, such as some short-limb dwarfing syndromes, that are incompatible with life. Nevertheless, as the delivery room is not the proper place for a careful physical examination, and as the most experienced team is probably not present, it is more appropriate to stabilize and transport the baby to the intensive care unit where careful examination to identify the disorder can be done.

Very rarely, a newborn baby has a normal heart rate and good peripheral perfusion but is hypotonic and does not breathe by itself in spite of appropriate oxygenation, and correction of blood sugar and potential acidosis. If there is no history of maternal diseases or fetal distress during labor, a congenital neuromuscular disease (Werdnig–Hoffmann disease, transient neonatal myasthenia gravis, congenital myopathies, severe neonatal form of myotonic dystrophy, congenital muscular dystrophy) should be considered.

Anomalies of the abdominal wall

Diaphragmatic hernia, omphalocele and gastroschisis can be detected by ultrasound examination in pregnancy. Therefore, when labor begins there is enough time for the most experienced team to be prepared for delivery. Some hours after delivery, the intestines fill with air because of swallowing. This occurs even more rapidly if after birth ventilation with a mask is required. In cases of diaphragmatic hernia the air in the intestines disturbs breathing, while in cases of gastroschisis it interferes with vein return, which causes preoperative conditions to deteriorate. Therefore, it is recommended to intubate these newborns immediately after birth,[117] and to insert a wide catheter to decompress the stomach. The newborn with gastroschisis should be placed on its side to prevent venous stasis.

Fetuses with congenital diaphragmatic hernia (CDH) are at high risk for severe pulmonary hypoplasia. They should be ideally delivered in a perinatal

center with a neonatal surgical department.[118] CDH presents with a deviation of the mediastinum to the right (shift of cardiac impulse), markedly reduced or absent breath sounds on the left (the most common side of the hernia), and a concave-appearing abdomen. Usually diagnosis has been established before delivery by ultrasound examination, but in any newborn with rapidly developing respiratory distress, urgent intubation without attempts at bag and mask ventilation is mandatory if there is any suspicion of CDH. In cases of clinically suspected or already diagnosed CDH, the resuscitation of the newborn includes tracheal intubation and positive pressure ventilation.

Hydrops fetalis

Clinically, hydrops is recognized at birth as anasarca, ascites and pleural effusion, and is generally classified as either immune or non-immune in nature. The introduction of Rh D immune globulin prophylaxis has so reduced the incidence of immune hydrops that more than 75% of neonatal hydrops cases show no evidence of associated hemolytic disease. Ultrasound examination in all pregnancies complicated by hypertension, preeclampsia, polyhydramnios or anemia could identify 80% of affected neonates before the 28th week of gestation.[119] The resuscitators should be experienced in tracheal intubation, chest compression, umbilical vessel catheterization, paracentesis, thoracentesis and pericardiocentesis.

Special considerations

Preterm neonates

Currently, VLBW infants account for more than 50% of perinatal mortality and more than 50% of neonatal deaths, and occupy more than two-thirds of the beds in neonatal intensive care units. As the survival of these infants depends more on experienced management than on the initial resuscitation,[120] every effort should be made to transfer the parturient to a perinatal center with experienced obstetricians and neonatologists, and neonatal intensive care facilities.

The incidence of perinatal depression, but not asphyxia, is increased among premature infants, because of their physiologic immaturity. Diminished lung compliance, weakness of respiratory musculature and reduced respiratory drive may increase necessity for assisted ventilation. Among 33,357 liveborn infants delivered at the Maternity Hospital of Ljubljana (1997–2002), 3.6% were bag and mask resuscitated (49% of them were preterm infants) and 0.4% were intubated and ventilated in the delivery room (65% of them were preterm; 35% had a gestational age of 27 weeks or less).[3] Very preterm infants have an increased risk of acute and chronic neonatal disorders (heat loss, IVH, periventricular leukomalacia, respiratory distress, necrotizing enterocolitis, chronic lung disease, retinopathy of prematurity). Current guidelines make no distinction between the techniques of resuscitation for term and very preterm infants with respect to ventilation and oxygen administration. Modifications of the basic approach may, nevertheless, be warranted for very immature infants.[121]

Volutrauma

It has been recognized that volutrauma (the adverse effects of a large tidal volume regardless of the pressure applied) plays an important role in lung injury.[122] The current practice, among other methods aimed at reducing lung injury, includes breathing on nasal continuous positive airway pressure (CPAP), low tidal volume ventilation (high-frequency ventilation), and gentle ventilation in the delivery room.[123] It has been demonstrated in a premature lamb model that a few large breaths applied manually at birth to a surfactant-deficient lung can produce lung injury, irrespective of whether artificial surfactant has been administered before or afterwards.[124,125] Self-inflating or flow-inflating bags either display no data on tidal volume or show only the pressure. It is known that positive end-expiratory pressure (PEEP) during ventilation increases lung surface area and compliance, preserves FRC, conserves surfactant, reduces hyaline membrane disease, and reduces expression of pro-inflammatory cytokines.[121] Adequate PEEP cannot be provided with self-inflating bags and is difficult to control with anesthesia bags. There are no formal recommendations regarding its use during resuscitation of the newborn.

CPAP is used ever more frequently in intensive care units and its early use together with surfactant administration reduces the need for intubation and subsequent mechanical ventilation of premature infants.[126] With the use of a T-piece or a Neopuff infant resuscitator (Fisher & Paykel, New Zealand), which is a modified T-piece, CPAP, variable PEEP and positive inspiratory pressure can be delivered, although they provide no data on tidal volume. The Neopuff is easy to use, even in the hands of inexperienced operators[127] and should be considered for resuscitation of preterm infants.

Oxygen toxicity

As noted above, clinical studies have shown that resuscitation can be carried out with room air without any adverse effect, and that there may in fact be some advantages of air over oxygen.[112,113] It was also found that oxidative stress is increased in newborn infants resuscitated with oxygen and is apparent even after 4 weeks of postnatal life.[114,115] Oxygen is even more toxic for preterm babies, as it has been shown that they have a lower capacity for induction of antioxidant enzymes than do term babies.[128] Recent results from several observational studies, summarized by Tin,[129] showed that keeping oxygen saturation levels below 90–95% in the first weeks postpartum, reduced the frequency of chronic lung disease and retinopathy (stage 3–4) in infants with birth weights < 1500 g.

Lower levels of saturation (< 94%) did not influence the mortality and neurodevelopmental outcome at 1 year.[130] Even if there is yet no definite answer to the question of what constitutes the lower safe limit of oxygen saturation, it is becoming clear that a more permissive approach to minor hypoxia may, like a permissive approach to hypercapnia, reduce the need for ventilatory support, the risk of chronic lung disease, and their associated health care costs.[131] It has also been shown that even short-term administration of 80% oxygen during initial stabilization at birth produces a persistent cerebral vasoconstriction with a lower CBF in preterm infants.[132] Oxidative stress influences apoptosis and cell growth, and may have long-term consequences on growth and development.[133] While we await the results of ongoing trials, it would seem wise to monitor oxygen saturation during resuscitation of preterm infants and use the lowest possible FiO_2 to reach normoxemia.

Limits of viability

Regionalization and new technology have increased the survival rate in preterm neonates. With survival of more and more of these tiny babies a lot of new questions have emerged: Are we using the new technology rationally and, more importantly, ethically? How small is too small and toward what goal should we aim: survival, or quality of life? Do we respect the ethical principles of beneficence and nonmaleficence; are we helping or hurting these tiny children? How do we determine what is in the best interests of the baby, and who is the most appropriate surrogate decision maker – parents or health care providers? Should we consider economic pressure to decrease expenses?[134] Every pediatrician working in the delivery room is sooner or later faced with these questions and is placed in the position of determining if resuscitation of a tiny baby is warranted. Characteristics of the individual physician, both personal and professional, and the presence of an ethics committee in the hospital influence this attitude.[135] With the decision to resuscitate comes the long-term commitment for the care of this child, and the emotional and financial investments are very high.[136] It is very difficult for the physician to be objective in the delivery room, where he or she may feel the pressure of the parents, obstetrician, and nurses, each of them with their own expectations.

Survival rates for extremely preterm infants have steadily increased in all weight or age groups during recent decades, whereas neurodevelopmental disability rates have, in general, remained unchanged.[137,138] Survival has increased from 20% to more than 50% between 23 and 24 weeks of gestation or, similarly, between 500 and 600 g of birth weight. Guidelines on life and death decisions in preterm infants have been formulated in different countries and varied from non-initiation of resuscitation at 22 weeks to provision of all reasonable care beyond 25 weeks.[139] In the gray zone between the opinions of the parents should be respected. Because in these tiny babies the risks of death and long-term morbidity are not negligible, it is important that, whenever possible, maternal interventions, mode of delivery, extent of resuscitative efforts, and discontinuance of therapy are discussed before the delivery begins.[140,141] The family should also be informed that resuscitation at delivery does not mandate continued support, that decision making continues beyond the first few critical hours, and that the child's future treatment will be based on almost continuous reassessment.

Does the preterm infant need prophylactic surfactant therapy?

Intratracheal surfactant administration at birth theoretically offers the advantage of optimal surfactant distribution within the alveoli. As the lung expands and fluid is reabsorbed, the surfactant is distributed to all parts of the lung. Even short-term ventilation of surfactant-deficient lungs results in areas of atelectasis and areas of hyperinflation, which causes uneven distribution of exogenous surfactant.[142] In several studies that compared prophylactic vs. rescue treatment, no great advantage of prophylaxis could be found, except in the smallest infants (26 weeks of gestation or less).[143] However, recent reports have shown that very preterm infants who received prophylactic surfactant developed less severe respiratory distress syndrome, needed lower peak inspiratory pressures, had a shorter duration of oxygen therapy, and less periventricular leukomalacia and IVH.[144,145]

When early surfactant administration is used it should be provided early, preferably in the delivery room or at least within 1 h of age.[146,147] Such treatment may interfere with initial resuscitation; nevertheless, preterm infants are intubated in the delivery room mostly for respiratory insufficiency and less often for severe asphyxia. Early surfactant administration improves ventilatory efficiency, which is of outmost importance for successful resuscitation.

Meconium-stained amniotic fluid

As noted above, morbidity and mortality from MAS seemed to improve after Gregory *et al.*[148] in 1974 recommended laryngoscopy and tracheal intubation with suctioning for all newborns delivered through thick particulate meconium. In 1976, Carson *et al.*[149] reported that additional obstetric suctioning of the oro- and hypopharynx before the shoulders were delivered further reduced the severity and frequency of MAS. The importance of tracheal intubation and suctioning for all newborns with meconium-stained amniotic fluid was, however, challenged by others who proposed selective tracheal suctioning only for severely depressed infants born through thick particulate meconium.[150,151] They believed that lung disease is primarily due to hypoxia, and that an unnecessary intubation of an infant with thin meconium or a

vigorous infant with thick meconium-stained fluid can expose it to unnecessary risk.

The concept of unselected tracheal suctioning was based on the assumption that MAS is primarily a postnatal event, that oronasopharyngeal suctioning at the perineum and tracheal intubation just after delivery prevents the moving of meconium into the trachea, and that all deaths from MAS could be prevented by these measures. It was reported subsequently that the introduction of De Lee suctioning did not influence the presence of meconium below the vocal cords or the rate of MAS.[40] It is now believed that chronic fetal hypoxia can result in meconium passage, and, in the presence of oligohydramnios, the meconium becomes thick. Further hypoxia induces gasping respirations that move the meconium into the trachea. The compromised fetus with decreased lung fluid outflow fails to clear the meconium from the respiratory tree.[152]

In the Ljubljana Maternity Hospital, we perform selective tracheal suctioning under laryngoscopic control with a thick catheter. If meconium is found in the trachea and the infant is severely depressed, we intubate the baby and perform lung lavage with 1–2 ml of normal saline. When the condition of the infant allows, the procedure is repeated as long as meconium is achieved. During lavage the tracheal tube is not withdrawn, and suctioning is performed with the widest bore catheter possible. During a 6-year period, 4795 (15.9%) term infants were born through meconium-stained amniotic fluid; 2.5% were aspirated, an additional 3.4% were bag and mask ventilated, and only 0.3% were intubated in the delivery room. Altogether 14 infants had signs of MAS, seven were mechanically ventilated, and only one died of extreme hypoxia.

Care after resuscitation

After resuscitation blood should be taken for blood gas analysis and glucose determination. Special efforts to avoid hypo- and hyperthermia should be made. When the infant is stabilized he or she should be transported to the neonatal intensive care unit. Severe asphyxia could lead to multiorgan failure; therefore, appropriate control of respiration, circulation, blood gas and electrolyte balance is important. Complete documentation of all interventions and medications used during resuscitation should be recorded. The use of standard resuscitation records is desirable because it offers the further advantage of uniform data collection to facilitate study and comparison of resuscitation techniques and outcomes.

The Apgar score is traditionally used in the delivery room to evaluate the physical condition of the newborn at birth and the immediate need for resuscitation. Heart rate, breathing efforts, muscle tone, reflex irritability, and color are recorded at 1 and 5 min after birth and then sequentially every 5 min until vital signs have established. The score is designed to facilitate clinical assessment of the newborn and guide resuscitative interventions, which aid in accomplishing transition from the fetal to the neonatal environment. The Apgar score should not be used to define birth asphyxia, or to predict subsequent child development.[153]

Ethical considerations

Cardiopulmonary resuscitation in the delivery room is a therapeutic modality that initiates a cascade of events that usually results in admission to the neonatal intensive care unit with assisted ventilation, often painful and expensive therapy, and sometimes ends with an imperfect outcome. The decision either to resuscitate or not must be made instantaneously, always without the advice of the ethics committee, usually without full knowledge of the baby's condition and future outcome, and commonly without consultation with the parents.[154]

Competent practice of neonatal intensive care today requires more than the knowledge of the relevant medical science. At least some understanding of medical ethics and associated dilemmas that are nowadays the subject of wide public concern is required. In the search for practical guidelines for solving medical dilemmas, ethical theorists advocate four principles on which to ground ethical analysis.[155]

(1) Respect for autonomy (self determination) – everyone is free to choose what is best for him/her.
(2) Beneficence (doing good) – the practitioner has a moral obligation to act for the benefit of the patient.
(3) Nonmaleficence (avoiding harm) – the practitioner has an obligation not to harm intentionally.
(4) Justice (fair distribution) – the practitioner should distribute benefits and burdens fairly, to treat equals equally.

Many physicians believe that there is an ethical difference between stopping a treatment once it is started, and not starting it in the first place (withdrawing vs. withholding treatment). A survey of opinions of attending physicians, house-staff, and medical students indicated that all felt much more comfortable in withholding treatments than in withdrawing them.[156,157] This opinion is strikingly different from the prevailing views among ethicists and lawyers who consider the decision to withhold or withdraw as equivalent under the condition that in either case the patient receives an adequate trial of therapy.[158,159] While newborns share with children and adults the right to live, there will occasionally be some who by reason of severe malformation, asphyxial injury or

extreme prematurity, have the right to die with dignity, without inappropriate or futile medical intervention. CPR should reasonably be withheld from such patients. The Royal College of Pediatrics and Child Health advised to withhold treatment in the following three situations: the no-chance situation, the no-purpose situation with massive physical or mental impairment, and the unbearable situation with progressive and irreversible illness.[160] Nevertheless, physicians should be aware that withholding CPR from critically ill newborns, based on assumptions of future mental and physical development or social adaptability, places decision makers on a slippery slope, the bottom of which holds that no person or value is sacred against social utility.[161]

The current guidelines recommend that non-initiation of resuscitation in the delivery room is appropriate for infants with confirmed gestation < 23 weeks or birth weight < 400 g, anencephaly or confirmed trisomy 13 or 18. In case of uncertainty, the resuscitation should be initiated and life preserved until enough information is gathered to provide counseling with the parents and to decide whether continuation or withdrawal of life support is in the best interests of the infant.

186 Childbirth and the pelvic floor

W. R. Cohen and R. Romero

A dramatic change in the distribution of delivery modes has occurred recently in many parts of the developed world. While the rise in cesarean rates that began in the 1970s had modulated by the 1990s, more recent changes have led cesarean rates to previously unimagined levels in many countries, and they continue to rise. Until recently, concerns about fetal and neonatal well-being drove most decisions for cesarean section; but now the need to protect maternal pelvic floor integrity has arisen as a justification for avoiding vaginal delivery. The medical profession and the lay public share the unease about the potential adverse effects of vaginal birth on the pelvic floor and the long-term consequences of such injury.

It is clear that damage to the musculofascial supports of the lower female genitourinary tract and anal continence mechanism can occur during vaginal birth, and there is evidence that such harm to pelvic floor structures and their innervation can cause or contribute to chronic genital, urinary, or defecatory pathology in later life (Table 186.1).[1–7] The magnitude of the contribution of parturitional trauma to the prevalence of pelvic organ prolapse and incontinence, which may not be manifest until many years after delivery, is not, however, known precisely. It is nevertheless increasingly cited to justify liberal use of cesarean delivery as well as to question the benefits of instrumental delivery and episiotomy.[8]

This nascent trend in obstetric thinking countervails the prevailing logic that has guided efforts to reduce the cesarean section rate during the last few decades and, if validated, would lead to a sea change in our concept of indications for cesarean delivery. The issue is of particular and increasing importance because pelvic floor disorders afflict primarily older women, and the aging of our population endows a practical urgency to develop a complete understanding of this complex area. Moreover, recent studies suggest that these disorders are considerably more prevalent than was recognized previously and that they contribute mightily to health care costs.[9–18] It is important that we determine what the etiology is of parturitional pelvic tissue injury, what the short- and long-term consequences of that injury are, and what obstetric or other factors make a patient vulnerable to serious adverse outcomes. Only with that information can we make informed medical judgments and rational obstetric care policies.

Pelvic surgery

Prevalence and cost

The prevalence of the symptomatic consequences of obstetric pelvic floor disruption is difficult to determine. While many studies exist, the reported frequencies of incontinence and genital prolapse vary a great deal. This is probably the consequence of an inhomogeneity in survey methods of ascertainment, in definitions of incontinence, and in study population demographics.[9] Urinary incontinence probably exists in at least 5–10% of the female population; many estimate it is much more common. Using a questionnaire approach, Crist *et al.* found that 34% of women reported some degree of urinary incontinence, the frequency and severity of which was related directly to age and parity.[19]

In a population-based study, Samuelsson *et al.* identified some evidence of genital prolapse (cystocele, rectocele, uterine prolapse, or absence of the urethrovesical crease) in about 30% of the general female population in Sweden.[20] Among parous women aged 20–60 years 44% were affected; 5.8% of nulliparas had these signs of pelvic floor incompetence. While age and parity were strongly associated with prolapse, only a small minority of cases were symptomatic or

of any functional significance. This observation emphasizes one of the important deficits in our knowledge of pelvic floor disorders in general. The rate at which minor degrees of anatomic prolapse, or subclinical abnormalities in the continence mechanism progress to a significantly symptomatic state is not discernible; neither do we understand how progression is influenced, or what therapeutic or lifestyle changes might hasten or slow its progress.

The prevalence of anal incontinence is also quite difficult to ascertain with certainty, but is doubtless more common than realized previously, and occurs predominantly in women.[4,10,11,13,21] A community survey in Wisconsin[10] showed that about 2–3% of women suffered from anal incontinence, with associated factors being advancing age, poor general health, and physical limitations. Anal incontinence often accompanies urinary incontinence and other pelvic floor disorders.[21,22] A population-based survey done in Australia in 1998[13] revealed that 35% of women had urinary incontinence and 3.5% had fecal incontinence. An additional 10.9% suffered from inability to control flatus. About one quarter of women had had previous surgery for incontinence or prolapse.

Kalantar *et al.*[23] found anal incontinence in 3.7% of a surveyed population of 65- to 93-year-olds in Australia, and Nelson *et al.*[10] reported an overall 2.2% incidence in the general population in a study done in the United States. Of the incontinent people, only 30% were older than 65 years, and 63% were women, findings consistent with those of other studies.[13] Some surveys suggest the problem of anal incontinence is even more widespread, and place the prevalence as high as 16%.[11] Several obstetric events and features have been identified as risk factors for anal incontinence. These include instrumental (especially forceps) delivery, episiotomy, and large birth weight.[1,4–6,24–27] All are factors known as well to be associated with risk of anal sphincter injury.

Pelvic floor dysfunction is more prevalent than previously realized. In addition to the inconvenience, risk, and emotional and physical disability that continence and genital prolapse disorders endow on individual women, the impact of these diseases on the public health and on health care costs is quite considerable. The lifetime risk of surgery for genital prolapse or urinary incontinence in an American female population was found to be about 11%;[28] a much larger number of affected women use non-surgical therapy or have no treatment. The number of women having surgery for urinary incontinence in the United States was 0.32 procedures per 1000 women per year in 1979; by 1997 the rate had increased to 0.60,[17] and in 1998 it was reported to have been 1.3.[15] It is likely higher today. This increase probably relates to several factors, including enhanced awareness of the problem among physicians and the lay public, the availability of new (and relatively simple) techniques for operative management, and the burgeoning size of the population at greatest risk.

The direct cost of care for urinary incontinence in women in the United States was estimated to be about $12.4 billion (in 1995 dollars),[29] and the cost of organ prolapse surgery more than $1 billion.[16] This amount is more than the cost of managing breast cancer, and in a league with that of many other chronic diseases. The need to understand and treat these problems has taken on a greater urgency recently because of the increasing longevity of the population and the transition of the post-World War II baby-boom generation into the age group in which pelvic floor problems become most prevalent. There is a need to develop our understanding of the causes of pelvic floor dysfunction if we are to make informed clinical judgments and fashion rational public heath policies to deal with them.

Mechanisms of obstetric injury

The mechanism of permanent parturitional injury to the birth canal and surrounding structures is the subject of controversy and uncertainty. We can predict *a priori* that possible mechanisms could include pudendal or autonomic nerve damage from excess direct pressure or traction, laceration and imperfect healing of pelvic tissues, stretching of muscle or connective tissue beyond its ability to recover strength and elasticity, and necrosis of pelvic soft tissues (from prolonged pressure by the fetus). One or more of these factors could cause or contribute to pelvic floor dysfunction in a particular case. Unfortunately, our inability to identify the mechanism of injury in many women and thereby to tailor treatment to address it confounds our efforts to help many patients.

Overt perineal trauma during vaginal delivery is not infrequent. Lacerations of the external anal sphincter (with or without accompanying tears of the anal–rectal wall) occur in about 1–4% of deliveries.[30–34] Risk factors include occiput posterior position, use of episiotomy, fetal macrosomia, and instrumental delivery. In addition to visible trauma, it is now clear that injuries to this area may be occult in a substantial number of cases.[26,35] Sultan *et al.*[26] showed that in a sample of primiparous women there was a 3% incidence of clinically diagnosed anal sphincter disruption; but anal sonography found sphincter defects in 35%. In another study, anal sonography done immediately after delivery revealed that 28% of patients had clinically undetectable anal sphincter disruptions.[36] These revelations raise many questions and concerns. While we have focused traditionally on the importance of repairing visible injuries, it is possible that most long-term damage is the consequence of invisible trauma that is perforce not repaired after delivery. Frudinger *et al.*[37] noted that some women with anal incontinence had intact sphincters. Thus, not only does occult sphincteric damage occur during delivery, but some women with anatomically intact sphincter mechanisms have

postpartum incontinence, presumably the consequence of some functional (neurologic or traumatic) disruption of the continence mechanism.

In the lower pelvis the pudendal nerve lies relatively fixed in Alcock's Canal, where it is vulnerable to direct compression by the fetal head and to traction as the fetal presenting part distends the perineal structures and pushes them caudad late in the second stage of labor. The fact that pudendal nerve injury has not been observed after elective cesarean delivery but does occur after cesarean delivery in the first stage of labor suggests that compression injury can occur.[38,39] Therefore, prevention of pudendal nerve injury is not necessarily avoidable by cesarean section, unless it is done prior to labor. Even then, there is some evidence that pregnancy *per se* may have an effect on pelvic innervation.[39]

Pudendal nerve dysfunction probably underlies many cases of urinary and fecal incontinence.[2,40–42] The extent to which this denervation is the sole result of vaginal delivery is still unclear. In one study cohort, up to 80% of primiparous women had some evidence of denervation of the pelvic floor following vaginal delivery.[42] In the majority of cases, prolonged pudendal nerve terminal latencies recovered within 6 months of delivery. It does appear that women whose symptoms of incontinence persist for several months after delivery are highly likely to have these problems persist.[43]

In a 5-year follow-up of women who had evidence of pudendal neuropathy 2 months after vaginal delivery, Snooks *et al.*[7] showed evidence of persistent pudendal nerve damage in women who delivered vaginally, as determined by the observation of increased EMG-derived fiber density in the external anal sphincter, increased pudendal nerve terminal motor latency and reduced maximal anal canal pressure. Associated risk factors for nerve injury were multiparity, forceps delivery, third-degree perineal tear, long second stage, and high birth weight. This damage to the pelvic floor innervation is usually unrecognized after delivery, and is generally not associated with immediate symptoms of pelvic floor dysfunction. While such damage presumably predisposes to pelvic floor disability later in life, the frequency at which this occurs, and the degree to which such damage is repaired or compensated for over time are not known. Perhaps, the presence of cofactors is important or even necessary in order for most parturitional damage to become manifest as clinical incontinence or genital prolapse.

Some healing or compensatory mechanisms undoubtedly influence the degree to which overt or occult pelvic floor trauma contribute to long-term dysfunction. As noted, evidence of at least partial denervation of the pelvic floor can be demonstrated in 80% of primiparas.[42] If all such affected women developed incontinence or prolapse, observed prevalences later in life would be much higher than reported. In addition, the natural history of incontinence is understood incompletely. Some women have symptoms that subside spontaneously, or as a consequence of lifestyle changes (weight loss, smoking cessation, use of pelvic floor exercises, etc.). While the development of stress urinary incontinence shortly after delivery clearly places a woman at increased risk of such problems later in life, not all such individuals have persistent symptoms. It is likewise astounding that as many as one-third of women may sustain anal sphincter injuries during vaginal delivery that are not recognized.[5,26,35,44] This is an intriguing observation for two reasons. It is on the one hand sobering to realize that so normal a process as vaginal birth could cause significant injury so frequently; on the other, it is reassuring that the body is clearly able to heal or to compensate for many of these injuries. (Were it not competent in so doing, we would observe a much higher prevalence of anal incontinence than we do.)

The literature on pelvic floor injury is replete with references to pudendal nerve dysfunction and its effect on continence and the strength of the pelvic floor. While the pudendal nerve may indeed play an important role in this regard, its precise contribution to maintaining pelvic visceral support and urinary and fecal continence is not well understood. In fact, there is recent evidence from monkeys and humans that the levator ani muscles receive their innervation from sacral nerve roots (S4-5) and not from the pudendal nerve, as has been assumed.[45,46] This may explain why not all women, even with evidence of major pudendal nerve dysfunction, are incontinent. Such observations are of considerable importance for three reasons: they underscore our relative ignorance about the complex functional anatomy of this area; they require rethinking some traditional concepts of obstetric pelvic floor denervation; and they suggest potential avenues for diagnostic and therapeutic procedures.

The mechanisms that link childbirth to fecal incontinence are also not completely clear. There is no doubt that vaginal delivery may have a contributing role, and severe overt trauma to the pelvic floor and sphincter apparatus, especially if not properly repaired, can obviously lead to problems, as has been amply demonstrated in the developing world;[47] but other factors figure importantly in the risk of developing defecatory dysfunction. Among an Australian cohort of women who had vaginal instrumental delivery and/or delivered a baby weighing more than 4000 g, nearly 7% reported fecal incontinence 1 year after delivery.[13] In this group of high-risk women, fecal incontinence was significantly associated with maternal age above 35 years and with the presence of joint hypermobility. It often coexisted with urinary incontinence, but was not (contrary to other data) associated with multiparity.

Direct damage to the anal sphincters or pelvic floor muscular or connective tissue may also be etiologic in incontinence disorders and pelvic organ descent and is often persistent. Mechanical injury to the external anal sphincter does not always heal with restoration of competent function.[48,49] In one study, all women with symptoms of postpartum fecal urgency and

anal incontinence had sonographically detectable mechanical disruption of the sphincter ani; these lesions persisted at 6 months.[50] The internal sphincter may be compressed, stretched, or lacerated during vaginal delivery. The integrity of this smooth muscle tissue and its autonomic innervation is also critically important in maintaining anal continence.[51] The thickness of the internal sphincter, as measured endosonographically, correlates well with anal luminal resting pressure and incontinence.[44] The importance of repairing a damaged internal anal sphincter during the repair of obstetric lacerations has not been sufficiently emphasized.[52,53]

In addition to its role in predisposing to incontinence, denervation of the muscles of the pelvic floor can also lead to genital prolapse.[2,22,41,54] By undergirding the female pelvic viscera, the levators and related musculature provide active support for the genital organs. When this support is lost, the levator hiatus widens and increased stress is placed upon the passive fascial supports of the pelvic viscera – the uterosacral and cardinal ligament complex and the endopelvic fascia – creating weaknesses or breaks in these supports and prolapse of the uterus, bladder or rectum. Often, several pelvic floor disorders occur concomitantly and require complex treatment strategies.

The role of parity and delivery mode

Implicit in the notion that vaginal delivery is a major risk factor for incontinence and prolapse is the assumption that parity has a direct relationship with risk, and that delivery by cesarean would eliminate risk. Not all studies support either assumption. Maclennan *et al.*[13] showed that pelvic floor problems were associated with pregnancy regardless of the mode of delivery, although other data[55] suggested that cesarean section reduced the risk of urinary incontinence regardless of the stage of labor in which it was performed.

In a cross-sectional population study, Rortveit *et al.*[56] administered a questionnaire to 27,900 women in Norway to analyze the relationships among age, parity and urinary incontinence. These data suggested that, while parity was directly related to the prevalence of urinary incontinence, so was age. Moreover, incontinence existed in a substantial proportion or nulliparous women, and the greatest effect of parity was in the youngest age groups, substantiating other data.[57] In other words, among women over 65 years old, the prevalence of urinary incontinence was not influenced by parity.

In a 15-year follow-up of a small cohort of women, Dolan *et al.*[40] found that increasing parity did not increase the risk of stress incontinence, suggesting that any pregnancy may expose a preexisting tendency to the disorder. Among women who had stress urinary incontinence either during or shortly after pregnancy, about two-thirds had symptoms 15 years later; one-third did not.

In an Australian study alluded to above[13] multivariate regression showed that in women advancing age, obesity, frequent coughing, and osteoporosis were significantly associated with pelvic floor disorders. Tobacco smoking may be a common denominator for many of the reported associations. Of interest is that while parity was a risk factor for pelvic floor dysfunction, the relationship was not linear, i.e. after the first child, increasing parity did not further enhance risk. Moreover, mode of delivery did not have a strong influence on risk. That is to say, women who had only cesareans were not significantly less likely to develop pelvic floor dysfunction than those who had delivered spontaneously; instrumental delivery did, however, have an adverse effect.

One may conclude from available data that, although vaginal delivery is clearly a contributor to, and sometimes a sole cause of, pelvic floor dysfunction, the degree to which increasing parity is an important risk factor is not clear. It is tempting to assume that if vaginal delivery causes or promotes pelvic floor pathology, then avoiding vaginal delivery would eliminate the risk of incontinence and prolapse; such is not the case. There is evidence that patients delivered late in the first stage of labor by cesarean section have documentable abnormalities in pudendal nerve function. This implies neurologic injury to the anal continence mechanism can occur, although in a series of such patients[27] no incontinence was noted 6 weeks after delivery. It is also clear that some injuries that occur during labor and delivery are self-repairable. For example, Arya *et al.*[58] studied urinary incontinence in patients after normal spontaneous delivery. Two weeks after delivery 13.3% of women had symptoms of urinary incontinence; only 2.9% did 1 year later.

It is presumed that most significant injuries to the pelvic floor structures occur during the second stage of labor. There is considerable substantiation for the idea that it is not appropriate to terminate the second stage of labor purely because an arbitrary amount of time has elapsed.[59–61] Rather, intervention by cesarean or instrumental vaginal delivery should be undertaken only when there is evidence of fetal compromise or an insurmountable labor dysfunction or cephalopelvic disproportion. None of the several studies that lend credence to that approach studied the effect of second-stage duration on the pelvic floor. Despite limited evidence linking the length of the second stage to birth canal injury, minimizing the duration of the second stage is viewed by some obstetricians as a strategy to help preserve pelvic floor integrity. This approach is not supported by all available evidence. Van Kessel *et al.*[62] demonstrated no relationship between second-stage length and the risk of stress urinary incontinence nearly 8 years after delivery; MacArthur *et al.*[63] and Arya *et al.*[58] reached the same conclusion regarding early onset of fecal and urinary incontinence, respectively. While other studies suggest long second-stage duration is a risk factor for pelvic floor dysfunction,[7,13] it is difficult to interpret this information. Studies

generally lack information about whether the rate of descent was normal, and the intensity and duration of bearing-down efforts is not known; moreover, they do not always correct for cofactors that are associated with injury such as birth weight, malposition, or pelvic architecture.

It is during the second stage that the most extreme stretching and compression of the birth canal and its supporting tissues occurs. While data do not exist to guide evidence-based management for all aspects of late labor, some reasonable guidelines can be asserted based on experience and current knowledge. One should avoid long periods in the second stage during which there is no descent. Such situations can focus prolonged pressure on tissues in a limited area and provoke compression injury or even pressure necrosis. Similarly, as long as the fetus is well oxygenated, there is no reason to rush descent with extreme bearing-down efforts. It is probable that gradual steady distortion of tissues is less likely to result in overstretching or tearing than is very rapid deformation. Several lines of evidence have shown that delaying pushing until the head is well engaged, and using open-glottis pushing are reasonable alternatives to more active management of the second stage and yield equivalent outcomes.[64–66]

Some data show that pelvic floor problems were associated with pregnancy regardless of the mode of delivery,[13] although Farrell *et al.*[55] suggested that cesarean section reduced the risk of urinary incontinence regardless of the stage of labor in which it was performed. Nevertheless, even women who have delivered only by cesarean section still have a risk of pelvic floor disorders.[13,67] This suggests that pregnancy *per se* (as opposed to vaginal birth) may have an influence, or that in some women non-obstetric factors play a predominant or exclusive role in the development of incontinence and prolapse. Nulliparous women sometimes develop pelvic floor dysfunction, confirming that pregnancy and delivery are not pure prerequisites. This and the fact that, as noted, stress urinary incontinence occurs in those who have delivered only by cesarean and even in men indicates that factors other than vaginal delivery are involved.

Non-obstetric factors

The matrix of influences that determine the risks of parturitional trauma and the likelihood it will progress to permanent dysfunction is complex (Table 186.2). Factors in addition to obstetric characteristics that have been demonstrated or postulated to cause or function as cofactors in producing injury include age, obesity, smoking, posture, coexisting gastrointestinal pathology, estrogen deficiency, chronic pulmonary disease, peripheral neuropathy, and differences in collagen composition or metabolism.[68–80] Many of these are probably genetically determined; women or their health-care providers may influence others.

The evidence for a genetic predisposition to the development of pelvic floor weakness and its associated continence problems is supported by clinical and laboratory observations. Urinary incontinence has a familial tendency[21,71] and the prevalence of stress incontinence varies considerably by race.[68] Moreover, women who develop genital prolapse tend to have hyperextensible finger joints,[69,76,77] and may be more likely to have various forms of hernia. All of these observations suggest genetic influences are involved. A heritable mechanism would presumably derive from factors that affect connective tissue strength or integrity. Some data support the idea that connective tissue is somehow deficient in women who develop pelvic floor dysfunction. For example, Boreham *et al.*[78] found a disproportionate increase in caldesmon expression as compared to smooth muscle-myosin heavy-chain proteins in women with pelvic organ prolapse. This imbalance in contractile proteins, perhaps genetically determined, could contribute to reduction in pelvic support through altered collagen.

There has also been[79] demonstrated reduced collagen content and increased turnover in the vaginal tissue of premenopausal patients with prolapse compared with controls. Other data regarding changes in collagen enzymes support the notion that the connective tissue structure or metabolism in women who develop pelvic floor dysfunction somehow predisposes them to prolapse or incontinence; but the alternative explanation, i.e. that these biochemical and structural changes are the consequence of pelvic floor weakness rather than the cause remains to be explored.

Heavy smoking and obesity are associated with urinary incontinence and other forms of pelvic floor dysfunction.[72] So are a variety of medical problems, including chronic pulmonary disease, gastrointestinal pathology, diabetes, peripheral neuropathies, and connective tissue diseases.[80] Demographic factors, particularly age, make an important contribution to risk.[2,13,21,75]

Based on a great deal of epidemiologic and experimental data, it is possible to conclude that the development of pelvic floor dysfunction that leads to pelvic organ prolapse and to urinary or fecal incontinence is multifactorial (Figure 186.1). It is clear that obstetric injury plays a significant role in this kind of disability; but it is as certain that other factors contribute substantially, and sometimes exclusively, to these problems. Genetic factors are certainly important, and their involvement in the genesis of pelvic floor dysfunction

is just beginning to be understood. Undoubtedly, host factors, both inherited and acquired, are important in determining whether an individual develops prolapse or incontinence, and when in life it will emerge.

While it is tempting to assume that delivering all babies by cesarean section would preclude the development of pelvic floor dysfunction in later life, this is clearly not the case.[27,38] This observation could indicate that pregnancy or labor *per se* are risk factors, irrespective of delivery mode, or that non-pregnancy-related factors cause pelvic floor problems. There is evidence to support both conclusions. Like all challenging health problems, those relating to female pelvic floor dysfunction are complex and will not yield to simple formulaic modes of treatment or prevention.

Episiotomy

Episiotomy was introduced to obstetrics in the mid-18th century in Europe. It came into use in America in the latter part of the next century, and became common as hospital birth, often by prophylactic forceps delivery, became widely practiced. Pomeroy[81] emphasized in 1918 that episiotomy could prevent pelvic tissue damage during delivery and suggested considering its routine use for nulliparas. DeLee,[82] a very influential obstetrician, advocated routine episiotomy along with elective forceps extraction, and by the 1940s these approaches were used commonly used in the United States. Over recent years, the benefits of routine episiotomy have been questioned, and its use has diminished considerably.[83,84] In the 1980s, episiotomy was performed in as many as 60–70% of vaginal deliveries in the United States; in 2000 the rate was about 20%.[85–87]

Although there is considerable polemic about the necessity for and the protective value of episiotomy, the procedure has been subjected to relatively little systematic investigation. This is unfortunate because the commonness of the procedure makes it a considerable contributor to discomfort and morbidity in the postpartum population. The study of episiotomy is challenging for several reasons, most prominent of which is that follow-up for a sufficient time to determine whether it prevents (or contributes to) pelvic floor dysfunction in late life is very difficult.

Gainey[88] examined 1000 consecutive women at their postpartum visits for evidence of pelvic floor damage. Among primiparas, the anovaginal portion of the urogenital trigone was spared trauma in those patients who had episiotomies. In another large series of women delivered by forceps, those who had routine episiotomy had less than half the incidence of clinically measured levator atrophy than those who had episiotomy done only when a laceration seemed imminent.[89] These and other data from that clinical era,[90] although neither controlled nor randomized, suggested a potential benefit from episiotomy. More recent data are less convincing in this regard, and make it difficult to support the use of routine episiotomy during vaginal delivery.[86,91–93] Some obstetricians use episiotomy selectively by resorting to it only when a spontaneous laceration seems about to occur; but there is evidence to suggest that this is not an effective approach to avoid major tears.[94]

While episiotomy is often used as a means to avoid serious perineal lacerations that would be anticipated otherwise to occur, this potential advantage of the procedure is not supported by the literature. In fact, almost all studies, including randomized trials, conclude that episiotomy increases the likelihood of anal sphincter and rectal wall lacerations. This is particularly true of median episiotomy, but applies as well to mediolateral incisions.[95–101]

There is no evidence that episiotomy preserves pelvic floor muscular function, at least in the short term. Röckner *et al.*[102] showed that pelvic floor

muscle strength, studied 8 weeks postpartum, was weaker in women who had a mediolateral episiotomy than in those who delivered spontaneously or had a spontaneous laceration. Similar data exist for median incisions.[97]

Episiotomy and laceration repair

Two major approaches to obstetric perineotomy are used. The mediolateral technique (currently favored in most European obstetric services) involves an incision that extends laterally and posteriorly from the base of the introitus; the median approach (the most common technique in the United States) is directed posteriorly in the midline from the fourchette. Both techniques have passionate advocates, and reasonably well defined advantages and shortcomings. The median approach is easier to perform and repair, causes less immediate discomfort during the early puerperium, is less prone to hematoma formation, infection and dehiscence, and is associated with less long-term dyspareunia. These advantages accrue, however, at the considerable price of many more extensions through the anal sphincters and rectal wall.

Gustafson[103] made several suggestions in 1940 to help minimize the risk of cystocele formation after delivery that remain relevant. These included avoiding overdistension of the bladder, maternal bearing-down efforts prior to complete cervical dilatation, extremely rapid labors, and injudicious use of forceps. He also indicated, as have others subsequently, that in order to minimize trauma, early episiotomy should be accomplished before excessive stretching of the vaginal and surrounding fascial tissues has occurred.

It is logical that to the extent damage to the birth canal and pelvic floor may be avoided by episiotomy, the procedure should be accomplished prior to the considerable distention and elongation of the vaginal tube that occurs during crowning of the fetal head. Decisions about the potential benefits of episiotomy are fruitless if one awaits evidence of impending laceration; damage may have already occurred.

The pelvic architecture is an important (and too often overlooked) consideration. If the anterior segment of the pelvic outlet is narrow, delivery of the head will occur at the expense of the posterior portions of the perineum as the head is directed away from the constricted subpubic arch. Such a pelvis might benefit from episiotomy, or at least from very thorough ironing out of the perineal tissues during labor. With narrowing of the posterior segment of the outlet and an ample angle anteriorly, injury to perineal soft parts is less likely. However, anterior injury may occur. Obstetricians who eschew episiotomy commonly observe small periurethral or periclitoral lacerations as the head is directed anteriorly when it crosses an intact perineum. Whether there are long-term consequences from such (apparently) small injuries for urinary function is not known. In addition to pelvic architecture, fetal position, size, and attitude influence the risk of birth canal laceration, and these must all be considered in optimizing a delivery strategy.

One of the major difficulties in interpreting the effects of episiotomy is that its most important potential consequences may not be manifest until decades after the delivery. Although visible lacerations at delivery and evidence of pelvic tissue relaxation postpartum are important, the most significant parturitional damage may be invisible at that time. As noted, occult rectal sphincter injury is not uncommon; similarly, hidden damage to muscles and fascia may occur that contributes to pelvic visceral prolapse later in life.

Many questions remain unanswered about the virtues and risks of episiotomy, and will remain so for some time. For those who wish to avoid the procedure, gradual stretching of the perineal tissues during the second stage of labor may reduce the risk of lacerations. To this end, the use of some water-soluble lubricating gel can be beneficial. In addition, the use of a delivery position that tends to stretch the perineal tissues laterally should be avoided. Thus, the dorsal lithotomy position leads to episiotomy being done more often because the tension that flexion and abduction of the thighs places on the perineal tissues makes them less able to stretch further as the fetal head crosses them. The lateral position has benefits in this regard, as may squatting.

Repair technique

Whatever kind of episiotomy is done, it is wise to remember that the perineum is a complex structure, and failure to perform a proper surgical repair can result in considerable (and sometimes permanent) misery for the patient. A thorough knowledge of the functional anatomy of the pelvic floor and meticulous surgical technique are necessary to provide optimal results. Remember that episiotomy severs the supporting fascial structures of the lower vagina; the consequences of poor repair are considerable.

The repair of third- and fourth-degree lacerations is of particular importance, as these are obviously potential contributors to anal continence abnormalities. These should be repaired by an individual fluent in the anatomy of the perineal area. There should be a layered anatomic closure without any tension on the suture lines. It is very important, especially if there has been a complete perineal tear, to repair both the external and the internal sphincters. The latter is often ignored, but is of considerable importance in maintaining rectal tone. The internal and external anal sphincters both contribute importantly to anal continence.[50] Some data suggest that as much as 85% of the resting tone of the anal canal is contributed by the internal sphincter muscle.[104,105] Consequently, where there is a complete perineal laceration (extending from the vagina posteriorly into the anal canal) every effort should be made to do an anatomically faithful repair to reapproximate both sphincters independently. The external sphincter is usually identified easily, but sometimes may retract from the point of laceration.

Table 186.3 Episiotomy decision factors

Fetal size
Fetal position and attitude
Pelvic architecture
Perineal length
Instrumental delivery
Prior pregnancy lacerations

The external sphincter muscle should be reapproximated, either end-to-end or overlapping; the important key is that it should not be under tension. The dense connective tissue sheath that surrounds the striated muscle of the sphincter should also be reapproximated. The internal sphincter can usually be identified during the repair. Good lighting is essential. It generally appears much paler and is considerably thinner than the robust muscle bundles of the external sphincter. Posterior to it is the anal canal's submucosa; anteriorly lies a thin condensation of connective tissue that separates it from the external sphincter and the vaginal submucosa. Remember that the internal sphincter extends cephalad at least 1 cm above the upper border of the external, and should be repaired to the full extent of its length using fine suture material.

Choosing whether or not to do an episiotomy should depend in part on the patient's anatomy (Table 186.3). Frudinger *et al.*[37] showed that more anal sphincter tears and anal incontinence were found in nulliparas with a narrow subpubic arch than in those with a wider arch. A narrow arch should prompt special attention to protection of the perineal and perianal structures. Women who have had third- or fourth-degree perineal lacerations in a previous pregnancy have a three- to fourfold increased risk of recurrence in a subsequent delivery.[106] This fact should also be considered when making decisions about management of the perineum.

Practical guidelines

Given the current state of our knowledge, what can be done by the clinician to minimize the risk of permanent pelvic floor injury that occurs during vaginal delivery? Several guidelines can be suggested, based on available evidence and the authors' experience:

(1) An organized and systematic approach to the management of labor is mandatory. Assess and judge the normality of labor by following progress in cervical dilatation and fetal descent and identifying dysfunctional labor with a consistent, reproducible and predictive system. That recommended by Friedman and coworkers[107,108] is the most widely used and best studied of such systems. It is important to recognize and treat labor abnormalities promptly. By so doing one can minimize the dangers to the birth canal when cephalopelvic disproportion is ultimately shown to be present.

(2) All decisions about allowing the labor to continue, or hastening its termination by oxytocin administration, or by cesarean or vaginal instrumentation should be made in the context of assessing the probability of a safe vaginal delivery. Safety in this case refers to the maternal pelvic floor as well as the fetus.

(3) Pay particular attention to marking progress in descent, fetal position, and the degree of cranial molding; all are useful clinical indicators of the probability of a vaginal delivery without maternal trauma. Occult and overt maternal injury is probably more likely in the presence of dysfunctional labor, especially if timely intervention is neglected.

(5) Use oxytocin judiciously. Creating unnecessarily rapid descent can lead to pelvic floor trauma.

(6) Minimize perineal tension as the head crosses the pelvic floor, i.e. do not fix the hips in extreme flexion when the patient is in the semi-sitting or lithotomy position. Extending the mother's legs somewhat during the terminal portion of expulsion may reduce injury risk. Consider other postures for delivery, such as squatting or lying in the lateral position.

(7) Consider lubrication of the lower vagina and outlet with water-soluble surgical lubricant as the head distends the perineum. This helps to aid the obstetric attendant to stretch the perineum manually and reduces shearing forces that contribute to the creation of lacerations.[61] There may be some benefit to antenatal perineal massage as well.[109,110]

(8) When instrumental injury is indicated, take into consideration that vacuum extraction is generally less likely to provoke major perineal laceration than forceps delivery.[58,111,112]

(9) Understand the pelvic architecture and its influence on the mechanism of labor and the risk of perineal trauma. More anal sphincter tears and anal incontinence occur in nulliparas with a narrow subpubic arch than in those with a wider arch.[37,113]

(10) Consider limiting strong maternal expulsive efforts to the time during the second stage when she feels a strong urge to bear down or (if she has sensory anesthetic blockade) until the head is well engaged in the pelvis.

(11) Perform a careful layered repair of episiotomies and perineal lacerations, using fine suture materials and meticulous surgical technique. Respect the imperative to restore anatomic integrity and to treat tissues gently.

(12) If a patient has had a third- or fourth-degree laceration in a previous pregnancy, is asymptomatic with regard to pelvic relaxation and symptoms of incontinence, and has an intact sphincter mechanism (determined clinically or by ultrasound), it is reasonable for her to have a vaginal delivery. But if these criteria are not met, cesarean delivery should be considered.

187 Effects of labor and delivery on the fetus

E. A. Friedman

There is little doubt that much of the untoward outcome encountered among fetuses and surviving infants is unrelated to events that occur during labor and delivery. Most often, bad results are either of unknown cause or due to identifiable problems afflicting the developing embryo and fetus during intrauterine life long before term. These latter include a wide range of influences from chromosomal defects, anatomic malformations, infections, metabolic disorders and toxins to the potentially devastating impact of preterm birth.[1–4] This observation that so many poor outcomes are unrelated to labor and delivery, however reassuring it may be, should not lull one into assuming that parturition is always a benign process for the fetus, lest obstetric practices and surveillance are not stressed in the interest of safeguarding fetal well-being during this crucial time *in utero*. Some have focused so much on the antepartum factors, essentially denying the impact of labor and delivery, as to imply that one can essentially ignore intrapartum risks.[5–8] Even such apologists, however, do reluctantly acknowledge that no fewer than 6% of bad results are attributable to problems encountered in labor or at delivery.[5] Others have demonstrated much higher frequencies of intrapartum causes, with rates as high as 34%.[9–12]

Regardless of the actual magnitude of the fetal risk from labor, it should be quite clear that the labor and delivery process is not always innocuous. Optimal clinical care requires (1) careful attention to the mother's labor progress to detect those abnormal labor patterns that place the fetus at risk; (2) close fetal surveillance to detect evidence of fetal compromise; and (3) gentle, cautious measures to ensure safe and atraumatic vaginal delivery. Recommendations for management have heretofore often been based largely on oracular pronouncements derived from accumulated clinical experience. In this era of evidence-based medicine with more confident decision making supported by objective information, it is essential to provide such documented evidence about which specific abnormalities of labor actually affect the fetus adversely and whether the deleterious effects of those disorders can be mitigated by appropriate clinical management.

Sources of injury

There are at least two major conditions that are recognized to expose the fetus to jeopardy in the course of labor and during the delivery process, namely, hypoxia and physical trauma. Intrauterine fetal hypoxia may develop in labor from the intermittent uterine contractions that compress uterine vessels traversing the myometrium to supply the intervillous space of the placenta with oxygen-rich maternal blood. While healthy, well-oxygenated fetuses usually withstand this stress well, the fetus that is already somewhat compromised by preexisting chronic hypoxia from some form of uteroplacental insufficiency may not. In such situations, the additional stress of uterine contractions may be sufficient to reduce marginally sustaining oxygenation to dangerous and damaging levels. Intrapartum hypoxia may also occur from umbilical cord compression. Fetal injury that results from oxygen deprivation may be mediated primarily by ischemia. When tissue hypoxia is severe, hemodynamic changes can occur that lead to selective or even global underperfusion of vital organs.

Physical trauma during labor and delivery may result from undue – that is, excessively prolonged and intense – mechanical forces exerted on the fetal head. These forces may cause extreme molding, which stretches or tears the supporting fasciae (specifically, falx cerebri and tentorium cerebelli) and the large venous sinuses coursing within them. The resulting intracranial hemorrhage can be devastating. Additionally, physical damage may be the consequence of excessive or inappropriately directed forces applied by instruments used to aid the delivery process, such as obstetric forceps and vacuum extractor.

There are no objective clinical means for determining when potentially deleterious extremes of molding

are occurring. Fetal heart rate monitoring, which is so sensitive for detecting fetal hypoxia, is inadequate for disclosing impending physical trauma, although heart rate patterns may become abnormal after damage has occurred. Several specific major labor aberrations, the adverse impact of which is to be discussed in more detail here, are associated with cephalopelvic disproportion that is likely to be manifest by hazardous degrees of molding. Understanding which labor patterns put the fetus at risk and recognizing when they develop are thus important clinical considerations. The obstetric health care provider who is knowledgeable in this regard is appropriately equipped to be alert to recognize those relevant abnormalities in the course of labor as they arise. He or she will then be prepared to pursue evaluation of the case expeditiously and astutely and, if necessary, to intervene aggressively to avoid the expected adverse fetal outcome.

There has been an understandable paucity of recent studies in this area, given the fact that controlled investigations cannot be carried because of ethical, moral and legal constraints. The only data available, therefore, are from reports detailing collected experiential information on outcomes stratified according to labor and delivery events. The investigations upon which these reports are based were carried out mostly without cautionary measures having been taken to ensure against confounding by the many concurrent conditions that prevail among the population samples under study. The only publication in which some attempt was made to deal with this issue was the monograph emanating from the National Collaborative Perinatal Project (NCPP) under the aegis of the U.S. Public Health Service.[13] It provided extensive, sophisticated analyses of data gathered prospectively from a large population of some 60,000 gravidas and their offspring delivered at 14 university hospitals in the United States. The data, collected during the interval from 1958 to 1974, focused on a group of nearly 18,000 term infants who were free of anomalies incompatible with intact survival and whose mothers' records contained adequate documentation of the labor course to reconstruct a meaningful pattern of progression in dilatation and fetal descent. The large database thus compiled was subjected to a sequence of analytic techniques to ascertain the relative impact of more than 2400 different factors on the fetus and surviving infant, including maternal demographic attributes and antecedent illnesses, extensive observations during pregnancy, complicating antepartum conditions, exposures to infections and drugs, as well as the full range of labor variables, such as fetal presentation, position, mechanisms of labor, labor progress, membrane status, pain relief, uterotonic stimulation, and the gamut of delivery procedures. Outcome variables included not only perinatal morbidity, mortality and nursery course, but also periodic follow-up neurological evaluations for mental and motor disorders, speech, language and hearing problems, and intelligence quotient determinations through 7 years of age. The long and detailed follow-up of the study infants makes the NCPP database notable, perhaps unique, and unlikely to be replicated or improved upon in the foreseeable future.

This unequalled resource is of special interest because the analyses undertaken with it addressed the issues of potential confounding and interaction of factors other than the labor–delivery process (but also mindful of the interaction among labor–delivery factors) that might have been acting simultaneously to affect outcome. A singular shortcoming of these studies is that the deliveries all took place before widespread electronic fetal heart rate monitoring was available. This deficiency is counterbalanced somewhat by the frequent, careful, close auscultation of the fetal heart that was carried out on nearly all NCPP patients. Other practice patterns have also changed over the years, particularly with less use of narcotic analgesia, more peridural anesthesia, fewer operative vaginal deliveries, almost no difficult instrumental delivery procedures, and many more cesarean sections. Nonetheless, the sophisticated statistical techniques applied to the study – including univariate and multivariate regression, aggregative hierarchical cluster and logistic regression analyses – were able to assess the specific effects of each of these practices in regard to their individual contributions to outcome (regardless of the frequency of their use in clinical practice), isolating those effects from the impact of the labor process itself. Thus, the findings derived from this extensive study of the NCPP database with reference to the impact of specific labor disorders on outcome should still be considered relevant to current-day obstetric activities.

Prolonged latent phase

The common labor disorder of prolonged latent phase (defined and characterized in Chapter 174, p. 1822) appears to have a pervasively deleterious effect on the fetus and surviving infant. This adverse influence was not disclosed in several early studies that failed to take confounding factors into account.[14–17] Later and more critical investigations showed the labor abnormality to be considerably less innocuous than had been originally thought.[13,18]

The NCPP study data demonstrated a significantly worse perinatal outcome in association with labors complicated by prolonged latent phase than after a normal labor pattern [composite adverse results, relative risk (RR) 1.77, $P=0.024$], particularly in offspring of multiparas, when controlled for the concurrent effects of antepartum, intrapartum and delivery factors.[19] Simple univariate analysis, done without controlling for confounding factors, showed prolonged latent phase labors were associated with consistent increases in bad results across the range of

outcomes that were studied from birth to 7 years of age: Stillbirths (RR 2.43 for multiparas and RR 3.0 for nulliparas, $P < 0.05$), neonatal deaths (RR 12.8 and 4.50, $P < 0.01$), depressed 5-min Apgar scores (RR 3.70 and 6.43, $P < 0.001$), and long-term sequelae reflected in Bayley mental (RR 1.99 and 1.90, $P < 0.05$), motor (RR 2.0, $P < 0.05$) and global scores at 8 months (RR 1.66, $P < 0.05$), abnormal neurological findings at 1 year (RR 1.71, $P < 0.05$), abnormal speech, language and hearing at 3 years (RR 1.28, $P < 0.05$) and low 4- and 7-year intelligent quotients (RR 1.18, 1.27 and 1.19, 1.34, $P < 0.05$).[20] These findings were further confirmed in logistic regression analyses, which showed significantly increased rates of perinatal mortality and birth asphyxia among infants born after prolonged latent phase (RR 1.55, $P < 0.05$). Increased frequencies of long-term effects were consistent with and paralleled those of the perinatal period. It was clear, however, that many babies who were born depressed, but survived, did well nevertheless, with no apparent ill effects from the stresses of labor and delivery.

Recently, confirmation and elaboration of these findings have been forthcoming in a report of an investigation by Chelmow *et al.*,[18] who studied 713 term gravidas with prolonged latent phase, excluding those with known antepartum risk factors for adverse outcome. These investigators also used logistic regression analysis to study the impact of labor on outcome, but limited their surveillance to the neonatal period only. Without the benefit of long-term follow-up, this otherwise good study could not provide the confirmation we seek of a truly persistent adverse impact. Poor perinatal results do tend to predict future bad outcomes among surviving infants, of course, but since the correlation is imperfect, they must be considered mere markers for that possibility. This limitation notwithstanding, Chelmow *et al.* found independent statistically significant associations with increased frequencies of neonatal depression [higher rates of low Apgar scores below 7 at 5 min of age, RR 1.97, confidence intervals (CI) 1.23–3.16] and the need for resuscitation (RR 1.37, CI 1.15–1.64). Cord blood pH determinations, however, were not found to be significantly decreased in this group. They also noted that prolonged latent phase labors were more likely to be associated with other labor aberrations: the total frequency of such disorders was 42.9% (vs. 16.3% among infants born after normal latent-phase durations, $P < 0.05$); subsequent active phase arrest and protraction abnormalities 30.3% (vs. 9.8%, $P < 0.05$); second-stage problems 20.5% (vs. 9.9%, $P < 0.05$); and a greater need for cesarean delivery (RR 1.65, CI 1.32–2.06). In addition, even after controlling for mode of delivery, there were more cases with thick meconium, maternal fever, intensive care nursery admission, prolonged maternal and neonatal hospital stay and maternal blood loss. Of interest, the criteria used by Chelmow *et al.* for the diagnosis of prolonged latent phase – namely, 12 h in nulliparas and 6 h in multiparas – were less stringent than those described by Friedman[21] and currently considered the standard for the definition (20 and 12 h, respectively).[22] That they demonstrated significantly adverse perinatal effects associated with these shorter 'prolonged' latent phases allows us to infer that a still greater impact could have been expected from their study if the longer cut-off durations had been used for diagnosis instead.

Having demonstrated with reasonable certainty that a prolonged latent phase exposes the fetus to harm, we should turn our attention to the more clinically pragmatic issue of whether that deleterious fetal impact can be mitigated by early diagnosis and timely intervention. Unfortunately, while this issue can be addressed inferentially, it cannot be satisfactorily resolved because no prospectively controlled investigation has as yet been carried out targeting the problem. Indeed, there has not even been a retrospective comparative study reported to date. There is information from the NCPP data bank, however, that shows the longer the latent phase is permitted to continue, the greater its potential harm to the fetus.[23] The frequency of neonatal depression (reflected in low Apgar scores at 5 min), for example, rose progressively with each passing hour in latent-phase duration in offspring of multiparas, from a low hovering at or below 3% up to 10 h, to a significantly increased 5.0% at 11 h, 7.7% at 12 h, 8.8% at 14 h (the cut-point for the diagnosis of prolonged latent phase in multiparas), 11.8% at 15 h, 12.8% at 16–19 h and 13.5% at 20 h or more. Similarly significant time trends were seen with a wide range of other outcomes among offspring of nulliparas when the latent-phase duration was stratified by its length, including the rates of stillbirths, neonatal deaths, mental and motor deficiencies at 8 months of age, neurologic defects at 1 year of age, and abnormal speech, language and hearing test results at 3 years of age; intelligence quotients were more often lower at 4 and 7 years of age as well, and the 7-year intelligence quotient data achieved statistical significance. It is clear from these data that the longer the latent phase is prolonged, the greater its adverse effect on the fetus.

To ensure that the effect shown in the foregoing univariate analysis of latent-phase prolongation did not reflect the confounding effects of other factors acting concurrently, logistic regression analyses were pursued.[24] Concern was appropriately generated over whether gravidas with prolongation of the latent phase might be those whose labors were augmented with oxytocin or whose subsequent labors were complicated by another labor disorders or some superimposed adverse influences to expose the fetus to potential harm. The analyses determined that some of the poor results associated with prolonged latent phase persisted even when the effect of many other variables were considered simultaneously. An RR of

1.77 ($P=0.024$), for example, was found for untoward perinatal outcomes in multiparas, but not in nulliparas. Other outcome variables either failed to show the same adverse effects or those effects were not so consistent or strong as they had been with the univariate analysis.[24]

This suggests that the impact documented previously was either subsumed by other factors acting on the fetus or somehow mitigated by subsequent interventions. Thus, whether efforts to shorten this labor aberration will improve outcome or not cannot be answered definitively. In the absence of such an answer, we are unable (and unwilling) to recommend an aggressive approach for the ostensible purpose of improving outcome. Our difficulty in this regard is compounded by the problem of clear prospective diagnosis of this condition. Too often, gravidas whose labors are not progressive for long periods may appear to have the labor aberration of prolonged latent phase, but they turn out in due course to have been in false labor instead, as diagnosed in hindsight when their contractions finally stop. To have intervened in those cases in which true labor had not yet actually begun would have exposed them and their fetuses to the recognized hazards of 'induction' of labor under suboptimal circumstances. Without the benefit of a well-conducted study to show the RRs and benefits of intervention in these cases – in which prolonged latent phase and false labor cannot be clinically distinguished prospectively – the conservative management regimen described earlier (see Chapter 174, pp. 1823–1825), therefore, seems more appropriate and logical for most cases.

Protracted labor patterns

The adverse impact of the two protraction disorders, protracted active-phase dilatation and protracted descent, as defined earlier (see Chapter 174, p. 1823), has been apparent from about the time these labor aberrations were first described.[15] All subsequent investigations of fetal and neonatal outcomes associated with these major labor aberrations, carried out in greater depth and sophistication, have only verified and strengthened the truth of this relationship.[15–17] From the beginning, perinatal mortality was found to be more than three times greater with these disorders than after normal labor, with recorded rates of 15.2 per 1000 and 4.9 per 1000, respectively, a statistically significant difference.[15] Long-term outcomes were similarly poor among surviving babies born after these types of labors, with more than twice the frequency of abnormalities found in tests of speech, language and hearing at 3 years of age (16.2% vs. 7.7%) and, in matched-pair analyses, significantly lower mean intelligence quotients at 4 and 7 years of age (reduced by 4.6 and 8.4 points, respectively).[16,17]

The ability to reduce or even eliminate confounding effects of other potentially deleterious influences acting simultaneously on the fetus, a capacity afforded by the large NCPP database, served to confirm the earlier findings and to make it clear that they were not spurious.[19] The composite perinatal risk increased, especially among those delivered of multiparas, more than twofold (RR 2.40, $P=0.05$).[19] Univariate analysis demonstrated that protracted labor patterns in nulliparas were associated with a trend toward increased risks of perinatal deaths (RR 1.57, not significant) and significantly more low Apgar scores at 5 min (RR 1.94, $P<0.05$).[25] Infants of multiparas showed even worse immediate effects, including perinatal mortality (RR 1.77, $P<0.05$), low 5-min Apgar scores (RR 1.97, $P<0.05$), as well as long-term adverse impact, such as abnormal neurological findings at 1 year of age (RR 1.41, $P<0.05$) and low mean intelligence quotient at 4 years (RR 1.22, $P<0.05$).[25]

When logistic regression analysis was applied to these data to diminish confounding and interactional effects, it became clear that protracted dilatation continued to yield bad outcomes. For nulliparas, for example, the RR for adverse composite results was 1.36 ($P=0.044$) and for perinatal morbidity and mortality 2.12 ($P=0.0052$). Step-up regression modeling, done to introduce variables seriatim, showed the composite risk to be still worse among babies born to nulliparas, at RR 2.38 ($P=0.021$); and for perinatal outcome, the results were even poorer, with RR of 3.75 ($P=0.00046$).[26] For offspring of multiparas, the results were comparable for perinatal outcome, producing an RR by step-up modeling of 3.04 ($P=0.0038$).[26]

As to protracted descent, outcome data for offspring resulting from such labors were just as impressive as those of protracted dilatation. For poor composite outcome in nulliparas, for example, there was an RR of 1.35 ($P=0.0037$) and in multiparas, 1.57 ($P=1.2\times10^{-6}$).[26,27] Logistic regression analysis showed this effect to be enhanced when confounding factors were taken into account (RR 2.55, $P=0.021$) for perinatal impact. Step-up modeling indicated this impact to be particularly resistant to the simultaneous effects of confounding factors, especially that of other labor disorders (RR 3.64, $P=0.3.5\times10^{-9}$).[26]

The question of whether these adverse effects can be mitigated by early diagnosis and expeditious management deserves to be answered, but cannot. No data are as yet available to help elucidate whether results are worse if the protraction disorder is allowed to continue for any length of time, as there was for prolonged latent phase (see above) and for arrest disorders, as will be shown below. The extensive NCPP analyses did not provide any insight into this matter because the duration of these disorders was neither recorded nor stratified. By contrast, we have already seen that logistic regression analysis verified that protraction disorders retained their adverse impact even when other factors were taken into account at the same time.

Inferentially, but without the kind of proof that ought to be forthcoming from a prospective controlled study, we can only surmise that intervention might succeed in diminishing those deleterious effects, but not entirely eliminate them. We are more confident that no measures used so far can eliminate them, but have to admit we have nothing objective to support the statement concerning the decrease in magnitude of effect. The latter is based on our conjecture that since so many of these cases are associated with cephalopelvic disproportion, some of the poor outcomes may reflect that factor rather than the labor disorder. Since the clinical diagnosis of cephalopelvic disproportion is not always made (or is sometimes made even though it may not exist), its presence may exert its ill effect without the health-care providers being aware of it. We have stressed the need to examine the cephalopelvic relations when confronted by either protraction or arrest disorders (see Chapter 174, pp. 1825–1828).

As stated, these investigations confirmed the bad effect that had been observed earlier and demonstrated that the impact seen was very likely the result of the labor disorder itself and not some other concurrently acting factor. It is regrettable, however, that there have been no more recent studies undertaken to verify these findings in an era when obstetrics is practiced with greater attention to continuous fetal surveillance and more expeditious intervention to effect delivery than was the case when the NCPP data were generated.

Arrest disorders

Arrest patterns of labor, which have been defined and characterized earlier (see Chapter 174, p. 1823), are recognized to be utilitarian clinical markers of cephalopelvic disproportion. When an arrest disorder is encountered in the course of labor, the probability of safe vaginal delivery is reduced to about half by virtue of the high likelihood that disproportion exists, ranging as high as 56%.[28–30] Accordingly, it is not unexpected that these abnormal labor patterns will perforce be associated with adverse outcomes among fetuses who are exposed to them in the course of labor and at delivery. This applies especially for those in whom vaginal delivery is attempted without the precaution of ensuring that the cephalopelvic relations are adequate and the prospects of such delivery are safe. Increased rates of perinatal deaths and morbidity in association with arrest disorders have been well documented.[31] The RR of perinatal deaths expected in association with arrest disorders of labor is 7.5, based on a rate of 36.6 per 1000 as contrasted with 4.9 per 1000 after normal labor progress.[31] Correcting for the type of delivery more than doubles the RR to 15.7, although the absolute mortality is reduced by this correction to 16.1 per 1000 as the perinatal mortality after normal labor is reduced even more to 1.5 per 1000.[32] A later study indicated higher perinatal losses of 40.2 per 1000 after arrest disorders compared with 11.8 per 1000 after normal labor patterns, showing a consistency of adverse effect.[33]

Even Nelson, who asserted that intrapartum events have little or no adverse effect on the fetus, has had to acknowledge that arrest disorders are clear exceptions (along with fetal heart rate and midforceps delivery).[1,34] She reported the results of a large case–control study examining many labor and delivery factors simultaneously in which there were nearly three times the frequency of arrest of progress among developmentally abnormal children, specifically 18.0% vs. 6.6%, a significant difference.[34] Not unexpectedly, significantly increased frequencies of midforceps procedures and cesarean delivery (RR 5.0), low Apgar scores (RR 1.6), requirement for intensive neonatal care (RR 1.4), and long-term neurologic handicap have also been reported following arrest of dilatation.[35] Of special interest in this last-cited report is that stratification by delivery method showed that vaginal delivery after an arrest disorder magnified the poor infant results, whereas cesarean delivery diminished the impact attributable to the labor disorder.

The NCPP investigation confirmed these outcome effects for arrest disorders.[36] Arrest of dilatation was associated with increased perinatal hazard, reaching statistical significance in multiparas (RR 1.68, $P = 0.049$).[36] Infants delivered after arrest of descent fared just as poorly or worse, with deleterious perinatal outcomes much increased among them (RR 1.53 for nulliparas, $P = 0.028$, and RR 4.02 for multiparas, $P = 1 \times 10^{-6}$).[36] Prolonged deceleration, another variant of the arrested labor patterns, was also associated with marginally to significantly increased perinatal death rates in nulliparas (RR 1.43, $P = 0.051$) and multiparas (RR 1.51, $P = 0.019$).[36] However, there was no evidence that this adverse effect persisted into later life among surviving infants. Moreover, when logistic analytic methods were brought to bear to assess the impact of these disorders while other factors were taken into account simultaneously, the adverse perinatal effect disappeared from all the aforementioned arrest patterns, except arrest of descent in multiparas. Perinatal mortality remained significantly high among this latter group (RR 3.35, $P = 1.4 \times 10^{-6}$).[26] The relationship was also upheld in the step-up logistic modeling assessment (RR 2.88, $P = 0.0038$).[26]

Based on these findings, one could surmise that much of the impact of arrest disorders on the fetus is subsumed by other factors acting simultaneously. These other factors most probably include uterotonic stimulation, the presence or absence of cephalopelvic disproportion, and the timing and type of delivery intervention taken to address the labor problem. In addition, the duration of the arrest pattern may also play a role in this regard, as evidenced by the correlation between longer arrest periods and more intense

and prolonged adverse effects.[37] For example, neonatal death rates increased progressively with duration of arrest of descent in nulliparas: the RR after a half hour of arrest in second stage was 1.45, which was increased, but not significantly different from those with normal second-stage progress; however, the RR of perinatal death was 3.97 after 1 h and 4.92 after 2 h of arrest ($P < 0.01$ for both).[37]

These findings clearly indicate that delayed diagnosis of an arrest disorder of labor is detrimental to the fetus. The benefit of early diagnosis can be assumed to have arisen because some form of evaluation may have been done to rule out cephalopelvic disproportion in those cases in which the labor was allowed to continue; alternatively, cephalopelvic disproportion was found – or presumed to exist – and cesarean delivery was then pursued. Operative delivery may thus have averted any adverse consequence from continuing the labor. If those cases in which the arrest pattern develops without concurrent cephalopelvic disproportion could have been specifically identified, as proposed earlier, labor might have been permitted to continue and an unnecessary abdominal delivery averted, presumably with no deleterious fetal effects. We have thus addressed the issue of possible mitigation of adverse effect of arrest disorders by early diagnosis and aggressive intervention, with somewhat clearer resolution. We do acknowledge, however, that we lack substantiation in the form of objective supportive data derived from a more reliable recent source, such as a well-designed clinical study.

Precipitate labor

It is generally accepted that fetuses may be damaged by labors that are very short in duration, or are characterized by excessively rapid cervical dilatation or fetal descent, or by quick delivery over an unsterile field without good control of the fetal head as it is expelled over the perineum. Because such rapid labors are often associated with tumultuous uterine contractions – that is, contractions that are powerful in strength, long in duration and quite frequently recurrent – such labors may thereby expose the fetus to the risks of both physical trauma and hypoxia. The mechanism by which precipitate labors cause fetal hypoxia is logically assumed to be one in which the intense and prolonged contractions obstruct the flow in the spiral arterioles that supply oxygenated maternal blood to the intervillous space of the placenta, thus depleting to hazardous levels the oxygen reserves from which the fetus can draw. Physical trauma may result from one of two different mechanisms, either from the rapid compression–decompression phenomenon of excessively rapid descent (causing tissue damage from the 'blast' effect) or from excessive molding of the fetal head resulting in damage to intracranial fasciae with ensuing hemorrhage.

This latter form of injury can be more easily understood by considering the tissue attribute of plasticity. This physical property permits tissues to be atraumatically stretched and reshaped when steady forces are applied to them over relatively long periods of time. An extreme example of tissue plasticity is orthodontic remodeling of teeth alignment; other examples include the changes the cervix and the perineum undergo in labor. If the same (or larger) forces are exerted instead at great speed, however, those tissues will fracture or lacerate instead. Thus, the normal fetal head molding process, which all fetuses in cephalic presentation experience in the course of vaginal delivery, is ordinarily harm-free. By contrast, the rapid deformation resulting from the excessive magnitude and speed of force to which that fetal head is exposed in many precipitate labors may not be so benign at all. The harm from this mechanism may also occur even without precipitate labor if the fetal head is unduly compressed and thereby remolded excessively over a relatively short time in the course of labor as the consequence of constraining cephalopelvic relations. This applies particularly if the uterine contractions are being simultaneously augmented by a uterotonic agent, such as oxytocin. The adverse fetal effects of cephalopelvic disproportion can thus be expected to compound those of uterine hypercontractility, if both occur concomitantly in a given labor, at minimum additively and perhaps synergistically as well.

We have addressed the clinical means for diagnosing precipitate labor patterns (see Chapter 174, p. 1829). What has not been well documented is the quantitation of the injurious impact of such labors on the fetus – that is, how bad the effect is and under what particular conditions in labor can it be expected to become manifest? There is a regrettable paucity of meaningful data available to probe these questions. One univariate clinical study dating back many years showed a statistically significant 45% relative increase in perinatal mortality among infants born after precipitate labor (15.5 per 1000 vs. 10.7 per 1000, $P < 0.05$).[38] Of those infants who died in this series, autopsies found 18.8% of the deaths were due to intracranial hemorrhage. Among surviving infants, neurological and developmental abnormalities were identified in significantly large numbers, including 20.0% with mental retardation (as opposed to 7.0% among those delivered after normal labor patterns, $P < 0.05$) and 20.0% with intelligent quotient scores of 70 or less (vs. 2.5% in the normal controls, $P < 0.01$).[39]

Some more recent studies have denied that precipitate labor is a risk factor for poor short- or long-term outcomes.[40–42] Others, however, have shown important adverse consequences, including increased perinatal mortality, need for neonatal intensive care and longer hospitalizations after birth, and neonatal complications.[43–45] The report by Bateman *et al.*, for example, demonstrated unattended births were associated

with neonatal mortality of 20.3 per 1000 [vs. 7.3 per 1000, odds ratio (OR) 2.82, $P < 0.05$], hypothermia $< 35°$ (OR 20.8, $P < 0.01$), hypoglycemia < 40 mg/dl (OR 4.41, $P < 0.05$), and polycythemia with hematocrit $> 65\%$ (14% incidence).[43] These effects were felt to be attributable mostly to the high proportion of premature births in their series. Comparably increased mortality and morbidity rates were also encountered in two other studies of similar deliveries, even though the frequencies of prematurity were lower.[44,45] Certain characteristics, which may be considered to represent risk factors, were found to prevail among gravidas with precipitate labors and deliveries, all occurring with significantly increased frequencies: they included the aforementioned increased incidence of prematurity (OR 2.99), plus low educational level (OR 6.11), multiparity (OR 6.18), prior preterm delivery (OR 4.03), and no prenatal care.[46]

It is clear from these observations that several identified confounding factors do exist (and other confounders not yet identified may also exist). These have to be taken into account if we are to ascertain the real impact of precipitate labor on the offspring, devoid of the concomitant effect of such powerful hazards as prematurity, among others. To this end, we turn again to the NCPP data, which is unique in affording us the opportunity to assess simultaneously the effect of all the confounders as they impact upon perinatal and long-term results. Univariate analysis showed that precipitate dilatation – defined objectively by excessively rapid rate of cervical dilatation in the active phase of labor – was associated with increased perinatal mortality (RR 6.99, $P < 0.05$), low Apgar scores at 5 min (RR 4.28, $P < 0.05$), abnormal global neurological examination findings at age 8 months (RR 1.67, $P < 0.05$), abnormal speech, language and hearing at 3 years of age (RR 1.79, $P < 0.05$) and low intelligence quotients at 4 and 7 years (RR 1.98 and 1.62, respectively, $P < 0.05$ for both) in nulliparas; and comparable results were found among offspring of multiparas.[47] Precipitate descent – defined by very rapid slope of descent in second stage of labor – was also accompanied by high perinatal mortality (RR 2.49, $P < 0.05$), low 5-min Apgar scores, abnormal speech, language and hearing at 3 years of age (RR 1.27, $P < 0.05$) and low intelligence quotients at 4 and 7 years (RR 1.67 and 1.37, respectively, $P < 0.05$ for both) in infants of nulliparas, with parallel findings in those delivered of multiparas.[47] Precipitate delivery – that is, uncontrolled delivery over the perineum – was determined to carry even higher rates of adverse outcomes, including stillbirths (RR 6.14, $P < 0.00001$), neonatal deaths (RR 6.34, $P < 0.00001$), low Apgar scores at 5 min (RR 2.61, $P < 0.001$) in nulliparas; stillbirths (RR 3.34, $P < 0.00001$), neonatal deaths (RR 2.95, $P < 0.00001$), low 5-min Apgar scores (RR 2.77, $P < 0.00001$), abnormal mental and motor scores at 8 months (RR 2.15 and 2.62, $P < 0.05$ for both), and low intelligence quotients at 7 years (RR 1.34, $P < 0.05$) in multiparas. Other long-term outcome results were also poorer than among infants delivered with good control of the delivery of the fetal head over the perineum, but those rates did not reach statistical significance.[48]

Limiting analysis of the NCPP study population to those weighing between 2500 and 4000 g, to eliminate the acknowledged high-risk factor of prematurity, focused the analysis somewhat more closely on the impact of the labor disorder itself. While short active-phase duration was found to retain its adverse impact (perinatal composite outcome effect, including deaths and Apgar scores < 4, RR 1.40, $P = 0.034$), rapid maximum slope of dilatation paradoxically did not (perinatal composite RR 0.95, a slight, but not statistically significant protective effect). Precipitate descent, when reflected in a very short second-stage duration, was associated with poor perinatal composite results (RR 1.34, $P < 0.039$), but when defined by rapid maximum slope of descent, it was not.[36] All labor variables considered together in the logistic regression analysis demonstrated that precipitate dilatation retained its adverse perinatal impact (RR 1.92, $P = 0.0034$) in babies delivered of nulliparas (but not those of multiparas). Precipitate descent defined by second-stage duration had an adverse effect (RR 1.21, $P = 0.012$), but not when it was diagnosed by maximum slope of descent, which again had a marginally protective effect (RR 0.79, not significant).[26] In the step-up logistic sequence for perinatal outcome, these relationships continued to reflect the bad influence of precipitate dilatation (RR 1.83, $P = 0.0060$).[26] The aforementioned marginally protective effect of precipitate descent was subsumed by other factors in this last analysis, but reemerged as those other factors were identified and corrected for. When logistic regression analysis was finally brought to bear on the full panoply of variables in the NCPP study, encompassing demographic, preexisting illness, antepartum and intrapartum factors, and delivery variables, foreshortened active-phase duration was still holding its own as an adverse factor affecting both composite and perinatal outcomes (RR 1.29 and 1.67, $P < 0.05$ for both) in nulliparas, as did precipitate descent, which served as an apparently protective factor for composite outcomes only (RR 0.71, $P < 0.05$).[24]

These data are difficult to interpret because they seem inconsistent. Rapid cervical dilatation and short active-phase duration are two aspects of the same phenomenon and can both be expected to have the same influence of the fetus. The same applies to the two related factors of rapid descent and short second-stage duration. When examined separately, short active phase showed its expected adverse fetal effects, but rapid dilatation did not; and similarly, short second stage did, but rapid descent did not. When both members of a related pair of variables are examined at the same time by statistical testing, only one or the other is likely to demonstrate statistical significance, but not both because the information they share about outcome is subsumed by one of them. What cannot be explained so readily, however, are the paradoxical effects seen for the two related pairs of factors, rapid

dilatation and short active phase, on the one hand, and rapid descent and short second-stage duration, on the other, given that the observed impact appeared to act in opposite directions. Confounding is the likeliest explanation, but there is probably another explanation: not all precipitate labors are comparable insofar as their potential for harm. Spontaneously occurring fast labors in multiparas may not be caused by tumultuous uterine contractions or uterotonic stimulation, but instead reflect the ready response of elastic maternal soft parts yielding atraumatically to normal (or even hypotonic) contractions. This latter form of facile, but rapid labor should not be anticipated to have the same bad effect on the fetus as the excessively forceful labor that is more likely to harm the fetus by means of physical trauma and hypoxia. While no study has been undertaken to elucidate the relative effects of these distinctive labor types, it is likely that their outcomes would be quite different. If the cases of precipitate labor in the NCPP data resource (which regrettably could not distinguish the two varieties), to which we have just alluded, were diluted with large numbers of such 'benign' labors, it would make it difficult to demonstrate the deleterious effects of the less benign form.

Conclusions

Labor abnormalities, as defined objectively on the basis of patterns of cervical dilatation and fetal descent, can, based on the evidence presented here, be associated with poor outcomes for the fetus and surviving infant. The adverse outcomes are apparently independent of the modality chosen for the delivery, although it should be clear that ill-advised attempts to effect delivery by traumatic instrumentation, such as difficult midforceps procedures, will probably diminish the potential for a good result. Contrastingly, timely intervention by cesarean delivery, when indicated, may have a beneficial impact by reducing the deleterious effect of the continuing abnormal labor progression pattern. This is not intended as license to proceed with cesarean delivery whenever such disorders are encountered during the course of labor, but rather to alert health-care providers to the need to recognize them early, to evaluate for potentially serious associated or etiological conditions that threaten the well-being and life of the fetus, and if such conditions are found, to proceed with the requisite intervention.

188 Maternal stress and labor

K. M. Paarlberg, A. J. J. M. Vingerhoets and H. P. van Geijn

Labor and delivery are among the most intense events a woman faces in life. Maternal distress or maternal anxiety in reaction to stressors can probably trigger the onset of labor (at term or preterm), and can predispose to an abnormal course of labor.[1] These stressors may be related directly to pregnancy (e.g. a fetal or maternal complication, or bad experiences in an earlier pregnancy), or may arise from other circumstances (e.g. family, work, social life or personality characteristics). All these kinds of stressors may influence the onset and course of delivery.

Depending on her ability to cope with stressful circumstances and dramatic changes occurring in her body, the woman's experience of giving birth may range from an intense but satisfying occasion to a most traumatic event, resulting in extreme states of distress. The distress may be experienced before, during or after delivery.[2]

This chapter reviews our understanding of the interplay between maternal distress and the onset and course of labor. The effects of maternal stress on the onset and course of labor, its role in preterm labor and the relation to intrapartum complications are discussed. Attention is then given to the main causes of maternal distress during labor, and finally, interventions are suggested to decrease maternal stress during labor, with emphasis on the therapeutic implications of the relevant issues.

Maternal intrapartum stress

Onset of labor

The onset of parturition is the result of a complex interplay of fetal and maternal hormones, including cortisol, catecholamines, interleukins, prostaglandins, maternal and placental CRH,[3] vasopressin, oxytocin and the oxytocin receptors in the myometrium.[4] Because the considerable inter-species differences do not allow generalization to human beings, the precise role of these substances in human labor are not fully understood. It is clear, nevertheless, that in humans, secretion of many of the hormones that participate in the initiation of labor may be influenced by stressful stimuli.[5] For example, the uterus of a woman who delivers preterm appears to be more sensitive to oxytocin during pregnancy than that of a woman who delivers at term.[6] The effects of oxytocin during human labor result from an increased number of oxytocin receptors rather than from increased levels of the circulating hormone.[7–9] Small quantities of oxytocin can trigger uterine contractions at levels that are completely ineffective in the non-pregnant state.[9] The increase in receptors is not only confined to the myometrium, but is also found in the decidua. Oxytocin has an additional separate action of stimulating the release of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), so that at the end of pregnancy there is a greatly increased secretion of $PGF_{2\alpha}$.[11] This represents a secondary effect of oxytocin on uterine contractility through prostaglandin release.[8] The transition from a relatively relaxed state to the onset of contractions can be seen as the result of stimulatory inputs or perhaps as a consequence of the loss or 'switching off' of mechanisms that promote relaxation. One such mechanism could be the activation of cyclic nucleotide (cAMP, cGMP) pathways. During the onset of labor, cAMP synthesis is decreased, and its catabolism is promoted, contributing to enhanced uterine contractility.[4]

Immunological activity is influenced via hormonal and neuronal pathways.[9,12–18] Increases in catecholamines or cortisol can suppress immune processes and may also rapidly alter numbers of immune cells via redistribution.[9,12–14] In addition, neuropeptides such as plasma β-endorphin, another hormone sensitive to stress exposure,[15,16] are known to mediate increases in natural killer (NK) cell activity. Exposure to chronic stressful situations (such as caregiving for Alzheimer patients and bereavement) has been shown to result in decreased NK cell activity.[14] Apart from hormonal factors, direct neural influences from the hypothalamus on the immune system have been described.[17,18]

A compromised immune system may have a negative effect on gestational length. Under circumstances of intrauterine infection (chorioamnionitis), decidual macrophages may be involved in premature labor through the premature release of prostaglandins and other inflammatory mediators in the decidua and fetal membranes, close to myometrial cells.[4] Given the

established relationship between exposure to stressful conditions and increased risk of infectious diseases,[19–22] it may be postulated that adverse psychological conditions enhance the susceptibility to infections such as chorioamnionitis and in that way can induce preterm contractions and/or rupture of membranes.

Course of labor

In primates and sheep, stressful conditions during labor (e.g. presence of observers and unfamiliar sounds) reduce oxytocin release and can thus delay the birth process.[6,23] Naaktgeboren and Bontekoe[23] measured uterine activity during labor in ewes. In anxious ewes uterine activity sank to zero when human observers were present. Uterine activity was recorded and the lamb born only when no observers were present. In less anxious ewes, the presence of observers did not evoke any change in the contraction pattern. Assuming that biological stress reactions in primates and sheep are comparable to those in human beings, it is plausible to hypothesize that stressful stimulation can negatively influence the progress of labor. Which mechanisms are involved is as yet not completely clear.

Omer and Everly[9] and Omer[12] presented an arousal model based on the results of experimental studies with rodents and humans. Catecholamines and oxytocin are hypothesized to mediate the influence of psychosocial factors in preterm labor. It is theorized that the threshold for uterine contractility can be lowered by constitutional tendencies or by acutely intense or chronically repeated central nervous system (CNS) stimulation. This state of hypersensitivity might then be perpetuated in a vicious circle by high adrenergic activity, neuromuscular tension and cognitive excitation. Neurologic hyperreactivity manifests itself by a cascade of physiologic responses in all efferent components of the limbic circuitry. This multiple response chain might affect the uterus in different ways: through norepinephrine secretion; through prolonged epinephrine secretion, causing a rebound effect, characterized by initial inhibition of uterine contractility followed by stimulation of contractility; through oxytocin release; through skeletal-muscular activation, which in turn influences (through interneurons) sympathetic neurons responsible for uterine innervation; and indirectly, through immunosuppression and, consequently, heightened vulnerability to infectious diseases.

Preterm labor

The results of research on the effects of maternal exposure to stressful events on onset of labor are consistent and unambiguous. There is ample evidence that preterm deliveries have often been preceded by stressful situations. In a prospective study in 2593 pregnant women,[24] anxiety, stress, self-esteem, mastery and depression were assessed at 25–29 weeks of gestation. Stress was found to be a significant predictor of spontaneous preterm birth even after adjustment for adverse health behaviors (tobacco, alcohol and drug use).

In addition, the study by Pritchard and Teo[25] demonstrated that the influence of chronic stressor exposure on preterm birth should also not be overlooked. These authors found a strong association between experiencing high levels of perceived difficulty with the household at 20 weeks of gestation and preterm birth.

Studies from more recent date show less consistency in their results than those of previous decades have shown.[26] Levi *et al.*[27] found a negative association between trait-anxiety and the duration of pregnancy. However, preterm birth did not occur in this group. In a prospective study by Norbeck and Tilden,[28] state-anxiety appeared to be unrelated to gestational complications, including preterm labor. In contrast, a prospective study by Omer *et al.*[29] yielded evidence that state-anxiety was more prevalent in pregnant women with preterm contractions or delivery than in a comparable group with term labor. It is not clear to what extent these contradicting findings could be attributed to differences in research methodology. Omer *et al*.[29] focused on preterm labor, whereas the Norbeck and Tilden study[28] combined preterm labor, anemia and preeclampsia. The selection of study participants was also different. Norbeck and Tilden excluded all women with preexisting medical risk factors in the beginning of pregnancy, whereas Omer *et al.*[29] did not. Therefore, in the study of Omer *et al.*, in which anxiety was measured at 4–6 months, and there was no control for medical risk, it may be that anxiety reflected early indications of risk which, in turn, could have influenced outcome.

The majority of the studies that focused on the relationship between negative psychosocial factors and preterm labor reported a positive association.[24,25,27,29–36] A marginal or absent relation was found in three.[28,37,38] The most recent studies were carried out prospectively.[24,25,27–29,35–38]

Prospective[24,36,38] and retrospective studies[29,30,32–34,38] have reported that stressful life events are more common in pregnancies resulting in preterm delivery. A few researchers[35,37,38] observed no differences in reported life events between a preterm and full-term birth group, but life events may well play an important role in the onset of preterm labor.

In order to obtain a reliable picture of the influence of psychosocial factors on preterm labor, it is important to study specific psychosocial and background variables prospectively in a large group of women. Such a research project has been carried out by Hedegaard *et al.*,[36] who found a dose–response relationship between stressor exposure (i.e. stressful life events, physical job strain and psychological job strain) assessed in the 30th week of pregnancy and risk of preterm delivery. In contrast, the same factors

measured in the 16th week of pregnancy were not related to preterm delivery.

Psychologic responses to stress are progressively attenuated throughout pregnancy. Glynn *et al.* examined the birth outcomes of women who had experienced an earthquake during pregnancy. The earthquake was rated as most stressful during the first trimester of pregnancy and as least stressful during the third trimester. Timing of the earthquake was inversely related to gestational age at birth: stress experienced early in pregnancy was associated with shorter gestation. Women who did not experience the earthquake during pregnancy had the longest mean gestational length.[39]

Given the results, it is tempting to hypothesize that stressful events can potentiate preterm contractions and may trigger preterm labor. However, the same kind of stressor may be perceived differently throughout pregnancy, depending on the phase of pregnancy, and therefore its effect may vary.

Intrapartum complications

Suppression of labor activity and prolonged deliveries due to anxiety, strong emotions, and stressful events has been reported in women since ancient times, and are known to occur in many other mammalian species.[23]

The literature shows a wide variety in severity and nature of the intrapartum complications that have been studied. Except for three studies,[40–42] the design was generally prospective. Most investigators found a positive relationship between psychosocial factors and the occurrence of intrapartum complications.[42–58] Reeb *et al.*[51] studied the occurrence of intrapartum complications in 140 urban black women. In the 8th month of pregnancy, demographic, biomedical and psychosocial factors (i.e. life events, maternal worries about adjusting to life with a new baby, emotional and instrumental support, depression and family size and functioning) were assessed. Intrapartum complications were defined as three or more significant problems occurring during labor and delivery. It was found that the four-factor equation: low family functioning, advanced maternal age, working during pregnancy and short stature, predicted intrapartum complications with a relative risk of 5.5 (95% confidence interval: 2.2–13.9). Clifford *et al.*[57] examined life events, social support and anxiety in the 16th, 28th and 36th week of pregnancy. Intrapartum complications were operationalized as 'noteworthy' medical events. Some serious outcomes were not included because their cause was either known or believed to be unrelated to psychosocial stress (e.g. cord around the neck, injury incurred at birth, malpresentation). It was found that the incidence of stressful life events and anxiety in the third trimester were significantly related to the risk of intrapartum complications.

A smaller number of publications reported no association.[27,40,41,59–67] In most investigations, trait-anxiety has been considered the main predictive variable of intrapartum complications. Retrospective[41,59] and prospective[27,46–49,64,67] studies have focused on the possible relationship between trait-anxiety and length of labor. Some investigators[46–49,67] found higher anxiety scores for women with prolonged labor compared with normally delivering women, while others[41,59,64] found no difference. One author[27] even reported shorter labor in women reporting high levels of trait-anxiety. These seemingly conflicting findings can be understood if one takes into account the course of the effects of epinephrine, which is the hormone most strongly associated with anxiety. The results of Lederman *et al.*,[47] who measured epinephrine plasma levels and self-reported anxiety of women during labor, showed a positive correlation between these two variables. High levels of anxiety and plasma epinephrine were associated with a pronounced decrease in uterine activity, particularly in the second stage of labor. However, after a while, uterine contractions returned to their initial level and a rebound effect often took place, leading to a pronounced increase in uterine contractility. The apparent contradiction between the stimulating and inhibiting effects of anxiety on duration of labor can be explained by taking into account the duration of receptor stimulation. Initially, epinephrine inhibits uterine contractility through stimulation of β_2-receptors in the uterine muscle, while norepinephrine stimulates contractility through α-receptors, which are also situated in the uterine muscle. As labor progresses, the amount of β_2-receptor stimulation decreases in favor of α-receptor stimulation. This phenomenon is probably due to upregulation or increased sensitivity of α-receptors caused by estrogen.[9,12] Epinephrine stimulation changes from an inhibiting to a stimulating effect on uterine activity, thereby reinforcing the effects of norepinephrine.

The clinical effects of epinephrine may be well illustrated by experiments in Guatamala and in the United States.[68–70] Sosa *et al.*[68] examined the effects of a supportive lay woman (doula) on the length of labor and intrapartum complications in healthy primigravid Guatemalan women. Hospital policies did not provide for any family member, friend, or continuous nurse caretaker to be present in the labor rooms, apparently as a consequence of the large number of deliveries, and limited space. It appeared that the length of time from admission to delivery was shorter in the supported groups than in the control groups. In addition, more mother–infant interactions were observed in the supported group. Klaus *et al.*[69] and Kennell *et al.*[70] further reported fewer perinatal complications and less medication (epidural analgesia and oxytocin stimulation) in the supported group than in the control group. Besides the possibility that the presence of a companion might account for the obstetrician making fewer interventions, a supportive companion may also reduce catecholamine levels by

reducing maternal anxiety and facilitating uterine contractile activity and uterine blood flow.

Most studies used the dichotomous distinction of 'normal' and 'abnormal' in their outcome variables.[40,42–46,48,50,51,53–57,59–67,71,72] In these investigations abnormal outcome variables could be anything from umbilical cord around the neck to a cleft palate and stillbirth. It is therefore difficult to draw any definitive conclusions from them regarding the influence of maternal stress during labor. In the majority of studies focusing on the relationship between anxiety and complications, higher trait-anxiety in the 'abnormal' delivery group was observed than in the 'normal' delivery group.[43–46,48,50,54,55,57,71,72] A smaller number of publications reported no differences.[60,62,64–67]

In summary, trait-anxiety appears to be positively associated with 'abnormal' delivery, in particular prolonged labor, but the inadequate operationalization of intrapartum complications prevents us from drawing clear-cut conclusions.

Causes of maternal distress during labor

How a woman will experience and perceive her delivery depends on numerous factors. Fear of childbirth (FOC) can be so intense that it may qualify as a legitimate diagnosis, often described with terms like 'clinical FOC'. This is a disabling fear that interferes with occupational or academic functioning, with domestic and social activities, or with relationships.[73] Women who suffer the most from FOC during pregnancy are likely to have the most intense fear during the delivery, and also suffer the most from it afterwards, independent of the kind of delivery that occurs. Due to enormous methodological problems, sound research regarding FOC is uncommon. Areskog *et al.*[74] investigated background factors associated with FOC. Between 32 and 34 weeks of gestation, pregnant women ($n=153$) were categorized as 'suffering' ($n=92$) or 'not suffering' ($n=61$) from FOC. Nulliparous ($n=93$) and parous women ($n=60$) were analyzed separately. FOC was more prevalent in nulliparous than in parous women (33% vs. 26%). In nulliparous women, more background factors associated with FOC were identified than in parous women. The significant background factors are summarized in Table 188.1.

In an earlier investigation,[2] the same authors found that, among women with severe FOC, various attributions of fear were involved, such as shape and well-being of the unborn child, fear of physical damage to the woman herself (such as birth canal lacerations), fear of not being able to control herself during the delivery and fear of losing dignity. Fear of delivery in parous women was very often based on previous experiences of traumatic deliveries. In contrast to a woman with, for instance a pathologic fear of spiders, a pregnant woman who suffers from FOC cannot avoid the delivery she fears and is therefore captured in a situation in which she is (slowly) forced to approach delivery, which is regarded as an unknown, uncontrollable and unavoidable event. The only way out for her will be an abortion in early pregnancy or a cesarean section, in spite of the risks of this procedure. In Finland, Sweden, and the United Kingdom, FOC is the reason for about 7–22% of cesarean section births on maternal request.[75] A vivid debate about a woman's right to choose the mode of delivery is currently going on in the obstetric literature, but discussion and analysis of the reasons for women to request a cesarean section, or of ways to help them overcome the fear of vaginal birth is only scanty.[75] Anxious people have a bias to perceive information as threatening. It has been shown that, at the end of pregnancy, pregnant women with severe fear of labor had only heard negative stories about deliveries, while women with low or mild fear of delivery mostly had heard positive accounts. Thus, like certain individuals who develop a specific phobia by means of vicarious experience or informational transmission, anxious apprehension could ensure that mostly negative information is processed and women consequently become so alarmed, that in their view the approaching delivery already is a catastrophe before the event has taken place.[73]

Psychological trauma and post-traumatic stress disorder after birth

Childbirth can be so traumatic that the new mother fulfills the criteria for post-traumatic stress disorder (PTSD), with its well-known symptoms such as nightmares, intrusive memories, depression, anxiety, difficulty bonding with the infant, fear of sexual intimacy, and avoidance of future childbearing.[76–81] In addition, there is limited evidence that experiencing a psychologic trauma during childbirth may lead to difficulty in bonding between mother and child resulting in long-term attachment problems.[77]

According to the literature, the percentage of women experiencing a birth as traumatic ranges between 20% and 30%, and of developing PTSD, between 2% and 6%.[81] In contrast to what might be expected, the highest incidence of postpartum PTSD is found in the group with obstetrically normal deliveries.[73] Psychosocial factors before birth play an important role in these traumatic experiences. Psychosocial predictors include preexisting psychopathology,[77,78,82] expectations,[78,82] nulliparity,[78] high trait anxiety,[82] and history of sexual trauma.[81] Soet *et al.*[81] found that women who had experienced a past sexual trauma were 12 times more likely to experience the delivery as traumatic. Lack of confidence in the ability to control pain together with low coping skills may be related to women's negative perceptions of birth. Event characteristics predicting

Table 188.1 Personal life experiences significantly related to fear of delivery in nulliparous and parous women[74]

Type of life experience	Significant in nulliparous women	Significant in multiparous women
Present pregnancy		
Fetal movements perceived late (≥22 gestational weeks in nulliparous women; ≥20 weeks in parous women)		*
Less verbal communication with the fetus	*	
Sexuality		
Ignoring sexuality in parental home	*	
Non-permissive attitude toward sexuality in parental home	*	
Negative experience of first intercourse		*
Childhood		
Negative life experience of childhood	*	
Poor relationship with father	*	
Psychological well-being		
Significant anxiety during last 2 years		*
Significant other psychological problems during last 2 years	*	
Disturbed emotional balance during present pregnancy	*	*
Psychological tension during the interview	*	
Strong dissimulation tendency	*	
Medical treatment		
First gynecological examination experienced as a psychological trauma		*
Fear of gynecological examinations at present	*	
Fear of pain in general	*	*
Earlier traumatic experiences of pain (except deliveries)		*
Fear of attending hospital services	*	
Verbal tradition concerning delivery		
Negative aspects dominant in apprehension of verbal tradition about delivery	*	

childbirth as a traumatic experience are patient's feelings of powerlessness,[81] pain during childbirth,[77,81,83] delivery of an ill or stillborn infant,[77,83] hostile and uncaring treatment by medical personnel,[77,78,83] inadequate information given to the patient,[82,83] patient's lack of consent,[83] and increasing medical intervention.[81,84]

Pain in labor

The pain of childbirth is one of the most severe forms of pain.[85] Elevation of catecholamines in maternal blood during labor is associated with pain, anxiety and prolonged labor.[47,86] Pain relief by epidural block decreases catecholamines, cortisol and adrenocorticotropic hormone secretion during labor.[87] This suggests that the hypothalamo-pituitary-adrenal axis is involved in the maternal response to pain.

Whipple *et al.*[88] investigated pain thresholds in 10 women, five of whom had had childbirth preparation according to Lamaze. The pain thresholds were measured by applying a gradually increasing force to a finger. In the group of women with childbirth preparation the pain detection threshold during labor was higher than before labor (21%) and 24 h postpartum (33%), whereas in the group without childbirth preparation, the pain detection threshold significantly decreased during labor (19%) compared to predelivery values. There were no significant differences between the intrapartum and 24-h postpartum values in this group. The authors concluded that 'in the women with childbirth preparation, an analgesic process is activated during labor'. The differences in pain thresholds were attributed to differences in anxiety during labor. Charles *et al.*[89] and Melzack *et al.*[90,91] found that women who followed childbirth

preparation courses reported less pain during the delivery than women without childbirth preparation, but there was still a lot of pain.

The phenomenon that pain detection thresholds may vary among women and even may vary over time in the same woman, may be explained by the 'gate-control' theory of Melzack.[92] The basis of this theory is that a neural mechanism (cells in the gelatinous substance) in the posterior horns of the spinal cord functions as a gate that can modulate the input of nerve impulses to the CNS. The extent to which the gate can increase or decrease the transfer is determined by the relative activity in thick (A-beta) and thin (A-delta and C) fibers and by descending influences from the brain. When the amount of information flowing through the gate exceeds a certain critical level, areas responsible for pain sensation and reaction to pain are activated. There is a central control system activating the special brain processes that keep nervous input under control. In addition, enforcing the 'gate-control' theory, a central inhibition mechanism has been localized in different areas in the brainstem.

Analgesia by overstimulation can be explained by high output of the transmission cells in the spinal cord. The output may exceed the critical level and cause pain, but could also activate the central system that inhibits the excitation level of the transmission cells. Psychologic processes, such as earlier experiences, attention and distraction, and positive and negative emotions, can influence pain experience by their effects on the gate system in the spinal cord. Some of these psychologic influences can open the gate and others can close it. The 'gate-control' theory elucidates the possibilities for pain relief by several different kinds of interventions including pharmacological means, acupuncture, massage, transcutaneous electrical nerve stimulation, application of heat and cold, as well as psychologic techniques.

Interventions to decrease maternal distress during labor

A limited number of efforts have been undertaken to prevent preterm labor and complications during labor by applying psychologic or social interventions. The kind of interventions can be roughly divided into two categories: (1) physical and mental relaxation techniques, and (2) social support. Physical and mental relaxation techniques have been used to prolong pregnancy in women at risk for preterm delivery.[9,93] Social support has been applied to prolong pregnancy duration[94] and to diminish perinatal complications.[68–70,94] Omer and Everly[9] referred to early Russian efforts to apply hypnosis in the prevention of preterm birth. They concluded that the results of these studies appeared promising. Relaxation techniques, in some cases combined with drug treatment, have contributed to clinically relevant prolongation of pregnancy.[93] In contrast, efforts to induced post-term delivery with the help of hypnosis failed.[9]

Earlier research showed that patients who had undergone a cholecystectomy used less pain medication and had more rapid recovery if they were in a room with a window so they could see natural surroundings than patients who only saw a blinded wall. It has been suggested, supported by biochemical measurements, that natural scenery has a powerful ability to promote relaxation.[95] Nowadays, experiments are carried out to mimic this effect by applying virtual reality as adjunct analgesic.[96] Whether this technique might be of help in obstetric patients still has to be investigated.

During prenatal care, a careful history, including relevant psychosocial factors, should always be taken.[97] The upcoming delivery should be discussed in a way that allows the woman as much control as possible. Joint decision making should be a pivotal part of counseling a women who is at risk for a traumatic experience during parturition. During the labor and delivery there should be ensured adequate communication and appropriate pain control. In contrast to earlier belief, PTSD cannot be prevented by psychologic debriefing.[98] It has, however, been suggested that by evaluation after birth a bridge may be provided for later screening and treatment, if required.[99]

As has been mentioned above, when supportive lay women (doulas) accompany laboring women, the length of time from admission to delivery in the supported women will be reduced, fewer perinatal complications will be seen, less intrapartum medication (epidural analgesia and oxytocin stimulation) will be necessary, and more mother–infant interaction will be expected.[68–70] These studies suggest that continuous human support during labor may be both beneficial for the labor course and perinatal outcome.

Conclusions

Maternal distress during labor can originate either from non-delivery-related background factors, such as negative life experiences in childhood, psychological problems, fear of pain in general, or from difficulties in coping with the intense experience of giving birth. The effects of exposure to psychosocial stressors may include initiating preterm labor, disrupting the normal labor course, experiencing labor as traumatic, and the development of PTSD.

Stressful events can promote the secretion of hormones that are involved in the onset of delivery, and that play a role in the regulation of the birth process. In addition, stress reactions may impair the immunologic defense against microorganisms that may colonize the uterus and initiate uterine contractions or weaken the chorion. Consequently, the membranes may become vulnerable and at risk for (preterm) premature rupture, resulting in preterm birth.

Once a woman is in labor, state-anxiety, due to loss of control and feelings of powerlessness, has been found to be positively related to 'abnormal' delivery, in particular prolonged labor, but the inadequate or inconsistent definitions of intrapartum complications used in the literature prevents the drawing of clear-cut conclusions in this regard. FOC is more frequent in nulliparous than in parous women. The most common causes of this FOC in nulliparous women are background factors, such as low psychologic well-being and negative life experiences in childhood, and in parous women previous experiences of traumatic deliveries. Pain experienced during parturition is mediated by psychological processes, such as earlier experiences, attention and emotions.[100] This can be understood by the 'gate-control' theory of Melzack, elucidating the possibilities for pain relief by, for instance, pharmacologic means, acupuncture and psychologic interventions. Several studies suggest that continuous human support during labor may be beneficial for the course of labor and perinatal outcome.

Therapeutic implications

Excessive maternal stress during delivery could be reduced by health-care providers in several ways. During pregnancy, a careful history should be taken, with particular attention to the patient's attitudes and feelings about pregnancy and delivery. During the delivery there should be ensured adequate communication and appropriate pain control. After the delivery it may be a good routine to evaluate the labor experience of the new mother. Postpartum depression should be acknowledged and treated when necessary. During subsequent pregnancies, a careful history should again be taken in order to be prepared for the upcoming delivery.[97] Joint decision making is a very important part of counseling women before and during labor.

Unfortunately, scientifically valid data about treatment of childbirth-related anxiety is almost nonexistent. The clinical practice of how to treat fear of pregnancy is based primarily on knowledge of treatment of similar problems in the non-pregnant state, clinical experience, and common sense. More basic knowledge of childbirth-related anxiety is crucial to develop adequate methods of treatment. There is ample evidence that many women experience great distress related to childbirth, which might have long-lasting consequences for their mental and emotional well-being.[73] In debates on women's right to choose elective caesarean section there should be more attention to the reasons why so many women apparently fear vaginal delivery. And a related question is how we can organize our labor ward in a way that it is more patient-friendly. In order to facilitate maternal–child bonding and future attachment, a new mother should welcome her baby in an atmosphere as peaceful as possible; health-care workers can, and have to, play a crucial role in this goal.

189 Intrapartum decision-making: a computational approach

J. E. Deaver

The medical literature provides clinicians with measures of effect that relate risks in patients exposed and unexposed to treatments and putative causative agents. Measures of effect include differences in risk between exposed and unexposed subjects and the ratio of these risks (relative risk), the latter being closely related to the odds ratio. Well-conducted trials in which exposures, usually treatments, are randomly assigned to patients are considered to provide the strongest evidence for effects. The high quality of evidence potentially generated by such trials is a function of the randomization process that produces equal proportions of potential confounders in exposed and unexposed groups. However, clinical decisions are made for individuals rather than groups. How should one extrapolate evidence obtained by the analysis of groups differing on a single exposure to the treatment of individual patients, each with his or her own multitude of traits? It has become popular to bridge the gap by attempting to make care uniform within groups. However, this approach only ignores the problem of within-group heterogeneity on a wide variety of factors including comorbid conditions and coexisting treatments for conditions other than the outcome addressed by a particular clinical guideline. Decision modeling is another approach to helping clinicians make the leap from clinical science to clinical practice. Decision modeling incorporates rather than ignores multiple factors that impact on outcomes and treatment decisions in individual patients. It is hoped that the reader will discover that decision modeling is helpful for difficult, not obvious, decisions.

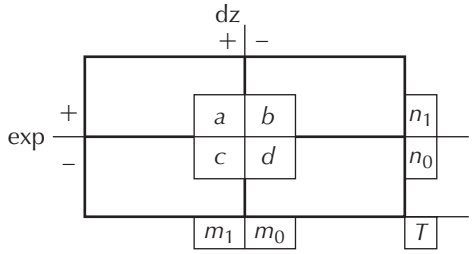
As a practical example of decision modeling, this chapter examines the decision about whether to perform a cesarean section in order to prevent shoulder dystocia. This topic was selected because prevention of shoulder dystocia has been an intractable problem. It and its associated birth trauma (primarily brachial plexus injury) are largely regarded as complications that cannot usually be predicted or prevented. One approach to reducing risk would be to perform cesarean deliveries on all patients with antepartum or intrapartum risk factors associated with shoulder dystocia. However, current risk assessment is insufficiently specific for this approach; the number of unnecessary cesarean sections that would result have risks that are simply too large in relation to the number of shoulder dystocias that would be prevented.

Decision analysis utilizes many tools, including decision trees, Markov and Monte Carlo process modeling, regression analysis, neural networks, and Bayesian analysis. This chapter will focus on the techniques of multiple logistic regression and Bayesian analysis. It is intended that the reader develop a basic understanding of how a decision analysis is conducted using these two methods. An understanding of logistic regression and Bayesian analysis will provide the interested reader with a solid foundation from which to explore other methods of decision analysis.

There may be a temptation for readers of the medical literature to regard decision analysis as a 'black box', because all of the above methods are computationally intensive, and to focus on the results of decision analysis without an appreciation of the inherent limitations and assumptions. If the methods of decision analysis seem less daunting and the results more fallible after reading this chapter, then a useful purpose will have been served.

Basic probability concepts, definitions, and formulas

Two-by-two tables are used to illustrate many of the concepts to be presented. By convention, the left margin of a two-by-two table is labeled with the exposure, the top margin with the disease or outcome, the right margin with row totals, and the bottom margin with column totals as shown in the following:



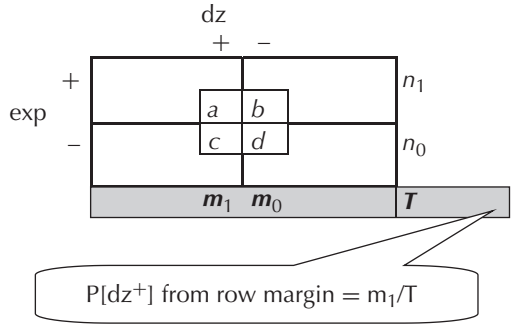
where 'exp' is the exposure including risk factors, tests, and treatments; 'dz' is the disease or outcome; '+' means positive (presence); and '–' means negative (absence). The cells '*a*' through '*d*', 'm_1', 'm_0', 'n_1', 'n_0', and '*T*' have numbers (*N*) corresponding to the following:

$a = \exp^{+}\mathrm{dz}^{+}$ ($N_{(\text{exposed diseased})}$),
$b = \exp^{+}\mathrm{dz}^{-}$ ($N_{(\text{exposed disease-free})}$),
$c = \exp^{-}\mathrm{dz}^{+}$ ($N_{(\text{non-exposed diseased})}$),
$d = \exp^{-}\mathrm{dz}^{-}$ ($N_{(\text{non-exposed disease-free})}$),
$m_1 = \mathrm{dz}^{+}$ ($N_{(\text{diseased})}$),
$m_0 = \mathrm{dz}^{-}$ ($N_{(\text{disease-free})}$),
$n_1 = \exp^{+}$ ($N_{(\text{exposed})}$),
$n_0 = \exp^{-}$ ($N_{(\text{non-exposed})}$),
$T = a + b + c + d = n_1 + n_0 = m_1 + m_0 = (N_{\text{total}})$.

Probability notation can be understood in terms of a two-by-two table. The unconditional (baseline or prior) probabilities have the following notation:

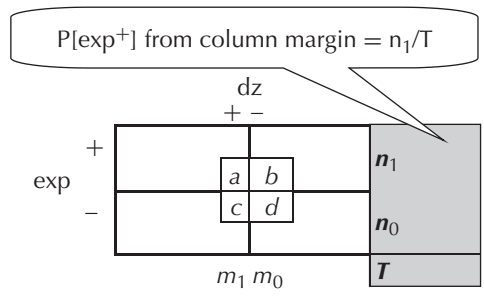
$$P[\mathrm{dz}^{+}]$$

read, 'the probability (or proportion) of diseased' prior to exposure, treatment or testing, and is equivalent to baseline disease prevalence. Prior probability of disease is derived from the two-by-two table *row* margin and is equal to m_1/T.



$$P[\exp^{+}]$$

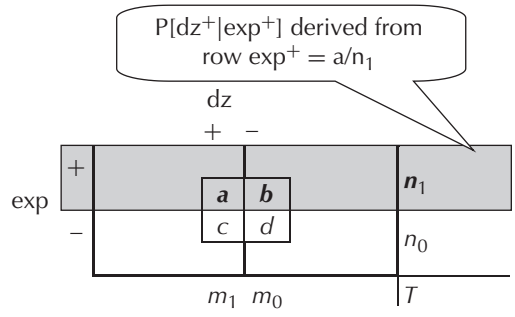
read, 'the probability (or proportion) of exposed (or treated or whose tests were positive)' without regard to disease, is equivalent to exposure prevalence. The prior probability of exposure is derived from the two-by-two table *column* margin and is equal to n_1/T.



Conditional or posterior probabilities have the following notation:

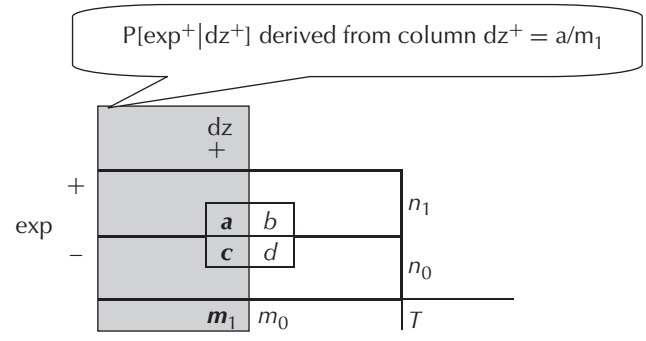
$$P[\mathrm{dz}^{+} \mid \exp^{+}]$$

read, 'the probability of disease presence *given that* exposure is present', and is equivalent to risk in exposed or to positive predictive value when the exposure is a test (see below). The probability is conditioned on an exposure level, in this case on exposure being present. This conditional probability is determined from a *non-marginal row* of the two-by-two table and is equal to a/n_1.



$$P[\exp^{+} \mid \mathrm{dz}^{+}]$$

read, 'the probability (or proportion) with positive test result *given that* disease is present', and is equivalent to sensitivity when exposure is a test (see below). The probability is conditioned on disease being present. This conditional probability is determined from a *non-marginal column* of the two-by-two table and is equal to a/m_1.



The following useful ratios, expressed in terms of a two-by-two table and in probability notation, are obtained from two-by-two table *columns*:

$a/(a+c) = a/m_1 = P[\exp^+ \mid dz^+] =$
sensitivity (true-positive rate or detection rate), when exposure is a test;

$c/(a+c) = c/m_1 = P[\exp^- \mid dz^+] =$
1 − sensitivity (false-negative rate), when exposure is a test;

$d/(b+d) = d/m_0 = P[\exp^- \mid dz^-] =$
specificity (true-negative rate), when exposure is a test;

$b/(b+d) = b/m_0 = P[\exp^+ \mid dz^-] =$
1 − specificity (false-positive rate), when exposure is a test.

The likelihood ratio of a positive test (LR^+) reflects how much greater are the odds of disease when a test result is positive and is found by the following:

Formula (1): Likelihood ratio (LR^+) =
sensitivity/(1 − specificity) =
true-positive rate/false-positive rate,

The probability (or proportion) of an attribute is the number with the attribute divided by the total of those with and without the attribute. After 100 tosses of a fair coin, one would expect 50 "heads" out of the total of 100 tosses. The probability (or proportion) of "heads" is 50/100 or 0.50.

The odds of an attribute are the number with the attribute divided by the remainder without the attribute. After 100 tosses of a fair coin, one would expect 50 "heads" and 50 "non-heads" or "tails". The odds of "heads" are 50/50 or 1.

Exposure odds are the number exposed over the number unexposed.

Unconditional odds of exposure are the odds of exposure without consideration for whether disease is present or absent.

Unconditional or prior exposure odds, $\text{odds}[\exp^+] = n_1/n_0$

Conditional exposure odds can be found for two strata, those with disease and those without disease.

$\text{odds}[\exp^+ \mid dz^+] = a/c =$ exposure odds in diseased stratum

$\text{odds}[\exp^+ \mid dz^-] = b/d =$ exposure odds in non-diseased stratum

Odds and probability (P) are interchangeable by using the following formulas:

Formula (2): $P = \text{odds}/(1+\text{odds})$

Formula (3): $\text{odds} = P/(1-P)$

Note that the exposure odds, $\text{odds}[\exp^+ \mid dz^+] = a/c$ and $\text{odds}[\exp^+ \mid dz^-] = b/d$ can converted to $P[\exp^+ \mid dz^+]$ (sensitivity; true-positive rate) and $P[\exp^+ \mid dz^-]$ (1 − specificity; false-positive rate), respectively.

The following useful ratios, expressed in terms of a two-by-two table and in probability notation, are obtained from two-by-two table *rows*:

$a/(a+b) = a/n_1 = P[dz^+ \mid \exp^+]$

$b/(a+b) = b/n_1 = P[dz^- \mid \exp^+]$

$c/(c+d) = c/n_0 = P[dz^+ \mid \exp^-]$

$d/(c+d) = d/n_0 = P[dz^- \mid \exp^-]$

Note that if exposure is a test, then $a/(a+b) = a/n_1 =$ positive predictive value (PPV). If the exposure is a risk factor, then $a/n_1 = \text{risk}_{(\text{exposed})}$ and $c/n_0 = \text{risk}_{(\text{unexposed}).}$ Then

$(a/n_1)/(c/n_0) = \text{risk}_{(\text{exposed})}/\text{risk}_{(\text{unexposed})} =$
relative risk (RR).

Disease odds are the number with disease over the number without disease.

Unconditional odds of disease are the odds of disease without consideration for whether exposure is present or absent.

Unconditional odds or prior odds of disease, $\text{odds}[dz^+] = m_1/m_0$.

Conditional odds of disease can be found for two strata, those exposed and those unexposed.

$\text{odds}[dz^+ \mid \exp^+] = a/b =$ disease odds in exposed stratum

$\text{odds}[dz^+ \mid \exp^-] = c/d =$ disease odds in unexposed stratum

The odds of disease in exposed divided by odds of disease in unexposed, or

odds ratio (OR) =
$\text{odds}[dz^+ \mid \exp^+]/\text{odds}[dz^+ \mid \exp^-] =$
$(a/b)/(c/d) = (a \times d)/(b \times c)$,

i.e., the OR is the ratio of two-by-two table cross-products.

Note that when a disease is rare, i.e., when the numbers in cells 'a' and 'c' of the two-by-two table approach 0, then $a/(a+b)$ approaches a/b and $c/(c+d)$ approaches c/d. Relative risk (RR), $a/(a+b)/c/(c+d)$, then is approximately $(a/b)/(c/d)$, which is the odds ratio (OR). When disease prevalence is low, the OR becomes a reasonable approximation of RR.

Bayes' theorem can be expressed in the following useful form that relates prior or baseline disease odds ($\text{odds}[dz^+]$) to posterior odds or the conditional odds of disease given a positive test result ($\text{odds}[dz^+ \mid \exp^+]$ where '$\exp^+$' is a positive test result)

based on the likelihood ratio of a positive test (LR^+) which is the ratio of test characteristics (sensitivity/(1 − specificity)).

Formula (4): Posterior odds = Likelihood ratio (LR^+) × Prior odds,
i.e.,
Conditional odds of disease given exposure = LR^+ × Unconditional odds of disease
i.e.,
$\text{odds}[dz^+|exp^+] = LR^+ \times \text{odds}[dz^+]$

Baseline prevalence (or prior probability) can be converted to prior odds using Formula (3); the posterior odds can be converted to post-test probability, or the positive predictive value of a test, using Formula (2).

As an example, suppose that we are given a baseline disease prevalence or prior probability, $P[dz^+] = 0.25$, and test sensitivity, $P[exp^+|dz^+] = 0.80$, and specificity, $P[exp^-|dz^-] = 0.90$. Then,

$LR^+ = \text{sensitivity}/(1 - \text{specificity}) = 0.80/(1 - 0.90) = 0.80/0.10 = 8.0$

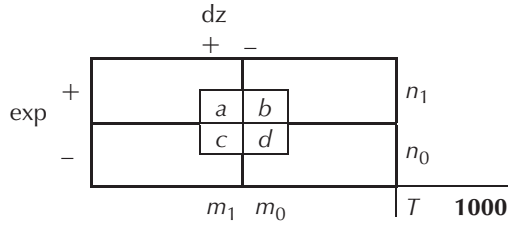
$P[dz^+]$ = baseline disease prevalence = prior probability of disease = 0.25

Prior odds or $\text{odds}[dz^+]$, from $\text{odds} = P[dz^+]/(1 - P[dz^+]) = 0.25/(1 - 0.25) = 0.25/0.75 = 0.333$

Posterior odds of disease given a positive test result or $\text{odds}[dz^+|exp^+] = LR^+ \times 0.33 = 8 \times 0.333 = 2.66$

Posterior probability $P[dz^+|exp^+]$, or positive predictive value (PPV) = 2.66/(1 + 2.66) = 0.73 (from P = odds/(1 + odds)).

A patient from a population with a baseline prevalence of disease 1-in-4 has a nearly 3-in-4 chance of disease given a positive test result. This result of Bayes' theorem can be confirmed by populating a two-by-two table to obtain PPV directly. Assume a population size (T) of 1000 patients.



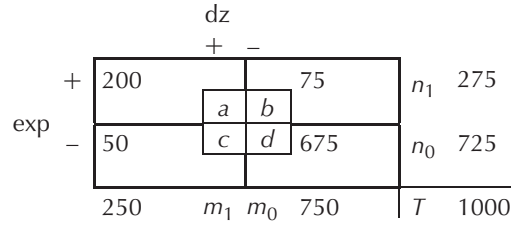
Then m_1 equals 250 given the baseline disease prevalence, $P[dz^+]$, that is $0.25 \times T$ and m_0, is the difference between T and $m_1 = 750$. This completes the row margin of the two-by-two table. Given that sensitivity, $P[exp^+|dz^+] = 0.80$, the quantities 'a' and 'c' can be obtained where, $a = 0.80 \times m_1 = 0.80 \times 250 = 200$; and $c = m_1 - a = 250 - 200 = 50$.

Given that specificity, $P[exp^-|dz^-] = 0.90$, the quantities b and d can be obtained where,

$d = 0.90 \times m_0 = 675$; $b = m_0 - d = 750 - 675 = 75$.

The fully populated two-by-two table contains the following quantities:

$n_1 = a + b = 200 + 75 = 275$ and
$n_0 = c + d = 50 + 675 = 725$



The ratio a/n_1 is the positive predictive value (PPV) or the posterior probability of disease given a positive test result, $P[dz^+|exp^+] = 200/275 = 0.73$, confirming the earlier result obtained by using the likelihood ratio form of Bayes' theorem.

Given the same test, i.e., when test characteristics (sensitivity and specificity) are held constant, posterior probabilities vary directly in relation to baseline disease prevalence (prior probabilities). For instance, if our test with sensitivity 0.80 and specificity 0.90 were applied to a population with a baseline disease prevalence, $P[dz^+]$, of only 0.10 (rather than 0.25 as in the example above), then the following illustrates this point using Bayes theorem. Recall that the likelihood ratio of the given test, a constant, is 8. Prior probability of disease, $P[dz^+] = 0.10$. Then our new prior odds is $0.10/(1 - 0.10) = 0.10/0.90 = 0.11$. The posterior odds = LR^+ × prior odds = $8 \times 0.11 = 0.88$. Our new posterior probability, $P[dz^+|exp^+]$ or PPV, is equal to 0.88/(1 + 0.88) = 0.88/1.88 = 0.47. The PPV associated with the same test is only 0.47 in contrast to the earlier result of 0.73. The difference is due to higher baseline prevalence in the first compared to the second example.

The general form of Bayes' theorem is written as

Formula (5):

$$P[A^+|X^+] = \frac{(P[X^+|A^+] \times P[A^+])}{(P[X^+|A^+] \times P[A^+]) + (P[X^+|A^-] \times P[A^-])}$$

If A = disease (dz) and X = exposure (exp), then:

$P[A^+|X^+] = P[dz^+|exp^+]$ = posterior probability of disease = positive predictive value,

$P[X^+|A^+] = P[exp^+|dz^+]$ = true-positive rate = sensitivity, and

$P[A^+] = P[dz^+]$ = prior probability of disease (baseline disease prevalence)

$P[X^+ \mid A^-] = P[\mathrm{dz}^+ \mid \mathrm{exp}^-]$ = false-positive rate = 1 − specificity

$P[A^-]$ = prior probability of non-disease = 1 − baseline prevalence of disease.

Therefore, if one is interested, as we have been, in deriving the probability of disease given an exposure level, in this case when exposure is present, and baseline disease prevalence and test characteristics are known, then Bayes theorem takes the following form [disease (dz) is substituted for A and the test exposure (exp) is substituted for X]:

Formula (6):

$$P[\mathrm{dz}^+ \mid \mathrm{exp}^+] = \frac{(P[\mathrm{dz}^+ \mid \mathrm{exp}^+] \times P[\mathrm{dz}^+])}{(P[\mathrm{dz}^+ \mid \mathrm{exp}^+] \times P[\mathrm{exp}^+]) + (P[\mathrm{exp}+ \mid \mathrm{dz}^-] \times P[\mathrm{dz}^-])}$$

or, equivalently,

Formula (7):

$$\mathrm{PPV} = \frac{(\mathrm{Sens} \times \text{baseline dz prevalence})}{(\mathrm{Sens} \times \text{baseline dz prevalence}) + [(1-\mathrm{spec}) \times (1-\text{baseline dz prevalence})]}$$

To use our example of a test with sensitivity 0.80 and specificity 0.90 applied to a population with baseline disease prevalence 0.25, then the general form of Bayes theorem provides the same PPV of 0.73, as follows:

$$PPV = \frac{(0.80 \times 0.25)}{(0.80 \times 0.25) + (0.10 \times 0.75)} = \frac{(0.20)}{(0.275)} = 0.73$$

The utility of the general form of Bayes theorem, as given in Formula (5), can be seen by deriving sensitivity from baseline *exposure* prevalence and the relative risk of disease. Compared to the previous example, we reverse the substitution of exposure (exp) and disease (dz) for the terms 'A' and 'X' in Formula (5). Rather than X = exposure and A = disease, here we instead let X = disease and A = exposure, in which case:

$P[A^+ \mid X^+] = P[\mathrm{exp}^+ \mid \mathrm{dz}^+]$ = sensitivity,

$P[X^+ \mid A^+] = P[\mathrm{dz}^+ \mid \mathrm{exp}^+] = \mathrm{risk}_{(\mathrm{exposed})}$,

$P[X^+ \mid A^-] = P[\mathrm{dz}^+ \mid \mathrm{exp}^-] = \mathrm{risk}_{(\mathrm{unexposed})}$,

$P[A^+] = P[\mathrm{exp}^+]$ = prior (baseline) exposure prevalence, and

$P[A^-] = P[\mathrm{exp}^-]$ = prior non-exposure prevalence = (1 − prior exposure prevalence).

Then Bayes theorem takes the following form:

Formula (8):

$$P[\mathrm{exp}^+ \mid \mathrm{dz}^+] = \frac{(P[\mathrm{dz}^+ \mid \mathrm{exp}^+] \times P[\mathrm{exp}^+])}{(P[\mathrm{dz}^+ \mid \mathrm{exp}^+] \times P[\mathrm{exp}^+]) + (P[\mathrm{dz}^+ \mid \mathrm{exp}^-] \times P[\mathrm{exp}^-])}$$

or, equivalently,

Formula (9):

$$\text{Sensitivity} = \frac{(\mathrm{risk}_{(\mathrm{exposed})} \times \text{baseline exp prevalence})}{((\mathrm{risk}_{(\mathrm{exposed})} \times \text{baseline exp prevalence}) + (\mathrm{risk}_{(\mathrm{unexposed})} \times (1-\text{baseline exp prevalence})))}$$

Assume that exposure is a risk factor with a baseline prevalence (prior probability of exposure) = 0.275. $\mathrm{Risk}_{(\mathrm{exposed})} = 0.73$. $\mathrm{Risk}_{(\mathrm{unexposed})} = 0.07$. Relative risk (RR) = 10.4. The 'sensitivity' of the risk factor for disease is $(0.73 \times 0.275)/((0.73 \times 0.275) + (0.07 \times (1-0.275))) = 0.80$. Sensitivity could be obtained alternatively by using the following forms of Bayes' theorem:

Formula (10): Posterior odds of exposure = RR × prior odds of exposure

or, when disease is rare, by,

Formula (11): Posterior odds of exposure = OR × prior odds of exposure

The prior odds of exposure = $0.275/(1-0.275) = 0.38$. Posterior odds of exposure given disease = $10.4 \times 0.38 = 3.95$. The posterior probability of exposure, $P[\mathrm{exp}^+ \mid \mathrm{dz}^+]$, or sensitivity = $3.95/(1+3.95) = 0.80$. From relative risk (RR) or odds ratio (OR) and baseline exposure prevalence, one can obtain sensitivity or the probability of exposure given disease, $P[\mathrm{exp}^+ \mid \mathrm{dz}^+]$.

Note that predictive value (the term used when exposure is a test) is synonymous with $\mathrm{risk}_{(\mathrm{exposed})}$ (the term used when exposure is a risk factor or treatment). Both are the posterior probability of disease given exposure, $P[\mathrm{dz}^+ \mid \mathrm{exp}^+]$.

One can determine $P[\mathrm{dz}^+ \mid \mathrm{exp}^+]$, the posterior probability of disease given exposure or positive predictive value or $\mathrm{risk}_{(\mathrm{exposed})}$, from $P[\mathrm{exp}^+ \mid \mathrm{dz}^+]/P[\mathrm{exp}^+ \mid \mathrm{dz}^-]$ (called the likelihood ratio if exposure is a test) and prior probability of disease.

One can determine $P[\mathrm{exp}^+ \mid \mathrm{dz}^+]$ (notice that 'exp' and 'dz' traded places), the posterior probability of exposure given disease or sensitivity, from $P[\mathrm{dz}^+ \mid \mathrm{exp}^+]/P[\mathrm{dz}^+ \mid \mathrm{exp}^-]$ (called the relative risk if exposure is a risk factor or treatment) and prior probability of exposure.

Creating a risk score for shoulder dystocia prevention

The above principles and formulas will be used to demonstrate the creation of a risk score for shoulder dystocia having a threshold (cutoff) value with sensitivity

and specificity such that the number of additional cesarean sections needed to prevent a case of shoulder dystocia is acceptably small. The steps in creating such a risk scoring system are as follows:

(1) Use multiple logistic regression modeling to determine the adjusted regression coefficients for various risk factors that are associated with shoulder dystocia. For demonstration purposes, we will confine the analysis to three risk factors for shoulder dystocia (assisted vaginal delivery, i.e., vacuum extraction and forceps deliveries, diabetes, and fetal macrosomia).
(2) Use regression coefficients to determine, for various combinations of exposures, risk scores either as probabilities of shoulder dystocia or odds ratios of shoulder dystocia (where the denominator of the odds ratio is the odds in patients with none of these risk factors).
(3) Determine the probability distribution of risk scores.
(4) Determine the receiver-operator characteristics (sensitivity versus specificity) of various thresholds (cutoff values) of risk scores given the probability distribution of scores.
(5) Choose a score threshold that will result in the most cases of shoulder prevented at an acceptable cost in terms of the risks associated with additional cesarean sections.

Adjusted coefficients from multiple logistic regression modeling

Multiple logistic regression modeling is a technique for estimating the independent contribution of multiple exposures to outcomes measured as binary or dichotomous variables, such as shoulder dystocia that has the values 'present' or 'absent'. The regression coefficients can be used to determine the probabilities of the outcome for combinations of $i=1$ to j exposures, each having the value x_i,

Formula (12): $$\mathrm{P}[\mathrm{dz}^+|\exp_{i=1,\ldots,j} \text{ having values } x_1,\ldots,x_j] = \frac{1}{1+e^{-(\beta_0+\sum_{i=1}^{j}\beta_i x_i)}}$$

From a logistic regression analysis of binary predictors of coronary heart disease (CHD),[1] the coefficients given in Table 189.1 were obtained:

Notice that the values (x_is) of these binary variables are either 1 or 0.

A female patient with no risk factors ($x_{\text{gender}}=0$, $x_{\text{smoking}}=0$, $x_{\text{age}}=0$, $x_{\text{hypertension}}=0$, $x_{\text{obesity}}=0$) in the above study has the following estimated probability of developing CHD:

$P[\mathrm{CHD}^+|\text{female, non-smoker, age} < 55\text{, normotensive, non-obese}] =$

$$\frac{1}{1+e^{-[(\beta_0+(\beta_{\text{gender}}\times 0)+(\beta_{\text{smoking}}\times 0)+(\beta_{\text{age}}\times 0)+(\beta_{\text{hypertension}}\times 0)+(\beta_{\text{obesity}}\times 0)]}}$$

Formula (12), in this case, simplifies to

$$P[\mathrm{CHD}^+|\exp_{i=1,\ldots,j}] = \frac{1}{1+e^{-\beta_0}}$$

so that the probability of CHD in a female with no risk factors is

$P[\mathrm{CHD}^+|\text{female, non-smoker, age} < 55\text{, normotensive, non-obese}] =$

$$\frac{1}{1+e^{-\beta_0}} = \frac{1}{1+e^{-(-4.567)}} = 0.0103,$$

i.e., there is only a 1% risk of CHD over the follow-up period defined by the study.

Therefore, only the coefficient for the intercept (β_0) is needed to estimate the probability of the outcome when the values of all predictors (x_is) are zero in which case all the $\beta_i x_i$s are also zero.

A male smoker who is young, hypertensive, and thin ($x_{\text{gender}}=1$, $x_{\text{smoking}}=1$, $x_{\text{age}}=0$, $x_{\text{hypertension}}=1$, $x_{\text{obesity}}=0$) has the following estimated probability for CHD:

$P[\mathrm{CHD}^+|\text{male, smoker, age} < 55\text{, hypertensive, non-obese}] =$

$$\frac{1}{1+e^{-[(\beta_0+(\beta_{\text{gender}}\times 1)+(\beta_{\text{smoking}}\times 1)+(\beta_{\text{age}}\times 0)+(\beta_{\text{hypertension}}\times 1)+(\beta_{\text{obesity}}\times 0)]}} =$$

$$\frac{1}{1+e^{-[(\beta_0+(\beta_{\text{gender}}\times 1)+(\beta_{\text{smoking}}\times 1)+(\beta_{\text{hypertension}}\times 1)]}} =$$

(since the x_is and $\beta_i x_i$s for age and obesity are zero). Therefore, the probability of CHD in this subject is

Table 189.1 CHD risk factors from the Atherosclerosis Risk in Communities (ARIC) study

Variables (i)/values (x_i)	β_i	Logistic regression coefficient	Odds ratio
Intercept	β_0	–4.567	
$i=1$, gender / male = 1, female = 0	β_1	1.311	3.71
$i=2$, smoking / yes = 1, no = 0	β_2	0.703	2.02
$i=3$, age > 54 years / yes = 1, no = 0	β_3	0.144	1.15
$i=4$, hypertension / yes = 1, no = 0	β_4	0.510	1.67
$i=5$, obesity / yes = 1, no = 0	β_5	0.192	1.21

$P[\text{CHD}^+ \mid \text{male, smoker, age} < 55, \text{hypertensive, non-obese}] =$

$$\frac{1}{1+e^{-(-4.567+1.311+0.703+0.510)}} = 0.115,$$

i.e., there is a 11.5% risk of CHD over the same follow-up period.

Rather than using probability to quantify risk, the odds ratio can be used. Since odds $= P/(1-P)$, the odds of CHD is $0.115/(1-0.115) = 0.13$ in young, hypertensive, thin male smokers; the odds of CHD is $0.0103/(1-0.0103) = 0.0104$ when no risk factors are present. The ratio of odds in young, hypertensive, thin male smokers relative to odds in a referent group having no risk factors, or odds ratio (OR) $= 0.13/0.0104 = 12.5$.

The odds ratio can also be calculated by obtaining, for each variable, the product term, β_i multiplied by the difference in x_is between the two groups, named 'a' and 'b' ($x_{ia} - x_{ib}$); the product terms are summed; this sum is exponentiated to obtain the odds for a combination of risk factors that are present (group a) contrasted to a group in which no risk factors are present (group b).

Formula (13):

$$\text{OR} = \frac{\text{Odds}[dz^+ \mid \exp_{i=1,\ldots,j} \text{ having value } x_{1a},\ldots,x_{ja}]}{\text{Odds}[dz^+ \mid \exp_{i=1,\ldots,j} \text{ having value } x_{1b},\ldots,x_{jb}]} = e^{\sum_{i=1}^{i} \beta_i (x_{ia} - x_{ib})}$$

Young, hypertensive, thin, male smokers compared to young, normotensive, thin, female non-smokers have the following values (x_{ia} vs. x_{ib}) of these five variables: $x_1 = x_{\text{gender}} = 1$ vs. 0, respectively; $x_2 = x_{\text{smoking}} = 1$ vs. 0; $x_3 = x_{\text{age}} = 0$ vs. 0; $x_4 = x_{\text{hypertension}} = 1$ vs. 0; $x_5 = x_{\text{obesity}} = 0$ vs. 0. Each difference is multiplied by the respective coefficients and these values are summed, the result of which is exponentiated. The odds ratio (OR) is therefore:

$$\frac{\text{Odds}[\text{CHD} \mid \text{young, hypertensive, thin, male smoker}]}{\text{Odds}[\text{CHD} \mid \text{young normotensive thin, female non-smoker}]} =$$

$$e^{(\beta_{\text{gender}} \times (1-0)) + (\beta_{\text{smoking}} \times (1-0)) + (\beta_{\text{age}} \times (0-0)) + (\beta_{\text{hypertension}} \times (1-0)) + (\beta_{\text{obesity}} \times (0-0))} =$$
$$e^{(\beta_{\text{gender}} + \beta_{\text{smoking}} + \beta_{\text{hypertension}})} =$$
$$e^{(1.311+0.703+0.510)} = 12.5$$

which is equivalent to the odds ratio we obtained by converting probabilities associated with the same two groups. Probabilities or relative probabilities (relative risks) or relative odds (odds ratios) can be used to construct risk scores. Odds ratios are commonly reported in the literature from which we will obtain our estimates of the effects of individual variables.

By using Formula (14), individual coefficients, β_is, can be obtained when odds ratios are reported in the literature.

Formula (14): $\beta_i = \ln(\text{OR}_i)$,

presuming a difference of 1 between two exposure levels.

Conversely, Formula (15) can be used to convert a coefficient to an odds ratio.

Formula (15): $\text{OR}_i = e^{\beta_i}$

Therefore, from the individual odds ratios reported in the literature, we can determine the individual coefficients by using Formula (14). Risk scores consisting of odds ratios for combinations of variables that differ from a referent group having no risk factors can be obtained using Formula (13). The advantage of this approach is that the coefficient for the intercept, which is usually not reported in the literature and which cannot be calculated by knowing odds ratios, is unnecessary for computing the score.

The literature was surveyed to identify, for a variety of exposures, their odds ratios for shoulder dystocia. The exposures surveyed included diabetes, fetal macrosomia, and assisted vaginal delivery by forceps or vacuum extractor.

The odds of shoulder dystocia are 1.7–6.0 times greater in diabetics compared to non-diabetics.[2–4] I assumed an odds ratio of 6 for the association of diabetes with shoulder dystocia.

The odds of shoulder dystocia are 3.5–20.4 times greater in neonates with birth weights more than 4000 g compared to smaller neonates.[2,4,5] I assumed an odds ratio of 20 for the association of macrosomia with shoulder dystocia.

The odds of shoulder dystocia are 1.9–3.5 times greater in assisted vaginal deliveries compared to spontaneous vaginal deliveries.[2,4] I assumed an odds ratio of 3.5 for the association of assisted vaginal deliveries with shoulder dystocia.

These selected odds ratios (OR_i) and their regression coefficients, calculated using Formula (14), are summarized in Table 189.2.

Table 189.2 Odds ratios for risk factors for shoulder dystocia (S)

Exposure (exp_i)	$OR_i = \frac{odds[S^+[exp_i^+]}{odds[S^+[exp_i^-]}$	Coefficients [ln(OR) = β]
i=A, assisted vaginal delivery*	3.5	$\beta_A = 1.25$
i=D, diabetes	6.0	$\beta_D = 1.79$
i=M, macrosomia	20	$\beta_M = 3.00$

*Vacuum extraction or forceps vaginal delivery

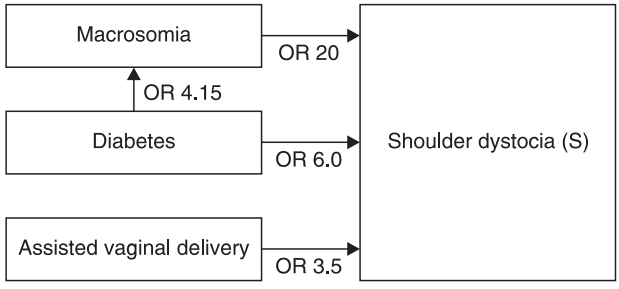


Figure 189.1 Associations between risk factors and shoulder dystocia.

Table 189.3 Selected prior probabilities based on literature review

Factor or outcome	Prevalence
Shoulder dystocia (S)	0.01
Macrosomia (M)	0.10
Diabetes (D)	0.05
Assisted delivery (A)	0.10

The direction and magnitudes of the effects of these risk factors on the outcome of shoulder dystocia are shown in Figure 189.1. Diabetes also influences the probability of macrosomia. The odds of macrosomia are 3–4.2 times greater in diabetic pregnancies.[6,7] I assumed an odds ratio of 4.2 for the association of diabetes with macrosomia.

One might expect for macrosomia and diabetes to negatively influence the probability of assisted vaginal delivery, although no data were available to support this hypothesis. One could also hypothesize that assisted vaginal deliveries, which are associated both with abnormal labor and with shoulder dystocia, merely confound an association between abnormal labor and shoulder dystocia. Shoulder dystocia might have occurred in these deliveries as a result of abnormal labor whether or not forceps had been applied. The prevalence of abnormal labor is likely to be increased with diabetes and macrosomia. Assisted delivery might also represent an intermediate (or intervening) variable in the effect of abnormal labor on shoulder dystocia, i.e., assisted vaginal delivery might be part of a causal pathway involving abnormal labor. Assisted vaginal delivery might also modify the effect of abnormal labor on shoulder dystocia. Since these causal pathways and interactions involving assisted vaginal delivery, abnormal labor, and either macrosomia or diabetes have not been studied, I assumed for purposes of this analysis that diabetes and macrosomia did not influence the probability of assisted vaginal delivery.

Whether macrosomia exists cannot be known prospectively. Our goal is a risk score based on prospectively available risk factors. Therefore, an ultrasound diagnosis of macrosomia should be substituted in our model for macrosomia. The odds ratios for the associations between an ultrasound finding of an EFW > 4 kg and both shoulder dystocia and diabetes are not available from the literature directly. We will determine these odds ratios using Bayesian methods and the reported associations between macrosomia and diabetes and between macrosomia and shoulder dystocia, and the reported sensitivities and specificities of an ultrasound diagnosis of macrosomia.

Prevalence data (prior probabilities) are necessary for what follows.

Langer *et al.* concluded from their review that shoulder dystocia complicates 0.1–1.7% of deliveries.[4] A prevalence of 1% will therefore be used for the prior probability of shoulder dystocia in our model.

Diabetes in some form complicates 2–8% of pregnancies.[3] The midpoint of this range, 5%, will be used for the prior probability of diabetes.

Vacuum extraction ands forceps deliveries account for 8–12% of all births.[8,9] The midpoint of this range, approximately 10%, will be used for the prior probability of assisted delivery.

Macrosomia, defined as birth weight more than 4000 g, occurs in 7.6–13.1% of pregnancies.[4,5] The midpoint of this range, approximately 10%, will be used for the prior probability of macrosomia.

The prior probabilities for purposes of this analysis are summarized in Table 189.3.

Based on their literature review, Rouse *et al.* concluded that typical sensitivities and specificities of ultrasound (USG > 4 kg) for fetal macrosomia (M) were 0.6 and 0.9, respectively.[10] The prior probability (baseline prevalence) of macrosomia, from Table 189.3,

Table 189.4 Association between ultrasound and macrosomia

USG >4 kg	M+	M−		
+	60 ($0.60\times m_1$)	90	n_1	150
−	40	810 ($0.90\times m_0$)	n_0	850
	100 (m_1)	900 (m_0)	T	1000

Table 189.5 Association between macrosomia and shoulder dystocia

M	S+	S−		
+	(0.69 × 10 = 7)	($n_1 - a$ = 93)	n_1 =	100
−	(m_1 − a = 3)	($m_0 - b$ = 897)	n_0 =	900
	10 (m_1)	990 (m_0)	T	1000

is 0.10. These values allow us to populate a two-by-two table as shown (Table 189.4).

Note that the prevalence of an ultrasound EFW > 4 kg is 0.15, higher than the prevalence of macrosomia because false positives ($n=90$) are in excess of false negatives ($n=40$). Sensitivity = 60/100 = 0.6 and specificity = 810/900 = 0.9. The posterior probability of macrosomia given a positive ultrasound finding, $P[M^+|USG^+]$ or PPV = 60/150 = 0.4.

We can then find the posterior probability of shoulder dystocia given macrosomia, $P[S^+|M^+]$, and the posterior probability of shoulder dystocia given a normal birth weight neonate, $P[S^+|M^-]$, as follows.

Recall that the posterior odds, odds[$exp^+|dz^+$] (or in this case, odds[$M^+|S^+$]), are obtained by multiplying relative risk (RR) by the prior odds of exposure, odds[exp^+] (or in this case, odds[M^+]).

The requisite data are as follows: RR (of shoulder dystocia in macrosomia relative to non-macrosomia) = 20 (the odds ratio from Table 189.2 is used as a reasonable approximation of RR); From Table 189.3, $P[M^+]$ (baseline prevalence or prior probability of the macrosomia exposure) = 0.1.

Prior probability, $P[M^+]=0.1$
Prior Odds[M^+] = 0.1/(1 − 0.1) = 0.111
Posterior Odds[$M^+|S^+$] =
RR × Prior Odds[M^+] =
20 × 0.111 = 2.22
Posterior $P[M^+|S^+]=2.22/(1+2.22)=0.69$.

A two-by-two table of this association between the exposure (macrosomia) and the outcome (shoulder dystocia) can be populated (Table 189.5). The bottom margin is populated based on the prevalence of shoulder dystocia from Table 189.3 (0.01); the right margin is populated based on the prevalence of macrosomia from Table 189.3 (0.10). Cells '*a*' and '*c*' are populated based on the posterior probability $P[M^+|S^+]=0.69$ (7/10). Cells '*b*' and '*d*' are populated when '*a*' and '*c*' are subtracted from 'n_1' and 'n_0', respectively.

Note that $P[S^+|M^+]=7/100=0.07$ and that $P[S^+|M^-]=3/900=0.0033$.

The 150 patients with a positive ultrasound finding of EFW > 4 kg (from Table 189.4), among whom 60 were macrosomic (n_1) and 90 were non-macrosomic (n_0), occupy the column margin of two-by-two (Table 189.6a).

The quantity '*a*' = $P[S^+|M^+]\times 60 = 0.07\times 60 = 4.2$. The quantity '*c*' = $P[S^+|M^-]\times 90 = 0.0033\times 90 = 0.3$.

The 850 patients with a negative ultrasound finding of EFW > 4 kg, among whom 40 were macrosomic (n_1) and 810 were non-macrosomic (n_0), occupy the column margin of two-by-two (Table 189.6b).

The quantity '*a*' = $P[S^+|M^+]\times 40 = 0.07\times 40 = 2.8$. The quantity '*c*' = $P[S^+|M^-]\times 810 = 0.0033\times 810 = 2.7$.

The marginal rows of Tables 189.6a and b are combined to show the association of ultrasound with shoulder dystocia (Table 189.7).

The original prior probabilities of positive ultrasounds (0.15) and shoulder dystocia (0.01) are preserved. Note that the odds ratio for the association of ultrasound findings of EFW > 4 kg and shoulder dystocia (Table 189.7),

$$\mathrm{OR}=\frac{(4.5\times 844.5)}{(5.5\times 145.5)}=4.75$$

substantially lower than the OR for the association of macrosomia and shoulder dystocia because the positive ultrasound group has normal-weight neonates

Table 189.6a Association between macrosomia and shoulder dystocia given a positive ultrasound finding

	−	5.5	844.5	$n_0 =$	850
		10	990	T	1000

	a	b	n_1
	c	d	n_0
	m_1	m_0	T

and the negative ultrasound group has some macrosomic neonates.

The association between diabetes and an ultrasound EFW > 4 kg can be determined as follows: Prior probabilities (from Table 189.3) of diabetes, $P[D^+]$, and of macrosomia, $P[M^+]$, are 0.05 and 0.10, respectively, as shown in the two-by-two table margins (Tables 189.8a and b).

The prior probability of diabetes, $P[D^+]$, is converted to the prior odds of diabetes, odds$[D^+]$, using formula (3). Odds$[D^+] = P[D^+]/(1 - P[D^+]) = 0.05/(1 - 0.05) = 0.053$.

An OR = 4.2 for macrosomia in diabetics relative to non-diabetics, as described previously, is used as a reasonable approximation of the RR.

Posterior Odds$[D^+|M^+]$ = OR × odds$[D^+]$ = $4.2 \times 0.053 = 0.223$

Posterior probability $P[D^+|M^+] = 1/(1 + 0.223) = 0.18$

Then the quantity 'a' in Table 189.8b = $P[D^+|M^+] \times 100 = 0.18 \times 100 = 18$. The values of '$b$' and '$c$' are determined by subtracting 'a' from 'n_1' and 'm_1', respectively. The value of 'd' is self-evident. Note that $P[D^+|M^-] = 32/900 = 0.036$.

The 150 patients with a positive ultrasound finding of EFW > 4 kg (from Table 189.4), among whom 60 were macrosomic, occupy the following two-by-two table row margin (Table 189.9a). The quantity 'a' = $P[D^+|M^+] \times 60 = 0.18 \times 60 = 10.8$. The quantity '$b$' = $P[D^+|M^-] = 0.036 \times 90 = 3.2$.

The 850 patients with a negative ultrasound finding of EFW > 4 kg (from Table 189.4), among whom 40 were macrosomic, occupy the following two-by-two table row margin (Table 189.9b). The quantity 'a' = $P[D^+|M^+] \times 40 = 0.18 \times 40 = 7.2$. The quantity '$b$' = $P[D^+|M^-] = 0.036 \times 810 = 29.2$.

The column margins from these two tables are combined in Table 189.10, which shows the association between diabetes and ultrasound findings. Note that

Table 189.8a Prior probabilities of diabetes and macrosomia

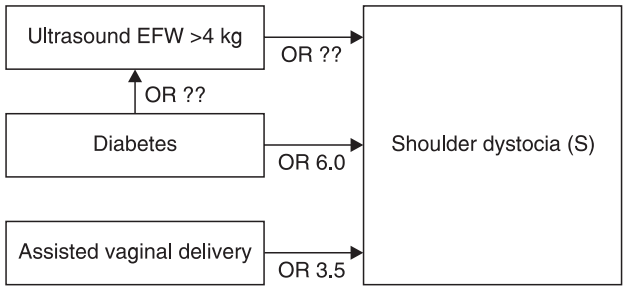

Figure 189.2 Unknown associations between prospective risk factors and shoulder dystocia.

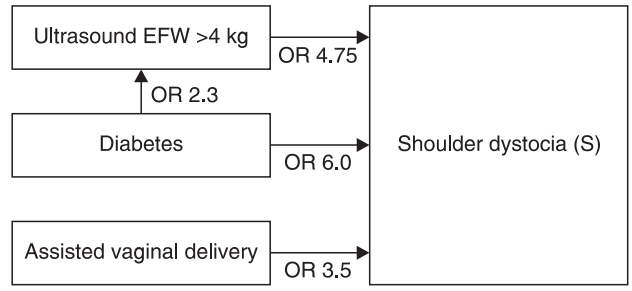

Figure 189.3 Results of Bayesian method to determine associations between prospective risk factors and shoulder dystocia.

Table 189.11 The effects of prospective risk factors (odds ratios)

Exposure (exp_i)	$OR_i = \frac{odds[S^+ \mid exp_i^+]}{odds[S^+ \mid exp_i^-]}$	Coefficients ($\ln(OR) = \beta_i$)
i=U, Ultrasound EFW > 4 kg	4.75	$\beta_M = 1.56$
i=A, assisted vaginal delivery*	3.5	$\beta_A = 1.25$
i=D, diabetes	6.0	$\beta_D = 1.79$

*Vacuum extraction or forceps vaginal delivery

the prevalence of a positive ultrasound finding (0.15) and of diabetes (0.05) is preserved. The odds ratio for an ultrasound EFW > 4 kg in diabetics relative to non-diabetics,

$$OR = ((a \times d)/(b \times c)) = ((14 \times 814)/(36 \times 136)) = 2.3,$$

is lower than the odds ratio describing the association of diabetes with macrosomia due to the misclassification of macrosomia by ultrasound as was described earlier.

The unknown effects in Figure 189.2 can now be replaced with these estimates determined using Bayesian methods (Figure 189.3).

Table 189.11 summarizes the selected odds ratios and their coefficients for these prospective risk factors. There are $2^3 = 8$ linear combinations of three exposures, each having two levels (present and absent). These combinations are as follows:

Assisted vaginal delivery (A^+)

	Ultrasound Present	Ultrasound Absent
Diabetes Present	$U^+D^+A^+$	$U^-D^+A^+$
Absent	$U^+D^-A^+$	$U^-D^-A^+$

Spontaneous vaginal delivery (A^-)

	Ultrasound Present	Ultrasound Absent
Diabetes Present	$U^+D^+A^-$	$U^-D^+A^-$
Absent	$U^+D^-A^-$	$U^-D^-A^-$

Scores are obtained by finding, for each combination, the odds ratio or the odds of shoulder dystocia in a given exposure combination divided by the odds of shoulder dystocia in a referent group. The referent group having no risk factors, i.e., where the values of all exposures (x_is) are zero, consists of patients with negative ultrasounds who are non-diabetic and have no indication for assisted vaginal delivery ($U^-D^-A^-$). These odds ratios for exposure combinations are obtained by exponentiating sums of the product terms, $\beta_i(x_{ia} - x_{ib})$, where β_is are the coefficients of individual exposures and $(x_{ia} - x_{ib})$ are the differences between values of individual exposures contrasting the combination of interest (group a) and the referent group (group b) as shown by Formula (13).

For instance, the odds ratio for shoulder dystocia (S) contrasting patients with an ultrasound EFW > 4000 g who are non-diabetic and have an indication for an assisted vaginal delivery, $U^+D^-A^+$, relative to the referent group having no risk factors, $U^-D^-A^-$, is determined based on the exposure differences, $(U^+ - U^- = 1 - 0 = 1)$, $(D^- - D^- = 0 - 0 = 0)$, and $(A^+ - A^- = 1 - 0 = 1)$ where U^+, D^+, and A^+ have the values 1, and U^-, D^-, and A^- have the values 0. The coefficient for each exposure is shown in Table 189.11.

$$OR = odds[S^+ \mid U^+D^-A^+]/odds[S^+ \mid U^-D^-A^-] =$$

$$e^{\beta_U(1-0)+\beta_D(0-0)+\beta_A(1-0)} = e^{\beta_U+\beta_A} = e^{1.56+1.26} = e^{2.81} = 16.6$$

The resulting odds ratios for all exposure combinations, which are the risk scores, are shown in Table 189.12.

Table 189.12 Odds ratios (risk scores) for exposure combinations

Exposure combination	OR	Formula	OR
$U^-D^-A^-$	$e^0=$	e^0	1
$U^-D^-A^+$	$e^{\beta_A}=$	$e^{1.25}$	3.5

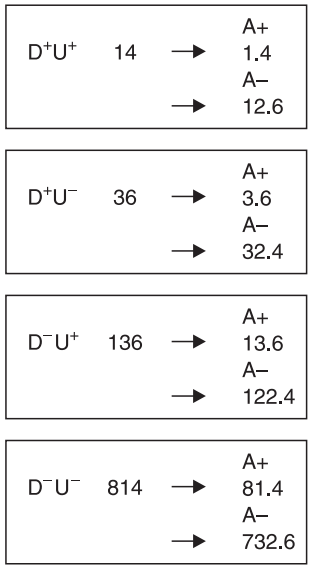

Figure 189.4 Combinations of diabetes and ultrasound stratified by assisted vaginal delivery.

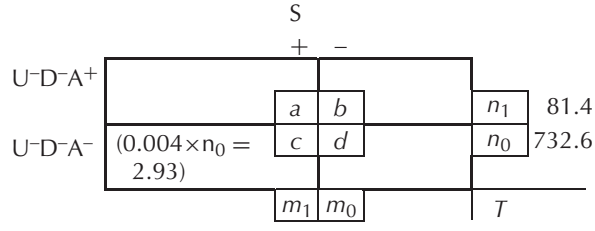
Joint distribution of combinations of risk factors for shoulder dystocia

Given three risk factors for shoulder dystocia, namely ultrasound EFW > 4000 g (U), diabetes (D), and indication for assisted vaginal delivery (A), that have binary (dichotomous) values [either present (+) or absent (–)] we would like to know the joint probability distribution of the resulting combinations for which we now have risk scores.

From Table 189.10, we have the number with each combination of D and U. We assume for our purposes that the assisted vaginal deliveries (or the indications for operative vaginal delivery) are not conditioned on diabetes or ultrasound findings. Therefore, the prevalence of assisted vaginal delivery ($P[A^+]=0.10$) is presumed to be constant across all strata of diabetes and ultrasound findings (Figure 189.4).

Table 189.13 shows the final distribution of exposure combinations rank-ordered by risk scores. The receiver–operator characteristics for various score thresholds can then be determined. Any combination, e.g., $U^-D^-A^+$, relative to the referent group, $U^-D^-A^-$, can be shown in a two-by-two table. Assume that the probability of shoulder dystocia in the lowest risk group, $P[S^+ | U^-D^-A^-]=0.004$ (the reason for the choice of this probability will become clear). The two-by-two table quantity 'n_1' is N in Table 189.13 for the exposure $U^-D^-A^+$; the quantity 'n_0' is N for the exposure $U^-D^-A^-$. The quantity 'c' = $P[S^+ | U^-D^-A^-] \times n_0 = 0.004 \times 732.6 = 2.93$. This is the number of shoulder dystocia cases ($N_{(\text{shoulder dystocia})}$) contributed by the $U^-D^-A^-$ exposure group (see Table 189.14)



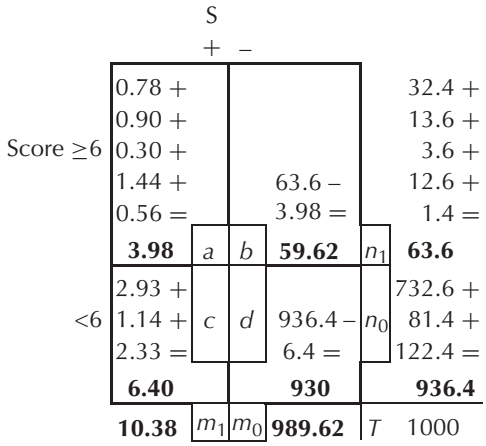
The prior odds of the exposure $U^-D^-A^+$ (where non-exposed = $U^-D^-A^-$) = $n_1/n_0 = 81.4/732.6 = 0.111$.

Recall that posterior odds of exposure given disease = OR × prior odds of exposure. The odds ratio from Table 189.12 is 3.5. Therefore,

posterior odds, $P[U^-D^-A^+ | S^+] = 3.5 \times 0.111 = 0.39$

This posterior odds of exposure given disease, in two-by-two table notation, is a/c = 0.39. By rearrangement, a = 0.39 × c. The quantity 'c', from above, is 2.93. Therefore, the quantity 'a' = 0.39 × 2.93 = 1.14. This is the number of shoulder dystocia cases ($N_{(\text{shoulder dystocia})}$) contributed by the $U^-D^-A^+$ exposure group (see Table 189.14).

Table 189.14 shows the prior and posterior odds, calculated in a similar fashion, for the remaining exposure combinations and the resulting distribution of shoulder dystocia cases. Note that there are 10 shoulder dystocia cases across all exposure combinations that



form the total population of 1000 subjects. In choosing a shoulder dystocia prevalence of 0.004 in the lowest-risk group ($U^-D^-A^-$), the original shoulder dystocia prevalence of 0.01 across all groups was preserved.

Table 189.13 and 189.14 were used to construct, for each score threshold, a table of sensitivities and specificities. Using a score threshold of 6 or higher, for example, the quantity 'n_1' in a two-by-two table, corresponding to the number of exposed (the number with a score ≥ 6) is found by summing the N's in Table 189.13 for OR's (risk scores) 6 and higher. The quantity 'n_0' is the sum of N's in table 189.13 for OR's < 6. The quantity 'a', corresponding to the number exposed and diseased (the number with a score ≥6 and shoulder dystocia) is found by summing the N's in Table 189.14

Table 189.14 Determination of probability distribution of shoulder dystocia by risk scores

Combination	OR (score)	N (total)	Prior odds of exposure	Posterior odds of exposure	*N* (shoulder dystocia)

for OR's 6 and higher. The quantity 'b' is the sum of N's in Table 189.14 for OR's <6. The remaining quantities are found by differences or sums. The quantity 'b' is n_1−a, 'd' is n_0−c, 'm_1' is a+c, and 'm_0' is b+d.

Sensitivity at this score threshold, $P[\text{Score} \geq 6 \mid S^+] = 3.98/10.38 = 0.38$. Specificity, $P[\text{Score} < 6 \mid S^-] = 930/989.62 = 0.94$. 1−specificity (the false-positive rate) = 0.06.

Similarly, the sensitivities and false-positive rates (1−specificity) for each score threshold were used to create Table 189.15.

The receiver–operator characteristics of the risk score are displayed in Table 189.16 and in Figure 189.5. We will explore the choice of a threshold value of the risk score at or above which cesarean section might be recommended to prevent shoulder dystocia. As noted, Langer *et al.*, based on literature review, reported that shoulder dystocia prevalence ranged from 0.001 to 0.17.[4] First, assume that baseline prevalence of shoulder dystocia in the population of interest is low (0.001). The baseline prevalence of shoulder dystocia affects the number needed to treat (NNT) or the number of cesarean sections required to prevent a single case of shoulder dystocia. The risk of shoulder dystocia in cesarean section, $\text{risk}_{(\text{cesarean})}$, is presumed to be zero. The risk of shoulder dystocia in vaginally delivered neonates, $\text{risk}_{(\text{vaginal})}$, is shown in Table 189.17. The absolute risk reduction (ARR) is the risk difference, $(\text{risk}_{(\text{vaginal})} - \text{risk}_{(\text{cesarean})})$. NNT = 1/ARR

≥3.5 vs. <3.5	333	267	600	1333	0.450
≥4.75 vs. <4.75	333	186	519	1333	0.389
≥6 vs. <6	333	64	397	1333	0.298
≥16.6 vs. <16.6	333	31	364	1333	0.273
≥21 vs. <21	333	18	351	1333	0.263
≥28.5 vs. <28.5	333	14	347	1333	0.260
≥99.75 vs. <99.75	333	1	334	1333	0.251

which, in this case where the risk in cesarean section is zero, equals $1/risk_{(vaginal)}$.

The risk scoring system in this low-prevalence scenario has no value. Even the highest risk score of 99.75 is an unacceptable threshold since 25 cesarean sections are required to prevent a single case of shoulder dystocia. Even then, only 10% of shoulder dystocia cases would be prevented.

When the baseline prevalence of shoulder dystocia in the population of interest is at the upper end of the range reported by Langer *et al.* ($P[S^+]=0.017$), $risk_{(vaginal)}$, is consequently higher and the NNT (number of cesarean sections to prevent a single case of shoulder dystocia) is lower, as shown in Table 189.18.

In this high-prevalence scenario, the risk scoring system performs quite well. A score threshold of 16.6 requires 6 cesarean sections to prevent a single case of shoulder dystocia and prevents nearly one-third of all shoulder dystocias.

We assume that our population, $T=1000$, consists only of vaginally delivered patients. Assume that the cesarean section rate is 25%. Let $x=$the baseline number of cesarean sections. Then,

$$0.25(x+1000)=x$$

$$0.25x+250=x$$

$$250=x-0.25x=0.75x$$

$x=250/0.75=333$ cesarean sections (at baseline).

The total number delivered is 1000 + 333 = 1333 by vaginal and abdominal routes. The number of additional cesarean sections (the number who are 'test positive') is added to the baseline number of 333 and the new cesarean section rate is calculated for each risk score, as shown in Table 189.19.

The risk score of 16.6 seems to be an acceptable threshold that would result in 31 additional cesarean sections, an increase in the cesarean section rate from 25% to 27%, and prevention of nearly one-third of 17 shoulder dystocia cases.

Practical issues

Prior probabilities of shoulder dystocia, macrosomia, diabetes, and assisted deliveries were selected from the literature, as were the effects of risk factors on shoulder dystocia and of diabetes on macrosomia, as well as the test characteristics (sensitivity and specificity) of ultrasound for diagnosis of macrosomia. While I used the midpoints of reported prevalence ranges, I used the highest reported estimates of effects. This suffices for illustration, but the reader is cautioned that a risk scoring system should ideally be examined across the full range of prior probabilities and effect estimates during a process of *sensitivity analysis*. The importance of sensitivity analysis is illustrated by the exploration of 'number needed to treat' across a range of shoulder dystocia prevalence. The risk scoring system had no value when the shoulder dystocia prevalence was at the lowest end of the range reported in the literature. Finally, I took the liberty of using unadjusted effect estimates since few adjusted estimates are available. Obviously, adjusted estimates are required before a model is suitable for further testing. Before a risk scoring system is put into practice, it should be tested against recent data from the actual population in which it will be used. Such data are often not available. However, as electronic patient records become increasingly available, there will emerge databases with a sufficient number of discretely coded variables to allow model testing. For that matter, such databases will provide more accurate prior probabilities and allow for logistic regression modeling to obtain adjusted effect estimates that are often not available from the literature. Regression modeling should be performed against a portion of the database; the remainder of the data are reserved for testing whether the resulting scoring system performs as expected against novel data.

190 Periconception care

A. Grunebaum

Introduction

Prenatal care is an important intervention in the early diagnosis and prevention of adverse pregnancy outcome. Since the introduction of prenatal care, early in the last century, women have been advised by their obstetricians to register for prenatal care only after they miss their period or when their pregnancy has been confirmed, and many obstetricians do not even give their patients an appointment for the first prenatal visit until late in the first trimester.

Periconception care, caring for couples before pregnancy, on the other hand is a relatively new approach to improve pregnancy outcome.

In its 'Healthy People 2010' report, the US Public Health Service has underscored the importance of preconception care by including several recommendations promoting the health of women before pregnancy (www.health.gov/healthypeople/). Benefits of periconception care, such as the early identification of potential problems and medical treatment before pregnancy, seem apparent, yet only recently evidence has emerged supporting improved outcomes in certain conditions (e.g. diabetes mellitus, phenylketonuria, and a previous pregnancy with a fetus with a neural tube defect).[1–3] De Weerd has shown that two of the major components of preconception care, smoking cessation and folic acid supplementation, can lead to a significant cost-saving balance.[4]

Periconception care begins prior to pregnancy at a time when preparations for pregnancy can be made. Periconception care usually involves one or more meetings prior to pregnancy between the couple trying to conceive and a doctor or another health care provider who is experienced in this area. Any doctor with interest in this area can provide many aspects of periconception care, but the obstetrician and gynecologist are best trained to handle most aspects of periconception care.

There is an evolving science showing that seeing a doctor prior to pregnancy, when the couple starts thinking about a family, can improve pregnancy outcomes for both the mother and the baby.

Since up to 50% of pregnancies are unintended,[5,6] promoting health and healthy lifestyles prior to pregnancy is crucial among all childbearing couples, especially as planned pregnancies have better outcomes than unplanned ones.[7] Thus, the overall goal of periconceptional care is to ensure that:

(1) Women and men are in their best health and practice healthy lifestyles before conception.
(2) Couples become aware that preconception, conception, pregnancy, birth, and childrearing are a continuum in which earlier events affect the present and the future.
(3) Physicians and care providers are able to identify prior to conception any issues and resolve them without being concerned about the ongoing pregnancy.

The best example of how periconception care can improve pregnancy outcome is supplementation with folic acid. An increase in the intake of folic acid among women planning a pregnancy was shown to prevent most neural tube defects.[8,9]

Freda *et al.*[10] summarized the thinking about preconception health into the following acronym: REFRAMED: Reproductive awareness; Environemental toxicants and teratogens; Folic acid supplementation; Review genetic history; Alcohol, tobacco, and other substance use; Medical conditions and medications; Evaluate immunizations and infectious diseases; Domestic violence and psychosocial issues.

The key elements of preconception care include the following.

(1) Obtaining a thorough personal, medical, and family history of the potential mother and father and an assessment of the health of both potential parents, although a greater emphasis is usually placed on that of the mother.
(2) Obtaining a genetic history about family members with genetic problems and congenital birth defects and conditions like hypertension, diabetes, mental retardation, blindness, and deafness and testing if indicated.
(3) Review of the reproductive and gynecologic history and prior pregnancies.

(4) Reviewing the couple's daily living habits and the environment, reviewing medications both prescription and over the counter and screening for exposure to potentially harmful substances both at home or at work; reviewing weight, diet, and food and providing specific nutritional and exercise counseling.
(5) Review and optimization of fertility.
(6) Medical and gynecologic examination, reviewing and screening for infectious diseases, and updating immunizations performing additional tests if indicated [e.g. blood samples and other tests of both parents if indicated, for example, human immunodeficiency virus (HIV), infectious diseases, and genetic predisposition].
(7) Male periconception counseling.

The key elements of periconception counseling include the following:

(1) Medical history and medication review
- Diabetes – identify prior to pregnancy and optimize control.
- Hypertension – avoid angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, and thiazide diuretics.
- Epilepsy – optimize control; folic acid, 1 mg/day.
- Deep venous thrombosis (DVT) – switch from warfarin (Coumadin) to heparin.
- Depression/anxiety – avoid benzodiazepines.

(2) Genetic history
- Review family history of genetic issues.
- Carrier screening (ethnic background): sickle cell anemia, thalassemia, Tay–Sachs disease.
- Carrier screening (family history): cystic fibrosis, non-syndromic hearing loss (connexin-26).

(3) Reproductive and gynecologic history
- Review prior pregnancy outcomes and counsel about recurrence.
- Review prior gynecologic history.
- Review history of pelvic inflammatory disease (PID) or other tubal issues.

(4) Living environment: diet, weight, food, and medications
- Folic acid supplement (400 μg routine, 1 mg diabetes/epilepsy, 4 mg previous neural tube defect).
- Assess weight, calculate body mass index (BMI), advise optimal BMI.
- Recommend regular exercise in moderation.
- Avoid hyperthermia (hot tubs, overheating).
- Assess risk of nutritional deficiencies (vegan, pica, milk intolerance, calcium or iron deficiency).
- Avoid overuse of vitamin A (limit to 3000 IU/day) and vitamin D (limit to 400 IU/day).
- Limit caffeine to two cups of coffee or six glasses of soda per day.
- Screen for domestic violence
- Household chemicals – avoid paint thinners and strippers, other solvents, and pesticides.
- Smoking cessation and avoidance of secondary smoking.
- Screen for alcoholism and use of illegal drugs.

(5) Fertility review and optimization
- Assess for regular ovulation, signs of polycystic ovarian syndrome (PCOS).
- Discuss fertility after birth control.
- Review frequency and timing of sexual intercourse.
- Refrain from using lubricants.

(6) Medical examination and testing; immunization
- Test for infectious diseases (e.g. HIV, syphilis).
- Hepatitis B immunization for at-risk patients.
- Preconception immunizations (rubella, varicella).
- Counsel about avoidance of infections [e.g. toxoplasmosis, cytomegalovirus (CMV), and parvovirus B19].
- Suggest a dental examination.

(7) Male periconception counseling and assessment
- Medical history and review.
- Review of potentially harmful exposure.
- Avoid exposure to heat.
- Avoid alcohol and smoking and other harmful substances.
- Suggest sperm analysis.

Medical history and health assessment

The first step

Because many medical problems place the mother and the fetus at risk,[11] the first step in identifying potential issues is to obtain a good medical and social history. Many doctors have their patients' first fill in a periconception questionnaire or health assessment form. This questionnaire can help in the counseling and care process and organizes the periconceptual approach.[12] Filling out this questionnaire is not only time-saving, but it also allows for a complete evaluation of the couple's medical and surgical history. In addition, it allows enough time to consider all answers and helps the provider to focus only on the significant issues.

Below is a sample questionnaire, which can be individualized for each special circumstance:

Sample periconception patient questionnaire

	Yes	No
Are you taking any prescription drugs?		
Are you using birth control pills or other hormonal contraceptives?		
Do you use over-the-counter (non-prescription) drugs?		
Do you take any vitamins, minerals, herbal supplements, or other food supplements?		
Do you take a multivitamin containing 0.4 mg of folic acid every day?		
Do you use any recreational or street drugs (e.g. marijuana, cocaine, crack, etc.)?		
Do you smoke cigarettes? If yes, how many per day?		
Do you breathe second-hand smoke?		
Do you drink beer, wine, or hard liquor?		
How many drinks does it take to make you feel high?		
Have people annoyed you by criticizing your drinking?		
Have you felt you ought to cut down on your drinking?		
Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover?		
Have you recently seen a dentist?		
Are you over- or underweight?		
Personal information: Tell us about you and your partner		
Family and genetic history: Tell us about your family and your genetic history		
Your daily living and the environment: Tell us about your daily routines and your environment.		
Are you exposed to any harmful agents?		
Diet and food: Tell us about your diet and food		
Trying to conceive history: Tell us about your attempts trying to conceive		
Gynecologic history: Tell us about your gynecologic history		
Medical history: Tell us about your medical history		
Infections: Have you ever had an infection or a sexually transmitted disease?		
Immunizations: Are you immunized against common childhood diseases and hepatitis B?		
Prior pregnancies: Tell us about your prior pregnancies		
What is your ethnic background?		
Have you or the baby's father ever been screened for special diseases related to your ethnic background?		
Have you or your partner had a baby with a genetic (inherited) problem or have there been any birth defects or mental retardation in the family?		
Does anybody in the family have a history of a genetic disease, such as cystic fibrosis, Tay–Sachs disease, hemophilia?		
Do you have a close family member with a medical condition, such as diabetes or a history of seizures?		
Did your mother have toxemia or high blood pressure in any of her pregnancies?		
Do you or a close family member have a history of blood clots?		
Do you have a close family member with ovarian or breast cancer?		

Please enter here and explain for any question where you checked a 'YES'.

Diabetes mellitus

Women with poorly controlled diabetes have a significantly higher rate of spontaneous abortion and increased risk of severe fetal anomalies compared with women who have good control. Preconception diabetic management decreases the risk of abortions and congenital anomalies and lessens the complications of pregnancy. Preconception is the optimal time to identify, evaluate, and treat hypertension, nephropathy, retinopathy, and thyroid disease in these patients and provide counseling on risks of pregnancy, requirement for increased visits, and close monitoring. In addition, periconception provides the opportunity to evaluate patients for relative contraindications to pregnancy, such as those with blood urea nitrogen greater than 30 mg/dl (10.7 mmol/l), low creatinine clearance, and coronary artery disease.

Hypertension

Most patients with chronic hypertension can expect an uncomplicated pregnancy, but will require

enhanced monitoring for the risks of pre-eclampsia, renal insufficiency, and fetal growth retardation. It is important that women with hypertension be evaluated before pregnancy to determine the severity of the hypertension and to recommend potential lifestyle modifications. Preconception is the best time to review and change medications for use during pregnancy. Methyldopa (Aldomet) and calcium channel blockers are commonly used during pregnancy. Drugs that should be avoided in the first and second trimesters of pregnancy are ACE inhibitors, angiotensin II receptor antagonists, and thiazide diuretics, which are associated with congenital defects.

Epilepsy

The incidence of malformations in infants of mothers with epilepsy who are treated with antiepileptic drugs is two to three times that of infants of mothers without epilepsy,[13] and they also have an increased risk of developing epilepsy. Preconception counseling should include optimizing seizure control, prescribing folic acid supplements, 1–4 mg/day, and offering referral to a genetic counselor. When possible, use of multiple anticonvulsants should be avoided. Using a single agent for the seizure type at the lowest protective level is preferable, and there is no single drug of choice. If a patient has been seizure-free for 2 years or longer, drug discontinuation with a long taper period (3 months) may be successful in individual cases, and tapering should begin 6 months prior to conception.[14]

Thromboembolism

Women with a history of a DVT have a 7–12% risk of recurrence during pregnancy, and those with a personal or family history of venous thromboembolism should be offered testing for thrombophilia before pregnancy. Those on warfarin (Coumadin) as maintenance therapy for DVT should be switched to heparin before conception, because warfarin is teratogenic. Heparin (in regular or low-molecular weight form) is indicated for prophylaxis and should be started as early in pregnancy as possible.

Depression and anxiety

About 10% of pregnant women have depression. Tricyclic antidepressants and selective serotonin reuptake inhibitors have not been shown to cause any teratogenic effects and may be used before conception. Rarely, maternal use of benzodiazepines has been associated with anomalies, such as cleft lip and palate, as well as a withdrawal syndrome in the newborn.

Asthma

Asthma is one of the most common medical illnesses likely to occur in women of childbearing age, with approximately 1% of pregnancies complicated by asthma. Optimizing preconceptional asthma control and reviewing use of the peak flow meter and personal best surveillance, and offering influenza vaccine ensures that the patient begins her pregnancy in optimal condition. The fewest medications needed to control symptoms of asthma should be recommended.

Cardiac diseases

Maternal morbidity from cardiac diseases is as high as 7% in combined New York Heart Association classes III and IV heart disease, compared to only 0.5% in combined classes I and II. Certain cardiac disorders, such as primary pulmonary hypertension, place women at very high risk during pregnancy (maternal mortality approaches 50%) and counseling prior to pregnancy may help couples decide on the best course. The preconception evaluation should therefore identify cardiac disease risk factors, determine the extent of disease, identify correctable problems, and provide the patient with detailed information about maternal and fetal risks. Close consultation before and during pregnancy with a cardiologist may help guide a patient though the pregnancy.

Autoimmune disorders

Autoimmune disorders, such as lupus, are not unusual among women of childbearing age. Patients should be counseled that the best time to attempt conception is during periods of inactive disease. Even women with quiescent disease or a distant history of disease should be carefully evaluated and counseled about maternal and fetal risks.

Obtaining a genetic history

Genetic issues

The woman's family history and ethnicity for genetic disorders (such as cystic fibrosis, sickle cell anemia, and Tay–Sachs disease) and malformations (such as neural tube defects) should be reviewed thoroughly during the periconception visit. The clinician should consider referring the patient to a genetic counselor or maternal–fetal specialist if there is a personal or family history of a child with a potential genetic disorder or if advanced maternal age is an issue.

Advanced maternal age

The periconception time period is the optimal time to educate patients about a woman's fertility 'biologic

time clock' and the purposes and techniques of prenatal diagnosis during pregnancy.

Women becoming pregnant at more advanced ages are at increased risk of

- Infertility
- Having fetuses with chromosomal abnormalities
- An increased likelihood of chronic medical illness.

Advanced maternal age is becoming more common as women postpone pregnancy because of educational and career goals. Many women are postponing childbearing until after age 35 years, which poses a higher risk of medical problems during pregnancy and chromosomal abnormalities in the fetus. Older couples should be counseled about genetic risks and the availability of antenatal testing (amniocentesis and chorionic villus sampling), which may not be options if the first visit for prenatal care is delayed. The risk of infertility also increases with age, rising to 20% in couples older than 35 years.

Carrier screening

The ethnic background of either partner determines whether genetic screening should be recommended for sickle cell trait, thalassemias, and Tay–Sachs disease carrier state. A family history that is positive for certain diseases, such as cystic fibrosis and congenital hearing loss, indicates the need for additional screening. The American College of Obstetricians and Gynecologists recommends that screening for Tay–Sachs disease, Canavan disease, cystic fibrosis, and familial dysautonomia should be offered for couples of Ashkenazi Jewish ancestry.[15]

Carrier screening by ethnicity

Ethnic origin	Screening recommended	Test	Frequency(%)
Black	Sickle cell trait	Sickle cell smear	10
	β-thalassemia	MCV < 70	5
European Jewish	Tay–Sachs disease carrier; Canavan, cystic fibrosis, familial dysautonomia	Hexosaminidase A	4
French Canadian	Tay-Sachs disease carrier	Hexosaminidase A	> 5
Mediterranean	α-, β-thalassemia	MCV < 70	10–20
Southeast Asian (Laotian, Thai, Cambodian, Hmong)	α-, β-thalassemia	MCV < 70	20–40
Indian, Middle Eastern	Sickle cell trait	Sickle cell smear	Unknown
	α-, β-thalassemia	MCV < 70	Unknown

MCV, mean corpuscular volume
From Cowchock *et al.*[16]

Thromboembolic disease

A family history of thromboembolic disease may identify a woman at risk for pregnancy complications and requires a thorough workup prior to pregnancy.

A reproductive and gynecologic history and review of prior pregnancies

The time prior to pregnancy is the optimal time to review gynecologic and prior pregnancy issues and counsel couples about improving health and future pregnancy outcomes. A review of the gynecologic and obstetric history can identify possible signs of infertility or issues that may affect future pregnancies.

Are menstrual periods regular or irregular and are there signs of PCOS? Patients with irregular periods may have hormonal and ovulation problems or may have PCOS. Treating these problems will improve the patients' chances of getting pregnant. Patients with a history of recurrent miscarriages may benefit from a workup and baby aspirin prior to pregnancy.

Previous pregnancy complications, such as a history of a preterm delivery, a baby with intrauterine growth restriction, diabetes, hypertension, or pre-eclampsia, have an increased risk of repeating in future pregnancies and should be assessed prior to the next pregnancy.

If the patient has had a history of PID, then testing for fallopian tube patency may save many months of futile attempts attempting to get pregnant. Patients with a history of prior ectopic pregnancies have a 20-fold increased risk and should be counseled to see a doctor as soon as they believe that they are pregnant.

Living environment: diet, weight, and food

Exposure to harmful agents

In a retrospective, register-based cohort study[17] of 43,470 pregnant women, there were 20.4% of women who purchased at least one drug classified as potentially harmful during pregnancy, and 3.4% purchased at least one drug classified as clearly harmful. The authors concluded that their study places emphasis on the need for careful prepregnancy counseling. Preconception care should review exposure to any potentially harmful drugs, review the need to take them, and offer alternatives. Drug or chemical exposure causes 3–6% of anomalies and periconception care is ideal to prevent potential teratogenic effects on the developing fetus by stopping harmful influences or switching to safer medications. The Food and Drug Administration (FDA) has defined risk factor designations A, B, C, D, and X to classify drugs used during pregnancy. Category X drugs should never be used during pregnancy and while trying to conceive. Category X drugs include

- Folic acid antagonsist
- Warfarin
- Isotretinoin
- Valproic acid (should be avoided by all women likely to become pregnant).[5]

Periconception retinoic acid can lead to fetal embryopathy[18] and the American College of Obstetricians and Gynecologists recommends that pregnant and preconceptional women should avoid taking more than 5000 IU of vitamin A daily, though one study showed no association between periconceptional vitamin A exposures at doses of > 8000 IU/day or > 10,000 IU/day and malformations in general.[19]

Alcohol

Alcohol consumption during pregnancy can lead to adverse pregnancy outcome, such as fetal alcohol syndrome and lower birth weight babies,[20,21] and many women stop consuming alcohol once they know that they are pregnant. But there is also an adverse effect on alcohol on women who are trying to conceive as it decreases their fertility and increases their risk of having a miscarriage. Alcohol consumption prior to conception is a potential risk factor to fetal outcome and an important consideration for those females planning to have children. In a study involving mice,[22] long-term alcohol exposure prior to conception resulted in lower fetal body weights. The authors showed that fetal growth and development can be affected by alcohol consumption even prior to the time of conception. However, even modest amounts of alcohol consumption during pregnancy can cause a negative impact on the fetus.[21]

The Surgeon General in the USA has advised that 'the best way to improve pregnancy outcome is to not drink any alcohol when you are trying to conceive and during pregnancy'.

Smoking

Approximately 18% of pregnant women in the USA report smoking tobacco and their pregnancy is at increased risk for such complications as abruptio placenta, pre-eclampsia, and preterm labor.[23] Additionally, tobacco is associated with decreased fertility rates and increased oocyte depletion rates as well as ectopic pregnancy.[24] Periconception is thus the optimal time to inform women about the risks associated with smoking prior to and during pregnancy.

Environmental toxins and exposure

Women trying to conceive and pregnant women should minimize the use of common household products, such as paint and paint removal products, bleaches, lye, and oven cleaners. A detailed occupational history, including household and hobby activities, occupational exposure to organic solvents, anesthetic gases, and antineoplastic agents, can reveal potential teratogenic exposures. Women susceptible to toxoplasmosis should be advised to stay away from undercooked meat sources and have someone else change the cat litter.

Folic acid supplementation

A minimum of 400 μg folic acid supplementation with or without a multivitamin decreases the risk of fetal malformations, such as neural tube defects, miscarriages, and cardiac malformations.[25,26] This positive effect can only be achieved when the supplement is taken prior to conception, at least 1–2 months before conception. In the USA, the average woman receives about 100 μg of folic acid/day from fortified breads and grains. Women trying to conceive and beginning at least 1–2 months before conception and continuing through the first 3 months of pregnancy should take a daily vitamin supplement containing at least 400 μg of folic acid. Higher dosages are indicated for special-risk groups. A dosage of 1 mg/day is recommended for women with diabetes mellitus or epilepsy. Mothers who have given birth to children with neural tube defects should take 4 mg of folic acid/day for subsequent pregnancies. Studies have shown that addressing folic acid use even at a single periconception visit can significantly improve mean red cell folate levels.[27]

Diet

Women trying to conceive and pregnant women should have a diet rich in iron, calcium, vitamins B, and low in saturated fats.[28] There are even diets suggested for women to improve fertility.[29] Except for added calories during pregnancy, women trying to conceive should follow the same diet as if they were already pregnant. If a diet deficiency is identified, a visit with a dietician may help the woman understand the importance of a healthy diet.

Caffeine

A high caffeine intake delays conception[30] and increases the risk for a miscarriage.[31] Women therefore should be advised to have not more than 300 mg of caffeine/day, which is equal to two 5-oz. cups of coffee, three 5-oz. cups of tea, or two 12-oz. glasses of caffeinated soda.

Fish

Mercury can have a deleterious effect on the developing fetus and there is evidence that especially large fish can contain excessive amounts of mercury. To prevent potential mercury toxicity on the fetus, the American FDA recommends the following for fish consumption before, during, and after pregnancy:

- *Fish to be avoided*: shark, swordfish, king mackerel, tile fish.
- *Fish to be limited*: a total of no more than 12 oz. per week of shellfish, canned fish, canned tuna, or farm-raised fish.

Weight

Both extremes of a woman's weight can lead to decreased fertility and an increase in adverse pregnancy outcomes. Women who are underweight (BMI < 20) are less likely to ovulate, have amenorrhea, infertility, and a low birth weight baby.[32] Obesity also has a negative effect on fertility and increases the risks for gestational diabetes, hypertension, preeclampsia, and cesarean section.[33] The optimal time to lose weight and try to reach an ideal weight (BMI 20–25) is before conception.

Exercise and nutrition

Regular moderate exercise is generally beneficial and the current evidence continues to demonstrate marked benefit to both the mother and the fetus if women exercise during pregnancy. The current recommendation is for women to continue their prepregnancy activity level when they become pregnant. Hyperthermia in the first trimester has been associated with increases in congenital anomalies. Pregnant women should limit vigorous exercise to avoid an increase in core body temperature above 38°C (100.4°F). They should be adequately hydrated, wear loose clothing, and avoid extreme environmental temperatures and not spend too long time periods in saunas or hot tubs.

Social risk factors

Pregnancy can be adversely affected by a woman's mental and social health and there is an association between pregnancy and risk of domestic violence.[34] The physician can use a simple four-question screening tool modeled after the CAGE questionnaire for alcoholism:

(1) How often does your partner hurt you?
(2) How often does your partner insult or talk down to you?
(3) How often are you threatened with physical harm?
(4) How often does your partner scream or curse at you?

Responses of 'often' or 'frequent' to any of these questions place the women at risk of domestic violence. The patient should receive information about community resources for battered women and emergency shelters.

Illegal drugs

Using illegal drugs during pregnancy can have deleterious effects on pregnancy outcome. Advising patients to stop these drugs prior to pregnancy and referring patients to drug treatment can improve their pregnancy outcome. Women using illegal drugs, such as cocaine, marijuana, or heroin, should be encouraged to quit before pregnancy. Cocaine use in pregnancy is associated with miscarriage, prematurity, growth retardation, and congenital defects, while marijuana use can cause prematurity and jitteriness in the neonate. Use of heroin may lead to intrauterine growth restriction, hyperactivity, and severe neonatal withdrawal syndrome. Women who use illegal drugs may need a referral to a special withdrawal program to be completed before conception. A methadone maintenance program is an alternative if the patient is unable to complete the withdrawal.

Environmental toxins

Hazard	Types	Associated outcomes	Sources of exposure
Metals	Lead	Abnormal sperm, menstrual disorders, miscarriages, stillbirths, mental retardation	Solder, lead pipes, batteries, paints, ceramics, smelter emissions
	Mercury	Impaired fetal motor and mental development	Thermometers, mirror coating, dyes, inks, pesticides, dental fillings, fish from contaminated waters
Solvents	Trichloroethylene, chloroform, benzene, toluene	Birth defects	Dry cleaning fluids, degreasers, paint strippers, drug, and electronics industries
Plastics	Vinyl chloride	Decreased fertility, chromosomal aberrations, miscarriages, stillbirths, birth defects	Plastic manufacturing
Pollutants	Polychlorinated biphenyl, polybrominated biphenyl	Low birth weight, stillbirths	Pesticides; carbonless copy paper; rubber, chemicals, and electronics industries; fire retardants; food chain
Pesticides	2,4,5-T and 2,4-D organophosphates	Birth defects, miscarriages, low birth weight	Farm, home, and garden insect sprays, wood treatment
Gases	Carbon monoxide	Low birth weight, stillbirths	Auto exhaust, furnaces, kerosene heaters, cigarette smoke
	Anesthetic gases	Decreased fertility, miscarriages, birth defects	Dental offices, operating rooms, chemicals industries
Radiation	Radiographs, radioactive materials	Sterility, birth defects	Medical and dental offices, electronics industries

Fertility review and optimization of fertility

Fertility review and testing

Women often assume that conception will happen quickly as soon as birth control has been stopped. However, only 50% of couples get pregnant after trying to get pregnant for 4–5 months, and 15% do not get pregnant even after trying for a year. Especially as women get older, they will encounter increased difficulties in getting pregnant. Any advice on how to improve fertility and maybe shorten the time period to get pregnant is important. Counseling couples about the basics of getting pregnant including timing and frequency of sexual intercourse and reviewing the mechanism of conception and the physiology of ovulation and the menstrual cycle is often crucial in helping them achieve a healthy pregnancy. Lubricants can decrease the chance of conceiving, and couples trying to conceive should be advised not to use any lubricants.

Unfortunately, many infertile couples are seen very late in their unsuccessful attempts to get pregnant. A quick review of fertility issues (e.g. regular ovulation and menstrual cycles, a history of PID, and a review of the mother's age) can assess whether an infertility evaluation may be indicated early on. For example, a sperm analysis is an easy test, which may be recommended before the attempt of trying to conceive. In about 50% of infertile couples there is a 'male' problem and if there is a problem it should be addressed before spending a long time trying to conceive in vain.

Conception after birth control

'When can I get pregnant after stopping the pill?' is among the first question women on the pill ask. There

are several different ways this question can be answered: First, there is the safety of getting pregnant after stopping the pill. Women should be informed that there is no known fetal harm if conception happens right after the pill is stopped. So, there is no medical need to wait for fetal reasons. However, it may take some time for regular fertility to begin after stopping the pill. Ovulation may happen as soon as 2 weeks after the pill has been stopped, but can sometimes take longer. Women should be advised to seek consultation if ovulation and the menstrual period have not returned within 2–3 months after the pill was stopped.

Many physicians advise waiting for at least one cycle before getting pregnant after removal of the intrauterine device. But there is little scientific evidence in this suggestion.

Medical and gynecologic examination, reviewing and screening for infectious diseases, and updating immunizations

Examination

The periconception examination should include a full physical examination (e.g. lung, breast, heart, abdomen, skin, extremities) as well as a gynecologic history and examination including a Pap smear and a culture for chlamydia and gonorrhea. The examination should focus on possible problems that may affect the pregnancy. If a mammogram is indicated it is best done prior to conception.

Screening for infectious diseases

During the preconception evaluation, a history of high-risk behavior, including multiple sexual partners, sexually transmitted diseases, blood transfusions, or intravenous drug abuse, should be obtained from both the patient and her sexual partner. In addition, safe sex for prevention of sexually transmitted diseases and early medical care for vaginal discharge should be discussed.[35] Testing a women and her husband for infectious diseases prior to pregnancy allows for early interventions, before the developing fetus can be potentially affected. A history of sexually transmitted diseases and a history of a prior ectopic pregnancy increase the risk of ectopic pregnancy.[36] Patients with those histories should be counseled to see their doctor as soon as they believe that they are pregnant. Depending on individual circumstances, clinicians may perform the following infection tests prior to pregnancy:

(1) HIV (both in husband and in wife)
(2) Syphilis (both in husband and in wife)
(3) Hepatitis B antigen and antibody (both in husband and in wife)
(4) Gonorrhea
(5) Chlamydia
(6) Testing for prior exposure to parvovirus
(7) Testing for prior exposure to CMV
(8) Testing for prior exposure to toxoplasma
(9) Testing for prior exposure to herpes (both in husband and in wife)
(10) Testing for varicella immunity
(11) Testing for rubella immunity.

Women susceptible to any of these should be counseled about immunization and about prevention of infections.

Human immunodeficiency virus

All sexually active women should be offered HIV testing. Most women who might transmit the HIV infection to their fetus are asymptomatic. Preconception testing for HIV is important because the Pediatric AIDS Clinical Trials Study Group has shown that treatment with zidovudine (Retrovir) reduces the risk of transmission to the fetus from 25.5% to 8.3%. Earlier treatment of HIV and other sexually transmitted diseases decreases the risk of transmission to the fetus. Vertical transmission results in an approximately 30% chance of fetal infection from an untreated HIV-positive mother, a risk that can be reduced substantially with preconception or early pregnancy treatment. During the preconception period, women should be educated about high-risk behavior and given advice on contraception.

Syphilis

The time prior to pregnancy is optimal to identify and treat syphilis because at that time there is no fetus yet to be concerned about giving appropriate medications.

Gonorrhea, chlamydia

Both of these organisms can lead to adverse pregnancy outcomes and to infertility if not treated appropriately. Treatment of both partners prior to pregnancy is preferred as it prevents unnecessary exposure of the fetus.

Hepatitis B and other immunizations

All women should be screened for hepatitis B, and those at high risk should be tested for the presence of both hepatitis B surface antigen and hepatitis Be antigen. The preconception time period is optimal to provide immunization and women who have not received the hepatitis B vaccine should be considered for immunization if they are at risk of sexually transmitted diseases or blood exposure. The vaccine may be given during pregnancy. Hepatitis B is the most common type of hepatitis in the USA.

Influenza

Pregnancy is considered a high-risk condition for influenza. According to CDC guidelines, all women who expect to be pregnant during the influenza season (November to April) should be vaccinated against influenza. The specific guidelines for immunizations for adults can be found under 'Update on Adult Immunization Recommendations of the Immunization Practices Advisory Committee' at www.cdc.gov/mmwr/preview/mmwrhtml/00025228.htm.

Rubella and varicella

Preconception evaluation should include tests for immunity to rubella and varicella. Women who have no immunity to varicella are at risk of development of varicella pneumonia, which has a maternal mortality rate as high as 40%. Because immunization against these includes live-virus vaccines, women should be advised not to get pregnant for at least 1 month after immunization.

Toxoplasmosis

Toxoplasmosis may cause congenital infections if the mother becomes infected during pregnancy, and testing during pregnancy can sometimes yield confusing results. Preconception is the optimal time to test for past exposure to toxoplasma. Currently, no immunizations are available for these infections. Women who have not previously been exposed to toxoplasmosis should be counseled to avoid contact with cat feces in litter boxes, wear gloves while gardening, and avoid eating raw or undercooked meat.[37]

CMV and parvovirus B19 (fifth disease)

CMV and parvovirus exposure in susceptible women is especially risky for child care and health care workers.[23] Periconception testing for CMV or toxoplasmosis may be advantageous in counseling women about infection prevention during pregnancy. Women with negative titers prior to pregnancy should receive extensive counseling on how to avoid infections during pregnancy. Persons at risk should wash their hands frequently and use gloves to prevent transmission.[38]

Dental hygiene

There has recently been scientific evidence that gum disease increases the risk of preterm delivery.[39,40] Therefore, every woman should have dental care and treatment prior to pregnancy and during pregnancy to prevent adverse outcomes.

Male periconception care

There is expanding scientific evidence of an association between male-associated health issues and pregnancy outcomes. Optimally, a couple should attend the periconception visit together and the woman's partner should be encouraged to be included in periconception counseling and care. Seeing the couple together allows the clinician to also educate men about risks, review their family history for genetic disorders, and screen for sexually transmitted diseases and sexual dysfunction, or refer them to a specialist. Paternal smoking as well as alcohol consumption have been associated with decreased fertility and adverse neonatal outcomes, such as low birth weight and an increased incidence of fetal malformations. It takes on average 10–11 weeks for sperms to be produced. To optimize male fertility, men should abstain from alcohol and tobacco, and exposure to potentially damaging substances for at least 3 months prior to conception. Other substances and chemicals may adversely affect spermatogenesis and male fertility. In addition, smoking by the father and passive smoking by the prospective mother can equally have a potential negative effect on pregnancy. Sperm production in the testes requires a temperature that is lower than the core body temperature. To maximize sperm production, men should therefore refrain from staying too long in saunas or hot tubs and prevent overheating of testes (e.g. not wear too tight pants).

Summary

Every obstetrician and gynecologist should focus on periconception care during each annual visit of women of childbearing age. Patients should be asked about conception plans and early prenatal care when a pregnancy is confirmed should be encouraged. Clinicians should encourage all women of childbearing age to receive periconception care, and some may require a periconception consultation with a maternal–fetal medicine or other specialist. Encourage women to eat a healthy diet, try to reach their optimal weight, not drink any alcohol and stay away from smoking, limit consumption of certain fish, and supplement their diet with folic acid (0.4 mg/day). Encourage couples to enhance their probability of conception with regular midcycle coitus, ovulation monitoring, and avoidance of lubricants that can decrease fertility. Suggest early evaluation if infertility is an issue, especially in women older than 35 years.

191 Maternal issues in thrombosis and thrombophilia

B. E. Grand and L. S. Voto

During normal pregnancy the hemostatic system changes to a hypercoagulable state. Pregnancy is associated with an increased risk of venous thrombosis, which is a leading cause of mortality at gestation.[1] Recently, acquired and inherited thrombophilia have been reported in women with early and late complications of pregnancy such as recurrent pregnancy loss, intrauterine growth restriction (IUGR), fetal loss and pre-eclampsia.[2,3]

Prevention and treatment of venous thromboembolism (VTE) and arterial thrombosis during pregnancy is an important issue. The relation of thrombophilia and fetal loss and the treatment of this complication are still controversial. This chapter focuses on recent advances in the management of thrombosis and thrombophilia in pregnancy with a special interest in the hematological aspects.

Hemostasis during normal pregnancy

Normal pregnancy is associated with an increase in clotting factors, a decrease of natural anticoagulants and an impairment of fibrinolytic activity. There is an increase in the concentration of fibrinogen, factors VIII, V, VII, IX, X, XII and von Willebrand factor. Protein C values remain within the normal non-pregnant range, while the protein S decreases during pregnancy. An acquired activated protein C (APC) resistance has also been described during pregnancy, and a reduction in the APC ratio has been associated with gestational vascular complications. There is an increase in the level of plasminogen activator inhibitor-2 (PAI-2) from the placenta, which leads to a reduction of fibrinolytic activity during the whole pregnancy, with a return to normal after delivery.[4] The D-dimer is elevated during pregnancy and may reflect increased coagulation activation and thrombin generation with increased secondary fibrinolysis. Finally, an increase in the level of platelet and endothelial microparticles is observed during pregnancy.[5] These microparticles have been associated with procoagulant complications.

In conclusion, these normal global hemostatic changes lead to an increase of the risk of thrombosis throughout pregnancy, which is particularly high after delivery.

Thrombosis, thrombophilia and pregnancy outcome

We can define thrombophilia as an acquired or hereditary hemostatic disorder that predisposes to thrombosis.

There is clear evidence in the literature that acquired and hereditary thrombophilias increase the risk of VTE and adverse pregnancy outcome. Recently, there has been a dramatic increase in the number of identifiable causes of thrombophilia.[6]

However, the heterogeneity in design and size of different studies makes it difficult to establish the real risk and to indicate adequate treatment if necessary. The presence of thrombophilia alone does not necessarily lead to a clinical event.

Maternal VTE

Epidemiology of VTE during pregnancy

There is an increased risk of VTE in pregnant women compared to non-pregnant women. VTE is one of the leading causes of maternal mortality and it could appear in any trimester with an increased risk during the puerperium. There is a striking predisposition for deep vein thrombosis to occur in the left leg (compressive effect by the right iliac artery on the left iliac vein).

Specific genetic defects that contribute to VTE include deficiencies of antithrombin, protein C, protein S, the G1691A mutation in the factor V gene (factor V Leiden), and the G20210A mutation in the prothrombin gene. These disorders underlie about 50% of episodes of VTE in pregnant and postpartum women.[7,8] The risk of VTE in women with thrombophilias is different when considering data obtained either from family studies or unselected women. The risk is higher in women with previous thrombosis and with symptomatic relatives. To date, there is no evidence to support routine screening of all pregnant

Table 191.1 Regimens of UFH and LMWH. ACCP Recommendations

- Minidose UFH: UFH 5000 U SC q12 h
- Moderate-dose UFH: UFH SC q12 h in doses adjusted to target an anti-Xa level of 0.1–0.3 U/ml
- Adjusted-dose UFH: UFH SC q12 h in doses adjusted to target a midinterval aPTT into the therapeutic range
- Prophylactic LMWH: e.g. dalteparin 5000 U SC q24 h, or enoxaparin 40 mg SC q24 h (although at extremes of body weight modification of dose may be required)
- Intermediate-dose LMWH: e.g. dalteparin 5000 U SC q12 h, or enoxaparin 40 mg SC q12 h
- Adjusted-dose LMWH: weight-adjusted, full-treatment doses of LMWH administered once or twice daily (e.g. dalteparin 200 U/kg, or tinzaparin 175 U/kg qd, or dalteparin 100 U/kg q12 h, or enoxaparin 1 mg/kg q12 h)
- Postpartum anticoagulants: warfarin for 4–6 weeks with a target international normalized ratio of 2.0–3.0

women for congenital thrombophilia. Thrombophilia screening is required in women with a personal or family history of VTE.[9]

Management of women with thrombophilia with or without VTE

Recently, information has been published on the management of women with VTE during pregnancy and primary and secondary thromboprophylaxis depending on quantification the risk of thrombosis or recurrence of thrombosis in women with a previous venous thrombosis. Risk factors are as follows: age above 35 years, unplanned cesarean section, bed rest, history of thrombosis, multiparity, gemellarity, severe ovarian hyperstimulation, antiphospholipid syndrome (APS) and hereditary thombophilia. Some women with prior VTE have an identifiable laboratory abnormality associated with thrombophilia; the significance of these abnormalities and the management of such individuals remain controversial. Despite the progress in risk stratification, in many cases without previous thrombosis, recommendations for prophylaxis are empirical.

The use of antithrombotic agents in pregnancy has been recently reviewed and is part of the *Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy: Evidence-Based Guidelines*.[10]

Antithrombotics in pregnancy

Recommendations about the use of anticoagulants during pregnancy are based on extrapolations of data from non-pregnant patients, from case reports and from case series of pregnant patients. The antithrombotic used in pregnancy include unfractionated heparin (UFH), low molecular weight heparin (LMWH), heparinoids (danaparoid), coumarin derivatives and aspirin. UFH has been the anticoagulant of choice in pregnancy. There is evidence that LMWH have potential advantages over UFH because they cause less heparin-induced thrombocytopenia (HIT), have a longer plasma half-life and a more predictable dose response. LMWH have a better bioavailability, a better safety profile with regard to osteoporosis and thrombocytopenia. A recent systematic review has addressed the safety of LMWH in pregnancy.[11] Heparins do not cross the placenta, so they are safe for the fetus. UFH doses should be adjusted to prolong a midinterval activate partial thromboplastin time (aPTT) into the therapeutic range [adjusted-dose subcutaneous (SC) heparin].

Coumarin derivatives cross the placenta and have the potential to cause both bleeding in the fetus and teratogenicity (nasal hypoplasia, stippled epiphyses) during the first trimester and central nervous system abnormalities after exposure during any trimester. Oral anticoagulants cause an anticoagulant effect in the fetus; we must be aware of this situation at the time of delivery. It is essential that some form of heparin therapy is instituted in the last 3–4 weeks of pregnancy. Optimally, there should be at least 1 week's washout of warfarin before delivery.

For women requiring long-term vitamin K anticoagulant therapy who are attempting conception, it is suggested to perform frequent pregnancy tests and substitute UFH or LMWH for warfarin when conception is achieved.

Heparin and LMWH are not secreted into breast milk and can be safely administered to nursing mothers. Suggested regimens of UFH and LMWH are given in Table 191.1.

Warfarin does not induce an anticoagulant effect in the breast-fed infant when the drug is given to a nursing mother. Therefore, the use of warfarin in women who require postpartum anticoagulant therapy is also safe, and women using this drug should be encouraged to breast feed.

Prevention of VTE in pregnancy

Although different recommendations have been published for the prevention of VTE,[12] levels of evidence are often low due to the lack of randomized trials in pregnancy and some studies have been done with small-sized samples. We must first examine if the women need VTE prophylaxis according to the risk factors. There is a consensus that the risk of VTE is higher in the postpartum period, and women with thrombophilia and/or history of VTE should receive prophylaxis during the postpartum for at least 6 weeks. In contrast, during the antepartum period recommendations are unclear. LMWH are commonly used, but the time to start and the doses are not well defined. A prophylaxis could be

Table 191.2 Prophilaxis of VTE in pregnancy. ACCP Recommendations

Prior VTE and pregnancy:
- In patients with a single episode of VTE associated with a transient risk factor that is no longer present, we recommend clinical surveillance and postpartum anticoagulants (**Grade 1C**). If the previous event is pregnancy or estrogen-related or there are additional risk factors (such as obesity), we suggest antenatal anticoagulant prophylaxis (**Grade 2C**).
- In patients with a single idiopathic episode of VTE who are not receiving long-term anticoagulants, we suggest prophylactic LMWH, or minidose UFH, or moderate-dose UFH, or clinical surveillance plus postpartum anticoagulants (**Grade 2C**).
- In patients with a single episode of VTE and thrombophilia (confirmed laboratory abnormality) or strong family history of thrombosis and not receiving long-term anticoagulants, we suggest prophylactic or intermediate-dose LMWH, or mini-dose or moderate dose UFH, plus postpartum anticoagulants (**Grade 2C**).
- In antithrombin-deficient women, compound heterozygotes for prothrombin G20210A and factor V Leiden and homozygotes for these conditions with a history of VTE, we suggest intermediate-dose LMWH prophylaxis or moderate-dose UFH (**Grade 2C**).
- In patients with multiple (two or more) episodes of VTE and/or women receiving long-term anticoagulants (e.g., single episode of VTE—either idiopathic or associated with thrombophilia) we suggest adjusted-dose UFH or adjusted-dose LMWH followed by resumption of longterm anticoagulants postpartum (**Grade 2C**).
- In all women with previous DVT, antenatally and postpartum, we suggest use of graduated elastic compression stockings (**Grade 2C**).

Thrombophilia and venous thromboembolism associated with pregnancy
- In antithrombin-deficient women, compound heterozygotes for prothrombin G20210A and factor V Leiden, and homozygotes for these conditions with no prior VTE, we suggest active prophylaxis (**Grade 2C**).
- In all other patients with no prior VTE and thrombophilia (confirmed laboratory abnormality), we suggest surveillance or prophylactic LMWH or minidose UFH, plus postpartum anticoagulants (**Grade 2C**).

administered throughout pregnancy in all women at risk of VTE. In other women the prophylaxis is often decided on a case-by-case basis. VTE has an equal distribution throughout gestation. The American College of Chest Physicians (ACCP) Guidelines[10] are given in Table 191.2.

Treatment of VTE in pregnancy

UFH has been the anticoagulant of choice during pregnancy. Actually, the results from randomized trials and meta-analyses comparing intravenous (IV) UFH and SC LMWH for the treatment of acute DVT and pulmonar thromboembolism (PE) in non-pregnant patients showed that LMWH is at least as safe and as effective as UFH. In pregnant women with acute VTE, two alternatives treatments are proposed: UFH followed by LMWH or adjusted SC dose of UFH. Some authors recommend that adjusted dose SC UFH or LMWH can be used for both initial and long-term treatments. Therapeutic LMWH must be discontinued 24 h prior to elective induction of labor or cesarean section.

In high-risk situations, we recommend the use of UFH, which can be initiated and discontinued a few hours prior to delivery. Postpartum anticoagulants should be administered for at least 6 weeks and in women with long-term indication of anticoagulation oral anticoagulants can be resumed.[11]

Prosthetic heart valves

Pregnant women with mechanical prosthetic heart valves represent a very high-risk group. There is consensus that these women need anticoagulation at the upper limit of the therapeutic range, but there is otherwise little agreement on the optimum management regimen. The role of LMWH during pregnancy in the treatment of women with mechanical heart valves is the subject of active debate. The publication quoted by Chan *et al.*[14] calculated the percentage risk of thromboembolic complications in women with mechanical valves and maternal death for three broad treatment strategies in pregnancy: only warfarin 3.9%; heparin in the first trimester, then switched to warfarin 9.2% and only heparin 33%. Some authors do not exclude the possibility of using LMWHs,[15] if administered in high enough doses and aggressively monitored. The publication of the *Seventh ACCP Conference Guidelines* on antithrombotic agents in pregnancy has specifically addressed this issue, so it is appropriate to review this controversial area. The authors of the recent consensus statement concluded that taking the current evidence into consideration there are still three treatment regimens that can be reasonably used in pregnant women with mechanical valves (Table 191.3).

Antiphospholipid syndrome

APS is defined by the combination of a clinical venous or arterial thrombotic event or an obstetric complication and the laboratory detection of antiphospholipid antibodies. The syndrome is primary when there is no evidence of an underlying disease and secondary mainly in the setting of systemic lupus erithematosus.[16]

Antiphospholipid antibodies are a heterogenous group of immunoglobulins IgG, IgM or, less frequently IgA. The association between antiphospholipid (aPL)

Table 191.3

- Adjusted-dose, twice-daily LMWH throughout pregnancy in doses adjusted either to keep a 4-h postinjection anti-Xa heparin level at approximately 1.0 to 1.2 U/mL or according to weight (**Grade 1C**), or
- Aggressive adjusted-dose UFH throughout pregnancy: *i.e.*, administered SC q12h in doses adjusted to keep the mid-interval aPTT at least twice control or to attain an anti-Xa heparin level of 0.35 to 0.70 U/mL (**Grade 1C**), or
- UFH or LMWH (as above) until the thirteenth week, change to warfarin (target INR: 3) until the middle of the third trimester, and then restart UFH or LMWH (**Grade 1C**).
- Long-term anticoagulants should be resumed postpartum with all regimens.
- In women with prosthetic heart valves at high risk,we suggest the addition of low-dose aspirin, 75 to 162 mg/d (**Grade 2C**).

Table 191.4 Revised classification criteria of the antiphospholipid syndrome[18]

Antiphospholipid antibody syndrome (APS) is present if at least one of the clinical criteria and one of the laboratory criteria that follow are met

Clinical criteria

1. Vascular thrombosis
   One or more clinical episodes of arterial, venous, or small vessel thrombosis, in any tissue or organ. Thrombosis must be confirrmed by objective validated criteria (i.e. unequivocal findings of appropriate imaging studies or histopathology). For histopathologic confirrmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.
2. Pregnancy morbidity
   (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or
   (b) One or more premature births of a morphologically normal neonate before the 34th week of gestation because of: (i) eclampsia or severe preeclampsia defined according to SD, or (ii) recognized features of placental insufficiency, or
   (c) Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.
   In studies of populations of patients who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of subjects according to a, b, or c above.

Laboratory criteria

1. Lupus anticoagulant (LA) present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis (Scientific Subcommittee on LAs/phospholipid-dependent antibodies).
2. Anticardiolipin (aCL) antibody of IgG and/or IgM isotype in serum or plasma, present in medium or high titer (i.e. >40 GPL or MPL, or >the 99th percentile), on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA.
3. Anti-b2 glycoprotein-I antibody of IgG and/or IgM isotype in serum or plasma (in titer >the 99th percentile), present on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA, according to recommended procedures.

antibodies and pregnancy loss was fist suggested more than 30 years ago, during the last meeting in Sapporo. Other pregnancy complications linked to placental insufficiency such as pre-eclampsia and fetal growth restriction are included in the definition of the APS. So the adverse obstetric outcomes included in the clinical criteria for the APS are recurrent early pregnancy loss, fetal death, pre-eclampsia and fetal growth restriction[17] (Table 191.4).

Antiphospholipid antibodies do not recognize anionic phospholipids, as has been believed for a long time.[18] These aPL antibodies recognize plasma proteins bound to suitable anionic surfaces; among them, b2-glycoprotein I and prothrombin are the most common and investigated antigenic targets.[18] b2-Glycoprotein I is required by the great majority of anticardiolipin antibodies to react with cardiolipin in immunoassays, whereas lupus anticoagulant activity in phospholipid-dependent coagulation tests is caused by subgroups of both antibodies. Other antigenic targets of the aPL are listed in Table 191.5. The interaction of aPL antibodies with their respective antigens at the phospholipid surface may lead to a prothrombotic condition. Most reactions that control the blood coagulation process occur at the phospholipid surface. The aPL antibodies used to define de APS in Sapporo Preliminary Criteria were: lupus anticoagulant (LAC) and anticardiolipin antibodies (17). Amendments to the Sapporo Criteria were proposed at a Workshop in Sydney before the Eleventh International Congress on antiphospholipid antibodies in 2004. Anti- b2-glycoprotein I Ig G and Ig M assays are added in the revised criteria (19). LAC assays should be done according to the International Society of Thrombosis and Haemostasis (ISTH) guidelines. In pregnancy we found that the most sensitive screening test to detect LAC was the diluted Russell viper venom time.[21]

Table 191.5 Antigenic targets for antiphospholipid antibodies

B2-Glicoprotein I
Activated protein C
Protein S
(human) prothrombin
Tissue type plasminogen activator
AnnexinV
Thrombomodulin
Oxidize low density lipoproteins
Factor XII , Factor VII/VIIa
Complement components H and C4b
High and low molecular weight kininogens
Endothelial protein C receptor (EPCR)

The mechanisms involved in the obstetric compromise are actually debated and the question about the possible causal role of the aPL is still an unanswered question. Multiple possible physiopathological mechanisms have been involved in the genesis of obstetric adverse complications. Whether there is a different mechanism when the obstetric complication comprises the early period of embryonic development and placentation or when placental insufficiency is the basis for late pregnancy complications is not known. Rand *et al.*[22] have proposed that the mechanism of recurrent pregnancy loss may be a consequence of aPL antibody-mediated disruption of annexin A5 binding to syncytiotrophoblasts. This finding would impact on the modulation of coagulation within the placenta, and predispose to intervillous clot formation and subsequent diminished capacity for nutrient and oxygen exchange. In a recent study antiannexin V antibodies were significantly increased in women with recurrent spontaneous miscarriage and recurrent implantation failures after *in vitro* fertilization.[23]

It has been suggested that the endothelial protein C receptor plays a relevant role in pregnancy maintenance, since EPCR knockout mice experience placental thrombosis and early embryonic mortality.[24] The EPCR is a potentially important target of aPL antibodies; it has been hypothesized that antibodies directed against endothelial protein C receptor (EPCR) may be involved in the development of the thrombotic and obstetric complications of the APS.[24]

Management of pregnant women with APS

The APS is an established and treatable cause of recurrent miscarriage.[25] The mechanism of aPL-associated pregnancy loss is related to the deleterious effect of these antibodies on embryonic implantation, trophoblast function and differentiation[26] and placental thrombosis.[27–29] Venous or arterial thrombosis can develop during the whole pregnancy and the postpartum period. Women with pregnancy loss and APS have a poor live birth rate in future untreated pregnancies. The treatment with a combination of aspirin and heparin significantly improves the live birth rate in these women. During the initial weeks of gestation, heparin can improve trophoblast invasion and differentiation, resulting in successful implantation. In later pregnancy, the anticoagulant effect can reduce placental thrombosis. The objectives of heparin treatment are prevention of maternal thrombosis and improvement of gestational outcome. In spite of the continued efforts in understanding the pathogenesis of obstetric complications of APS, there are few therapeutic trials. There is a recent excellent review of randomized therapeutic trials by Empson *et al.*[31] Low-dose aspirin and heparin are recommended for obstetric APS.[32] This recommendation lies in the results of a few trials with important differences in trial design.[33] In our experience, when we treated patients with prophylactic doses of enoxaparin 40 mg daily and 100 mg of aspirin, live birth occurred in 39 of the 49 treated pregnancies (79%).[34]

The major problem we actually face in the definition of the APS lies in the aPL assays. In spite of the international efforts to standardize laboratory testing for antiphospholipid antibodies, there is a considerable inter- and intralaboratory variation in their detection.

Assay problems contribute to the controversies in our understanding and definition of this syndrome. We hope that in the near future a better obstetric and laboratory definition of the APS, with different levels of risk, in well-designed therapeutic trials, will provide us better evidence regarding the management of obstetric APS.[35]

Inherited thrombophilias, pregnancy loss and gestational vascular complications

The increase in the number of identifiable causes of thrombophilia during the past 10 years introduces a new question: Are these thrombophilic abnormalities directly related to fetomaternal complications or can they increase thromboembolic risk and other obstetric complications?[36] Thromboembolism is a major cause of maternal death and thrombotic complications may also affect the uteroplacental circulation. Recent data have linked thrombophilia to other obstetric complications such as pregnancy loss, pre-eclampsia and IUGR. It has been hypothesized that recurrent pregnancy loss (RPL) represents an exaggerated hemostatic response to pregnancy leading to thrombosis of the uteroplacental vasculature and subsequent fetal loss.[37] Prevalence studies of inherited thrombophilic defects in women with pregnancy loss suggest an etiological role for inherited thrombophilias. Previous observations suggest an association between RPL and uncommon inherited thrombophilic states such as protein C, protein S, antithrombin and disfibrinogenemia. Actually, the association between the main

thrombophilic polymorphisms factor V Leiden and prothrombin G20210 A mutation is well established. A large number of case–control studies found a high prevalence of factor V Leiden in women with RPL.[38,39] A systematic review noted an increased prevalence of the prothrombin G20210 mutation. Several other studies found no association with fetal loss. Rey *et al*.[40] reported an association between early and late loss. Various other thrombophilic defects may play a role in pregnancy loss: hypofibrinolysis, factor XII deficiency, high factor VIII levels and hyperhomocysteinemia.[41] A meta-analysis concluded that the C677T methylenetetrahydrofolate reductase (MTHFR) polymorphism was not associated with fetal loss. In spite of these results, maternal vascular disease of the placenta has been described, and these results highlight the importance of folic acid supplementation in patients with C677T homozygosity phenotypic expression. Inherited thrombophilias has been described in association with other pregnancy complications such as pre-eclampsia and IUGR.[42,43]

The prevalence of inherited thrombophilias is up to 20% in the normal population and the probability of a successful pregnancy outcome is high. Therefore, routine screening of all pregnant women is not warranted. Screening is recommended for women with the following previous complications: fetal loss including three or more in the first trimester, two or more in the second trimester, or any stillbirth, early, severe or recurrent pre-eclampsia or severe IUGR.[44]

Management of pregnant women with inherited thrombophilias, pregnancy loss and gestational vascular complications

The current evidence for antithrombotic therapy in women with inherited thrombophilia and recurrent pregnancy loss is limited to a few uncontrolled case series and a cohort study. A number of prospective studies have demonstrated the benefit of LMWH.[45–48]

A recent multicentric group coordinated by Brenner[49] published the results of the LIVE–ENOX study. The LMWH enoxaparin increases the rate of live births in comparison to what happened during previous pregnancies and decreases the incidence of complications in thrombophilic women with recurrent pregnancy loss. They also found that doses of 40 mg/day and 80 mg/day led to similar clinical results. The potential therapeutic benefits of LMWH for women with pregnancy complications and thrombophilia were presented in a recent debate.[50,51] Though preliminary data suggest that prophylactic anticoagulation may improve gestational outcome, confirmation in prospective randomized trials in thrombophilic women with unexplained recurrent fetal loss is needed.

Conclusions and comments

Pregnancy is an acquired hypercoagulable state and thromboembolism is a major cause of maternal death. There is growing evidence implicating congenital and acquired thrombophilias in the pathophysiological mechanism underlying miscarriage, fetal loss, pre-eclampsia and IUGR. The APS is an established and treatable cause of recurrent miscarriage. Maternal antithrombotic therapy is currently being evaluated in women with hereditary thrombophilia, fetal loss and gestational vascular complications.

Appropriate counseling should be offered to women with VTE and/or poor obstetric outcome associated with thrombophilia.

192 Hypertension in pregnancy

L. S. Voto and J. Ortí

Introduction

Hypertension in pregnancy continues to be a major concern for perinatal health all over the world. When the cause of a disease is unknown, new theories are unavoidably generated and renewed hopes of progress emerge.

Hypertension is one of the main causes of prematurity, perinatal mortality, and maternal death in both industrialized and developing countries. According to the literature, its incidence worldwide ranges from 0.1% to 35%[1] as it is affected by a multiplicity of factors.

Edema in pregnancy is considered to be a controversial sign, as it may appear in pregnant women without necessarily being associated with any pathology. However, edema has been detected in the most severe cases of hypertension and has led to a diagnosis of eclampsia only in the presence of maternal seizures.

High levels of proteinuria are indeed good indicators of the severity of hypertension. Proteinuria appears late in the disease and has been found to be more significant with higher diastolic blood pressure.[2]

In any event, it is pre-eclampsia, i.e., hypertension plus proteinuria, pure or superimposed upon chronic (preexisting) hypertension, that will increase the risk of both maternal and perinatal morbilidy and mortality.

Physiopathology

Increased blood pressure in pregnancy results from a concatenation of polysemic events. Numerous clinical and experimental studies provide evidence that points to reduced trophoblastic perfusion, i.e., tissue ischemia, as the trigger of gestational hypertension.

In normal pregnant women, vasodilation of the spiral arteries can be up to four times their usual gauge, which reduces their peripheral resistance and favors intervillous space perfusion.[3] This is due to the trophoblastic invasion of the placental bed which ends at 20–21 weeks' gestation, and which destroys the vascular musculoelastic layer, thus preventing the action of vasopressor agents. In contrast, in preecalmpsia, the second trophoblastic migration does not take place; therefore, the musculoeslastic layer remains intact, reducing the gauge of blood vessels and giving rise to atheromatose plaques due to decreased blood flow. This paralysis of trophoblastic migration might be mediated by the maternal immune system.[4]

As stated by Gant in the early 1970s, pre-eclamptic pregnant women develop vascular sensitivity to angiotensin II. His studies demonstrated that in these patients the balance between the prostacyclin (vasasodilator) and thromboxane ring (the most powerful vasoconstrictor in the body) is lost in favor of the latter. As a result, blood pressure increases and the coagulation chain is activated.[5]

Gestational hypertension is a truly endothelial disorder, and among the multiple functions of the endothelium is the secretion of such substances as prostaglandins, endothelin, nitric oxide, and protein C. When a noxa causes endothelial damage, anticoagulant and vasodilator production decreases. Alterations in intercellular unions and in the water and protein transport expel these elements outside the cells.

Endothelin 1 levels have been shown to be more elevated in preeclamptic than in normal pregnant women, whereas prostacyclin and nitric oxide, the most important vasodilating and antiaggregating factors, are markedly reduced.[6]

We might then conclude that there is an inadequate expansion in plasma volume, an increased sensitivity to angiotensin II, a ruptured prostacyclin/thromboxane ring and an untimely activation of the coagulation mechanism, leading to decreased multiorgan perfusion. Therefore, pregnancy-induced hypertension is likely to be caused by an abnormal trophoblastic invasion, leading to decreased uteroplacental blood flow, placental ischemia, placental release of cytokines, endothelial dysfunction due to an increase in endothelin 1 and thromboxane A2 (two vasoconstricting substances), a reduction in prostacylin and nitric oxide levels (two powerful vasodilating substances), and a rise in vascular sensitivity to angiotensin II.

Epidemiologic studies agree that the immunological maladaptation of the fetal graft plays a major role in the defective placentation that gives rise to placental ischemia. This ischemia can be caused by several factors, the most important of which are:

a) immunological maladaptation
b) genetic predisposition
c) vascular mediators.

Endothelial dysfunction: all roads of the pathogenesis of hypertension in pregnancy lead to endothelial dysfunction.

The alterations found in the plasminogen activator and/or in the balance between the plasminogen activator and the inhibiting function of the prostacyclin/thromboxane balance seem to lead to increased platelet aggregation and vasoconstriction. These morphological and functional changes in endothelial cells would be responsible for triggering a clinical syndrome characterized by arterial vasospasm, and increased platelet aggregation and capillary permeability, manifested clinically as hypertension, edema, proteinuria and, sometimes, thrombocytopenia and organic hypoperfusion.

Epidemiologic findings seem to confirm the presence of a maladaptation syndrome:

- Pre-eclampsia is more frequent in primigravidas, but less frequent in subsequent gestations if pregnant by the same husband.
- Women with a history of abortion and blood transfusions are at a lower risk of pre-eclampsia.
- There is an inverse relationship between the length of cohabitation and the incidence of pre-eclampsia.
- Women who use barrier contraceptive methods are twice as likely to develop pre-eclampsia compared with those who do not.
- The incidence of pre-eclampsia is higher in women who have conceived with donor semen.

In spite of these epidemiologic facts, no alterations in IGM, IgA, IgG and IgD levels have been demonstrated yet in normal or pre-eclamptic pregnant women. HLA-G expressed on trophoblast would be responsible for immune tolerance. An alternative hypothesis suggests that maternal production of blocking antibodies plays a role in the survival of the fetal graft. The decrease in the production of these antibodies would result in a direct maternal reaction against both endovascular and intersticial trophoblastic invasion. Placental ischemia and the activation of polynuclear neutrophiles appear to be the most severe consequences of the altered maternal immune response, which in turn sets in motion a chain of events ending up in endothelial damage and dysfunction, and in typical pre-eclamptic symptomatology.

Genetic predisposition

It would be of great value in the prediction of pre-eclampsia to find the relationship between pre-eclampsia and a susceptible gene. Unfortunately, this gene – other than the one found in family relations – has not been discovered yet.

Vascular mediators

Pathologies such as chronic hypertension, diabetes, immune disorders, chronic renal failure, subclinical metabolic or hemostatic abnormalities facilitating thrombophilia (protein S deficiency, resistance to activated protein C, anticardiolipins, hyperhomocysteinemia), all of which have an impact on the vascular system, are associated with a higher risk of developing pre-eclampsia.

The unidentified point of union

The unidentified point of union between placental pathology and the chain of events leading to disorders in maternal circulation might be called the X factor. Genetic predisposition, the presence of a susceptible gene, and of vascular pathology are likely to be the modulating factors in the pre-eclamptic process.

The role of the placenta in the etiopathogenesis of pre-eclampsia

The presence of pre-eclampsia in women with trophoblastic disease or with an abdominal pregnancy points to the importance of the placental role and to the irrelevance of the decidua in the development of the pre-eclamptic syndrome.

As a result of trophoblastic invasion, the diameter of spiral arteries shows a four- to sixfold increase when compared to that in non-pregnant women; and disorders in that invasion can be demonstrated quite early in pregnancy, towards the end of the first trimester.

Some experimental findings suggest that, prior to trophoblastic invasion, there is reduced perfusion in the implantation site. Furthermore, pregnancy is associated with a 10-fold increase in uterine blood flow, 90% of which goes to the invervillous space. Towards the end of gestation, blood flow may reach 750 ml/min. The number of spiral arteries can be predicted early in pregnancy (about 120). In their adaptation to the increased blood flow, during the first trimester, the decidual segment of spiral arteries undergoes the degeneration of the internal elastic medial wall, as well as the disappearance of the smooth muscle and of elastin in the inner and outer medial tunic. A change is observed in the structure of vascular walls due to hyaline and fibrin. The second adaptation phase takes place during the second trimester and is characterized by intense trophoblastic invasion limited to the internal part of the medial tunic of spiral arteries.

Whereas blood pressure in the radial arteries is 70–80 mmHg, in the villous spaces it is about 10 mmHg, which shows a gradient that clearly benefits the fetus. Normal morphological changes in the placental bed prevent maternal spiral vessels from responding to vasopressor agents by reducing the number of smooth muscle cells capable of responding to them.

Cases with acute atherosclerosis show discontinuity of endothelial cells, focal interruption of the basal membrane, platelet deposits, mural thrombosis and fibrinoid necrosis. There are also disorderly proliferative changes in the vascular intima cells, resulting in hyperplasia of the myointimal and medial tunic smooth muscle cells, which could be caused by the mitogenic effects of platelet growth factors.

The marked reduction in fetal villous cell subendothelial fibronectin is a clear indicator of extensive endothelial damage in pre-eclampsia. An important characteristic of acute atherosis is the extensive lipoid necrosis of smooth muscle and myointimal cells, resulting from chronic hypoxia and/or from cytotoxin action. Acute atherosis is not only found in pre-eclamptic primigravidas, but also in the pre-eclamptic placentas of women with chronic hypertension, or with diabetes, renal failure and/or lupus, and it can lead to reduced intervillous blood flow, increased intrinsic vascular resistance and an elevated response to vasopressor substances.

The pathophysiology of pre-eclampsia

Normal pregnancy is associated with an increase in plasma renin activity and in the concentration of plasma renin, renin substrate, and angiotensin II. In contrast, pre-eclampsia is responsible for the suppression of the renin–angiotensin system. Regardless of the levels of renin present, aldosterone plays a role, either directly or indirectly, in the etiopathology of gestational hypertension.

In normal gestations, angiotensin stimulates prostacyclin production through the walls of uterine and systemic arterial blood vessels. Pre-eclampsia would therefore suggest a defective production of angiotensin II. In a recent study, Ito *et al.* demonstrated that angiotensin-converting enzyme (ACE) is present mainly in venous endothelial cells of placental villous stem cells, and that ACE activity, ACE protein expression, and ACE messenger RNA expression are higher in pre-eclamptic placentas than in normal pregnancy. Furthermore, they also found that, *in vitro*, hypoxia promotes the expression of ACE messenger RNA and its activity in endothelial vein cells. Consequently, venous endothelial cells both in the placenta and the umbilical vein would play a major role in the regulation of the fetoplacental renin–angiotensin system, and, in hypoxic conditions such as pre-eclampsia, the fetus can induce placental ACE activity.

The pathophysiological alterations characteristic of pre-eclampsia are manifested both at a local level (defective placentation and reduced placental perfusion) and at a systemic level (prostacyclin and nitric oxide deficiency in the vascular endothelium).

These changes raise endothelial sensitivity to vasopressor substances, platelet activity and thrombogenesis. Reduced placental perfusion enhances oxidative stress, and anomalous fetal and maternal vascular endothelium leads to prostacyclin deficiency. The increase of oxidative stress and prostacyclin and nitric oxide deficit result in vascular endothelium dysfunction, impairing other organs such as the placenta, kidneys, liver, pancreas, lungs, brain, and the hematopoietic system. The different clinical signs of pre-eclampsia stem from the dysfunction of all these organs.

To sum up, the pathophysiology of toxemia in pregnancy involves:

- Abnormal placentation leading to placental ischemia and oxidative stress.
- Prostacyclin and nitric oxide deficiency, which increases blood cell sensitivity to vasopressor agents, thrombin activity and platelet aggregation, and enhances the homeostatic system.
- Structural and functional disorders in endothelial cells.

Hypertension would therefore be the homeostatic response of the fetoplacental unit to these alterations, and should then be considered a consequence rather than a cause of the disease.

Diagnosis of gestational hypertension

The patient should be seated for a minimum of 5 min before blood pressure is measured. The sphygmomanometer cuff should be wrapped around the patient's upper arm at heart level. If the reading is abnormal, blood pressure should be measured three more times at 1-min intervals. In pregnant women, the first and the fifth Korotkoff sounds are recorded as systolic and diastolic blood pressure, respectively, as they are easily recognizable and better related to intra-arterial blood pressure.

Hermida *et al.* studied the effectiveness of the blood pressure load in the diagnosis of hypertension in pregnancy. They analyzed 2014 blood pressure series recorded by ambulatory monitoring for 48 h every 4 weeks, from the first antenatal visit until delivery in 205 normotensive pregnant women and 123 with gestational hypertension or pre-eclampsia. The blood pressure load test was defined as the 'percentage of values higher than 140/110/90 mmHg (systolic/mean arterial/diastolic blood pressure) during active hours or 120/95/80 mmHg during resting hours'. The blood pressure load was also obtained by comparing with the limits recorded while reducing the previous limits by 15 mmHg until a final threshold of 126/95/75 mmHg (day) and 105/80/65 mmHg (night) was reached.

The sensitivity for the blood pressure load was over 55% during all gestation when the highest limits used were considered. However, sensitivity was higher than 73% when day limits of 125/95/75 mmHg and night limits of 105/80/65 mmHg were used as references before 26 weeks' gestation, and when the tested limits of 130/100/80 and 110/35/70 (day and night, respectively) were used after week 26.

These findings show that the optimum reference limits to calculate blood pressure must take into account both gestational age and active and resting time values. In fact, the criteria for defining gestational hypertension according to blood pressure readings should be revised, as adverse outcomes have occurred with diastolic blood pressure equal to or higher than 85 and 95 mmHg before 36 weeks' gestation and at term, respectively.

A greater risk is also associated to the levels of proteinuria: fetal death rate is three times higher when proteinuria is $\geq 2+$. When diastolic blood pressure is 95 mmHg or higher, there is also a threefold increase in fetal mortality rate (Perinatal Collaborative Study, USA).

However, fetal mortality can be nine times higher in the presence of both diastolic hypertension and proteinuria (95–105 mmHg with 2+ proteinuria), showing a synergic effect of diastolic blood pressure and proteinuria.

Risk factors for pre-eclampsia

- Primiparity: relative risk (RR) of 3
- Age: a J-shaped curve; women over 40 years of age show a RR of 3
- Multiple gestations: RR 5
- Chronic hypertension: RR 5
- Chronic renal disease: RR 20
- Antiphospholipid syndrome: RR 10
- Severe pre-eclampsia in previous gestation: RR 10
- Homozygous carriers of angiotensinogen T235 gene: RR 20
- Inverse correlation between gestational age when the disease is manifested and the risk for recurrence.

Proteinuria

Proteinuria is an excellent predictor of the extent of renal glomerular damage. Our experience shows that pre-eclampsia can be diagnosed when proteinuria is higher than 300 mg/l in 24-h urine samples. When renal dysfunction is already present, urinary levels of proteins, and mainly of albumin, will be elevated. However, as glomerular damage occurs late in the course of gestational hypertension, measurable proteinuria may not be useful for early detection of the disease. In any case, patients should be screened for proteinuria because its detection will affect both the prognosis and the treatment of this illness.[7]

Edema

The presence of edema has less predictive value than proteinuria in the diagnosis of pre-eclampsia. Edema is common in normal pregnancies and therefore lacks specificity. A ponderal sudden increase in weight gain (over 500 g in a week), especially if sustained through time, can be a clear indicator of edema in the absence of other complications.

Risk factors[8]

- Nulliparity
- Maternal age < 25 or > 35 years
- Multiple pregnancy
- Obesity
- Family history of pre-eclampsia–eclampsia
- History of pre-eclampsia in previous gestations
- Abnormal Doppler ultrasound scan of uterine arteries between 13 and 24 weeks' gestation
- Pregestational diabetes mellitus
- Thrombophilia.

Other diagnostic factors

If the first antenatal visit occurs after 20 weeks' gestation, the patient may not be aware of her blood pressure values, making diagnosis of either gestational or preexisting hypertension more difficult.

Cardiovascular function

Pregnancy-induced hypertension usually has little or no impact on cardiac function. Nevertheless, if the hypertensive condition is severe during the third trimester, the patient may present with reduced cardiac preload and minute volume, as well as increased postload. An electrocardiogram must be ordered in any event and, in cases where heart valve pathology is suspected, an echocardiogram is also recommended.[9]

Renal function

In the course of the disease, it is the kidneys that are most impaired, showing alterations in renal perfusion flow and depuration. Glomerular endotheliosis is a highly characteristic sign of pre-eclampsia and can be diagnosed after a careful study of renal function with urine cultures and screening tests for creatininemia, creatinine clearance, uricemia, and proteinuria in 24-h urine. Postpartum renal biopsy would be very useful to diagnose renal pathology, but due to its invasive nature, it should not be performed as a routine procedure.[10]

Ophthalmoscopy

Ophthalmoscopy can reveal vascular narrowing, edema, hemorrhage, exudates, and a cotton-like

fundus If the patient complains of blurred vision, there is likely to be subretinal fluid coming from choroidal plexus exudation. In all cases, ocular changes usually resolve completely some time after delivery.

Hematologic follow-up

At present, coagulation disorders are known to be a consequence rather than the origin of this syndrome. Disorders in coagulation factors, thrombocytopenia and hemolysis, are the most common complications. Thrombocytopenia is secondary to endothelial damage and may be associated with the appearance of schistocytes (fragmented erythrocytes), spherocytes, reticulocytes and hemoglobinuria in peripheral blood, which are characteristic of the condition known as microangiopathic hemolysis.[11]

Liver function

Only in very severe cases is hepatic function altered. However, a hepatogram should be ordered in all cases, mainly after the patient is diagnosed with HELLP (hemolysis, elevated liver enzymes, low platelets).

Classification

The classification of hypertension in pregnancy continues to be a problem as the etiology of the disease is still unknown. None of the classifications attempted so far is broad enough to cover all the possible types. Recently, the US National Institutes of Health (NIH) and the Working Group on High Blood Pressure in Pregnancy have proposed a new classification, which has added the term *gestational hypertension* to describe patients presenting with hypertension in pregnancy but without proteinuria, leaving *pregnancy-induced* or *temporary hypertension* to be used for postpartum diagnosis.[12]

The classification proposed by both American institutions is as follows:

(1) Chronic hypertension
(2) Pre-eclampsia–eclampsia
(3) Chronic hypertension with superimposed pre-eclampsia
(4) Gestational hypertension: this comprises two subgroups:
    (a) Temporary hypertension in pregnancy without pre-eclampsia: where blood pressure values return to normal within 6 weeks postpartum
    (b) Chronic hypertension: this type is diagnosed during gestation and blood pressure values continue to be elevated after the sixth week postpartum.

In order to include all the pathologies of gestation in one classification, the International Society for the Study of Hypertension in Pregnancy (ISSHP) has classified the disease into four groups[13]:

Group A
A.1. Gestational hypertension
A.2. Gestational proteinuria
A.3. Gestational hypertension with proteinuria or pre-eclampsia

Group B
B.1. Chronic hypertension
B.2. Chronic renal disease
B.3. Chronic hypertension with superimposed pre-eclampsia

Group C
Unclassified hypertension and/or proteinuria

Group D
D.1. Hypertensive emergency
D.2. Eclampsia

Group A comprises all cases where proteinura or hypertension or a combination of both appears and resolves during pregnancy. Group B includes cases with preexisting hypertension or previous renal pathologies plus pre-eclampsia as an aggravating factor. All those cases where it is not possible to make an accurate diagnosis of the origin of hypertension, either because of a late prenatal visit or deficient follow-up in remote puerperium, are classified into Group C.

We recommend adopting this classification of hypertension in pregnancy because:

- It allows the classification of patients according to the characteristics of their own gestations.
- It enables physicians to reclassify the patient within each group according to the clinical evolution of the disease.
- It clearly distinguishes patients with pre-eclampsia (pure or superimposed) from those with preexisting hypertension.
- It includes a group for unclassifiable cases, which prevents inaccurate labeling.
- It allows the analysis of cases with nephropathy with or without hypertension.

Pathological anatomy of the placenta in pre-eclampsia

The extravillous trophoblast encompasses all the trophoblastic cells which are not in contact with the basal membrane of chorionic villi. It has two components: the interstitial trophoblast and the

endovascular trophoblast. The giant multinuclear cells of the interstitial trophoblast infiltrate into the placental bed.

In 1967 Brosens described the trophoblastic permeation of decidual and myometrial spiral arteries by extravillous trophoblast, which penetrates the spiral arteries migrating through the distal end of decidual vessels at 9 weeks' gestations and reaching myometrial vessels at 14–15 weeks' gestation.

Trophoblastic invasion leads to the destruction of the muscular elastic tissue and of the nervous tissue, turning the uteroplacental vasculature into a low resistance, low pressure and high blood flow system without maternal vasomotor control.

Five years later, Brosens demonstrated the absence of a physiological transformation of uteroplacental arteries in pre-eclampsia. There are, however, other vascular lesions such as atherosis which was described by Hertig back in 1945. In 1985, Klurfel showed vascular endothelial infiltration by macrophages. In addition to atherosis, there is fibrinoid necrosis.

Over 60% of pre-eclamptic placentas show vascular atherosis mainly in decidual necrosis and infarcted areas. The endothelium is disrupted in 80% of the patients with pre-eclampsia, probably resulting from increased oxidative stress and production of vasoactive substances as well as from alterations in cytokine production. The vascular bed in pre-eclamptic patients is characterized by a higher number basal and spiral arteries with greater tortuosity and by a reduction in their luminal diameter. Medial disorganization and hyperplasia in myometrial arteries are also displayed, more frequently than atherosis, in pre-eclamptic patients.

In normal pregnancy, 40% of all decicual lymphocytes are CD56+ uterine natural killer cells, and 60%, CD3+ T-lymphocytes; about 30% of the latter are CD8+ T cells. In contrast, in pre-eclamptic pregnancies with intrauterine growth retardation (IUGR), there is a higher proportion of CD56+ uterine natural killer cells and CD8+ T lymphocytes in the decidua (70% of all CD3+ cells). In pregnancies without IUGR no increase in CD56+ uterine natural killer cells has been observed, while CD8+ T lymphocytes have been found to be significantly elevated compared with the normal level (50% of all CD3+ cells).[14]

Impact of pre-eclampsia on the placenta

Changes in the villous structure

Normally at 32 weeks' gestation placental membranes are vasculosyncytial and the syncytiotrophoblast forms clusters, knots or sprouts which are attached to the villi or remain loose in the intervillous lakes, comprising 30% of a term placenta villi.

In pre-eclampsia, the cytotrophoblast proliferates and the syncytiotrophoblast becomes thinner while the basal membrane grows thicker. These placentas show signs of reduced uteroplacental blood flow and are known as Tenney–Parker placentas. Macroscopically, they are little, fibrotic, and dark, which is due to the polyglobulia developed by fetuses with IUGR, placental color resulting from fetal blood circulating in villous capillaries. Besides, as a consequence of chronic hypoxia, fetal blood vessels in villous stem cells display fibromuscular hyperplasia and obliterant endarteritis,[15] often accompanied by thrombosis triggered by fetal blood hypercoagulability in the presence of prolonged hypoxia. Chronic hypoxia may also lead to syncytiotrophoblastic rugosity, which favors the thrombosis of circulating blood in the intervillous space.

Treatment of hypertension in pregnancy

The majority of treatments carried out at present are symptomatic and highly controversial; they do not cure the disease and are mainly aimed at preventing or reducing maternal and fetal risk.

Significantly lowering maternal blood pressure does not necessarily improve the pregnancy condition, as can be seen in cases of chronic hypertension where early reduction of blood pressure does not preclude the later development of superimposed pre-eclampsia.[16]

Ideally, an antihypertensive drug should be harmless for both mother and fetus, it should not have adverse side effects, and it should be effective, easy to dose, adequately presented and reasonably priced. It goes without saying that, unfortunately, no such drug is available on the market yet.

Rationale for treatment

The rationale for the treatment of hypertension in pregnancy is as follows:

- Pregnancy-induced hypertension should be defined according to changes in blood pressure values, but it is not a hypertensive disorder.
- Although its etiology is still unknown, it has been found to originate in alterations in the uteroplacental unit.
- Elevated blood pressure might be triggered by the need for better fetoplacental perfusion
- Drug treatment of pre-eclamptic hypertension would reduce placental perfusion and affect normal fetal growth.
- Therefore, treatment is carried out in spite of its deleterious effect on the uteroplacental unit, and is aimed at protecting the mother. Treatment is indicated only when blood pressure values can lead to a cerebrovascular accident.[17]

Treatment principles

Our specialist team follows the principles below:

- Hypertension is considered moderate if blood pressure ranges from 140/90 to 159/99 mmHg, and severe if it is 160/100 mmHg or higher.
- Drug treatment is used when blood pressure is 160/100 mmHg or higher to avoid irreversible maternal cerebrovascular damage.
- The decision to start treatment is based on the highest blood pressure values recorded twice 24 h apart, with the patient at bedrest.[18]

The choice of treatment depends on the characteristics and severity of maternal hypertension, the age of pregnancy and fetal condition. At present, the following drugs are available.

Alpha-2 receptor agonists

Alpha-methyldopa

Therapeutic action: central hypotensive action
Reduced peripheral resistance
Route of administration: oral
Dose: 500–3000 mg/day.

Beta-blockers

Atenolol

Therapeutic action: beta-receptor blockade. Atenolol antagonizes competitively endogenous and exogenous beta-sympathetic stimulation.
Route of administration: oral
Dose: 50–250 mg/day.

Calcium-channel blockers

Niphedipine

Therapeutic action: calcium-channel blocker
Route of administration: oral
Dose: 20–40 mg/day.

Amlodipine

Therapeutic action: selective calcium antagonist. Amlodipine reduces peripheral vascular resistance
Route of administration: oral
Dose: 10–40 mg/day.

Angiotensin converting enzyme inhibitors (ACE)

Enalapril

Therapeutic action: enalapril curtails the conversion of angiotensin I to angiotensin II
Route of administration: oral
Dose: 5–30 mg/day
Only used in cases of persistent postpartum hypertension.

Direct action vasodilators

Hydralazine

Therapeutic action: arterial vasodilator which blocks calcium influx into the cell. It relaxes smooth muscle of arterioles
Route of administration: IV or IM
Dose: 5 mg/day as IV bolus, followed by 5–10 mg doses every 20 min (until a total dose of 40 mg is administered). Continue with the effective dose reached within 6 h.

Anticonvulsivants

Magnesium sulfate

Therapeutic action: myoneural presynaptic inhibition; peripheral vasolidators; minimum hypotensive action
Route of administration: IV
Dose: (1) Slow IV bolus of 2 or 4 g; (2) 1 g infusion every hour, up to 3 g/h. Magnesemia is measured and possible reduction of patellar reflex, respiratory insufficiency and diuresis (oliguria) are strictly checked.

Diazepam

Therapeutic action: anticonvulsant; myorelaxant
Route of administration: IV
Dose: (1) slow IV bolus of 40 mg; (2) 10 mg/h infusion

Management and treatment of moderate hypertension

(1) Weekly blood pressure measurement
(2) Reduced physical activity at home
(3) Laboratory tests
(4) Fetal vitality check-ups:
    (a) Ultrasound scan
    (b) Antepartum non-stress test
    (c) Vascular Doppler ultrasound scan
(5) No elective induction of labor unless for obstetric reasons.

Management and treatment of severe hypertension

(1) Hospitalization
(2) If blood pressure is not reduced with bed rest, one of the following drugs should be prescribed:
    (a) Atenolol: 50–250 mg/day
    (b) Alpha-methyldopa: 500–2000 mg/day
    (c) Amlodipine: 10–40 mg/day
(3) Laboratory tests (more frequent than in outpatients)
(4) Patients with chronic hypertension who respond to treatment can then be followed up as outpatients
(5) Patients with gestational hypertension should remain in hospital because the risk of seizures does not disappear with the use of hypotensive drugs.

Follow-up

If blood pressure continues to increase in spite of the therapeutic measures taken and/or if clinical symptoms appear (headache, visual problems, irritability), the protocol for the treatment of hypertensive emergencies must be followed (see below).

The guidelines for pregnancy interruption are as follows:

Before interruption. Assessment of fetal growth and vitality: The fetus will be affected by the disease, and will show alterations in both growth and vitality. Ultrasound scans should be used to follow fetal growth, and to study amniotic fluid volume and any changes that might occur in it. Any reduction in amniotic fluid volume will be an indication of compromised vitality and a sign of an adverse outcome.

Fetal vitality can be evaluated before the third trimester through the study of blood flow velocity waves: an increase in systolic peak and a reduction in end diastolic flow will be an indication of a higher resistance in the uteroplacental and umbilical beds, and therefore, of imminent compromise in fetal vitality. During the third trimester, evaluation of fetal vitality by means of antepartum non-stress tests is recommended since its effectiveness is not affected by the use of hypotensive drugs.[19]

Criteria for pregnancy interruption

- Moderated hypertensive condition with a mature fetus (over 37 weeks' gestation)
- Severe hypertensive condition with a fetus over 34 weeks gestational age
- Severe hypertensive condition with an immature fetus in the presence of damaged maternal health and/or treatment failure
- Eclampsia.

Route of delivery

The route of delivery will depend on the hypertensive condition and the degree of fetal distress and/or IUGR.

In the presence of mild or moderate hypertension, there is no contraindication to vaginal delivery, unless there is an obstetric indication for surgical delivery.

In cases with severe hypertension, the route of delivery will depend on the degree of fetal distress and of IUGR: if the fetus is highly compromised, surgical delivery through the abdominal wall is recommended. If the vaginal route is attempted, intrapartum fetal monitoring is mandatory. However, any complication in the progress of labor and/or any sign of intrapartum fetal distress must be taken as an indication for a cesarean section.

Anesthesia

General anesthesia is preferred in cases of severe hypertension and eclampsia. In mild or moderate hypertension, however, an epidural can be used if a sudden hypotension is avoided and if the dose is fractioned and administered through a catheter.[20]

Treatment of eclampsia

- Protect the patient:
  - Prevent tongue biting
  - Suction the pharynx
- Administer oxygen
- Do blood and urine tests
- Insert a Foley catheter to measure urine output
- Administer magnesium sulfate ($MgSO_4$).

(1) If the patient has seizures, start with a slow intravenous bolus (7–14 drops per minute) of 4–6 g of $MgSO_4$, diluted in 10 cm^3 of 5% dextrose solution. If seizures recur within 2 h, the same diluted bolus can be administered again.
(2) In the absence of seizures but with prodromic signs, we recommend administering an $MgSO_4$ infusion and avoiding a bolus.[21]

When a patient shows signs and/or symptoms of magnesium toxicity[22]:

- Interrupt magnesium administration immediately
- Maintain adequate oxygenation
- Perform an ECG (arrhythmias are likely)
- Administer diuretics
- IV calcium gluconate is an adequate antidote.

Treatment with $MgSO_4$ should be administered for at least 24 h after achieving its therapeutic effect or until the cause of its indication has ceased.

Alternative medications for the treatment of seizures

- Sodium thiopental: slow, diluted IV dose of 250 mg
- Diazepam: 100 mg in 500 cm^3 of 5% dextrose solution, 5–7 drops per minute. A slow IV bolus of 40 mg is also possible. (Diazepam is an important fetal and maternal respiratory depressant.)[23]

If the patient presents with high blood pressure concomitant with seizures, administer simultaneously parenteral hypotensive medication.

The patient's prognosis can be complicated by[24–26]:

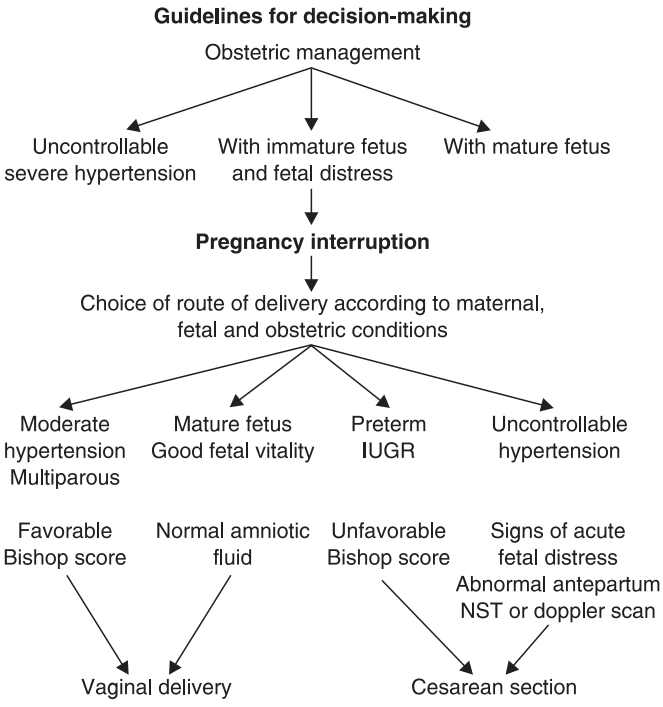
Pulmonary edema
- Weak and fast pulse
- Pulmonary stertors
- Decrease in blood pressure

Prolonged coma
- Focus signs
- Cerebral hemorrhage

Renal failure
- Reduced urinary output.

Treatment of hypertensive emergencies

A hypertensive emergency is a condition in which a sudden increase in blood pressure is accompanied by clinical symptoms such as intense headaches, scotomas, blurred vision, photopsia, tinnitus, increased osteotendinous reflexes, and epigastralgia. It usually occurs in patients with preexisting hypertension, and can be treated with various drugs, but in all cases, a



sudden decrease in blood pressure should be avoided as it can have a deleterious effect on the fetus.

Clonidine: Start with a slow 0.25 mg IV bolus and then continue with 0.75 mg diluted in 500 cm^3 of dextrose solution, at a rate of 7 drops per minute.[27]

Hydralazine: This drug is the most widely used all over the world in hypertensive emergencies in pregnant women with pre-eclampsia. It is less effective in patients with preexisting hypertension. Attack dose: slow 5 mg IV bolus (dilute the 20 mg ampoule in 10 cm^3 of dextrose solution). Wait for 15–20 min. If blood pressure does not go down, administer 5–10 mg at 20-min intervals until a 40 mg dose is given. Maintenance dose: this should be the same as the attack dose which resulted in a favorable response.

Sodium nitroprusiate has been shown to be effective in the treatment of non-pregnant patients, but its use can lead to cyanhydric poisoning. Diazoxide is no longer used at present. There are numerous articles in the literature reporting the effectiveness of the use of labetalol, which seems to have become the 'drug of choice' in the treatment of hypertensive emergencies. In contrast, hydralazine has not been on our market for long; therefore, our results with it can only be considered preliminary. Kean,[28] however, has published an interesting article about the use of hydralazine. Except in extreme cases and in the absence of other drugs, converting enzyme inhibitors such as intravenous enalapril are not recommended as they can result in acute fetal renal failure and even intrauterine fetal death. Enalapril has been found to be effective in cases of acute ventricular failure.[29] Our experience with the use of enalapril in the treatment of a hypertensive emergency during puerperium has been satisfactory.

Hypertensive emergencies and/or eclampsia are the most severe clinical conditions of the gestational hypertension syndrome. Appropriate diagnosis and timely therapeutic measures can help to prevent the worst outcome: maternal death.

Prevention of gestational hypertension

State of the art and future perspectives[30]

The efforts made to prevent a disease depend on its prevalence and on the consequences it has in both the individual and the community. Prevention is successful if it allows us to determine the cause of the disease, to detect an early and latent stage of the pathology and to establish effective and safe intervention measures.

The incidence of gestational hypertension without proteinuria ranges from 10% to 15% of pregnancies. Whereas pre-eclampsia occurs in 2–8% of pregnancies, eclampsia is observed in 5–8 out of 10,000 gestations.

Risk. The main risk entailed by pregnancy-induced hypertension is that it may develop into pre-eclampsia and therefore result in potentially severe complications in both the mother and the fetus/neonate.

Pre-eclampsia affects different systems and is characterized by:

- Vasoconstriction
- Blood flow disorders
- Endothelial cells dysfunction
- Hemostatic system alterations.

Maternal morbidity and mortality may occur due to:

- Renal failure
- Liver dysfunction
- Heart and lung failure
- Seizures (eclampsia)
- Cerebral hemorrhage
- Death.

These disorders are found to be more serious in countries with low-budget hospitals and where prenatal care is not easily accessible.

Perinatal morbidity and mortality may occur due to:

Abruptio placentae
Intrauterine fetal growth retardation
Acute and chronic fetal distress
Elective preterm delivery.

The epidemiologic studies detailed below are described in their corresponding articles as cited in the *References section*.

Risk factors for gestational hypertensive disorders

Maternal history

Nulliparity
Previous pre-eclampsia/eclampsia

Age: older than 40 years or younger than 20 years
Short intervals between gestations
Partner with whom the patient has had a pre-eclamptic pregnancy
New partner
Smoker
Mother or sister with a history of pre-eclampsia/eclampsia.

Maternal Disorders

Chronic hypertension and renal disease
Obesity, insulin resistance
Diabetes mellitus (gestational and type 1)
Factor V Leiden, protein S deficiency
Antiphospholipid antibodies
Lupic anticoagulant
Hyperhomocysteinemia

Fetal factors

Multiple gestation
Hydatidiform mole
Chromosomal abnormalities (trisomy 13, tryploidy)

Early markers with predictive value

These markers must be sensitive and specific and should detect the anomaly while prevention of the clinical development of the disease is still possible.

The test should be safe, simple, inexpensive, and appropriate for the patient. Unfortunately, in pre-eclampsia, none of the tests available leads to accurate diagnosis either in low- or high-risk patients; they do not comply with the all criteria mentioned above.

The predictive methods developed so far are the following:

Methods for the prediction of hypertensive disorders in pregnancy recommended between 1985 and 2003

Standard or modified methods of antinatal care

Elevated blood pressure (mean blood pressure)
Ambulatory automatized monitoring of blood pressure; chronobiological study of blood pressure
Tests for microproteinuria

Biophysical tests

Isometric exercise, roll-over test

Biochemical test and markers

- Sensitivity to angiotensin II
- Plasma volume, hemoglobin concentration, hematocrit
- Serum uric acid levels
- Different coagulation factors (activity of the antigen associated to factor VIII, antithrombin III, thrombin–antithrombin III, protein C)
- Platelet count, platelet volume, platelet volume and angiotensin 2 receptors
- Human chorionic gonadotrophin
- Endothelial activation markers (fibronectin, Von Willebrand factor, tissue plasminogen activator, plasminogen activator inhibitor, thrombomodulin, endothelin, laminin)
- Urinary calcium excretion
- Urinary excretion of prostacyclin metabolites
- Urinary kallikrein/creatinine ratio.

Doppler methods

Analysis of the velocity waveform in the uterine artery.

Given the multiple factors leading to pre-eclampsia, it is difficult to develop a sole test that is at the same time predictive, sensitive and specific. As a consequence, the decision to implement prophylactic measures in certain patients should be based on the presence of risk factors stemming from preexisting diseases, from their obstetric history or from their current gestation associated with an increased risk for pregnancy-induced hypertension.

Preventive approaches

The term *prevention* refers not only to primary prevention (stopping the disease from developing), but also to the act of reversing or slowing the process of the disease before it becomes clinically manifest (secondary prevention).

Primary prevention is achieved only if the cause of the disease is apprehended and then prevented or manipulated; therefore, it is not possible in gestational hypertension, where the etiology is unknown. We are still unable to determine why there is a faulty union between the trophoblast and maternal tissue leading to disorders in uteroplacental adaptation and trophoblastic invasion, and also to an exaggerated inflammatory response in the mother and to endothelial damage in pre-eclampsia.

S*econdary prevention* is the only prevention possible in pre-eclampsia, and can be summarized as follows:

Measures for secondary prevention of pre-eclampsia used between 1985 and 2003[31]

Intervention in lifestyle

Reduced physical activity: less stress

Intervention in diet

Low-sodium diet; energy, protein, magnesium, zinc, calcium, vitamin, linoleic acid, and fish oil supplementation

Pharmacologic intervention

Diuretics; antihypertensive drugs; anticoagulants and nitric oxide donors; acetyl salicylic acid.

Lifestyle

There is no evidence that changes in lifestyle have a preventive effect on the development of pregnancy-induced hypertension. Robilliard *et al.*, however, have found a strong correlation between gestational hypertension and the length of sexual cohabitation. The risk of developing this disease in primigravid and multiparous women is inversely proportional to the length of cohabitation.[32]

Diet

Observational studies indicate that a balanced diet with an adequate daily calorie intake benefits both the pregnant mother and the baby. This preventive measure is also taken into account in the prevention of cardiovascular diseases in general.

Below we will analyze some dietary components and their likely relation with hypertensive disorders of pregnancy.

Sodium restriction

In two clinical controlled trials of 603 women, no evidence was found of the prophylactic effect of sodium restriction in the patients' diets. Besides, clinical experimental studies indicate that strict sodium restriction in pregnancy may not be completely harmless as it interferes with the physiological increase in cardiac one-minute volume and the expansion of plasma volume, which are already markedly reduced in pre-eclamptic patients.

While there seems to be no reason to prescribe a low-sodium diet in healthy pregnant women, it should be recommended in patients sensitive to salt who suffer from chronic hypertension and are already on a sodium restricted diet.

Energy and proteins

A recent meta-analysis of 13 controlled studies of less than 25% of the total energy has shown a small but statistically significant reduction in low birth weight and fetal and neonatal death rates. The evidence, however, is not enough to evaluate other potential benefits. Although some studies show that a high-energy intake is associated with an increased risk for pre-eclampsia, in controlled studies there is no clear evidence that weight loss or reduced weight gain might lead to a decrease in the incidence of pregnancy-induced hypertension.

It is important to note that a severe limitation in weight gain reduces birth weight and, therefore, might be dangerous for the fetus.

Magnesium and zinc

Magnesium has been shown to relax vascular smooth muscle, by interfering with calcium entry, and to promote prostacyclin synthesis.

Recent controlled clinical trials have demonstrated the efficacy of magnesium sulfate in the prevention of eclampsia in pre-eclamptic women and in the management of eclampsia. However, prevention of hypertensive disorders of pregnancy with the use of magnesium supplements has so far been unsuccessful. The systematic review of seven controlled clinical trials involving 2689 women did not show any beneficial effect of the daily oral intake of a magnesium supplement during pregnancy.

Zinc is an essential oligo-element in many metabolic pathways. In a recent cohort study, no association was found between maternal plasma concentrations of zinc and any pregnancy outcome parameters in almost 3500 women from a low socioeconomic class.

Calcium

The hypothetical mechanism of action of calcium supplementation is the reduction in parathyroid hormone secretion,[33] which would in turn decrease the levels of free ionized calcium in the smooth muscle and lead to a reduced response of vasopressor agents and to vasodilation.

Bucher *et al.* undertook the meta-analysis of 14 controlled but heterogeneous clinical studies involving a total of 1218 pregnant women who received a daily 1.5–2 g calcium supplement. Results showed calcium supplementation to be associated with a significant reduction in systolic and diastolic blood pressure, with an odds ratio for pre-eclampsia of 0.38 (95% CI: 0.22–0.65), as compared with the placebo group. It also demonstrated that there is a tendency towards a lower incidence of preterm deliveries, IUGR, and perinatal death. Almost all these studies included populations with a low-calcium diet, which would explain why a randomized controlled study of the use of a daily 2 g calcium supplement in healthy nulliparous pregnant women from week 21 to delivery carried out in the United States did not have satisfactory results.

To conclude, currently available data seem to indicate that calcium supplement in pregnancy reduces the risk of pre-eclampsia in communities with a low calcium intake. Yet no beneficial effects on perinatal outcome have been demonstrated so far.

Linoleic acid and fish oil

The large chain omega-3 essential polysaturated fatty acid derivatives of linoleic acid, such as eicosapentaenoic acid or docosahexaenoic acid in sea fish oil, seem to protect against thromboembolic and hypertensive disorders.

Dietary polysaturated omega-3 fatty acids are the precursors of series 3 prostanoids, and combined with arachidonic acid, they produce changes in prostanoid synthesis leading to a reduction in the vasoconstriction and thrombotic effects of thromboxane A2.

The intake of omega-6 linoleic acid derivatives found in vegetable oils such as sunflower oil has been found to have similar effects.[34]

Controlled clinical studies carried out to assess their possible beneficial effects in gestational hypertension have demonstrated that the use of fish oil supplements helps to prolong the length of gestation. However, fish oil has not been found to prevent either the development of pre-eclampsia or its complications. The same conclusions apply to vegetable oils.

Vitamins

Oxidative stress is known to be a major pathophysiological mechanism leading to endothelial damage and malfunctioning in pre-eclampsia. Vitamins C and E are powerful inhibitors of reactive oxygen and lipid peroxidation. The levels of both these vitamins have been found to be rather low in pre-eclamptic patients.

In a randomized clinical study, a total of 283 women at high risk of developing pre-eclampsia, as determined by the anomalies in the uterine artery Doppler waveform or by a previous history of this disease, received a daily 1000 mg supplement of vitamin C and 400 IU of vitamin E from 16 to 22 weeks' gestation until delivery, and were compared with a placebo group. No difference was found in the incidence of pregnancy-induced hypertension in both groups, but the incidence of pre-eclampsia was 17% in the control group, and only 8% in the study group (OR 0.39, 95% CI: 0.17–0.90). Improvement in the biochemical indicators of endothelial and placental vascular function was also observed in the treated group.

As vitamins B6 (piridoxin), B12 (cobalamin) and folic acid, together with specific enzymes, are involved in metionin bioconversion to homocystein, their deficiency might result in hyperhomocysteinemia, which is associated with thromboembolic events and pregnancy complications including pre-eclampsia.

Pharmacologic interventions

Diuretics

Diuretics are known to reduce blood pressure and edema, which does not necessarily imply they have a beneficial effect on the pathophysiology of pre-eclampsia. Furthermore, all the articles in the literature reporting meta-analyses of controlled studies agree that there is not enough evidence to support a probable preventive effect of diuretics on the development of pre-eclampsia and its complications.

On the other hand, no deleterious effects on the fetus or gestation have been found with the use of diuretics. Therefore, treatment with diuretics may be continued in pregnant women who require it due to a preexisting pathology.

Antihypertensive drugs

If systolic and diastolic blood pressure is 160 and 110 mmHg or over, respectively, antihypertensive medication must be prescribed immediately given the high risk for such serious complications as abruptio placentae, cerebral hemorrhage, hepatic and renal failure. In patients with mild or moderate hypertension, the administration of antihypertensive drugs does not prevent the development of pre-eclampsia.

In a recent systematic review of 19 heterogeneous studies involving 2402 pregnant women who underwent antihypertensive treatment and were controlled with a placebo group, the risk of developing severe hypertension was found to be 50% lower in treated patients. However, no differences were found in the incidence of proteinuric pre-eclampsia, perinatal death, preterm delivery or low birth weight.

The use of beta-blockers, as compared with methyldopa, was analyzed in 11 studies involving 787 women. Beta-blockers were found to be more effective than and as safe as alpha-methyldopa. It is important to note that results which showed an association between atenolol and intrauterine growth retardation were not corroborated by other studies.

To conclude, there is no evidence in the controlled clinical studies available in the literature that the use of antihypertensive treatment in women with mild or moderate hypertension, whether chronic or gestational, might prevent the development of pre-eclampsia and eclampsia.

Angiotensin converting enzyme inhibitors and, therefore, angiotensin II receptor antagonists, seem to be the only contraindicated drugs during gestation as they have been found to be associated with fetal skull ossification defects, fetal growth restriction, oligohydramnios and neonatal renal failure.

Anticoagulants and nitric oxide donors

The high prevalence of genetic thrombophilia in patients with early and recurrent pre-eclampsia and intrauterine growth retardation might indicate that the hemostatic system is pathogenetically involved. As a consequence, many authors have proposed the use of aspirin and heparin as a preventive measure and to improve fetal outcome in patients with hereditary thrombofilia and also in patients at a high risk for renal disease.

In a randomized controlled study, Seki *et al.* administered ozagrel hydrochloride, a thromboxane A2 synthetase inhibitor, to 20 women at risk of developing pre-eclampsia from 20 weeks' gestation until delivery. These were compared with 20 women who received placebo. There was a significant decrease in the incidence of pre-eclampsia in the treatment group (RR 0.52) without affecting perinatal outcome.

Nitric oxide. In a controlled randomized study, transdermal nitric oxide (NO) donor glyceryl trinitrate patches and placebo patches were applied to 40 pregnant women at high risk of developing pre-eclampsia. The criterion for inclusion was the presence of abnormal Doppler waveforms in umbilical artery. No reduction in the incidence of pre-eclampsia and of intratuterine fetal growth restriction was observed in treated patients as compared with controls.

In conclusion there is still no evidence to support that heparin, thromboxane synthetase inhibitors and NO donors have a role in the prevention of pre-eclampsia.

Acetylsalicylic acid

Aspirin inhibits prostanoid synthesis through the acetylation and inhibition of cyclooxygenase, the key enzyme in the arachidonic acid cascade. The inhibition of prostanoid synthesis is selective and it depends on the aspirin dose: a low daily dose (0.5–1.5 mg/kg body weight) produces a dose-dependent inhibition in platelet TxA21 synthesis, reaching almost complete inhibition with a 1.5 mg/kg. As platelets do not have a nucleus, they are unable to resynthetize TxA21; consequently, their recovery depends on new platelet production by the bone marrow.

In contrast, the low concentration of aspirin in endothelial cells is not affected, and they continue producing PGI2, even when aspirin is no longer present in the patient's circulation.[35,36]

Several studies suggest that higher doses of aspirin may also affect the early interaction between the trophoblast and the decidua. In 1994, CLASP carried out a multicenter controlled clinical trial of a daily dose 60 mg of aspirin among 8021 women with mixed parity and at low to moderate risk for hypertensive disorders of pregnancy and/or fetal growth restriction. It is important to note that the reduction in the incidence of proteinuric pre-eclampsia (12%), fetal growth restriction (11%), and perinatal death (20%) observed in the group treated with aspirin, when compared with the placebo group, was not statistically significant. However, low-dose aspirin was found to reduce significantly the rate of preterm delivery (20%). Post hoc analysis of the data in the CLASP trial showed that the earlier the onset of treatment, the greater the reduction in the development of pre-eclampsia.

The results of this trial showed that aspirin had no therapeutic effect in 1343 women with pregnancy-induced hypertension or IUGR. The differences observed were not statistically significant either in women with moderate or low risk among a population of 28,000 women.

Through meta-analysis, it can be concluded that the results of the randomized controlled studies conducted in over 30,000 pregnant women at low, moderate, or high risk of developing pre-eclampsia indicate that prophylactic use of low-dose aspirin as from the 12th week of gestation will prevent the development of pre-eclampsia in about 15% of high-risk women. It will also lead to a similar reduction in the rate of low birth weight for gestational age and preterm deliveries. A lower and not statistically significant decrease in perinatal mortality will also be observed. The number of women at low or moderate risk who have to be treated in order to prevent one single case of pre-eclampsia is high (about 100), but it is much lower in high-risk patients.

It should be noted that neither in the CLASP trial nor in any other report has the prophylactic use of low-dose aspirin been associated with any deleterious effect on gestation, delivery or the newborn. Furthermore, follow-up of those babies from delivery to date has not revealed any aspirin-related complication.

Discrepancies among clinical studies

The decision to publish articles in the literature is usually biased towards those which report positive results even though the populations involved may be small. It is also a fact that in the large populations analyzed in multicenter studies high-risk patients may be overlooked and others may be wrongly classified as pre-eclamptic, thus underestimating the preventive effect of low-dose aspirin.

Sources of discrepancy among reported results:

- Gestational age at the time of inclusion in the trial (before or after 20 weeks' gestation)
- Time of the day when aspirin is administered: several controlled studies have demonstrated a more marked effect on blood pressure when aspirin is taken 8 h after waking up; even better results have been obtained if aspirin is taken at bedtime.
- Dose: early trials conducted in small populations report the use of daily doses of 100–150 mg, while later large multicenter studies have used much lower doses (50–75 mg daily). This dose will inhibit platelet thromboxane but may not be enough to affect placental thromboxane.
- We still do not know if a higher dose of aspirin might have other benefits without increasing side effects.
- Protocol adherence: in large multicenter studies it is not possible to corroborate whether the protocol has been followed correctly.
- Results reported in small randomized clinical studies should not be underestimated in favor of large multicenter trials as the former enable better control over eligibility criteria, objectives, time of treatment administration and protocol adherence by both researchers and patients.

Conclusions for obstetric practice

Preventive measures require the accurate identification of high-risk patients – about 2–8% of healthy nulliparous pregnant women. So far this selection can only be based on their obstetric and clinical histories and on the presence of known maternal and fetal risks. Unfortunately, no biophysical or biochemical markers are available yet which can predict the development of a hypertensive disorder during pregnancy.

Current studies do not support the prophylactic use of low-dose aspirin or calcium supplements in pregnant women at low or moderate risk for hypertension in pregnancy. This involves healthy nulliparous women, and those with a history of mild pregnancy-induced hypertension or with mild chronic hypertension.

A daily dose of 60–80 mg of aspirin from week 12 to delivery seems to be safe and effective when used in a definite group of high-risk patients in order to either prevent pre-eclampsia or delay its development and reduce its severity and complications.

In contrast, calcium supplement appears to be effective only in high-risk pregnant women with a low dietary calcium intake.

Recommended treatment protocol

(1) Daily administration of 60–80 mg of aspirin from week 12 to delivery in pregnant women with
   (a) a history of severe pre-eclampsia or elcampsia before 32 weeks' gestation
   (b) a history of severe fetal growth restriction, with or without pre-eclampsia, due to reduced uteroplacental blood flow
   (c) a family history of pre-eclampsia/eclampsia (in the mother or sister)
   (d) severe chronic hypertension and/or renal disease.

(2) Daily administration of 1.5–2 g elemental calcium supplement in high-risk women categorized as above and with a low dietary calcium intake, assessed according to their consumption of milk and other dairy products.

To conclude, given the multiplicity of clinical forms of this syndrome and the absence of early signs it is still not possible to predict its development. This, compounded by poor prenatal care, impedes the resolution of the disease.

We health care providers in Latin America should strive to reach the community *before* a gestation is conceived so that the antenatal visit does not constitute the first contact between the health center and the patient. The future is still uncertain; in the meantime, the medical community continues to provide new answers.[37]

193 Diabetes and pregnancy

F. A. Van Assche

Introduction

Although substantial progress has been made in the physiopathology and management of diabetes and pregnancy, major problems remain unsolved. Furthermore, diabetes in pregnancy remains an important medical complication, with implications for mother and child in the short and long term. Gestational diabetes does not significantly increase perinatal mortality; however, fetal hyperinsulinism and macrosomia are present. The case for the preexisting insulin-dependent pregnant diabetic has improved, but major complications, such as congenital malformations, sudden fetal death and the association with pre-eclampsia, need better understanding.

Screening for gestational diabetes

Gestational diabetes is defined as carbohydrate intolerance of variable severity with onset or first recognition during the current pregnancy.[1] Gestational diabetes occurs more frequently in older and overweight pregnant women. It is a heterogenous disorder and affects 2–3% of pregnancies in the Western world.[2,3] The metabolic adaptation that occurs during normal pregnancy involves apparent deterioration of glucose tolerance and hyperinsulinism, but only in a minority of women are the diagnostic criteria for gestational diabetes present.[4] Insulin secretions are increased during pregnancy and there is evidence that insulin resistance exists.[5,6] The morphological basis for this hyperinsulinism during pregnancy is marked B cell hypertrophy and hyperplasia, and hyperactivity of individual B cells.[7]

The diabetic ketoacidosis, hyperosmolar coma and vascular complications seen in type I diabetes are extremely rare in gestational diabetes. Cousins[8] found that the incidence of pre-eclampsia was increased in women with gestational diabetes. Perinatal mortality and morbidity are affected by this complication. Gestational diabetes is also a risk factor for the development of diabetes in later life. The first studies were those of O'Sullivan,[9] who reported a high incidence of diabetes mellitus many years after pregnancies complicated by gestational diabetes. Further studies have confirmed this original findings.[10–14]

In the past, gestational diabetes was reported to be associated with increased perinatal mortality.[15–17] More recently, it has been shown that perinatal mortality associated with gestational diabetes is not different from that of the general population. However, gestational diabetic women receive more obstetric attention and there is increased perinatal mortality in undiagnosed gestational diabetes.[18] Perinatal mortality therefore remains an indication to screen for gestational diabetes. Perinatal morbidity, in particular fetal macrosomia, is also increased in gestational diabetes. Fetal macrosomia is associated with an increased number of operative deliveries and with shoulder dystocia.[19,20] There is also evidence that infants born to mothers with gestational diabetes have an increased risk of becoming diabetic in later life.[21]

It therefore remains necessary to screen for gestational diabetes and if possible to perform general screening of all pregnant women.[22] However, there are a large number of glucose challenge procedures, with no agreement on the diagnostic criteria for gestational diabetes and there is not much hope of standardization in the near future.[22] Venous or capillary blood can be used and the glucose load can be oral or intravenous, with a glucose challenge of 50, 75 or 100 g. The original Somogyi–Nelson method of glucose measurement has been changed over the years to the glucose oxidase or hexokinase method. Furthermore, there are geographical, ethnic and racial differences in the deterioration of glucose metabolism.[23] Screening for glycosuria is not a strong index of gestational diabetes, since in pregnancy glucose in the urine does not reflect hyperglycemia. In the USA screening of the total pregnant population is advised using a 50-g 1-h challenge test; the American College of Obstetricians and Gynecologists advocate a glucose threshold of 140 mg/100 ml or 7.8 mmol/l (using venous plasma or serum and glucose oxidase or hexokinase techniques). Screening should be performed at 26–28 weeks, but retesting later in pregnancy might be reasonable for some patients such as obese and older women.[22] The use of the glucose reflectance meter may facilitate general screening in the future. However, lack of precision of the meters can be responsible for missing pregnant women who need further testing.[24,25] Other challenge tests and also random blood glucose testing have been

Table 193.1 Glucose challenge test criteria

	mg/100 ml	Glucose threshold mmol/l
Fasting	95	5.3
1 h	180	10.0
2 h	155	8.7
3 h	140	7.8

used but do not show any advantage over the 50-g challenge test.[22] The measurement of glycosylated hemoglobin and glycosylated proteins has inadequate sensitivity and specificity for screening.[26,27]

The standard method for the diagnosis of gestational diabetes still remains the 100-g oral glucose challenge, although the WHO has recommended a 75-g load (as in the non-pregnant population). The interpretation of the test goes back to the original study of O'Sullivan and Mahan.[28] Carpenter and Coustan,[29] using venous plasma and the glucose oxidase or hexokinase techniques, converted the O'Sullivan and Mahan[28] criteria as shown in Table 193.1. These criteria are close to the data of the European collaborative study where a glucose load of 75 g was used, but the blood sampling varied in the different centers.[30]

It must be stressed that international comparisons of the prevalence of diabetes during pregnancy are difficult because of the different methods and cutoff points for diagnosis. Furthermore, there are major ethnic variations.[31]

Gestational diabetes remains a risk factor for mother and child. It is therefore necessary to screen for this disorder during pregnancy. Universal screening with a 50-g 1-h glucose challenge is recommended. The final diagnosis is made with a 100-g oral glucose tolerance test. This clearly means that women with risk factors (severe obesity, a history of diabetes in the family, a personal birth weight of more than 4500 g, pre-eclampsia, polyhydramnios, fetal macrosomia, perinatal death and congenital anomalies) need a 100-g oral glucose tolerance test.

Prepregnancy care

There is growing evidence that tight control of diabetes before pregnancy improves fetal and maternal outcome. Education and management may prevent congenital malformations and early pregnancy loss and can also improve the maternal condition.[32] Many studies have shown that congenital malformations are more numerous in infants of type I diabetic mothers[33–38] and these are becoming the leading cause of perinatal morbidity and mortality in such infants. Kucera[39] reviewed the world literature between 1930 and 1964; the incidence of congenital malformations in diabetic pregnancies was 4.8% compared with 1.65% in normal pregnancies. Anomalies of the central nervous system, heart, skeleton, gastrointestinal tract and genitourinary tract are predominant. Poor metabolic control and the severity of diabetes is correlated with the high incidence of congenital anomalies.[34,40] An association is also found with a high level of glycosylated hemoglobin in the first trimester of pregnancy.[41] Furthermore, optimal treatment with insulin in the critical periods of organogenesis reduces the rate of fetal malformations in the rat.[42,43]

The first study in human pregnancy showing a reduction of congenital malformations by intensive diabetic management prior to conception was from Karlsburg, Germany.[44] The incidence of congenital malformations was 0.8% in the pregnancies of women given intensive treatment prior to conception and 7.8% in those pregnancies where intensive treatment started at 8 weeks. Studies in Europe and the USA confirmed these positive findings.[45–48] Strict metabolic control early in pregnancy reduces the number of congenital malformations at birth but does not prevent the excess frequency at conception, as is the case with tight glycemia control prior to conception.[38]

The relationship between poor diabetic control before conception or early in pregnancy and an increased rate of spontaneous abortion is not so clear. Miodovnik and colleagues[49] concluded that control of blood sugar is crucial around conception and in the early weeks of pregnancy to reduce the risk of an early abortion. Abortions after 10 weeks are probably due to congenital malformations. Studies in diabetic rats have shown delayed morphological development of blastocysts even in the preimplantation period and also more degenerate embryos.[50]

It therefore seems necessary for each diabetic woman planning a pregnancy to undergo preconception counseling. The presence of hypertension, vasculopathy, proliferative retinopathy and neuropathy must be investigated. Proliferative retinopathy should be treated by laser coagulation. The woman and her partner should be told that in the case of severe diabetes, certainly in association with hypertension, life-threatening complications for herself and the fetus do exist and exceptionally she should be advised not to become pregnant.

The most important goal of preconception care is to motivate intensive self-management in order to obtain normoglycemia. The woman must be instructed on self-monitoring her blood glucose and must learn about diet, physical activity and an efficient insulin regimen. Only when permanent normoglycemia is achieved can the future of the conceptus and maternal health be assured.

The key points of preconception counseling are clearly described by Steel,[51] who was one of the first to indicate the importance of this approach. After 20 years' experience in Scotland, it is still the case that all diabetic women should, at reproductive age, be visited by health-care providers, and that this should be regarded as a preconception visit.[51]

Medical approach of the pregnant diabetic woman

Normoglycemia from the preconception period until the time of delivery must be achieved in pregnant women with preexisting diabetes. In order to achieve this goal, intensive education of the diabetic woman is necessary. The skills, knowledge and experience of doctors and non-medical advisers are also important. During their reproductive years, diabetic women must be treated by a diabetologist with clinical and research interests in diabetic pregnancy. Of even more importance, a multidisciplinary approach is necessary, including general practitioner, nurse, dietician, physician, obstetrician and neonatologist. In most centers care is performed in a combined obstetric–diabetic antenatal clinic.

Self-monitoring of capillary blood glucose must be taught before conception and continued throughout pregnancy. There is no evidence that any special insulin regimen is better than others.[52] Frequent daily use of short- and medium-acting insulin and pen injectors or pumps delivering insulin subcutaneously are accepted alternatives. Optimal blood glucose levels are 4.0 mmol/l (80 mg/100 ml) preprandial and 6.0 mmol/l (120 mg/100 ml) postprandial. Since hypoglycemia can occur in the first trimester, it is advisable to use the same dose of insulin as that used before conception. With further progression of pregnancy the dose of insulin will increase. There is universal agreement that the measurement of glycosylated hemoglobin is the gold standard for the evaluation of good diabetic control. Levels below 7.5% should be achieved.[52] During labor and delivery, blood glucose is controlled by an intravenous infusion of dextrose and insulin.

Gestational diabetes can be treated by diet alone or by diet and insulin therapy. It is usual to start with dietary control. When blood sugar levels remain high or when fasting blood glucose is elevated, insulin should be given and adjusted in order to maintain normoglycemia. One insulin injection daily in the morning will control hyperglycemia. Weiss and associates[53] have suggested intensive management of the fetus in gestational diabetes by measuring insulin in the amniotic fluid. In the case of fetal hyperinsulinism, treatment with increasing doses of insulin is advised.

The intention of controlling fetal hyperinsulinism is to prevent macrosomia and neonatal complications. A review of current practice shows that only 15% of women with gestational diabetes require insulin.[54] However, intensive treatment with insulin has reduced the rate of macrosomia.[55] Moreover, experimental and epidemiological data indicate that long-term complications can be prevented by correct insulin therapy during gestational diabetes.[56]

There are no clear data available concerning the use of active agents in delaying digestion or absorption of nutrients. The use of oral hypoglycemic agents is a matter of controversy and is mostly regarded as contraindicated in Western medicine.

Obstetric approach of the pregnant diabetic woman

Perinatal mortality in the pregnancies of women with preexisting diabetes has been reduced over the last few decades. Congenital malformations and unexpected stillbirths remain the leading causes of death. Intrauterine deaths can still occur in type I diabetic pregnancies with poor control and in women with complications such as polyhydramnios, pre-eclampsia, macrosomia and intrauterine growth retardation.[57] The most important obstetric management therefore includes the detection of congenital anomalies, fetal surveillance and the prevention or early detection of complications of pregnancy. Congenital malformations can be detected by ultrasound examination between 16 and 20 weeks of pregnancy. Pedersen and Mølsted-Pedersen[58] have shown that fetuses with early growth retardation have a higher incidence of congenital malformations. Ultrasound is also the most suitable method for the evaluation of fetal growth. Increased thoracic diameter and increased abdominal circumference are markers for macrosomia.[59] However, the exact prediction of fetal weight remains difficult.[60] In diabetic vasculopathy, asymmetrical growth retardation can be detected during the second half of pregnancy.[61] Biophysical methods, such as fetal heart rate monitoring and the biophysical profile are superior to the older fetoplacental function tests for fetal surveillance, certainly during the third trimester. It is our experience that abnormalities of these tests are more ominous for the fetus of a diabetic woman than for the fetus of a woman with other complications of pregnancy.

Maternal complications are still frequently seen in pregnancy complicated by diabetes.[8] Hypertension during pregnancy and pre-eclampsia are increased in gestational diabetes and in the pregnant woman with preexisting diabetes. Garner and coworkers[62] found an incidence of preeclampsia of 9.9% in diabetic pregnancies compared with 4.3% in non-diabetic women. Van Assche and colleagues[63] found an increased production of thromboxane between 28 and 32 weeks of pregnancy in diabetic women without clinical vascular complications at the time of testing. The highest levels were found in those women who subsequently developed pre-eclampsia. It was concluded that increased thromboxane generation could be related to the occurrence of preeclampsia and the use of antiplatelet therapy to prevent pre-eclampsia warrants further investigation. However, preeclampsia will keep its secrets and prevention of the disease will be difficult. When polyhydramnios is found, fetal anomalies must be excluded and re-evaluation of strict

diabetic control is advisable.[8] Polyhydramnios can be caused by excessive fetal urine production secondary to hyperglycemia. Premature rupture of the membranes, preterm labor, cord prolapse and abruptio placentae are known complications. Preterm labor can lead to the birth of a premature baby. On the other hand, the use of β-agonists and corticosteroids can result in maternal hyperglycemia, hyperinsulinemia, hypocalcemia, ketoacidosis, pulmonary edema and angina.[64] When these drugs are used, intensive diabetic monitoring is mandatory. Magnesium sulfate and calcium channel blockers may be worthwhile alternatives.[65] While the incidence of urinary tract infections is not increased in diabetic pregnancies, pyelonephritis increases the risk of perinatal morbidity.[66]

In older studies it was recommended that type I diabetic women were delivered between 35 and 36 weeks of pregnancy in order to avoid the high number of intrauterine deaths. In the last decade it has been suggested that diabetic pregnancies under tight control and without complications should be allowed to continue to term. Under these circumstances, an amniocentesis to determine fetal maturity seems unnecessary. For cervical ripening and induction of labor, local prostaglandin E_2 administration is of substantial benefit. Close supervision of the progress of labor and continuous electronic fetal monitoring are mandatory. The incidence of cesarean section varies between 17 and 83%.[60] Failed induction, macrosomia causing obstructed labor and fetal distress are the main reasons for abdominal delivery.[8] Coustan and associates[67] have shown that with close supervision the cesarean section rate can be reduced without increased perinatal risk. However, in the presence of a macrosomic fetus cesarean section is advisable in order to avoid shoulder dystocia. Indeed the physique of the infant with broad shoulders and a short neck may predispose to the dangerous complication of shoulder dystocia.

The obstetric management of the mother with gestational diabetes is mainly concentrated upon the detection of fetal macrosomia. Maresh and Beard[68] suggest that in the absence of any obstetric complication spontaneous labor can be awaited. However, in more severe gestational diabetes, certainly in the case of macrosomia, management similar to that of the pregestational diabetic is recommended.[69] Congenital malformations and early fetal loss are probably not increased in gestational diabetes.

The effect of maternal diabetes on the fetus and offspring

Alterations in the intrauterine environment affect fetal growth and development. In diabetic pregnancies not complicated by vasculopathy, fetal hyperinsulinism and macrosomia are mostly present. However, when vasculopathy and nephropathy are associated intrauterine growth restriction and hypoinsulinism are common findings. Both conditions may have long-term consequences. At present, human and experimental data in the rat are available. The advantage of research in the rat is that a better exploration of the working mechanisms is possible.

Offspring of rats that were hyperglycemic throughout the last week of gestation, at adulthood, appear as normal healthy animals with a normal body weight, normal basal glucose and insulin levels and a morphologically normal endocrine pancreas.[70,71] When stressed, however, glucose tolerance appears to be impaired, and the effect is divergent whether the youngster had passed its intrauterine life in a mildly or in a severely diabetic mother. When the maternal hyperglycemia was mild and resulted in fetal hyperinsulinemia, the induced increase in amino acid turnover is maintained in adulthood, and the β-cell response to glucose stimulation is deficient, while the insulin receptor system appears to be unaffected.[71–73] When the maternal hyperglycemia was severe and resulted in fetal hypoinsulinemia, the adult offspring not only displays a deregulation of the stimulated insulin output, but also insulin resistance in the liver and the peripheral tissues.[72,74] When the mothers were malnourished during pregnancy, whether in a qualitative (protein deficiency) or a quantitative (50% restriction) way, glucose tolerance is also impaired in the offspring.[75,76]

Pregnancy causes a considerable stress on the glucose and insulin metabolism of the mother and implies important adaptations of the endocrine pancreas at the structural and functional levels. The mass of islet tissue doubles and the activity of the β-cells is enhanced.[77] Normal pregnancy is associated with hyperinsulinemia and insulin resistance. When these youngsters of diabetic or malnourished mothers with impaired glucose tolerance become pregnant, they develop gestational diabetes.[71,78,79] This implies that their fetuses also will develop in an abnormal intrauterine milieu and have to adapt to it. Indeed, they display the typical features of fetuses from mildly diabetic mothers, and when they become adult they develop impaired glucose tolerance and gestational diabetes.[77,78] A diabetogenic tendency is thereby transmitted from one generation to another, without any genetic involvement, but as a result of the fact that the fetus developed in an abnormal intrauterine milieu. In the human a number of epidemiological studies also point to the importance of the intrauterine milieu for the development of the fetus. A higher incidence of non-insulin-dependent diabetes and of gestational diabetes is reported in children from diabetic mothers than from diabetic fathers,[80] and a higher incidence of diabetes is present in offspring from diabetic great-grandmothers via the maternal than via the paternal line.[81] Systematic treatments of diabetic mothers during pregnancy may result in a

decreased incidence of diabetes in their children.[82] The most convincing data on the intrauterine transmission of the diabetogenic tendency in the human derive from studies of Pettitt and coworkers[83] on the Pima Indians, a population with a high incidence of diabetes. Glucose tolerance is much more frequent in children from mothers who had diabetes during pregnancy than in children from mothers who developed diabetes only after that pregnancy. The difference is convincing: 33% vs. 1%.[83] Recent epidemiological studies, relating birth files from 50 years ago with the health condition of these people now, also demonstrate a significant relationship between body weight at birth, whether or not related to a known metabolic pathology of the mother, and the incidence of impaired glucose tolerance and diabetes in adulthood.[84]

We can conclude that even a minor disturbance in maternal metabolism induces alterations in the fetal metabolism with lasting consequence for the offspring, even over several generations. The effect is situated at the level of insulin secretion (number, sensitivity, synthesis and secretion of β-cells) but also at the level of the insulin receptor system (number and sensitivity of receptor and postreceptor mechanisms).

Conclusion

At the beginning of the century a large number of diabetic women died before the age of reproduction or were too unwell to ovulate. When pregnancy occurred, maternal morbidity and mortality were high and only a few children were born alive. The discovery of insulin was beneficial for the mother but perinatal survival was still rare. With improvements in diabetic care, perinatal mortality improved but remained very high. Clinical and fundamental research brought the knowledge that for the treatment of the fetus of a diabetic mother, normoglycemia is obligatory. To protect the fetus during conception, tight control is necessary before conception. This implies commitment from physician, obstetrician, neonatologist and non-medical personnel. The diabetic woman herself and the environment take the major responsibility for care and management.

The most important goals for the future are the further reduction of congenital malformations, the early detection and prevention of pre-eclampsia, the prevention of diabetic complications during pregnancy and further investigation of the mechanisms of long-term effects.

194 Disorders of the respiratory system in pregnancy

C. Nelson-Piercy and J. Moore-Gillon

Introduction

Asthma is the commonest preexisting medical condition to complicate pregnancy, tuberculosis is becoming more common and pneumonia and cystic fibrosis are important causes of maternal mortality. This chapter discusses the physiological changes in the respiratory system during pregnancy, and the effect of asthma and other respiratory disease on pregnancy, as well as the effect of pregnancy on respiratory disease and the management of asthma, pneumonia, tuberculosis, sarcoidosis, cystic fibrosis and restrictive lung disease in pregnant women.

Physiological changes

There is a significant increase in oxygen demand in normal pregnancy due to the 15% increase in metabolic rate and the 20% increase in consumption of oxygen. There is a 40–50% increase in minute ventilation, mostly due to an increase in tidal volume, rather than in respiratory rate. This maternal hyperventilation leads to a reduction in partial pressure of arterial carbon dioxide, with a compensatory fall in serum bicarbonate and a mild respiratory alkalosis.

Later in pregnancy, the elevation of the diaphragm caused by the enlarging uterus leads to a decrease in functional residual capacity, but diaphragm excursion is unaffected so vital capacity is unchanged. A potential source of diagnostic confusion is awareness of the physiological hyperventilation of pregnancy, which leads to a subjective feeling of breathlessness in up to three-quarters of women at some time during pregnancy.

Patients with severe lung disease are less likely to deteriorate in pregnancy than those with severe cardiac disease. This is because there is a relatively greater reserve in respiratory function. Thus, although there is a comparative (about 40%) increase in both cardiac output and minute ventilation in pregnancy, for minute ventilation this represents a smaller fraction of the maximum increase possible by the body. If there is severe lung disease, however, right heart failure may be precipitated because of the increase in blood volume and cardiac output in pregnancy.

Asthma

Asthma is the commonest chronic illness of young adulthood, affecting at least 3% of women of childbearing age.[1] It is therefore often encountered in pregnancy, and this provides a valuable opportunity to diagnose asthma, and to optimize the treatment of women already known to have asthma.

Pregnancy and the severity of asthma

Pregnancy itself does not usually influence the severity of asthma. The course of asthma during pregnancy in individual patients is unpredictable. A review of more than 1000 pregnant asthmatics reported in nine studies found a worsening of asthma in 22%, improvement in 29% and no change in 49%.[2] Women with only mild disease are unlikely to experience problems, whereas severe asthmatics are at greater risk of deterioration, particularly late in pregnancy.[2,3] Those women whose symptoms improve during the last trimester of pregnancy may experience postnatal deterioration.[3,4]

Although in most individuals the severity of the disease process itself is probably unaffected by pregnancy, many asthmatics do experience a deterioration in symptoms. This may relate to increased awareness of the physiological hyperventilation of pregnancy. Of greater concern is the deterioration in disease control caused by reduction or even complete cessation of medication due to fears about its safety.

Asthma and the outcome of pregnancy

For the majority of women, asthma has no adverse effect on pregnancy outcome, and women should be reassured accordingly. Severe poorly controlled

asthma, associated with chronic or intermittent maternal hypoxemia, may adversely affect the fetus and thus be associated with a significant decrease in mean birth weight, and an increase in the proportion of low birth weight neonates,[5,6] but recent studies have in general been very reassuring. Schatz and colleagues[7] compared nearly 500 pregnant asthmatics with non-asthmatic pregnant controls, and found the overall perinatal prognosis for women with actively managed asthma during pregnancy did not differ significantly from that of the non-asthmatic population. The incidence of pre-eclampsia, preterm births, low birth weight infants, intrauterine growth retardation, congenital malformations and perinatal mortality was similar in both groups.

Similarly, a retrospective study from India found no significant difference in antenatal complications, duration of pregnancy, mode of delivery, incidence of prematurity and low birth weight and perinatal mortality in asthmatic compared to non-asthmatic women.[6] A recent study looking specifically at the effects of acute attacks of asthma during pregnancy found no detrimental effect on birth weight, incidence of malformations, hypoglycemia or the need for phototherapy for jaundice during the neonatal period.[8] However, it is important to note that in this study the attacks were relatively mild and promptly treated.

There are other studies which do report a slight increase in the risk of premature labor[5,7,9–11] and low birth weight,[12–14] but some of the literature includes retrospective studies without adequate controls. Although a large prospective study did find a greater than twofold risk of preterm labor in asthmatics,[10] another prospective study[15] supports the findings of Schatz and coworkers[16] of no increase in either low birth weight or preterm delivery. A study from Quebec found that women with early and recurrent idiopathic preterm labor were significantly more likely to report asthma symptoms or physician diagnosed asthma than controls although there was no association with methacholine responsiveness, a measure of severity of asthma, suggesting that non-atopic noncholinergic mechanisms may link bronchial and uterine smooth muscle lability.[17] In summary, it would seem that any influence on birth weight and prematurity is small and related to the severity and control of the asthma.

Some studies have reported an increased incidence of pregnancy-induced hypertension/pre-eclampsia in asthmatic women.[5,8,18] Using a study population of over 24,000 women without essential hypertension, Lehrer and colleagues[18] found a significant association between pregnancy-induced hypertension and asthma. This is not a consistent finding[11,16] and caution is needed when interpreting these studies, since women with asthma are likely to be reviewed, and therefore to have their blood pressure measured more frequently than non-asthmatics during the antenatal period. It may be the detection rather than the incidence of raised blood pressure that is increased in asthmatics. A recent study from Finland demonstrated a significantly higher incidence of pre-eclampsia in asthmatics treated with theophylline (with more severe disease) but not in non-theophylline-treated asthmatics compared to non-asthmatic pregnant controls,[19] suggesting that the association with hypertensive disorders of pregnancy may be related to the severity of the asthma. Low-dose aspirin is gaining acceptance as prophylaxis for certain women at very high risk of early-onset pre-eclampsia,[20] but it is worth remembering that some asthmatics may develop severe bronchospasm with aspirin, and pregnant asthmatic women should be asked about a history of such sensitivity before being treated with low-dose aspirin.

Some studies suggest a possible increased incidence of transient tachypnea of the newborn,[21] neonatal hypoglycemia,[15] neonatal seizures[22] and admission to the neonatal intensive care unit,[11] in the babies of asthmatic women, but again these effects are small and are related to the degree of control of the asthma.

In summary, there is some evidence in asthmatic mothers for an increased incidence of small and preterm infants, but this risk appears to be small and may be minimized by maintaining good control of asthma throughout pregnancy. A relationship between asthma and hypertension or pre-eclampsia has also been suggested, but again any effect seems to be very small.

Management

Treatment of asthma in pregnancy differs little from the management in the non-pregnant patient. Effective control of the disease process and its accompanying symptoms is a priority. The focus should be on explanation and reassurance concerning the safety of the drugs used to treat asthma in pregnancy and during lactation. Education of asthmatic women prior to conception as well as during pregnancy are integral parts of management since decreasing or stopping inhaled anti-inflammatory therapy during pregnancy is a frequent cause of potentially dangerous deterioration in disease control. A team approach involving the obstetricians and midwives, the physician and the woman herself is the ideal. Emphasis on the safety of medication, including systemic steroids, helps ensure that women – and their doctors – do not discontinue, reduce or withhold vital drugs during pregnancy.

Two recent studies have shown that regular inhaled corticosteroids are beneficial in pregnant women with asthma. The first, a large prospective study from Finland, found that in women not initially treated with inhaled anti-inflammatory treatment during pregnancy the incidence of acute attacks of asthma was 17%, compared to only 4% in those on inhaled anti-inflammatory treatment from the start of pregnancy.[8] The second, smaller prospective study found the readmission rate for asthma exacerbations was

decreased by 55% in women receiving inhaled beclomethasone at discharge following admission for asthma exacerbations compared to those not receiving this drug.[23]

Only minimal amounts of inhaled corticosteroid preparations are systemically absorbed.[24] Most of the information is for beclomethasone dipropionate (e.g. Becotide®, Becloforte®, Filair®, Beclazone® and other proprietary brands). Studies have shown no increased incidence of congenital malformations or adverse fetal effects attributable to the use of inhaled beclomethasone in pregnancy,[9,25,26] There is less information about budesonide (Pulmicort®), but it is widely used and appears to be safe. Fluticasone propionate (Flixotide®) is a newer inhaled corticosteroid and it too appears to be safe.

The addition of systemic corticosteroids to control exacerbations of asthma is safe, and these must not be withheld if current medications are inadequate. Prednisolone is metabolized by the placenta and very little (10%) active drug ever reaches the fetus. Sadly, media-fed concern about drugs falling within the broad category of 'steroids', combined with 'post-thalidomide' anxiety regarding the use of *any* drug in the first trimester, continue to hamper efforts to ensure that asthma remains optimally controlled throughout pregnancy. Findings from a single 40-year-old report of an increased incidence of cleft palate in the offspring of rabbits treated with massive doses of cortisone early in gestation[27] have been wrongly extrapolated to human pregnancy, where this has never been reproduced, despite the extensive use of steroids during pregnancy for a variety of conditions. There is no evidence of an increased risk of abortion, stillbirth, congenital malformations, adverse fetal effects or neonatal death attributable to maternal steroid therapy.[5,9,28] Although suppression of the fetal hypothalamic–pituitary–adrenal axis is a theoretical possibility with maternal systemic steroid therapy, there is no evidence from clinical practice to support this. The adrenocortical reserve of six newborns whose mothers had received long-term systemic steroids has been formally assessed and the response to exogenous adrenocorticotropic hormone was normal.[29]

Oral steroids will increase the risk of gestational diabetes, and cause a deterioration in blood glucose control in those women with established impairment of glucose tolerance in pregnancy. Blood glucose should be checked regularly, and the hyperglycemia is amenable to treatment with diet and, if required, insulin, and is reversible on cessation or reduction of steroid dose. The development of hyperglycemia is not an indication to discontinue or decrease the dose of oral steroids, the requirement for which must be determined by the asthma.

Transfer of β_2-agonists from the systemic circulation across the placenta is relatively rapid,[30] but very little of a given inhaled dose reaches the lungs, and only a minute fraction of this reaches the systemic circulation. A prospective study of 259 pregnant asthmatics treated with inhaled β_2-agonists showed no difference in perinatal mortality, congenital malformations, birth weight, Apgar scores or delivery complications when compared with asthmatics not using β-agonists and non-asthmatic controls.[31] Experience with the use of the inhaled long-acting β_2-agonist salmeterol (Serevent®) in pregnancy is growing. It appears free from fetal toxicity, it is not discontinued in pregnant asthmatics who require it for good asthma control, and may be introduced during pregnancy.

Inhaled disodium cromoglycate (Intal®), and the more recently introduced Nedocromil (Tilade®), appear to be safe for both mother and fetus, although there are, as yet, insufficient data to support routine use of the latter. Similarly, no adverse fetal affects have been reported with the use of anticholinergic drugs.

Both theophylline and aminophylline readily cross the placenta and fetal theophylline levels are similar to those of the mother.[32] Theophylline has been shown to be a cardiovascular teratogen in animals, and one report has suggested a possible link between theophylline and three cases of congenital cardiac anomalies in the human.[33] Stenius-Aarniala and colleagues[19] have recently published a series of 212 theophylline-treated asthmatics. The incidence of congenital malformations in the group receiving theophylline during the first trimester (2.5%) was not significantly higher than that in asthmatic or non-asthmatic controls, and only one of three abnormalities in the theophylline group was a case of congenital heart disease. There is no conclusive evidence of ill effect or malformation in the human fetus,[34] despite extensive use of theophylline in the past. Some have noted transient tachycardia or irritability in neonates of mothers receiving xanthines, but others have found that mean neonatal heart rate and Apgar scores were unaffected by maternal theophylline use.[19,32] The study of Stenius-Aarniala and colleagues[19] found a twofold increase in the frequency of jaundice in the neonates of theophylline-treated mothers, but this may relate to disease severity rather than the drug itself.

Acute severe attacks of asthma are treated as medical emergencies as in the non-pregnant[35] and, if needed, intravenous aminophylline or intravenous β_2-agonists should not be withheld.

The ionizing radiation from a chest x-ray is approximately 0.2 rad [less than 1/20th of the maximum recommended exposure in pregnancy (5 rad)], and abdominal shielding will minimize the exposure to the fetus. If a chest x-ray is clinically indicated, this investigation must not be withheld just because the patient is pregnant.

Asthmatic attacks in labor are rare. Women should not discontinue their prophylactic inhalers during labor, and there is no evidence to suggest that β-agonists given via the inhaled route impair uterine contraction or delay the onset of labor. Women receiving oral

steroids (> 7.5 mg prednisolone daily for > 2 weeks prior to delivery) should receive parenteral hydrocortisone (100 mg three or four times a day) to cover the stress of labor, and until oral medication is restarted. Prostaglandin E_2, used to induce labor, to ripen the cervix or for early termination of pregnancy, is a bronchodilator and is safe. The use of prostaglandin F_{2a} to treat life-threatening postpartum hemorrhage may be unavoidable, but it can cause bronchospasm,[36,37] and should be used with caution in asthmatics. All forms of pain relief in labor, including epidural analgesia and Entonox, are appropriate for asthmatic women, although in the unlikely event of an acute severe asthmatic attack, opiates for pain relief should be avoided. Epidural rather than general anesthesia is preferable because of the increased risk of chest infection and atelectasis associated with the latter. Ergometrine has been reported to cause bronchospasm, but this does not seem to be a practical problem when syntometrine (oxytocin/ergometrine) is used for the prophylaxis of postpartum hemorrhage.

The risk of atopic disease developing in the child of an asthmatic woman is about 1 in 10, or one in three if both parents are atopic. There is some evidence that this risk may be reduced by breast feeding,[38,39] which provides another reason to encourage this practice.

All the drugs discussed above, including oral steroids, are safe to use in nursing mothers. Prednisolone is secreted in breast milk,[40,41] but there have been no reported clinical side effects in infants breast-fed by mothers receiving prednisolone and concerns regarding neonatal adrenal function are unwarranted with doses below 30 mg/day.

Pneumonia

Bacterial pneumonia is no more common in pregnancy than in non-pregnant women of the same age, matched for smoking status. However, viral pneumonia, for example, influenza pneumonia, is more severe in pregnancy[42] and pregnant women are particularly susceptible to varicella zoster (chicken pox) pneumonia and the maternal and fetal mortality is high.[43]

Patients with suggestive symptoms of cough (often dry at first), fever, rigors, breathlessness or pleuritic pain or signs of purulent sputum, coarse crackles or signs of consolidation on auscultation should have a chest x-ray.

Bacterial pneumonia

Bacterial pneumonia can kill previously fit young people, pregnant or not. Cases in pregnant women must always be regarded as potentially very serious, and always be managed in conjunction with a respiratory specialist. A respiratory rate of ≥ 30/min, a diastolic blood pressure of ≤ 60 mmHg and a serum urea of ≥ 7 mol/l are particularly poor prognostic signs.

Initial investigations should include an assessment of blood gases. Dangerous degrees of hypoxia may not be detectable clinically. Moreover, oximetry alone will only ensure adequate oxygenation, and a patient on oxygen supplementation may progress to the point of respiratory arrest from respiratory muscle fatigue without an oximeter giving any warning.

Initial antibiotic management must include drugs that will cover the likely pathogens (*Streptococcus pneumoniae*, *Hemophilus influenzae*, *Mycoplasma pneumoniae*, *Legionella*) and a regimen combining amoxycillin and clarithromycin or cefuroxime is usually used.[44] The precise microbial etiology may not be clear at the onset of treatment (and may never be established), and the possibility of non-bacterial causes (see below) should be kept in mind. Staphylococcal pneumonia is more common at times of influenza epidemics. It has a high mortality, and requires a different drug regimen.

Clearance of renally excreted drugs increases in pregnancy and therefore higher doses are required. Tetracyclines should be avoided after about 20 weeks' gestation since they can cause discoloration of the teeth. Iodine-containing cough medicines are also contraindicated because iodine is taken up by the fetal thyroid and may cause hypothyroidism and fetal goitre.

Remember that pleuritic chest pain, hemoptysis, breathlessness and cardiovascular collapse can be caused by the pneumococcus and not just by a pulmonary embolus.

Varicella

Chicken pox is more common and more severe in pregnancy than at other times and the maternal and fetal morbidity and mortality are high. Infection occurs in 0.05–0.07% of pregnancies[45] and about 10–20% of infected women develop varicella pneumonia associated with maternal mortality as high as 40%.[46,47] Later gestational age (perhaps due to increased immunosuppression) at the onset of varicella pneumonia is a significant risk factor for maternal mortality,[48] and the maternal disease appears to be worse in the latter half of pregnancy.[46] A history of previous infection, and therefore likely immunity, is usually reliable in the case of chicken pox since the clinical features are so unique. A live attenuated vaccine has recently become available in the USA and should be offered before conception to non-immune women.[45] Because of the substantial risk accompanying chicken pox infection in pregnancy, non-immune pregnant women exposed to varicella should be given zoster-immune globulin (ZIG).[47] Women should be asked about previous chicken pox infection before they are prescribed steroids in pregnancy, and those found not to be immune should be given ZIG. Those women who do develop clinical varicella should be treated with acyclovir.[49]

Anyone with varicella should be seen away from the antenatal clinic to minimize the risk to other

pregnant women. Maternal and neonatal morbidity and mortality in cases of maternal varicella pneumonia may be improved by the use of intravenous acyclovir and mechanical ventilation.[50] This probably justifies the prophylactic use of intravenous acyclovir in those women who develop cutaneous varicella.[51] Smego and Asperilla[48] reviewed 21 cases of varicella pneumonia complicating pregnancy and found no adverse effects of acyclovir given in the second and third trimesters.

The fetus is at risk of congenital varicella with maternal infection in the first 12–16 weeks of pregnancy. The risk of teratogenicity is about 2%.[47] There is a risk of neonatal varicella if infection occurs within 10 days of, and especially 4 days before, delivery. ZIG administered at birth does not prevent all cases of neonatal infection, which has 30% mortality.[45]

Pneumocystis carinii pneumonia

The increasing number of women of child-bearing age who are seropositive for human immunodeficiency virus (HIV) has contributed to the increased incidence of pneumonia in pregnancy.[52] The most common opportunistic infection in patients progressing to AIDS is *Pneumocystis carinii* pneumonia (PCP). PCP is associated with adverse obstetric outcome, particularly if the diagnosis is not suspected.[53] PCP should be treated with high-dose cotrimoxazole (trimethoprim/sulfamethoxazole) with or without pentamidine. Despite the theoretical risks of neonatal kernicterus or hemolysis from sulfonamides given at term, there is increasing evidence that trimethoprim/sulfamethoxazole is safe in pregnancy.[53] Because PCP is an important cause of AIDS-related maternal mortality, HIV-infected pregnant women with a history of this opportunistic infection or with a $CD4^+$ cell count of < 200 cells/ml should receive prophylaxis with either cotrimoxazole or nebulized pentamidine.[54]

Tuberculosis

Rates of tuberculosis (TB) are increasing in Europe, the United States and developing countries. This recent resurgence is in part, but not wholly, due to the susceptibility of HIV-infected patients to TB infection. In Britain and the USA there are reports of increasing rates among the homeless and in inner city populations.

The onset is usually insidious with cough, hemoptysis, weight loss (or failure to gain weight) and night sweats. Diagnosis may be delayed in pregnancy because of inappropriate reluctance to carry out a chest x-ray. Less commonly, urinary tract, abdominal, lymph node or bone TB may present in pregnancy.

Tuberculosis is diagnosed by the typical appearances on a chest x-ray and sputum examination for acid-fast bacilli (Ziehl–Nielsen stain). Culture of the organism, *Mycobacterium tuberculosis* (MBTB) takes about 3 weeks, and if there is no sputum, washings from bronchoscopy must be obtained.

There is little evidence to suggest that tuberculosis has a detrimental effect on pregnancy or that pregnancy adversely affects disease progression and in neither HIV-positive nor HIV-negative women is recent pregnancy associated with an increased risk of developing active TB.[55]

Management

The principles of management are similar in pregnant and non-pregnant patients. The advice of a respiratory physician or infectious diseases specialist should always be sought. Active disease should be treated with a prolonged supervised course of more than one drug to which the organism is sensitive. Before sensitivities are available most patients are given triple/quadruple therapy with rifampicin, isoniazid and pyrazinamide and/or ethambutol. Liver function tests should be monitored regularly in patients taking rifampicin and all patients taking isoniazid should also be prescribed pyridoxine 10 mg/day to reduce the risk of peripheral neuropathy. The above drugs can all be safely given in pregnancy but streptomycin has been associated with a high ($> 10\%$) incidence of eighth nerve damage[56] and should be avoided throughout pregnancy.

The risk of the neonate developing active tuberculosis is high and advice should be sought from the TB specialist supervising the mother's treatment as to the use of antituberculous chemoprophylaxis and BCG vaccination in the infant. HIV-negative infants born to HIV-positive mothers are at great risk of TB and should also routinely be given BCG.[57] The amounts of antituberculous drugs excreted in breast milk are not sufficient to dissuade women from breast-feeding.

Sarcoid

Sarcoid is uncommon in pregnancy, perhaps affecting 0.05% of all pregnancies in the UK. There may be chest symptoms, but the patient is often asymptomatic. Extrapulmonary manifestations include erythema nodosum (which may also occur as an isolated finding in pregnancy without evidence of an underlying associated cause), anterior uveitis, hypercalcemia, fever, or central nervous system (CNS) involvement.

Sarcoidosis is a multisystem granulomatous disorder of unknown etiology. It has pathological similarities to TB, but unlike tuberculosis, the granulomata are non-caseating. The commonest feature on chest x-ray is bilateral hilar lymphadenopathy but there may be extensive pulmonary infiltration progressing to fibrosis. Although there may be no obvious infiltration in the lung fields, the lung parenchyma is usually involved and diagnosis can be made by transbronchial biopsy. Serum levels of angiotensin converting enzyme may be altered in normal pregnancy

and cannot therefore be used to help diagnosis or monitor disease activity as in the non-pregnant patient.

The course of sarcoidosis is largely unaffected by pregnancy, although those with active disease may have resolution of their x-ray changes during pregnancy,[58] and there is a tendency for sarcoidosis to relapse in the puerperium.[59] Any improvement that is seen antenatally may be due to the increased levels of endogenous cortisol present in pregnancy.[60]

Management

Sarcoidosis often resolves spontaneously, but indications for steroid treatment include extrapulmonary, especially CNS or eye disease, hypercalcemia or functional respiratory impairment. The safety of steroids in pregnancy has been discussed above, and they should be continued or started in pregnancy if clinically indicated. As with asthmatics on maintenance steroids, labor and delivery should be covered with parenteral hydrocortisone if women are taking more than 7.5 mg daily of prednisolone. Women should be advised not to take supplemental vitamin D, which may precipitate hypercalcemia in patients with sarcoidosis.

Cystic fibrosis

Advances in the care of children with cystic fibrosis (CF) have resulted in increasing numbers surviving into adulthood. The median age at death for CF patients is now over 30 years. This increase in longevity is due to several factors including increased emphasis on chest physiotherapy, early use of effective antipseudomonal antibiotics, improved fat absorption and nutrition using microsphere pancreatic enzyme supplements and the centralization of expertise in CF centers.[61]

Males with CF are usually sterile, but female fertility, especially in the well nourished, is normal. Women with CF who become pregnant are usually older at the time of diagnosis of CF, which probably reflects inherent differences in the severity of the disease itself. This may be due to different genetic errors or altered gene penetrance.[62] Pregnancy is well tolerated by many mothers with CF, but these women need expert joint care in a specialist obstetric unit and CF center.[63] CF is a multisystem disease, and during pregnancy, the obstetrician must work with the multidisciplinary team including physiotherapists, physicians and dieticians with particular expertise in the care of these patients.

Effect of pregnancy on CF

Most patients with CF die in early adult life, but with a few exceptions (see below) pregnancy does not increase this risk. Maternal mortality, although significantly increased compared with normal women, is not significantly greater than in non-pregnant age-matched women with cystic fibrosis.[62] But even if a CF woman survives pregnancy, she may deteriorate and die while the child is still young and it is important that such issues are discussed with the woman and her partner prior to pregnancy.

Factors adversely affecting maternal prognosis include maternal pulmonary hypertension, cyanosis and hypoxemia. Mortality is increased in women with moderate to severe lung disease [forced expiratory volume in 1 s (FEV_1) less than 60% of predicted normal values] at the onset of pregnancy,[62,64] and maternal survival is positively correlated with prepregnancy FEV_1%.[64]

Women with CF have difficulty gaining weight in pregnancy. Even those without pancreatic insufficiency are often underweight at the onset of pregnancy. The more underweight the mother prepregnancy, the greater the risk of cesarean section, and weight gain during pregnancy is positively correlated with prepregnancy FEV_1%. One year after delivery, however, there is no overall weight change.[64] Other problems encountered are deterioration in lung function with worsening dyspnea, exercise tolerance and oxygen saturation, pulmonary infective exacerbations and congestive cardiac failure. There is usually a loss of lung function during pregnancy, but this is regained following delivery. Edenborough and coworkers[64] described the outcome in lung function of 18 pregnancies in 17 women. They found a mean loss of FEV_1 of 13% and a loss of forced vital capacity of 11% by the end of pregnancy, but this was largely regained by 1 year postpartum. The patients showed a large variability in the pattern of lung function changes. The same authors found no change in microbiological status, and none of their women became colonized with *Pseudomonas* for the first time in pregnancy.

Effect of CF on pregnancy outcome

The rate of spontaneous abortion is not increased in CF pregnancies. Despite the frequent use of high doses of antibiotics in these women, the rate of congenital abnormalities in reported series is not increased.[62,64]

Factors predicting a poor obstetric outcome are the same as those adversely affecting maternal outcome and include pulmonary hypertension, cyanosis, arterial hypoxemia (oxygen saturation $< 90\%$), moderate to severe lung disease ($FEV_1 < 60\%$ predicted) and poor maternal nutrition. Perinatal mortality in the study of 129 pregnancies in 100 women in the USA[62] was 11.3% (all born to mothers with poor respiratory status), but a smaller, more recent study from the UK[64] of 22 pregnancies in 20 women had no perinatal losses. This may reflect advances in care, but also selection of lower-risk women with relatively preserved lung function. Those with very severe lung disease and deemed to be at high risk may be advised against pregnancy or are advised to have a termination of pregnancy.

The commonest complications during pregnancy are prematurity and intrauterine growth retardation. The preterm (< 37 weeks) delivery rate is increased in

CF pregnancies (26.8% in the series of Cohen and associates[62] and 33.3% in that of Edenborough and colleagues[64]). All mothers with moderate to severe lung disease in the study of Edenborough and coworkers[64] delivered preterm infants (all by cesarean section). The indication in all cases was deteriorating maternal pulmonary function. Chronic hypoxia (oxygen saturation $< 90\%$) and cyanosis both increase the risk of small-for-gestational-age infants. Birth weight is positively correlated with prepregnancy lung function (probably related to longer gestations).[64] Women with preserved pancreatic function have an improved pregnancy outcome.[65] Poor maternal weight gains are predictive of both prematurity and stillbirth.[62]

Management

Prepregnancy counseling is desirable with determination of the carrier status of the partner. Since all women with CF are homozygous, all offspring will be carriers of the CF gene. The risk of a child being born with CF is 2–2.5% if the carrier status of the father is unknown (based on a carrier rate in the general UK population of about 1 in 25), and 50% if the father is heterozygous for the gene.

Pregnant women with CF should always be jointly managed in a CF center and an obstetric unit with experience in the management of such women. Medical management during pregnancy should include attention to adequate maternal nutrition, control of pulmonary infection, avoidance of prolonged hypoxia and regular assessment of fetal growth.

Over 90% of adult CF patients have pancreatic insufficiency and require enzyme supplements. High-calorie dietary supplements may be required in order to maintain maternal weight, since patients with CF (even without malabsorption) have high energy requirements, which will be further increased by pregnancy. Of adults with CF, 20% have diabetes and a further 15% have impaired glucose tolerance (IGT). Insulin requirements increase in pregnancy and those with IGT will be at risk of gestational diabetes.

Strict adherence to chest physiotherapy regimens must be encouraged. Some women decrease their physiotherapy due to fears concerning the fetus. These fears should be allayed. Most of the older, more established antibiotics used to treat pulmonary infective exacerbations in CF have a good safety record in pregnancy, and as stated above, the congenital abnormality rate in CF pregnancies is not increased. Appropriate caution is needed when considering the use of new drugs for which there is little information in pregnancy. The risks to the fetus from poor maternal health probably outweigh the risks to the fetus from transplacental passage of drugs.[63] Some patients may be taking prophylactic antibiotics either orally or via a nebulizer. Except in the case of tetracycline, which is contraindicated in pregnancy because of the effects on fetal teeth and skeleton, these should usually be continued throughout pregnancy. Infective exacerbations should be aggressively treated and this often requires admission to hospital and intravenous penicillins and aminoglycosides or cephalosporins in cases of resistant pseudomonas. Antibiotic therapy must be dictated by the results of sputum cultures. Caution is needed when using intravenous aminoglycosides, whether the patient is pregnant or not, and regular monitoring of drug levels is required. Some patients with CF respond to bronchodilators, and women should be reassured that inhaled and nebulized corticosteroids are safe in pregnancy.

Toward the middle and end of the third trimester, women with CF may become increasingly breathless often without any obvious infective exacerbation. If there is resting hypoxia, and especially if oxygen saturation is in the 80s or low 90s, admission for bed rest and oxygen therapy is advised. In some women, symptom deterioration warrants early delivery. Cesarean section is only necessary for obstetric indications and general anesthesia should be avoided if possible. Instrumental delivery may be indicated to avoid a prolonged second stage. Patients with CF are particularly prone to pneumothoraces, which may be precipitated by prolonged attempts at pushing and repeated Valsalva maneuvers in the second stage of labor.

In view of the risk of fetal growth retardation, the mother should be scanned regularly throughout pregnancy. If the growth rate slows down, it may sometimes be improved by admission of the mother for bed rest, nutritional supplements and oxygen.

In most cases, CF women deliver vaginally at term.[63] Breast feeding should usually be encouraged, although the mother may continue to require nutritional supplements in the puerperium especially if she is breast feeding. Most of the drugs used will be secreted into the breast milk, but this is rarely a contraindication to breast feeding.

Severe restrictive lung disease

Patients with restrictive lung disease, due to, for example, kyphoscoliosis, are less likely to deteriorate in pregnancy than those with severe cardiac disease for the reasons described above. It is difficult to predict with any accuracy the minimum vital capacity compatible with successful pregnancy outcome in patients with kyphoscoliosis and other causes of severe restrictive lung disease. Although figures such as 1 l[66] or 50% of predicted have been suggested, women with more severe impairment have had successful pregnancies.[67,68] Polycythemia gives an indirect assessment of the degree of hypoxia, and in itself is associated with an increased risk of thrombosis due to hyperviscosity.

Women with severe kyphoscoliosis are often delivered prematurely due to deterioration in respiratory function in the third trimester, and by cesarean section because of associated abnormalities of the bony pelvis and of abnormal presentations of the fetus.[69] Each

case must be assessed individually, but, whatever the underlying cause of respiratory insufficiency, significant hypercapnia or hypoxia, and pulmonary hypertension and cor pulmonalae are associated with less favorable pregnancy outcome.

Conclusions

Respiratory diseases are common in the population generally and are thus common in pregnancy. They can cause much maternal morbidity – most of it preventable – even when the risk to the fetus is extremely small. Whilst severe respiratory disease may be apparent before pregnancy, and the woman already under specialist care, other cases may come to light for the first time during the antenatal period. All those involved in the care of pregnant women should have some knowledge of respiratory disease, and, in particular, how to recognize present or future problems and the need for specialist advice.

195 Cardiac disease in pregnancy

D. J. Williams and M. de Swiet

Introduction

Cardiac disease is after psychiatric causes, the second most common cause of maternal death in the UK.[1] Furthermore, symptoms such as breathlessness and signs such as an ejection systolic murmur reflect the physiological changes of healthy pregnancy and are present in up to 90% of the pregnant population.[2] Distinguishing between benign physiological change and significant pathology is an important part of good maternal and perinatal practice. In the developed world the pattern of maternal heart disease has changed radically over the last 50 years, but it has changed little in the developing world. As a prelude to a discussion of the assessment and management of heart disease during pregnancy, we describe the physiological changes of healthy pregnancy and how the pattern of heart disease in pregnancy has changed over a single generation.

Cardiovascular changes during healthy pregnancy

In normal pregnancy, cardiovascular changes are recognized as early as 5 weeks after the last menstrual period, i.e. 3 weeks after conception[3] (Table 195.1). At this time an increase in heart rate and ventricular function combine with a fall in total peripheral vascular resistance to significantly increase maternal cardiac output.[3,4] This trend persists until 24 weeks' gestation by which time cardiac output has increased by approximately 45%, from 4.8 to 7.2 l/min.[3] In the third trimester, cardiac output falls when the gravid uterus compresses the inferior vena cava.[6] Whether or not this fall is evident when measured in the left lateral position remains controversial.[3,7] During labor, cardiac output increases from a basal mean of 7.9 to

Table 195.1 Change in cardiovascular variables in pregnancy[3–5]

Variable	Non-pregnant	Pregnant	Change (%)
Aortic area (cm^2)	3.66	4.16	+13
Cardiac output (l/min)	4.9	7.2	+47
Heart rate (beats/min)	75	88	+17
Stroke volume (cm^3)	66	87	+32
Systolic blood pressure (mmHg)	115	111	−3
Diastolic blood pressure (mmHg)	72	55	−24
Peripheral vascular resistance (dynes/s/cm^5)	1326	875	−34
Pulmonary vascular resistance (arbitrary units)	2.85	2.17	−24
Blood volume (ml)	2600	3850	+48
Red cell mass (ml)	1400	1652	+18
Hemoglobin concentration (g/dl)	12.0	10.4	−15
LV end systolic diameter (cm)	2.90	3.04	+5
LV end diastolic diameter (cm)	4.49	4.79	+7
LA diameter (cm)	3.12	3.63	+16
LV wall thickness (cm)	1.48	1.89	+28
Left ventricular mass (g)	120	183	+53
Peak LV cavity d*D*/d*t** (cm/s)			
Systolic	7.8	10.7	+27
Diastolic	12.2	17.7	+45
Ejection fraction (%)	72.4	77.3	+7

Values for pregnancy are those at rest giving the maximum change from the non-pregnant state before labor, irrespective of gestational age; LV, left ventricle; LA, left atrium

*d*D*/d*t* is the rate of change of diameter

10.6 l/min during contractions,[8] returning to prelabor levels within 24 h. Within 2 weeks of delivery cardiac output almost returns to prepregnancy levels.[9]

Total extracellular fluid volume increases by 6–8 l, with a relatively greater increase in intravascular compared with interstitial fluid volume.[5] However, arterial and venous dilatation in the first and second trimesters creates a relatively underfilled state associated with a fall in blood pressure.[10,11] By 32 weeks' gestation, plasma volume has increased to a maximum of 40% above prepregnancy levels (approximately 1.2L).[12] Although the mechanism of vasodilatation in healthy pregnancy has not been fully elucidated, there is accumulating evidence that increased activity of nitric oxide synthase has an important role.[13,14]

Increased erythropoietin levels stimulate red cell production from early pregnancy,[15] but as the rise in plasma volume is relatively greater than the increase in red cell mass, there is an apparent anemia. Nevertheless, the hemoglobin concentration should not normally fall below 10 g/dl.[16] Plasma colloid oncotic pressure (COP) falls by about 15% in normal pregnancy secondary to a fall in plasma albumin concentration. Edema is usually prevented by a similar fall in interstitial COP.[17]

In anticipation of hemorrhage at childbirth, normal pregnancy is characterized by low-grade chronic intravascular coagulation within both the maternal and uteroplacental circulation.[18] There is evidence for increased levels of clotting factors, especially fibrinogen[19] and depression of fibrinolysis.[20]

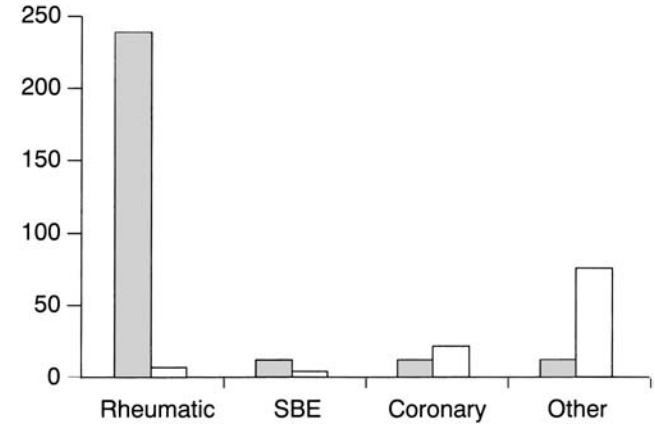

Figure 195.1 A comparison of the causes of death due to heart disease in pregnancy between 1952–1960 (shaded bars) and 1991–2002 (clear bars).[1]

Maternal mortality from heart disease

The best data regarding maternal mortality from heart disease in pregnancy come from the *Confidential Enquiries into Maternal Deaths in the UK*.[1] In the 9-year period following the beginning of the *Confidential Enquiries*, from 1952 to 1960, heart disease caused about one-quarter of all indirect (i.e. not 'direct' obstetric) maternal deaths. This amounted to 42 maternal deaths from heart disease per million maternities. During this period the picture was dominated by rheumatic heart disease, predominantly mitral stenosis, which caused 239 of the 277 cardiac deaths (Figure 195.1 and Table 195.2). There were also 12 deaths from endocarditis, 13 deaths from coronary artery disease and 13 deaths from other causes. This is probably a similar pattern to that seen at present in developing countries, though in Africa a considerable number of women die from dilated cardiomyopathy (not puerperal cardiomyopathy) associated with its high local prevalence, even in the non-pregnant population.

In the 12 years from 1991–2002, the death rate from heart disease represents about one-third of all indirect maternal deaths, but now this equates to 18 deaths per million maternities.[1] Furthermore, the pattern of death from heart disease in the UK is completely different from 1952 to 1960 (Figure 195.1). Between 1991–2002, there were 117 deaths from acquired heart disease (Table 195.3) and 38 deaths from congenital heart disease (Table 195.4). The majority of the 117 deaths from acquired heart disease were either ischemic (27) or due to rupture of aneurysm of the thoracic aorta or its branches (28). The women who died from ischemic heart disease were in general older than other women during pregnancy. It is not clear whether these data demonstrate an increased risk of dying from ischemic heart disease in pregnancy or merely reflect the older age at which women now become pregnant and the higher prevalence of smokers in this age group. Those dying from congenital heart disease included 22 with pulmonary vascular disease, who had either primary pulmonary hypertension or Eisenmenger's syndrome. Nearly all healthcare workers, with the exception of cardiologists, seem to be unaware of the seriousness of pulmonary hypertension in pregnancy.

Between 1991–2002, there were 28 deaths from dissecting aneurysm, a persistent observation in repeated maternal mortality reports, possibly related to increased shear stresses and thinner vessel walls in pregnancy. Indeed, rupture of other blood vessels in

the brain or abdomen (splenic artery aneurysm, renal artery aneurysm) are more common in pregnancy. Again, an aging reproductive population may be part of the explanation, though women who died from aneurysm were not as old as those who died from ischemic heart disease.

With regard to the standard of care provided, deaths from ischemic heart disease (I.H.D.) were usually sudden and probably little more could have been done to prevent them. However, they all had risk factors, such as smoking and a family history of I.H.D. Patients with aneurysms had often been ill for several days before they finally died and usually the condition had not been considered a possibility.

Cardiovascular examination in pregnancy

History

As in all medical specialties, the history is of paramount importance in the assessment of patients with heart disease. In developed countries, women have frequent medical examinations throughout their lives and cardiac lesions are usually identified long before they attend an antenatal clinic. The family history is important for conditions such as hypertrophic cardiomyopathy and congenital heart disease.

The most frequent symptom of cardiac disease in pregnancy is dyspnea. However, this is difficult to assess as it is a variable feature of healthy pregnancy.[21] Furthermore, syncope is also common in normal pregnancy, but can be a symptom of severe aortic stenosis, hypertrophic cardiomyopathy (HCM), Fallot's tetralogy, Eisenmenger's syndrome or dysrrhythmias. Palpitations are often a symptom of dysrrhythmias. Chest pain is usually a symptom of ischemic heart disease, but is also associated with HCM or severe aortic stenosis. However, attempts to predict the outcome of heart disease in pregnancy by assessing the severity of symptoms in the first trimester have proved unreliable.[22] A precise anatomical diagnosis and knowledge of the outcome from previous pregnancies is more useful.[2]

Physical signs

The hyperdynamic circulation of pregnancy causes alterations in the cardiovascular system that mimic heart disease. The peripheral pulses are full, bounding and often collapsing suggesting aortic regurgitation to the untutored. Premature atrial and ventricular ectopic beats are common in normal pregnancy.[23] From midgestation onward, the jugular venous pressure becomes more obvious and may be raised due to increased intrathoracic pressure secondary to increased intra-abdominal pressure.[24] The apex beat is more forceful and because of the increase in cardiac output may suggest cardiomegaly in normal patients. However, if the apex beat is more than 2 cm outside the midclavicular line, this should be considered abnormal.[2] On auscultation, the first heart sound is loud and a third heart sound is audible in most pregnant women, reflecting rapid ventricular filling.[25] Rarely, during the last trimester, increased mammary blood flow can produce a bruit that varies with the pressure of the stethoscope.[2]

Investigations

Chest x-ray

The gestational increase in cardiac output and pulmonary blood flow causes an increase in cardiothoracic ratio and pulmonary vascular markings. A chest x-ray is indicated in a pregnant woman who has new onset of dyspnea. If the fetus is properly screened from x-rays the dose of radiation is less than 10 days of background radiation.

Electrocardiogram (ECG)

The heart rate increases gradually throughout normal pregnancy to reach a mean of 88 beats/min in the third trimester.[3] As the diaphragm becomes elevated, the heart gradually changes position and the QRS axis

moves to the left.[26] Q waves and inverted T waves are frequently seen in lead III and aVR.

Echocardiography

Echocardiography is a safe and accurate method of discriminating significant heart disease from the physiological changes of healthy pregnancy. It is particularly useful when serially monitoring known valvular and myocardial lesions throughout pregnancy. A degree of regurgitant flow across the tricuspid, mitral and pulmonary valves was found in 41–90% of apparently normal pregnant women, depending on the valve and the stage of gestation.[27] Certain heart lesions are more accurately identified by transesophageal echocardiography. This involves passing a transducer mounted on the end of a flexible endoscope into the esophagus. Bacterial vegetations, intracavity thrombi and prosthetic valve dysfunction are all more accurately identified with transesophageal echocardiography.[2] Furthermore, non-invasive Doppler echocardiography can be used as effectively as Swan–Ganz catheterization for hemodynamic monitoring of the critically ill pregnant patient.[28]

Stress testing

The exercise ECG of healthy pregnant women reveals a shorter time to onset of maximum ST depression compared with non-pregnant women, but no difference in the time to resolve these changes.[29] In the absence of symptoms of ischemic heart disease these changes should be considered normal.[29] However, exercise testing prior to pregnancy, while monitoring the ECG and blood pressure, is useful for assessing cardiac reserve in women with ischemic heart disease, aortic stenosis or impaired ventricular function.[24]

Specific conditions occurring during pregnancy

Rheumatic heart disease

Although the incidence of rheumatic heart disease has fallen dramatically in the developed world, it used to be, and still is in the developing world, the most common cardiac cause of death during pregnancy. Acute rheumatic fever, following infection with a group A β-hemolytic streptococcus, is rare during pregnancy, even in developing countries.[30] However, the consequences of the acute disease, resulting in damage to heart valves, have major implications for the pregnant patient.

Mitral stenosis causes far more death and morbidity during pregnancy than any other rheumatic valve lesion (Table 195.2). Breathlessness is the most common presenting symptom of mitral stenosis, which becomes worse during pregnancy because affected women are unable to increase their cardiac output by the same degree as normal pregnant women.[31] This is due to the gestational increase in heart rate, which reduces diastolic filling time through the stenotic mitral valve. The consequent rise in left atrial pressure, and gestational increase in pulmonary blood volume, makes these women particularly vulnerable to pulmonary edema in the third trimester.[2] Furthermore, contraction of the uterus and relief of inferior vena cava compression immediately after delivery causes an increase in intravascular volume and a sharp rise in left atrial pressure, which can also result in acute pulmonary edema.[32,33] Conversely, peripartum hemorrhage can offset the increase in intravascular blood volume.[7] Patients who enter labor with a pulmonary artery wedge pressure of less than 14 mmHg are unlikely to develop pulmonary edema.[32]

The management of severe mitral stenosis should be aimed at improving left ventricular diastolic filling by slowing down the heart rate with β-blockers.[34] The dose should be titrated according to the patient's symptoms and heart rate.[30] Diuretics are necessary for the treatment of pulmonary edema and cardioversion may be needed to treat atrial fibrillation (see later). Pregnant women with mitral stenosis and atrial fibrillation should be anticoagulated with low molecular weight heparin e.g. dalteparin 5000 units daily (the risk of thromboembolism is not as high as with mechanical heart valves).[30] If the clinical condition deteriorates despite medical treatment, then balloon or surgical valvotomy during pregnancy gives good results.[35]

The cardiovascular adaptations to pregnancy allow women with mitral regurgitation to tolerate pregnancy well. Systemic vasodilatation off-loads the left ventricle and stretching of the left atrial wall keeps left atrial pressure down.[30] However, infective endocarditis remains a concern, so antibiotic prophylaxis is required for a complicated or surgical delivery.

Rheumatic aortic stenosis is less common in women than in men and is usually associated with mitral valve stenosis. Although the symptoms of coexistent mitral stenosis dominate, patients can present with chest pain, syncope or even sudden death. The severity of aortic stenosis can be estimated by calculating the pressure gradient across the valve with echocardiography. However, this gradient can be overestimated in pregnancy due to increased flow across the valve, while a fall in stroke volume, in patients with severe aortic stenosis, causes a reduction in gradient.[30] Medical treatment is aimed at improving function with coexistent mitral stenosis, but if the clinical condition deteriorates, then the fused commissures of the rheumatic aortic valve can be divided by balloon valvotomy, until valve replacement becomes necessary.[30] Epidural anesthesia causes peripheral vasodilatation and further increases the valvular gradient. Care should therefore be taken to avoid hypotension, while in those with a large preexisting aortic valve gradient, epidural anesthesia should be avoided.

The gestational fall in peripheral vascular resistance improves cardiac output through a regurgitant aortic valve. Hence, aortic regurgitation is usually well tolerated during pregnancy, although pulmonary edema can occur with poor left ventricular function.[2]

Rheumatic tricuspid valve disease almost always coexists with mitral valve disease and the latter dominates the clinical picture.[36] Tricuspid regurgitation is more common than stenosis, but in healthy pregnancy there is also a functional regurgitation through the tricuspid valve.[37] Patients with tricuspid regurgitation have a raised right atrial pressure with 'v' waves in the jugular vein that become more obvious during pregnancy. Right heart failure presents with systemic edema and may require treatment with diuretics. Tricuspid stenosis in the presence of sinus rhythm is associated with an 'a' wave in the venous pulse and right atrial hypertrophy on an ECG. Echocardiography can recognize a rheumatic tricuspid valve, which if unsatisfactorily treated with diuretics requires definitive treatment with valvotomy.

Infective endocarditis

Infective endocarditis is a microbiological inflammation of the endothelial lining of the heart chambers, heart valves or great vessels.[38] It is characterized by fever, positive blood cultures, vegetations on heart valves or congenital defects, embolism and immunological phenomena.[39] Almost all patients with endocarditis have a heart murmur. However, increased blood flow during normal pregnancy intensifies murmurs from preexisting heart lesions and makes changes in auscultatory findings more difficult to interpret. The decline of rheumatic fever in the developed world has led to a reduction in the prevalence of abnormal heart valves and, consequently, a reduction in the incidence of infective endocarditis. Furthermore, puerperal sepsis related to criminal abortion remains a source of endocarditis only in the developing world.[39]

A group from Duke University have modified the criteria for a diagnosis of infective endocarditis to include echocardiographic evidence of a vegetation as well as fever and positive blood cultures with an organism that typically causes infective endocarditis.[40] Particularly virulent organisms, such as *Staphylococcus aureus*, can damage normal valves, but more usually, vegetations form at the site of known heart defects where there is damaged endothelium. The range of pathogenic organisms is similar to that of the non-pregnant state, although the urogenital tract is a source of enterococcal endocarditis following obstetric surgical intervention.[41] Previous antibiotics may suppress fever and cause negative blood cultures. Transesophageal echocardiography provides a better view of a vegetation or paravalvular abscess than transthoracic echocardiography. Once a clinical diagnosis has been made, three sets of blood cultures must be sent and then antibiotics initiated immediately. The most serious complications of infective endocarditis include valve destruction, embolism and immunological phenomena including a crescentic glomerulonephritis. As in the non-pregnant state, surgery is indicated for heart failure secondary to valve destruction.

In one series, there were no cases of infective endocarditis following a normal delivery in over 2000 cardiac patients.[42] Furthermore, although endocarditis was present in over 10% of cardiac deaths between 1985 and 1993,[1] very rarely was it acquired at the time of delivery. British microbiological[43] and cardiological[44] working parties have therefore been persuaded that, except for women with a history of previous infective endocarditis or prosthetic heart valves, this relatively high incidence of endocarditis is not a justification for routine antibiotic prophylaxis at the time of normal delivery. However, the *Confidential Enquiry* into maternal deaths during 2000–2002 included two women who died from bacterial endocarditis (one on a ventricular septal defect after a normal delivery), out of 44 deaths from cardiac disease.[1] This demonstrates that endocarditis can occur on heart lesions following normal delivery with catastrophic results. Since it is difficult to predict if a delivery will remain 'uncomplicated', it is the authors' personal recommendation to give antibiotic prophylaxis to all women with structural heart lesions at the time of normal delivery. We recommend a similar strategy to the UK recommendation for cardiac patients having an operative delivery.[43] This is to give 1 g amoxycillin intramuscularly and 120 mg of gentamicin intravenously at the time of induction of anesthesia (or onset of labor), and then 500 mg amoxycillin orally (we prefer intravenously) 6 h later (or every 6 h while the patient is still in labor). Drugs are variably absorbed during labor; therefore, we do not give 3 g oral amoxycillin to cover an anticipated normal delivery. Alternatives to amoxycillin include either vancomycin 1 g intravenously over 1 h or teicoplanin 400 mg intravenously.

Artificial heart valves and anticoagulation

Artificial heart valves are either mechanical or bioprosthetic (made of animal tissue). Women with diseased heart valves who are contemplating pregnancy should be advised to have children early, before a prosthetic valve becomes necessary.[45] When there is no alternative to heart valve replacement in a young woman, the risks of anticoagulation for a mechanical valve need to be weighed against the accelerated deterioration of a bioprosthetic valve during pregnancy.[46–48]

Warfarin crosses the placenta into the fetal circulation where it is a more potent anticoagulant. This is due to reduced production of vitamin K-dependent clotting factors by the fetal liver, rendering it at greater risk of hemorrhage throughout pregnancy and for up to 2 weeks after the mother stops warfarin.[45] The quoted risk of fetal embryopathy (chondrodysplasia punctata) from taking warfarin in the first trimester is 6%,[51] but this ignores the fact that warfarin-induced fetal embryopathy is dose-dependent.[45] In women

taking less than 5 mg/day the risk of embryopathy is likely to be even less.[49]

Low molecular weight heparin does not cross the placenta, but it is less effective in preventing prosthetic valve thrombosis than warfarin.[47,48,50] Furthermore, heparin has a similar miscarriage rate to warfarin,[51] but otherwise has few maternal side effects.[52] There are small case-series of low molecular weight heparin successfully preventing mechanical valve thrombosis during pregnancy, but this mode of anti-coagulation to prevent valve thrombosis has yet to be evaluated.[53]

There is no optimal strategy for anticoagulation of women with metal heart valves during pregnancy. The author (D.W.) favours switching to LMW heparin at therapeutic doses aiming for a 3–4 hr. post dose anti Xa level of > 1.0 u/mL and a trough level of at least 0.5 u/mL. It might be possible to reduce the rate of valve thrombosis (currently estimated at approx. 10% on LMW heparin), by using higher doses, but this remains speculative. Low dose aspirin (75–150 mg) density is a safe and possibly effective adjunct to low molecular weight heparin in women with mechanical heart valves or an otherwise increased risk of intra cardiac thrombosis.[52]

Anticoagulation at the time of delivery is particularly difficult. Converting to i.v. infractionated heparin peripartum is very difficult to manage, due to variability in the APTT at term. Timing the dose of LMW heparin to minimise haemorrhage and restarting 4–6 hours post-partum may minimise the risk of valve thrombosis. Delaying reintroduction of warfarin for 3–5 days will reduce the risk of secondary postpartum haemorrhage.

A woman presenting with thrombosis of a heart valve will become acutely breathless. Sudden death is unusual, as the valves usually stick half open. This results in muffling of the prosthetic heart clicks and stenotic and regurgitant murmurs of the obstructed valve.[45] Echocardiography will confirm the diagnosis. Thrombolysis is the treatment of choice for thrombosis of right-sided heart valves,[45] but has also been successful for thrombosis of left-sided prosthetic heart valves.[54] However, emergency heart valve replacement is usually necessary.

The hemodynamic stress of pregnancy leads to accelerated damage of bioprosthetic valves, with all the attendant risks of subsequent valve replacement.[47,48,55] Consequently, these women should have serial echocardiography throughout pregnancy to assess valve integrity.[45]

Warfarin does not pass into breast milk, so is safe for the breast-fed infant.

Myocardial infarction

Coronary artery disease is an unusual occurrence in young women, but the incidence is increasing.[1] The reasons include more smokers, especially among young professional women, more obesity, more drug abuse, particularly with cocaine, and delay of pregnancy until a later age. Other rarer causes include vasculitis and congenital coronary anomalies.

Although early atheromatous disease of the coronary arteries is probably under-reported, myocardial infarction in pregnancy is often caused by coronary artery dissection.[56] Women therefore present suddenly, without prodromal angina and usually in the third trimester or postpartum.[57,58] The dissection usually begins within 2 cm of the ostium of the left anterior descending artery, causing an infarct of the anterior wall of the left ventricle.[59] The preponderance of arterial dissections associated with pregnancy may be related to increased hemodynamic shear stress on thin and dilated vessels.

Myocardial infarction is diagnosed in the usual way by noting typical ECG changes and enzyme rises. The MB isoenzyme of creatinine phosphokinase is released from the myometrium postpartum; therefore, cardiac troponin must be measured peripartum, to diagnose a myocardial infarction.[60] If possible, immediate coronary angiography is indicated to discover the cause of the infarct.[59] If an intracoronary artery thrombosis is identified, it can be lysed with a local injection of streptokinase, remembering that there is a risk of bleeding from the genital tract, if delivery has just occurred or is imminent. However, the first choice for treatment of acute coronary syndrome in pregnancy is percutaneous catheter intervention. Women with coronary artery dissection have survived thrombolysis with normal ejection fractions.[61] Major dissections threatening a large territory of anterior wall are best repaired with urgent coronary artery bypass grafting, preferably after delivery of a viable fetus.[59] However, both balloon angioplasty and coronary artery bypass grafting have been performed successfully during pregnancy.[59,62]

The size of the infarct can be reduced by β-blockers given as soon as possible after the diagnosis.[59] Although angiotensin converting enzyme inhibitors cause oligohydramnios and reduce renal blood flow in the fetus, the benefits to a mother, who has had a large infarct, probably outweigh the risks to the fetus. Cesarean section creates less physical demand on the impaired left ventricle and is therefore preferable to vaginal delivery. Epidural anesthesia is acceptable, especially in women who have had a small infarct, but some believe a general anesthetic causes less hemodynamic stress and is therefore preferable for patients with poor ventricular function.[59] Oxytocic drugs constrict coronary arteries as well as the uterus and should be avoided. Ergotamine, used to prevent postpartum hemorrhage, can also provoke coronary artery spasm and has caused fatal myocardial infarction in a previously healthy woman.[59]

Arrhythmias

As ischemic heart disease is rare in women of childbearing years, its clinical sequelae such as angina,

heart failure and arrhythmias are also unusual. However, women with non-ischemic disease of cardiac conducting tissue, such as Wolff–Parkinson–White syndrome, have supraventricular tachycardias more frequently during pregnancy.[63] The precise reason for this observation must in some way relate to the cardiovascular and hormonal changes of healthy pregnancy.[64]

In general, antiarrhythmic drugs are safe in pregnancy and should be prescribed according to clinical need.[64] Most experience has been gained with digoxin, quinidine and β-adrenergic blocking drugs. Digoxin crosses the placenta to give similar drug levels in the fetus as in the mother,[65] hence its use as a first-line treatment of fetal supraventricular arrhythmias *in utero*.[66] Quinidine, procainamide and lignocaine are all well tolerated and relatively safe in pregnancy.[64] Similarly, β-blockers are also well tolerated, especially in later pregnancy, but atenolol can cause intrauterine growth retardation when taken during the first half of pregnancy.[64,67] Amiodarone can cause fetal thyroid dysfunction[68] and should be reserved for life-threatening arrhythmias.[64] Verapamil has been widely used for the treatment of maternal supraventricular arrhythmias, but adenosine is now gaining favor, especially in the second and third trimesters.[69]

Supraventricular arrhythmias

Almost all narrow complex tachycardias have a supraventricular origin. Chronic atrial fibrillation in women of childbearing age is usually associated with rheumatic mitral valve disease.[70] Under these circumstances, anticoagulation throughout pregnancy is essential, due to the increased risk of cardiac thrombus and embolization.[71] Fast atrial fibrillation can be treated with digoxin or combined with β-blockers if necessary.[72]

Atrial fibrillation in the absence of structural heart disease may be secondary to cardiomyopathy (particularly puerperal cardiomyopathy), thyroid disease, excessive alcohol, infection or sick sinus syndrome, but usually no cause is found.[73] In the presence of risk factors, anticoagulation is necessary and the choice between warfarin and low molecular weight heparin depends on the type of underlying heart disease (see sections on artificial valves and rheumatic fever).

The treatment of atrial fibrillation depends on the underlying cause, precipitating factors and duration of the episode. Direct current cardioversion is safe in pregnancy,[74] but there are only anecdotal data on the outcome of chemical cardioversion in pregnancy. Women who have had atrial fibrillation for longer than 2 days should be anticoagulated for 3 weeks prior to cardioversion. However, it may be possible to reduce this time and thereby improve the likelihood of successful cardioversion, by excluding atrial thrombi with transesophageal echo.[75] If no thrombus is detected, then patients can be fully anticoagulated at the time of cardioversion and for 4 weeks postcardioversion.[75] Type 1c antiarrhythmic drugs, such as flecanide, are most effective at maintaining sinus rhythm after cardioversion and treating paroxysmal atrial fibrillation. Flecanide is probably safe in pregnancy, as it is given to the mother for the treatment of fetal supraventricular tachycardia.[76] However, in the absence of controlled trials in pregnancy, β-blockers remain a sensible first choice, especially in relation to thyrotoxicosis, for the treatment of maternal paroxysmal atrial fibrillation.[73] Quinidine is useful and safe in pregnancy if a β-blocker fails. Digoxin is of no benefit in preventing paroxysms of atrial fibrillation.[77]

Ventricular tachycardia

It is important to make the diagnosis of a broad complex tachycardia, not only to avoid inappropriate treatment (that can be fatal in the case of verapamil given to a patient with ventricular tachycardia), but also to provide an accurate prognosis and plan for follow-up. Broad complex tachycardias can be either ventricular or supraventricular associated with bundle branch block or pre-excitation.[78] A wide complex tachycardia with atrioventricular dissociation is almost diagnostic of ventricular tachycardia.[78] The presence of fusion and capture beats and concordance of the QRS complex across the chest leads confirm the diagnosis. However, when the hemodynamic situation is stable, further clarification can be gained using echocardiography to identify dissociated atrial activity. If diagnostic difficulty persists, then atrioventricular block with either vagal stimulation or intravenous adenosine can terminate supraventricular tachycardia and a.v. nodal re-entry tachycardias.[79] In the same way, retrograde ventriculo- atrial conduction can be blocked to reveal the characteristic features of an underlying ventricular tachycardia.[78]

There is an increased awareness of ventricular arrhythmias in pregnancy.[64] If paroxysmal ventricular tachycardia is well tolerated, there is a place for conservative management.[80] The first-line treatment for idiopathic ventricular tachycardia during pregnancy should be β-blockade with metoprolol or failing that, sotalol.[64,81] Electrophysiological testing is usually not required for the treatment of most tachyarrhythmias and because of the high dose of radiation[82] associated with invasive electrophysiology, it has a limited role during pregnancy.

Bradyarrhythmias

Bradycardias are unusual in pregnancy. They may be secondary to vasovagal episodes, iatrogenic (b-blockade), or more rarely, sick sinus syndrome or complete heart block.[73] Congenital complete heart block can present for the first time during pregnancy with syncope. This is particularly true during the second stage of labor when the Valsalva maneuver

can lead to further slowing of the heart rate.[83] It is therefore recommended that even asymptomatic women with complete heart block should have labor covered with a temporary pacing wire.[83] Physiological permanent pacemakers adapt to the physiological increase in heart rate during pregnancy. Women with fixed rate pacemakers also do well, presumably by increasing their stroke volume, but if symptoms related to an inappropriate bradycardia develop, then the pacemaker can be set at a faster rate.[2]

Cardiac arrest in pregnancy

In late pregnancy, resuscitation in the supine position may fail as venous return and cardiac output are compromised by aortocaval compression by the fetus.[5] Turning the patient to relieve the compression can overcome this problem.[84] If necessary, cardioversion can be used without apparent harm to the fetus.[74] If resuscitation is failing, emergency cesarean section in the accident and emergency department may help maternal cardiac output. If resuscitation has failed, but the fetus is still viable, an emergency cesarean section should be carried out within 15 min.[85]

Pericardial disease

Three main syndromes affect the pericardium: acute pericarditis, pericardial tamponade and constrictive pericarditis. Acute pericarditis is most commonly 'idiopathic' or related to a viral infection.[86] Rarer causes include tuberculosis, pyogenic infection, autoimmune disease, postinfarction, irradiation, neoplasia and trauma.[86] Chest pain and fever are the most common symptoms. Pericardial pain can be differentiated from the pain of myocardial ischemia by its accentuation on inspiration and movement of the thorax. There is a pericardial rub on auscultation and widespread, concave ST elevation on the ECG. Admission to hospital allows time to investigate an underlying etiology. Symptomatic relief with salicylates or non-steroidal anti-inflammatory drugs is acceptable, except close to term, when there is a risk of narrowing of the patent ductus arteriosus. Acute pericarditis may cause a pericardial effusion, which can be identified by echocardiography. If the effusion becomes too large, tamponade will develop, impeding ventricular filling and reducing cardiac output. This can present during pregnancy and is life-threatening unless aspiration or pericardiotomy is performed urgently.[87] Pregnant women with constrictive pericarditis are unable to accommodate the gestational increase in blood volume and may therefore present for the first time during pregnancy.[88] The ventricles cannot distend during diastole; therefore, the stroke volume is reduced and there is a compensatory tachycardia. Symptoms resemble those of right-sided cardiac failure, but with a normal-sized heart. There is an elevated venous pressure, systemic edema, which often includes hepatomegaly and ascites. Pulmonary edema is not a problem. There is frequently pericardial calcification on a chest x-ray, which together with a normal-sized heart and typical echocardiographic features, allows differentiation from a cardiomyopathy.[86] Without pericardectomy, maternal cardiovascular adaptation cannot take place and fetal outcome is compromised.[88]

Cardiomyopathies

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is characterized by hypertrophy of the undilated left ventricle in the absence of an abnormal hemodynamic load, but in the presence of disorganized cardiac muscle.[89,90] It is an autosomal dominant condition with variable penetrance.[91] It can present as a chance finding, following investigations for an asymptomatic murmur, or as sudden death.[92] Other symptoms include syncope, palpitations, exertional chest pain and dyspnea.

On examination, there is a typical late systolic murmur, accentuated by standing and attenuated by squatting. Investigations include echocardiography, which will identify symmetrical or asymmetrical thickening of the left ventricular wall. An ECG will typically reveal left atrial P waves and left ventricular hypertrophy with strain. Once diagnosed, a 24-h ECG will identify arrhythmias and an exercise test will assess tolerance and changes in blood pressure. A failure of the blood pressure to rise may suggest an inability to increase stroke volume and an increased risk of syncope.

Asymptomatic pregnant women with HCM do well.[93] Although there are reports of women dying in pregnancy, sudden death in pregnancy is unusual.[94] It appears that the overall risk of sudden death from HCM is not increased by pregnancy.[90] However, a family history of sudden death or episodes of syncope or near syncope are poor prognostic signs. If there are symptoms of syncope then it must be deduced whether this is secondary to arrhythmias or hemodynamic instability. Short bursts of ventricular tachycardia can be treated with amiodarone, but there has been no controlled trial to test whether amiodarone is effective in preventing sudden death.[90] Indeed, asymptomatic bursts of ventricular tachycardia on ECG ambulatory monitoring are no longer thought to be a poor prognostic feature.[95] Similarly, the degree of outflow tract obstruction does not predict a poor outcome.[96] Arrhythmias should be treated appropriately, bearing in mind that the hypotensive action of verapamil may aggravate syncope in patients with HCM.[90] Symptoms of palpitations or chest pain might be improved with β-blockers, such as propranolol, as the

bradycardia will improve coronary artery filling and left atrial emptying.[90]

Normal vaginal delivery is safe, but should take place in hospital with continuous ECG monitoring. Blood volume must be maintained throughout delivery, as a reduction in venous return will aggravate the gradient across the outflow obstruction. Therefore, peripartum blood loss must be replaced promptly and filling pressure kept up, if an epidural anesthesia is used. For similar reasons induction of labor with prostaglandins is best avoided.[90]

Peripartum cardiomyopathy

In the UK the incidence of peripartum cardiomyopathy is less than 1 in 5000.[2] There is no predisposing cause of the heart failure that develops peripartum (within 1 month of delivery and up to 6 months postpartum).[97] However, women with multiple pregnancies and gestational hypertension are more likely to develop peripartum cardiomyopathy.[98] Cases range from mild left ventricular dysfunction to sudden onset of gross heart failure and death within days of delivery. Symptoms include dyspnea, orthopnea and palpitations. Signs of heart failure include tachycardia, hypotension, elevated jugular venous pressure, basal crepitations, third heart sound and mitral regurgitation. Arrhythmias are common and thrombus within a dilated left heart can embolize systemically at presentation and before the clinical onset of heart failure.[99]

An ECG will show sinus tachycardia, possibly with runs of supraventricular or ventricular arrhythmias. A chest radiograph can reveal a grossly dilated heart and pulmonary edema.[99] Echocardiography usually reveals dilatation of all four chambers of the heart and hypokinesia of the left ventricule. Functional regurgitation through the mitral, tricuspid and pulmonary valves can be present in normal hearts during pregnancy, but will be more obvious in patients with a peripartum cardiomyopathy.[99]

The prognosis depends on the severity of the initial insult. While some women make a good recovery, others gradually decline to death or have a cardiac transplant.[100] Even women who have made an apparently full recovery are likely to have lost some cardiac reserve in the initial insult. Therefore, the hemodynamic challenge of a future pregnancy will always carry risks. Women who have made a good and sustained recovery will do best in a subsequent pregnancy, but serial echocardiography to assess left ventricular function is sensible as the possibility of relapse remains. Women with residual left ventricular dysfunction and an ejection fraction less than 50% should be discouraged from a further pregnancy.

Pulmonary vascular disease

Pulmonary hypertension may be either primary, when there is no demonstrable cause, or secondary to underlying cardiac or vascular disease. Whatever the etiology, pulmonary hypertension is life-threatening in pregnancy.[1]

Primary pulmonary hypertension

This is a rare disease characterized by increased pulmonary vascular resistance of unknown etiology. Diagnostic criteria used by the National Institutes of Health (NIH) include a mean pulmonary artery pressure of more than 25 mmHg at rest, without evidence of left-sided cardiac valvular disease, myocardial disease, congenital heart disease or clinically important respiratory, connective tissue or thromboembolic diseases.[101] However, clinical and pathological features of primary pulmonary hypertension (PPH) are seen in patients with human immunodeficiency virus (HIV), a history of cocaine abuse, portal hypertension and in those who take appetite suppressant drugs such as fenfluramine.[102] Women are affected twice as often as men.

Symptoms of PPH usually begin with dyspnea and easy fatigability.[102] However, the non-specific nature of these symptoms often means that the disease is not diagnosed until severe.[102] Consequently, women who become pregnant with recognized PPH have severe disease and a maternal mortality of about 40%.[103,104]

On examination, signs include a loud second heart sound, pulmonary ejection click and, occasionally, an early diastolic murmur of pulmonary regurgitation. An ECG may show right atrial P waves and evidence of right ventricular pressure overload.[103] An echocardiogram can exclude other cardiac disease, but also reveal elevated pulmonary artery systolic pressure and a dominant right ventricle.[103] A normal ventilation–perfusion scan will discriminate between PPH and the large perfusion defects typical of chronic major vessel thromboembolic pulmonary hypertension.[102]

Due to the 40% maternal mortality and possibility of disease progression during pregnancy, any patient with PPH should be advised to have a termination. If the patient insists on continuing the pregnancy, then maximum rest is advised due to the limited ability to increase cardiac output and the possibility of right ventricular failure.

Increased pulmonary vascular resistance is created by a combination of vasoconstriction, thrombosis *in situ* and medial hypertrophy of the vessel wall. Management of PPH is therefore aimed at correcting these abnormalities. Vasodilators such as calcium channel blockers produce a sustained improvement in 25–30% of patients.[105] Anticoagulation with LMW heparin will reduce the risk of thrombosis within the damaged pulmonary artery during the hypercoagulable state of pregnancy.[106] Oxygen and pulmonary vasodilator therapy can provide symptomatic relief for hypoxic patients and diuretics have a place when right heart failure causes gross hepatic congestion and ascites. However, a high right filling pressure is required for maintenance of cardiac output; therefore, any fall in intravascular volume due to blood loss

must be replaced promptly. Postpartum management should take place in the intensive care unit with monitoring of the central venous pressure, systemic blood pressure and oxygen saturation.[103] Occasionally, right ventricular function recovers postpartum, but often, despite all precautions, symptomatic deterioration is relentless until death.[103] When death ensues, it is usually postpartum, precipitated by hypotension secondary to blood loss, arrhythmia, thromboembolism or right ventricular failure.[103]

Pulmonary embolism

When the hypercoagulable state of healthy pregnancy combines with a thrombophilia, immobilization, venous stasis, cesarean section or obesity, the incidence of thromboembolism increases markedly.[1] There were 25 maternal deaths from pulmonary embolus (PE) documented in the latest triennial *Confidential Enquiry into Maternal Deaths*.[1] Seventeen of these cases occurred postpartum (10 after cesarean section) and only 4 antepartum. A subclinical thrombophilia can manifest for the first time with thromboembolism during pregnancy. Thrombophilia may be secondary to deficiencies of antithrombin protein C and protein S as well as abnormalities of procoagulant factors, specifically factor V Leiden and prothrombin gene polymorphisms.[135]

Pulmonary embolism can be rapidly fatal or cause minor pleuritic pain. Although massive pulmonary embolism requires emergency treatment to save life, small PEs may herald a large fatal embolus and need to be fully investigated and anticoagulated.

A woman with massive PE may present with dyspnea and collapse. Examination may reveal an elevated venous pressure, a third heart sound and soft second sound. The cardiac monitor may show sinus tachycardia in the absence of a cardiac output, i.e. electromechanical dissociation. Emergency care should include elevation of the legs, turning the late pregnant patient onto her side, oxygen and colloid administration to improve right ventricular filling.[107] Inotropes are unnecessary due to maximal endogenous release of catecholamines.[107] When there is more time, as in a subacute PE, the ECG may show evidence of right atrial and ventricular dilatation with a typical S1 Q3 T3 pattern and T wave inversion in leads V1 to V4.[107] A chest X-ray may show dilatation of the pulmonary artery, then pulmonary oligemia. Echocardiography may reveal a dilated right ventricle that is hardly moving and a hypercontractile left ventricle. The patient should then be sent for immediate cardiac catheterization via the brachial artery, so as not to dislodge more clot from the inferior vena cava. The embolus can then be agitated and fragmented by the catheter itself.[107,108] The fragments of clot then pass into the peripheral pulmonary vasculature where they lyse rapidly and spontaneously.[108] If the facilities of a cardiac catheterization laboratory are not available, systemic thrombolysis should be used in acute massive pulmonary embolus. Subsequent treatment with intravenous heparin should start with 40,000 units/24 h, then adjusted to keep the partial thromboplastin time around two times control values.[109] Long-term prophylaxis could then continue with self-administered subcutaneous low molecular weight heparin. Twice daily injections of low molecular weight heparin (e.g. enoxaparin 1 mg/kg twice daily) are gaining popularity, and proving to be safe and effective.[112] About 1 week postpartum, women who find injections difficult can safely transfer to warfarin, as it does not pass into breast milk. Anticoagulation should continue for 3 months postpartum.

Small pulmonary emboli may present with mild pleuritic pain, hemoptysis or mild dyspnea. All preliminary investigations may be normal, but if suspicion persists, then there should be no hesitation in performing a perfusion scan (no need for a ventilation scan). The dose of radiation is not enough to be harmful to fetus. If available, magnetic resonance angiography is a sensitive and probably safe method for diagnosing pulmonary emboli in pregnancy.[113] Small PEs may become large and fatal; therefore, pregnant women should be anticoagulated in the same way as for larger PEs.

Around the time of delivery, sudden cardiovascular collapse with central cyanosis may be secondary to amniotic fluid embolus. This is almost invariably followed by disseminated intravascular coagulation and is often fatal.[114] The diagnosis can sometimes be confirmed by histological identification of fetal squames in maternal central venous blood,[115] although these have also been found in normal pregnancy. Treatment is aimed at supporting the circulation, contracting the uterus and correcting disseminated intravascular coagulation by monitored infusion of colloid and fresh frozen plasma.

Congenital heart disease

Improvements in cardiac surgery and pediatric care have meant that more women with congenital heart disease survive until a fertile age and become pregnant.

Acyanotic heart disease

Mitral valve prolapse

Mitral valve prolapse is a relatively common finding in young women of childbearing age. It is usually diagnosed when an asymptomatic systolic murmur leads to echocardiography. One or both of the mitral valve leaflets prolapse into the left atrium during systole, associated with or without mitral regurgitation.[116] Echocardiography recognizes some patients with a slight bowing of the mitral valve into the left atrium, but with an otherwise normal valve this is

of no clinical consequence and should lead to reassurance of the patient.[116] Occasionally, patients present with palpitations caused by ectopic beats and even more rarely tachyarrhythmias.[116] However, generally mitral valve prolapse is a benign condition, which is well tolerated during pregnancy.

Mitral valve prolapse can be inherited as an autosomal dominant condition, usually associated with an asthenic habitus,[117] or secondary to acute rheumatic carditis, following mitral valvotomy and connective tissue disorders such as Marfan syndrome.[116] The typical auscultatory findings are of a late systolic click followed by a murmur with an accentuation at the end of systole. When regurgitation becomes more severe, the click and the murmur are heard earlier. However, the gestational increase in left ventricular volume during pregnancy causes a diminution of these auscultatory findings.[118]

Mitral valve prolapse is well tolerated in pregnancy. An increase in cardiac volume reduces valve prolapse and systemic vasodilatation diminishes mitral regurgitation.[116] However, infective endocarditis remains a significant concern.[119] Therefore, antibiotic prophylaxis is required for women who have more than trivial mitral regurgitation. Occasionally ulcerated areas on the mitral cusps attract non-bacterial platelet aggregates. These can separate and lead to cerebral embolism, but this possibility should not lead to prophylactic anticoagulation in all patients with mitral valve prolapse.[119]

Marfan syndrome

This is an autosomal dominant condition caused by a defect in the fibrillin gene that leads to abnormal collagen synthesis.[120] Characteristic clinical features affect the cardiovascular system, eyes and skeleton. The most important cardiac abnormalities are dissection of the aorta, aortic regurgitation and mitral valve prolapse. Advice to women with Marfan syndrome planning a pregnancy must be based on a cardiovascular assessment. If the aortic root is measured at less that 4 cm on echocardiography then the likelihood of aortic dissection is small.[121] Out of one series of 26 pregnant women with Marfan syndrome only one died, from endocarditis.[121] However, families 'breed true', as exemplified by two women who had a dissection of the aorta during pregnancy, despite an aortic root diameter less than 5 cm, but with a family history of aortic root dissection.[122] The risk of dissection persists for up to 6 months postpartum. During pregnancy hypertension must be aggressively treated with β-blockers to reduce hemodynamic stress on the aortic root. Identification of the putative gene is possible to make a prenatal and presymptomatic diagnosis.[123] Cesarean section is the safest form of delivery for women with an enlarged aortic root.

Atrial septal defects

An interatrial defect (ostium secundum type) allows blood to shunt from the left to the right atrium. Consequently, the right atrium and ventricle become dilated and pulmonary blood flow increases. This causes a pulmonary flow murmur and prominent venous pulsation, both of which become even more pronounced during pregnancy. However, an atrial septal defect is often not detected until adult life, when patients present with dyspnea or syncope from supraventricular arrhythmias. During pregnancy, acute blood loss must be avoided, as the consequent systemic vasoconstriction and reduced venous return leads to an increase in the left to right shunt, reduced left ventricular output and cardiac arrest.[124] More complicated atrioventricular defects (ostium primum defects) are associated with mitral regurgitation and direct shunts between the left ventricle and right atrium. Unlike secundum defects, which are not associated with endocarditis even in the non-pregnant state, these lesions require prophylactic antibiotics peripartum.[124]

Ventricular septal defect

Ventricular septal defects have usually been identified prior to pregnancy, but may be picked up by color flow Doppler, after referral for investigation of a pansystolic murmur. Patients are at risk of infective endocarditis and require antibiotic prophylaxis at the time of delivery. At delivery the shunt that is left to right in the acyanotic patient can reverse if there has been major blood loss on top of the gestational vasodilatation of pregnancy. If the ventricular septal defect is restrictive there is a loud pansystolic murmur, but with a large ventricular septal defect there is often pulmonary hypertension. Following closure of a ventricular septal defect in childhood there is no added risk due to pregnancy, except when there is residual pulmonary hypertension. This is of variable severity, so exercise tolerance and functional reserve of the right ventricle should be assessed before pregnancy.[124] Those with significant pulmonary hypertension should be treated in the same way as women with primary pulmonary hypertension (see above). One report suggests that nearly one-quarter of offspring will be born with ventricular septal defects.[125]

Persistent ductus arteriosus

During fetal life, blood flows from the pulmonary artery through the ductus arteriosus into the aorta. If the ductus does not close at the time of birth, then blood will flow in the opposite direction from the aorta into the pulmonary artery. This can be recognized with a collapsing pulse and a continuous murmur at the left second intercostal space. A large shunt leads to pulmonary artery hypertension and congestive cardiac

failure and should be closed before pregnancy. Furthermore, widely patent persistent ductus arteriosus are at increased risk of dissection during pregnancy.[126] There is also a small risk of infective endocarditis.[124] Small persistent ductus arteriosus may be identified on auscultation and echocardiography, but if there is a normal pulmonary artery pressure then pregnancy does not present any added difficulty.

Coarctation of the aorta

Women who become pregnant with coarctation of the aorta are at increased risk of aortic dissection, rupture of an associated berry aneurysm, infective endocarditis and heart failure.[127] However, the overall mortality rate of a pregnant woman with coarctation of the aorta is currently less than 3%.[124] Hypertension should be aggressively treated, exercise curtailed and cesarean section performed (if labor is expected to be difficult or prolonged) to reduce the possibility of dissection. One-third of all patients with an aortic coarctation have an associated bicuspid valve, which is vulnerable to endocarditis. Surgical repair of the coarctation is usually performed in childhood with improvement of long-term outcome, but late local complications such as dissection or aneurysm are still possible.[124]

Ebstein's anomaly

Ebstein's anomaly consists of downward displacement of the tricuspid valve into the right ventricle, usually associated with an atrial septal defect. Cyanosis, arrhythmias and dyspnea are common problems, depending on the severity of the condition. Reduced systemic vascular resistance of pregnancy should aggravate cyanosis by increasing the right to left shunt. However, Ebstein's anomaly seems to be well tolerated during pregnancy.[128] There were no maternal deaths or serious complications following 111 pregnancies in 44 women (10 after surgical repair) with Ebstein's anomaly.[128] There were 85 live births, of which five had congenital heart disease. Women who were cyanosed had smaller babies than acyanotic women (2.53 kg vs. 3.14 kg, $P < 0.001$).[128]

Cyanotic heart disease

Women with cyanotic congenital heart disease even without Eisenmenger's complex (see below), carry a high risk of maternal cardiovascular complications 14/44 (32%).[129] These include heart failure (8), thromboses (2), bacterial endocarditis (2) and supraventricular tachycardia (2).[129] However, only 41 of 96 pregnancies resulted in a live birth, perhaps because of fetal hypoxemia secondary to maternal cyanosis.[129]

Eisenmenger's syndrome

The clinical picture of pulmonary hypertension and a right to left shunt through an atrial septal defect, ventricular septal defect or aortopulmonary shunt is known as the Eisenmenger complex. The patient is breathless and cyanosed. High pulmonary and low systemic vascular resistance aggravates the cyanosis. Consequently, gestational vasodilatation combined with even minor blood loss or a vasovagal episode can be fatal.[130] Women with Eisenmenger complex who continue with a pregnancy have at least a 30% maternal mortality rate.[131] Sadly, they should be advised against pregnancy and to terminate an ongoing pregnancy. If continuation of pregnancy is insisted upon, they should have as much bed rest as possible and complete bed rest in the lateral position, from the third trimester onward.[130] There is an increased risk of thromboembolism, which should be countered with prophylactic L.M.W. heparin e.g. enoxaparin 40 mg once daily. Overall experience in the management of delivery in this condition is limited and therefore no consensus regarding the mode of delivery has been reached. Vaginal delivery is recommended by some[130,131] while cesarean section under general anesthetic is favored by others[132] as it provides a controlled hemodynamic environment. Either way, there should be intensive cardiac and blood gas monitoring.[130] Hypotension must be avoided at all costs, whether induced by epidural anesthesia, blood loss or arrhythmias. Most maternal deaths occur peripartum; therefore, the mother must stay in hospital, near resuscitation facilities, for at least 7 days postpartum.[130]

Tetralogy of Fallot

The tetralogy of Fallot consists of pulmonary outflow obstruction, due to infundibular narrowing of the pulmonary outflow tract and pulmonary stenosis leading to right ventricular hypertrophy. There is a ventricular septal defect, over which lies the aorta. Due to the high resistance to flow through the pulmonary outflow obstruction, venous blood passes from right to left through the ventricular septal defect. Cyanosis worsens as the pulmonary stenosis progresses. During pregnancy, the fall in peripheral vascular resistance increases the right to left shunt and dyspnea gets worse. Any hypotension related to blood loss at the time of delivery will also increase the right to left shunt. Fetal outcome is poor in pregnant women with uncorrected tetralogy of Fallot and maternal cardiovascular complications are common.[130] After surgical correction of the anomaly there is a much improved maternal and fetal outcome.[133] Prepregnancy assessment with echocardiography and stress testing to assess cardiovascular reserve will help determine the likelihood of a successful outcome for the mother during pregnancy. There is an increased risk of a congenital heart defect in the offspring.

Transposition of the great vessels

Transposition of the great vessels occurs when the aorta arises from the right ventricle and the pulmonary artery from the left ventricle, associated with a communication between the two circulations. An operation to redirect oxygenated blood into the right ventricle and aorta and systemic venous blood into the left ventricle and pulmonary artery now allows women to survive until adulthood. One series of nine women who had 15 pregnancies, following this operation, resulted in 12 healthy live births.[134] There were two spontaneous abortions and one intrauterine death.[134] However, prepregnancy assessment of right ventricular function with echocardiography and exercise testing is essential before advising pregnancy.[130]

Tricuspid atresia and the Fontan procedure

In tricuspid atresia, blood is unable to pass through the tricuspid valve and therefore exits the right atrium through an atrial septal defect. Blood then passes through a ventricular septal defect back into the right ventricle and into the pulmonary circulation. The Fontan procedure creates a connection between the right atrium and pulmonary artery while closing off the atrial septal defect and ventricular septal defect. In general, maternal outcome depends on the state of health at the beginning of pregnancy and fetal outcome on the level of central cyanosis.[2]

Heart transplantation and pregnancy

A survey of international cardiac transplant centers identified 30 women who had had pregnancies following heart transplantation: 27 heart and 3 heart and lung recipients.[100] The cardiovascular changes of pregnancy were well tolerated. There were six episodes of mild to moderate rejection, requiring an increase in prednisolone. Different combinations of prednisolone, azathioprine and cyclosporin were used throughout all pregnancies. Of the women 48% had preexisting hypertension and 24% developed preeclampsia. There were no maternal deaths during pregnancy, but three women died within 30 months of delivery. Two died after stopping their immunosuppressive therapy and one developed cryptococcal meningitis 2 years postpartum. Four women had heart transplants following peripartum cardiomyopathy and all survived without any recurrence of their original heart disease. Preterm labor occurred in nine cases (36%). There were 27 live-born infants with two sets of twins. There were no fetal deaths or anomalies, but 20% had fetal growth retardation.[100] Overall, it is sensible to advise heart transplant patients who wish to conceive that although most pregnancies are successful, complications are common. Furthermore, those women with poor cardiac reserve may not survive to raise their children.

196 Disorders of the musculoskeletal system in pregnancy

C. Gordon

Introduction

Musculoskeletal symptoms are common in pregnancy. Many women suffer mild non-specific arthralgia and myalgia, which require no specific intervention. Some pregnant women develop more clear-cut and distressing symptoms such as parasthesiae due to carpal tunnel syndrome, mechanical low-back or pelvic pain. Occasionally, transient osteoporosis of the hip or osteoporotic vertebral fractures occur. Most of these cases occur in women without underlying disease but about 3% of pregnant women will have a chronic musculoskeletal disorder. In addition to the effect of the pregnancy on the disease, the effect of the disease on the pregnancy needs to be considered.

Rheumatoid arthritis (RA) is the most common inflammatory arthropathy and the best studied, but other inflammatory rheumatic diseases will be mentioned in this review as well. Systemic lupus erythematosus (SLE) is the most common systemic connective tissue disease, usually develops in women of child-bearing age and may present for the first time in pregnancy or soon after delivery. Differentiation between a flare of lupus and pre-eclampsia and toxemia of pregnancy is important for appropriate management. Similarly, it is essential to detect and treat antiphospholipid syndrome, which may complicate SLE or present as a primary disorder often in pregnancy or the puerperium. Genetic disorders of collective tissue matrix proteins are a rare but important group of diseases to be aware of. These, like the inflammatory collective tissue disorders and vasculitides, can be life-threatening to the mother and fetus during pregnancy and delivery. These individual conditions will be considered in more detail below, but first a few general points will be discussed.

Management of musculoskeletal disorders during pregnancy must take into consideration the risk of investigations and drug therapy to the fetus. In general, radiological procedures should be kept to a minimum especially in early pregnancy but, with appropriate shielding, can be performed if the results will significantly affect management. Ultrasound is the safest way to look for synovial effusions and to guide needle aspiration, particularly in the hip. Isotope, computerized tomography (CT) and magnetic resonance imaging (MRI) scans can usually be deferred until after delivery.

Female patients of reproductive age with any rheumatic disease need to be aware of the implications of their disease and its treatment on their fertility, risk of fetal loss and ability to bring up children from the time of diagnosis. Close support from their partner, family and friends will be invaluable as pregnancy and parenthood can be very tiring and stressful for such women. It is often helpful for a family member or friend to come to clinics with them, to encourage the patient to ask relevant questions and to help remember what was said at the consultation. Close liaison is required between the obstetrician, rheumatologist and any other physicians involved in the care of the pregnant patient. Review by a physiotherapist and discussion with an anesthetist about pain relief and anesthesia should be arranged.

In some cases, difficult issues such as termination of pregnancy may have to be discussed if the patient has life-threatening systemic disease. However, in most patients therapy can be adjusted to control the disease without significant risk to the mother or fetus. In general, it is preferable to plan pregnancy in advance so that the disease is under good control and drug treatment is appropriate at the time of conception and throughout fetal development (Tables 196.1–196.3). Although it is often preferable to discontinue drugs in pregnancy, the likely consequences of this need to be considered as well as the risk of continuing therapy. There is little point in stopping all drugs if the disease will flare, putting the mother at risk of significant

Table 196.1 Analgesic and anti-inflammatory drug use in pregnancy

Drug	Main use in musculoskeletal disorders	Possible risks to fetus	Contraindicated in pregnancy	Contraindicated in breast feeding
Paracetamol	Analgesic (mild)	Unlikely	No	No
Codeine	Analgesic	Respiratory depression, withdrawal syndrome	No (caution)	Caution
Aspirin	NSAID, anti-thrombotic	Low with low doses, neonatal hemorrhage, pulmonary hypertension, renal anomalies?	No (low doses)	No (low doses)
Ibuprofen	Mild NSAID for RA	Renal anomalies?, premature closure ductus, pulmonary hypertension	Caution first and third trimester	No (low dose, and other arthritides short-acting)
Indometacin	Potent NSAID for AS	Congenital malformation, prolonged gestation, pulmonary hypertension	Yes	Yes

NSAID, non-steroidal anti-inflammatory drug; RA, rheumatoid arthritis; AS, ankylosing spondylitis

Table 196.2 Antirheumatic drug use in pregnancy

Drug	Main use in rheumatic disease	Possible risks to fetus	Contraindicated in pregnancy	Contraindicated in breast feeding
Hydroxychloroquine	SLE (RA)	Eye or ear abnormalities? (risks with chloroquine)	No (low dose)	No (low dose)
Sulfasalazine	RA	Congenital malformations?, possible kernicterus (none confirmed)	No (caution first and third trimesters)	No (avoid high dose)
Gold salts: Myocrisin	RA	None confirmed intramuscularly, Auranofin oral	No (low dose)	No (low dose)
D-Penicillamine	RA	Cutis laxa, connective tissue abnormalities	Yes	Yes

SLE, systemic lupus erythematosus; RA, rheumatoid arthritis

systemic disease and fetal loss. Combined clinics for patients with connective tissue diseases provide the most efficient service for these patients, as close monitoring of the pregnancy and the disease is required and this arrangement avoids the need for multiple clinic visits each month.[1,2]

Musculoskeletal disorders due to pregnancy

Carpal tunnel syndrome

Carpal tunnel syndrome is the most common entrapment neuropathy.[3] It is common in patients with synovitis of the wrist but also occurs frequently in healthy women in the third trimester of pregnancy (21% of women in one series), possibly due to fluid retention.[4] It causes sensations of burning, tingling and numbness in the distribution of the median nerve, usually on the palmar surface of the radial three and one-half digits and palm of the hand. More severe cases will have weakness of abductor pollicis brevis and the pain may radiate proximally in the forearm. Cases presenting in pregnancy without an associated arthropathy usually resolve after pregnancy and do not require surgery. Treatment consists of the provision of a wrist support splint, particularly for use at night when symptoms are often worst, and local steroid injection for more severe cases.

Transient osteoporosis of the hip

This is a rare but well-recognized condition, which presents in pregnancy as hip pain on movement or

Table 196.3 Immunosuppressive drugs used in pregnancy

Drug	Main uses in rheumatic disease	Possible risks to fetus	Contraindicated in pregnancy	Contraindicated in breast feeding
Methotrexate	RA, psoriatic arthritis	Facial and skeletal abnormalities	Yes	Yes
Cyclosporin A	RA, SLE, psoriatic arthritis	Spontaneous abortion? (not teratogenic in animals)	Caution (limited data)	Yes
Glucocorticoids	RA, AS, SLE, vasculitis	Cleft palate hypoadrenal, small for dates?, stillbirth?	No, caution high dose	No, caution high dose
Azathioprine	SLE, RA, vasculitis	None definite	No, caution high dose	Caution, conflicting
Cyclosphamide	SLE, vasculitis	Facial, skin, limb and visceral abnormalities	Yes	Yes

RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; AS, ankylosing spondylitis

weight-bearing, more often on the left than the right, sometimes with radiation to the anterior thigh and knee.[5,6] It may be due to pregnancy-related hormonal changes and local compression of vessels or nerves resulting in a transient algodystrophy (reflex sympathetic dystrophy). However, it can occur early in pregnancy, in the non-pregnant state and in other joints, leaving the etiology unclear. It is important to distinguish other causes of pain in the hip region, which require different management. The pain may be due to a femoral or inguinal hernia or may be referred from the sacroiliac joints or lumbar spine. Obturator nerve compression at the pelvic brim due to engagement of the fetal head can cause pain in the upper anterior thigh. The hip pain may be part of a generalized preexisting arthropathy or may be an isolated joint flare in which case infective arthritis must be excluded (even if there is a history of previous hip involvement, for example in RA). Pregnancy-induced osteomalacia and osteonecrosis (aseptic necrosis, particularly in patients with sickle cell anemia or SLE) should also be considered.

X-rays, isotope and MRI scans should be avoided until after the delivery but can be used to confirm osteopenia with preservation of joint space and to exclude synovitis. Ultrasound can be used to look for an effusion and to guide aspiration in suspected infection. Treatment usually involves short-acting non-steroidal anti-inflammatory drugs (NSAIDs) like ibuprofen, up to the third trimester and postpartum, with paracetamol and codeine if required in the third trimester (Table 196.1). Physiotherapy is advised as there is often significant muscle wasting. A walking stick or crutches may be necessary, but the prognosis is usually good with full clinical and radiological recovery within 6 months.

Vertebral osteoporosis

Severe osteoporosis may develop in pregnancy and cause vertebral fracture(s).[7,8] This presents with severe, localized back pain with loss of vertebral height, usually in the third trimester or puerperium of a first pregnancy. Sometimes there is evidence of generalized osteopenia, and occasionally fractures of the femur have occurred as well. Under 20% of reported cases have had a predisposing cause such as treatment with heparin or steroids, or previous anorexia nervosa, structural protein or metabolic bone disease. Bone biopsies suggest that there is a failure of osteoblast activity but the etiology remains obscure.[8] However, the prognosis is generally good with resolution of pain and no further vertebral collapse after delivery, and few patients suffer a recurrence in subsequent pregnancies.

Mechanical low-back and pelvic pain

Low-back and pelvic pain are very common in pregnancy, particularly in the last trimester. The pains probably result from postural changes (increased lordosis) due to the enlarging fetus, ligamentous laxity and increased mobility of the pelvic bones.[9] Relaxin, which enhances collagenase production and plasminogen activation, is present at increased levels in pregnant women with severe pain.[10] Pain settles after delivery and investigation is not indicated unless there are neurological signs suggesting nerve root or cord compression.

Inflammatory arthropathies

Rheumatoid arthritis

RA is the commonest inflammatory arthritis, which affects about 2% of the population and three times as many women as men. The peak age of onset is 40 years. RA presents as a symmetrical polyarthritis typically involving wrists, metacarpophalangeal and proximal interphalangeal joints. Active disease is usually associated with considerable fatigue, anemia of chronic disorders and a high erythrocyte sedimentation rate,

CRP (C–reactive protein) and viscosity. Rheumatoid factor positive patients may develop a more serious systemic disease with, for example, nodules, pleuropericarditis, lymphadenopathy, weight loss and vasculitis.

The effect of pregnancy on RA

Pregnancy is associated with a marked reduction in the symptoms of RA in about 70% of cases.[11] This improvement is most marked in the third trimester and often occurs despite patients stopping or reducing NSAIDs, and antirheumatic or immunosuppressive therapy (Tables 196.1–196.3). Unfortunately, the remaining 30% of patients have persistent symptoms and drug treatment needs to be given to prevent the mother from developing significant loss of function. RA rarely develops for the first time during pregnancy but there is an increased risk of RA appearing in the first year after a delivery. There is also considerable risk of a postpartum flare of existing arthritis within 3 months of delivery.[12]

Protection against the development and activity of RA in pregnancy may be due to neuroendocrine and sex hormone changes that suppress immunological and inflammatory processes.[9,11,13] Use of the oral contraceptive pill has also been reported to protect against the development of RA.[14] Natural immunosuppressive mechanisms that act in pregnancy to prevent rejection of the fetus and to reduce arthritis include changes in cytokines, such as increased interleukin (IL) 10 levels,[15] pregnancy-associated a_2-glycoprotein, induction of maternal antibodies or regulatory T cells in response to paternal HLA antigen exposure, or changes in the maternal T cell repertoire induced by fetal HLA peptides.[9,11]

The effect of RA on pregnancy

There is no evidence that RA patients have reduced fertility but they may take longer to conceive than healthy women.[11] RA in the mother is unlikely to affect the development of the fetus or increase the risk of maternal complications in pregnancy. Spontaneous abortion and stillbirth rates are slightly increased compared with healthy controls but successful pregnancy and uncomplicated delivery usually occur. Pre-eclampsia may be less common in RA patients than in the general population. Involvement of the hip joints, even if previously replaced, rarely interferes with delivery. If a general anesthetic is needed, temporomandibular and cricoarytenoid joint disease may make intubation difficult. The risk of atlantoaxial instability needs to be considered.[16] All RA patients should wear a cervical collar so that the staff takes greater care by being visibly reminded that the cervical spine, roots and cord are at risk of damage.

Other inflammatory arthropathies and spondyloarthropathies

There is an increased risk of systemic gonococcal disease with arthritis during pregnancy, especially in the third trimester, probably due to the state of relative immunosuppression. Reactive arthritis due to gut infections and *Chlamydia* may also present for the first time in pregnancy, although there are few data on this type of arthritis in pregnancy.[16,17] With appropriate and prompt antibiotic therapy for these infections, there is no evidence that the inflammatory processes in these arthropathies are associated with impaired fetal development or increased risk of maternal complications of pregnancy.

Lyme disease, a tick-borne inflammatory disease caused by the spirochete *Borrelia burgdorferi*, may present with erythema chronicum migrans or chronic inflammation in the joints, skin or nervous system during pregnancy. *B. burgdorferi* can cross the placenta and there have been a few cases of stillbirth and neonatal death ascribed to such transmission. However, it appears to be a rare event.[18,19] Nevertheless, a low threshold for aggressive antibiotic regimens for Lyme borreliosis in pregnancy has been recommended. There are no reports of congenital abnormalities or adverse maternal pregnancy complications in women with a history of Lyme disease.[19]

Acute gouty arthritis due to uric acid crystals is very rare in women before the menopause unless there is a specific enzyme defect that causes overproduction of purines (usually with a family history) or significant renal impairment. However, hyperuricemia (without arthritis) is common in preeclampsia and toxemia of pregnancy due to impaired renal clearance of urate.[18] High urate levels and raised diastolic blood pressure are associated with increased perinatal mortality. Transient hyperuricemia is seen during normal labor and for 1–2 days postpartum.[20]

Psoriatic arthritis, juvenile chronic arthritis and palindromic rheumatism behave similarly to RA, generally with improvement of symptoms during pregnancy and a high risk of postpartum flare. Adult Still's disease can flare or present in pregnancy and the postpartum period and may require treatment with prednisolone.[21] The spine disease associated with psoriasis and inflammatory bowel disease, which resembles ankylosing spondylitis, tends to improve in pregnancy. However, true ankylosing spondylitis is less likely to remit in pregnancy.[17,22] Spine and hip disease may make epidural anesthesia and vaginal delivery difficult. Postpartum flare is common in ankylosing spondylitis and the other inflammatory arthropathies.

Treatment of inflammatory arthropathies in pregnancy

Although most drugs used in the treatment of rheumatic disease do cross the placenta, few are definitely teratogenic in humans and many healthy babies have been born to mothers who were taking various antirheumatic drugs at the onset of pregnancy. Table 196.1 lists the analgesic and anti-inflammatory drugs. Advice on the use of antirheumatic drugs during pregnancy and

lactation is given in Table 196.2. Immunosuppressive drugs are reviewed in Table 196.3.[11,23–26] Prednisolone, azathioprine and paracetamol are the safest drugs in pregnancy.[2,25,26] There has been considerable experience in their use during pregnancy for a variety of disorders. In inflammatory arthritis, which cannot easily be controlled by aspirin or low-dose NSAIDs, it is best to use intra-articular steroid injections or low-dose oral prednisolone. Gold (Myocrisin) injections may be continued in pregnancy at low doses (20 mg intramuscularly) monthly to prevent relapse but are usually avoided.[23,24] Ankylosing spondylitis can be difficult to treat, as patients are often very dependent on potent NSAIDs, such as indometacin, which have to be stopped in pregnancy. Steroid therapy is disappointing, but may be helpful if moderate doses (for example, 20 mg/day) are used with analgesics and physiotherapy to control the incapacitating pain and stiffness that may otherwise occur during periods of physical inactivity.

Connective tissue disorders

Systemic lupus erythematosus

This is the commonest systemic autoimmune disease, occurring in about 1 in 2000 women,[27] and is most prevalent in people from the Caribbean, the Indian subcontinent and the Far East. Almost any system in the body can be affected. The commonest manifestations include fatigue, non-erosive polyarthritis in rheumatoid distribution, photosensitive rashes, mouth ulcers, alopecia, Raynaud's phenomenon and pleurisy. More serious manifestations are endocarditis, lung fibrosis, pulmonary hypertension and various forms of renal and neurological disease.[28] SLE is associated with the production of autoantibodies directed against a variety of antigens, such as antinuclear antibodies and antibodies to double-stranded (ds) DNA, extractable nuclear antigens (e.g. Ro and La) and hematopoietic cells (resulting in hemolytic anemia, leukopenia or thrombocytopenia).

Effect of pregnancy on SLE

This has been a debatable issue for some time.[2,29] There is evidence that sex hormones may increase autoantibody formation. Estrogens, in particular, can predispose to the development of lupus in mouse models and human SLE.[10] Many patients do not tolerate the oral combined contraceptive pill due to exacerbation of lupus and, until recently, many physicians considered pregnancy relatively contraindicated, as pregnancy frequently caused SLE to deteriorate significantly. This impression may have developed because patients often reduced or stopped their drugs when pregnancy was diagnosed, an action that usually precipitates active disease.

There have been a number of retrospective and prospective studies assessing the risk of lupus flare in pregnancy.[2] These have suffered from a number of problems such as lack of controls, inappropriately matched controls, small numbers and failure to define flare. Overall, they have suggested that the frequency of flare is between 21% and 82%, and is similar or increased during pregnancy compared with non-pregnant patients. Only one study matched for disease activity at the beginning of the study. This showed that flare was reduced in patients with inactive disease at the time of conception, compared to those with active disease, and non-pregnant patients with inactive or active disease.[30] Two recent controlled prospective studies[31,32] using patients when not pregnant as their own controls as well as a separate non-pregnant group showed that lupus flared in about 65% of pregnancies. This was more common than in the controls (about 40% flared). The flares were usually mild, occurred after the first trimester or postpartum, were independent of therapy and were more likely in those with active disease at conception.

SLE in pregnancy with active renal involvement is the most worrying, as deterioration poses considerable risk to the mother and fetus.[2,16] Steroids should not be used prophylactically as they can aggravate pregnancy-induced hypertension and preeclampsia, and do not appear to reduce the risk of flare. However, prednisolone and azathioprine can be used in pregnancy (see Table 196.3) and should be continued at prepregnancy doses, and increased or started as clinically indicated to prevent serious clinical deterioration.

Identifying active lupus disease in pregnancy, particularly with renal involvement, can be difficult as it needs to be distinguished from preeclampsia, which may coexist. It is important to identify more specific features of active SLE such as malar rash, red cells in the urine and rising titers of anti-dsDNA antibodies (see Table 196.4). Proteinuria and hypertension due to pre-eclampsia can be associated with thrombocytopenia, pregnancy-induced musculoskeletal pain and palmar erythema.[29] Assessment of the complement proteins C3 and C4 is less helpful, as these levels usually rise in pregnancy and a fall in active SLE may not be detected unless frequently checked. Increased levels of complement degradation products (C3a, C3d, Ba and Bb) may be a more reliable measure of active lupus.[33]

Effect of SLE on the pregnancy

Retrospective and prospective studies have found that patients with SLE are at increased risk of fetal loss due to spontaneous abortion and stillbirth. Recent studies suggest that fetal loss occurs in about 20% of SLE pregnancies.[2,34] Different frequencies for fetal loss between studies are likely to reflect variable patient selection and disease activity, as well as differences in obstetric care and fetal monitoring between clinical centers. Factors that probably contribute to the increased risk of fetal loss include disease activity overall, type and severity of renal involvement and a hypercoagulable state due to the presence of antiphospholipid antibodies.

Table 196.4 Diagnosis of lupus flare in pregnancy

Unreliable features	Reliable features
Facial/palmar erythema	True lupus rash
Arthralgia	Synovitis
Anemia	Mucosal ulcers
Low platelets	Leukopenia
Hypertension	Red cells in urine
Proteinuria	Casts in urine
Low C4/high C4d	Anti-DNA antibodies
Classical pathway activation	Alternative pathway activation

Antiphospholipid antibodies have been associated with recurrent miscarriages and stillbirth. They are detected usually as a 'lupus anticoagulant' and/or anticardiolipin antibodies and are not necessarily associated with SLE (see 'the antiphospholipid syndrome' below).[2]

Preterm delivery is more common in SLE patients than in controls. In one study, 24% of pregnancies in diagnosed SLE patients ended in preterm labor compared with 6% of the pregnancies before SLE was diagnosed.[34] More recently, 43% of live births in a lupus cohort were preterm with a mean gestational age of 34 weeks.[35] In 76% of these cases fetal distress and/or intrauterine growth retardation had prompted induction of labor. This intervention appears to have improved outcome, with the live birth rate rising from 31% to 82% for these women compared with their own previous obstetric history.[35] In another study, premature rupture of membranes was found to be more common in SLE pregnancies than controls and accounted for 25% of preterm deliveries.[36] Active disease at conception, renal involvement, hypertension, Raynaud's phenomenon and antiphospholipid antibodies may indicate patients at risk of preterm delivery.[2]

Neonatal lupus syndrome

Fortunately, this is a rare manifestation of maternal autoantibody production, which may present with transient skin rashes, liver dysfunction, hematological abnormalities or congenital heart block in the newborn.[29,37] The condition is due to cellular damage by passively acquired maternal IgG autoantibodies. The skin rashes and cytopenias disappear after about 8 weeks as the maternal autoantibodies are cleared from the neonatal circulation and the tissues regenerate. As cardiac tissue cannot regenerate, heartblock is persistent but can be treated by the insertion of a pacemaker. This may be delayed until the child is about 10 years old but in severe cases, congenital heartblock may be associated with perinatal death due to myocarditis and cardiac failure. Maternal dexamethasone administration may reduce this inflammation and improve fetal outcome but the heartblock remains irreversible.[37]

The skin rashes and heartblock are associated with anti-Ro (SS-A) antibodies in the mother. There is some evidence that mothers with anti-La (SS-B) and anti-Ro antibodies are at increased risk of having a child with congenital heartblock. The mothers often have a history of photosensitive rashes and are usually known to have SLE. In some cases the birth of a child with neonatal lupus is the first and only manifestation of autoantibody formation in the mother. Over subsequent years, typical features of SLE develop in about 50% of these mothers. The remainder usually develops some lupus-like features such as photosensitivity and arthralgia. Only 5–10% of mothers with anti-Ro antibodies give birth to a child with neonatal lupus, but there is a one in three chance of a further child with congenital heartblock after the birth of a first child with this form of neonatal lupus.

Antiphospholipid syndrome

The antiphospholipid antibody syndrome is characterized by the development of recurrent venous and arterial thromboembolism, fetal loss due to placental thrombosis and infarction and thrombocytopenia associated with the production of high levels of IgG antiphospholipid antibodies.[2,38] Other clinical features include cardiac murmurs, pulmonary hypertension, hemolytic anemia, livedo reticularis and neurological disorders such as migraine, epilepsy, chorea and stroke. The antiphospholipid syndrome occurs in about 15% of SLE cases but can occur spontaneously (the primary antiphospholipid syndrome) or in association with other autoimmune conditions.[39] Antiphospholipid antibodies are present in about 10% of patients with recurrent miscarriage.[40]

Antiphospholipid antibodies can be identified by a variety of tests.[38] Antibodies to cardiolipin and other negatively charged phospholipids can be measured directly by ELISA techniques. Some antiphospholipid antibodies interfere with phospholipid-dependent coagulation tests. They can cause a prolonged activated partial thromboplastin time (APTT) by acting as an inhibitor of coagulation *in vitro*. The effect of this 'lupus anticoagulant' (LA) cannot be corrected by the addition of normal plasma. It is paradoxically associated with an increased risk of thrombosis, not bleeding, *in vivo*. The Russell viper venom test is a more sensitive and specific test for LA than the more commonly performed APTT screen.[2,40] As transiently positive results are found for both anticardiolipin antibodies and LA (e.g. in infection), it is important to obtain a confirmatory test at least 6 weeks later. Persistently high levels of IgG anticardiolipin antibodies and the Russel viper venom test appear to be the best predictors of fetal loss.[40,41]

The antiphospholipid syndrome may present for the first time during pregnancy, most commonly with deep vein thrombosis or recurrent second-trimester fetal loss. First- and third-trimester losses and intrauterine

growth retardation (IUGR) may also occur. Hemolysis, elevated liver enzymes and low platelets (HELLP) syndrome and hepatic infarction have been reported in several patients with antiphospholipid antibodies. There is a risk of recurrence of all these complications in subsequent pregnancies.[42–44] The fetus should be assessed carefully for evidence of fetal distress and IUGR from 26 weeks onward, as premature delivery may reduce the risk of intrauterine death in a potentially viable fetus. Doppler blood flow waveforms can be used to assess utero-placental blood flow with conventional assessments of fetal growth, heart rate, movement, tone and maturity.[1,2]

Management of the antiphospholipid syndrome

This is a debatable issue as there are few randomized controlled studies. The evidence increasingly supports the use of low-dose aspirin (75 mg) in patients with anticardiolipin antibodies and/or LA and a history of recurrent miscarriages.[45] More recent work supports the addition of subcutaneous heparin.[46] Many doctors will prescribe low-dose aspirin, at least between weeks 10 and 34, to all patients with any serological evidence of antiphospholipid antibodies or SLE, to reduce the risk of fetal loss and IUGR as the risk of such aspirin therapy is minimal compared with the disease-associated risk.[47] For patients with antiphospholipid antibodies and a history of venous or arterial thrombosis, subcutaneous heparin (unfractionated or low molecular weight) is required. Low-dose aspirin is often given as well.[45,46] When not pregnant, they require high-dose warfarin therapy to keep the international normalized ratio greater than 3.0.[48]

There is no evidence that oral prednisolone therapy provides additional protection from the deleterious effects of antiphospholipid antibodies with the primary antiphospholipid syndrome. There is even some evidence to suggest that pregnant patients given steroids and low-dose aspirin do less well than those given aspirin alone (increased risk of hypertension and pre-eclampsia). For patients on heparin and prednisolone there is an increased (additive) risk of osteoporosis. However, patients with SLE who are taking prednisolone to control their overall disease should continue with this therapy, at the lowest dose possible to keep the disease suppressed. For the unfortunate patients with recurrent fetal loss despite heparin and aspirin therapy, uncontrolled studies suggest that treatment with intravenous γ-globulin or plasma exchange may be helpful monthly throughout pregnancy.[2,39,49–52]

Systemic sclerosis

Systemic sclerosis (scleroderma) is a multisystem disease of unknown etiology that is characterized by the overproduction and growth of connective tissue, especially collagen, with associated microvascular obliteration and vascular damage. Immune dysfunction, inflammation and endothelial damage involving growth factor and cytokine activation are probably involved in the pathogenesis. The prevalence is about 1 in 10,000 and it is three times more common in women than in men. The peak age of onset is 30–50 years. In the past, most women would have completed their families by this time but it is now becoming a more frequent problem in pregnancy. Typical features include thickened shiny skin (scleroderma), microstomia, telangiectasia, Raynaud's phenomenon, esophageal dysmotility, pulmonary fibrosis and hypertension. The most serious manifestations are cardiac failure, pulmonary hypertension, digital gangrene and renal failure.

There have been no prospective and very few case-controlled studies of pregnancy in systemic sclerosis. In contrast to previous reports, recent work suggests that infertility and fetal loss are not increased,[53] but prematurity and intrauterine growth retardation are more common than in controls.[54] The disease does not necessarily change during pregnancy. However, those with diffuse cutaneous disease and antitopoisomerase antibodies have a poorer prognosis than those with limited cutaneous disease and anticentromere antibodies. Patients with aggressive skin disease, especially those within 5 years of onset, are at most risk of deteriorating during pregnancy with life-threatening systemic complications, especially hypertensive renal crisis and pulmonary hypertension. Acid reflux, esophagitis, constipation, arthralgias and hypertension are common problems, which often deteriorate in pregnancy. Blood pressure should be checked several times a week in diffuse disease.

Nifedipine, paracetamol and ranitidine should be prescribed if needed. NSAIDs should not be given as they can precipitate hypertension and renal crisis in addition to fetal risks. Pre-eclampsia can be difficult to distinguish from renal involvement but this does not affect management. Angiotensin-converting enzyme (ACE) inhibitors are indicated in resistant systemic hypertension, particularly if there is proteinuria, elevation of serum creatinine or microangiopathic hemolytic anemia indicating life-threatening renal crisis.[53] The risks of ACE inhibitors causing fetal abnormalities, impaired placental perfusion and intrauterine death appear to be less than the risk of maternal and fetal death without such treatment. D-Penicillamine can cause fetal abnormalities and is usually stopped before pregnancy (Table 196.2). In patients with aggressive disease it has been continued in some cases without ill-effect.[53] Steroids increase the risk of renal crisis and should be avoided unless aggressive fibrosing alveolitis, pericarditis or inflammatory myopathy develop.[54] Anesthesia may be complicated if there is cardiac, respiratory or renal involvement, and if the skin and esophageal changes are severe. A Swan–Ganz catheter may be necessary for monitoring during and after delivery. Epidural anesthesia is often preferred, as it promotes peripheral vasodilatation and avoids problems with intubation and the risk of inhalation. Lower than normal

doses of all agents are recommended as systemic sclerosis patients are often very sensitive. Systemic hypertension with renal impairment, acute pulmonary hypertension and cardiac failure may develop for the first time in the postnatal period.[55,56]

Vasculitis

Vasculitis is a term used to describe a heterogenous group of diseases characterized by an inflammatory cell infiltrate and necrosis of blood vessel walls. The size, site and number of blood vessels involved determine the clinical consequences of this vascular inflammation. Vasculitis may be primary, for example, Wegener's granulomatosis, or secondary to a systemic disease such as SLE. These conditions are all rare especially in pregnant women, as the onset is usually after the age of 40 years and cyclophosphamide therapy may induce premature menopause. However, as treatment of these previously lethal conditions improves, the association of vasculitis and pregnancy may be encountered more frequently. Polyarteritis nodosa and Wegener's granulomatosis may deteriorate or present for the first time in pregnancy with high risk of maternal morbidity and mortality.[56,57] The prognosis is best in patients who are in remission on low dose or no immunosuppression. Cessation of drugs may contribute to disease flare in pregnancy, so prednisolone and azathioprine should be continued or used as necessary but cyclophosphamide should be avoided (Table 196.3). Fetal outcome is usually good unless maternal disease is very severe in early pregnancy.

Genetic syndromes with musculoskeletal manifestations

Familial Mediterranean fever

This genetic disorder occurs predominantly in people of Mediterranean and Middle Eastern origin, especially Sephardi Jews and Armenians.[58] It is characterized by brief attacks of fever at irregular intervals, which may be associated with arthritis, pleurisy, peritonitis and erysipelas-like erythema. Untreated patients develop systemic amyloidosis, which causes proteinuria due to nephropathy and may result in death from renal failure before the age of 40. This can be prevented by continuous colchicine therapy,[59] which also prevents symptomatic attacks in about 65% and reduces the frequency and severity of attacks in a further 30%. Two cases each of trisomy 21 and Down's syndrome have been reported in 620 colchicine-treated pregnant women. It is not clear that the chromosomal aberrations were due to colchicine but amniocentesis is recommended for those who wish to assess this potential risk in pregnancy.[58]

Marfan's syndrome

This genetic disorder affecting the extracellular matrix protein fibrillin has an autosomal dominant inheritance, is relatively common in all racial groups and has a prevalence of about 1 in 20,000.[60,61] The characteristic clinical features include tall stature, disproportionately long limbs (and digits) relative to trunk length, chest wall deformities (e.g. pectus excavatum), scoliosis, high arched narrow palate and ligamentous laxity. The patients often have flat feet, which can increase the risk of mechanical back pain, and may have limited extension of some joints. Most are myopic and have non-progressive upward subluxation of the lens. The most serious problems are mitral valve prolapse and dilatation of the aorta due to cystic medial necrosis. Symmetrical aortic dilatation begins at the sinus of Valsalva and may cause aortic regurgitation as well as dissection or rupture. Timely surgical intervention when the aortic root is 55–60 mm may prevent such a catastrophic outcome. Pregnancy poses a very high risk of precipitating this in patients with moderate aortic dilatation.[60] Women should receive multidisciplinary advice both before and during pregnancy.

Ehlers–Danlos syndromes

This is a heterogenous group of genetic disorders affecting structural proteins, particularly type I and type III collagen, fibronectin, enzymes involved in connective tissue synthesis or copper metabolism.[60,61] Most show autosomal dominant inheritance but some are autosomal or X-linked recessive. It is the more severe, type IV Ehlers–Danlos syndrome (ecchymotic or arterial form) that is the most dangerous in pregnancy due to the additional risk of rupture of the uterus and preterm delivery at this time.[61,62]

These patients have characteristic faces with large eyes, thin nose and lips, easy bruising and thin skin with prominent venous pattern affecting the hands and feet Only the small joints of the hand are hypermobile and peripheral joint contractures may develop. Spontaneous pneumothorax and mitral valve prolapse occur frequently. Repeated gastrointestinal and arterial ruptures, usually involving the iliac, splenic or renal arteries or aorta, result in peritonitis, hematomas and eventually death. There is a defect in the synthesis or secretion of type III collagen, which is usually inherited in an autosomal dominant manner, but spontaneous mutations in one of the collagen type III alleles may occur.[61] Although pregnancy may be uneventful, the risk of uterine rupture and the tendency toward friable tissues means that delivery, anesthesia and surgery can be fraught with difficulties, so pregnancy should not be undertaken lightly.

Conclusion

In all cases, everyone involved in the care of the pregnant patient with a musculoskeletal disorder must be aware of the underlying disease and its potential effects on the mother and fetus. Full discussion of the likely advantages and disadvantages of any treatment plan must take place. Even with systemic rheumatic disease, providing that it is stable at the onset of pregnancy, the prognosis is usually good with careful monitoring of maternal disease and fetal development.

197 Thyroid function in pregnancy

C. Paul

Introduction

Normal thyroid function in pregnancy is essential for the normal growth and maturation of the fetus. Any disturbance of thyroid function, either from disruption of the hypothalamic–pituitary–thyroid axis or from non-thyroid disease can have a profound effect on this process. The antibodies present in maternal serum in autoimmune thyroid disorders readily cross the placenta, as do many of the drugs used to treat maternal thyroid disease. These factors may also significantly influence fetal development. In this chapter, these processes in normal pregnancy and the ways in which they may be altered by disease will be discussed. The implications for both mother and fetus and the relevant treatments available will be considered.

Over recent years maternal and fetal thyroid physiology and the relationship between the two have been well studied. Improved understanding of these processes has opened up interesting possibilities in the field of fetal therapy. One such example is the use of thyroid hormones for the acceleration of fetal lung maturity in preterm labor. This is currently the subject of important research and will also be discussed later in this chapter.

Development of fetal thyroid

Embryology

The development of the thyroid gland commences during the fourth week of embryonic life. Initially, an endodermal thickening forms in the floor of the pharynx. This grows downward forming the thyroid diverticulum. This diverticulum branches into two and continues to migrate downward as the embryo grows. It passes in front of the developing hyoid bone and laryngeal cartilages during its descent. The developing gland is attached by a fine stalk, the thyroglossal duct, to its original site on the tongue – the foramen cecum.

By the seventh week the thyroid gland has usually reached its normal position in the neck. At this time it is composed of a right and a left lobe connected by the isthmus. The distal part of the thyroglossal duct forms the pyramidal lobe and the remainder usually disappears.

Placental transfer of thyroid hormones

The fetal hypothalamic–pituitary–thyroid axis and thyroid gland develop independently of maternal thyroid hormone status, and become functional toward the end of the first trimester. However, thyroxine (T4) has been isolated from celomic and amniotic fluid from as early as 6 weeks' gestation,[1] at concentrations that vary directly according to maternal serum concentrations. This T4 must therefore be derived from the maternal circulation.

After the first trimester, transfer of tri-iodothyronine (T3) and T4 across the placenta does occur, but it is slow and maternal levels remain higher than fetal levels.[2] Neither thyroid-stimulating hormone (TSH) nor thyroid-binding globulin (TBG) is able to cross the placenta. Maternal thyrotropin-releasing hormone (TRH) reaches the fetal circulation,[3] but is not required for the release of TSH from the fetal pituitary.[4]

Fetal thyroid function

By 12 weeks' gestation the fetal pituitary gland contains TSH. The thyroid gland is able to synthesize T3 and T4. TBG, T4 and TSH are all measurable in fetal serum.[5,6] The concentrations of TBG, TSH, free T3 and T4 and total T3 and T4 all increase with gestation.[7] Free and total T4 levels reach adult levels by 36 weeks, but T3 levels remain lower than adult levels throughout pregnancy. TSH levels in the fetus also continue to increase throughout gestation despite rising T4 concentration and remain higher than the maternal levels.

Hypothalamic maturation is an important part of thyroid system development. This process commences at between 4 and 5 weeks' gestation and continues until the third trimester. TRH has been

detected in hypothalamic tissue by radioimmunoassay from 10 weeks' gestation.[6] The fetal pituitary is very sensitive to TRH.[8] A response is seen from around 20 weeks' gestation and negative feedback develops during the second trimester.[9]

Changes at delivery

Delivery results in stimulation of TSH release from the pituitary. This reaches a peak at 30 min of age. The level of TSH then falls rapidly during the first 24 h but more slowly over the next 2 days. T4 (both free and total) levels reach a peak at 24 h of age and then gradually decrease over the first few weeks of life.[6] There is a small peak in T3 production during the first hours after birth; this is followed by a more sustained rise commencing within 4 h and maintained for up to 36 h. These increased T3 levels are thought to arise from both increased secretion of T3 and increased conversion of T4 to T3. In preterm infants the pattern of TSH and T4 release are similar, but the magnitude of the changes is lower than in term infants.

Normal maternal thyroid function in pregnancy

During pregnancy, many of the normal maternal physiological changes that occur, such as increased heart rate, cardiac output and circulating blood volume, may complicate the assessment of maternal thyroid function. This difficulty is compounded by the fact that the size of the thyroid gland increases in pregnancy.[10] This has long been known to be so and, in fact, was a physical sign used in ancient times to diagnose the onset of pregnancy.[11] Despite this, most women in normal pregnancy are assumed to be euthyroid, and only the presence of an obvious goiter is considered pathological.[9]

The increased estrogen level in pregnancy stimulates the synthesis and reduces the hepatic clearance of TBG.[12] Serum TBG concentrations continue to rise from the beginning of the first trimester until around 24 weeks' gestation. The level then reaches a plateau, which is maintained until approximately 2 weeks after delivery.[13] There is a compensatory increase in the production of T4 and T3. The total serum levels of these hormones are significantly elevated in pregnancy; however, as in the non-pregnant state it is the unbound or free T3 and T4 that are responsible for thyroid activity.

Over the years there has been some disagreement regarding the exact nature of the changes in free thyroid hormone concentrations in pregnancy. This is probably due to difficulties in comparing different assay techniques. Now that measurements are more reliable and consistent it is accepted that there is a small increase in the free T4 concentration during the first trimester and a small decrease thereafter.[14]

Table 197.1 Summary of changes in thyroid function in normal pregnancy

	First trimester	Second and third trimesters
Thyroid volume	↑	↑
TBG	↓	↑
Total T3 and T4	↑	↑
Free T3 and T4	↑	↓
TSH	↓	↑
Iodine uptake	↑	↑
Iodine clearance	↑	↑

TBG, thyroid-binding globulin; T3, tri-iodothyronine; T4, thyroxine; TSH, thyroid-stimulating hormone

In most women these changes are within normal non-pregnant ranges.[15,16] There is a corresponding change in TSH levels, which fall in the first trimester and later rise as the T4 levels fall. Again, these levels remain within the normal limits in most women.[17]. The overall increase in thyroid function is thought to be primarily due to stimulation of the gland by substances released from the placenta. These are human chorionic gonadotropin (hCG),[17] chorionic TSH[18] and a placental TSH-releasing factor.[19] Chorionic TSH has only been found in one-third of pregnant women, and even in them the levels are so low that the hormone is unlikely to be of clinical significance in thyroid regulation. The effect of placental TRH on fetal and maternal thyroid function is, likewise, yet to be defined. There is, however, good evidence to suggest that hCG plays a significant role in maternal thyroid stimulation.[17] Throughout pregnancy there is a negative correlation between the levels of hCG and TSH. This supports the theory that it is hCG that stimulates the thyroid gland, leading to suppression of TSH in early pregnancy, and is thus responsible for the increase in maternal thyroid function.[6]

It has been suggested that the reduced serum concentration of iodine in late pregnancy may be another factor involved in the reduction of thyroid activity at this time.[13] The fall in serum iodine levels is due to the increased renal clearance of iodide and the increased requirements of the fetus. The increased demand for iodine is of little clinical significance in most developed countries where iodine intake is sufficient. A summary of the physiological changes occurring in pregnancy is given in Table 197.1.

Abnormalities of maternal thyroid function

Maternal hyperthyroidism

Incidence

The exact incidence of hyperthyroidism in pregnancy is unclear; however, it is generally estimated to occur

in somewhere between 1 in 500 and 1 in 2000 pregnant women.[9,13]

Etiology

Autoimmune disorders. Autoimmune disorders, including the hypermetabolic phase of Hashimoto's thyroiditis, account for the majority of cases of maternal hyperthyroidism in pregnancy. The most common of these disorders is Graves' disease. In most women the onset of this disease precedes the pregnancy. Symptoms of thyrotoxicosis may be exacerbated in the first trimester of pregnancy due to the small increase in thyroid function at this time. As the pregnancy progresses, many women with Graves' and other autoimmune diseases experience some degree of remission, because of the mild immunosuppression occurring in normal pregnancy. The return of autoimmune activity in the postnatal period often results in relapse of the condition after delivery.[21]

Other thyroid causes. Acute thyroiditis is another relatively common thyroid disorder in pregnancy. This is commonly preceded by a viral illness, is usually self-limiting and seldom requires treatment. Solitary toxic adenomata and toxic multinodular goiter may also occur but are less common.

Non-thyroid conditions. As already discussed, hCG is known to have thyroid-stimulating properties. In trophoblastic disease the greatly increased levels of this hormone may result in biochemical or clinical evidence of hyperthyroidism.[22,23] In addition, there is production of acidic variants of hCG, which have even greater stimulatory properties.[24] Overt thyrotoxicosis is actually quite rare in these women, the hyperthyroidism resolves as the hCG levels fall following treatment for the trophoblastic disease, and antithyroid drug therapy is rarely indicated.

Although the cause of hyperemesis gravidarum is unknown, it is more common in pregnancies in which the levels of hCG are higher than normal. It is particularly common in multiple pregnancies and women with trophoblastic tumors. It is likely that in hyperemesis, as discussed above for trophoblastic disease, the elevated hCG levels are responsible for the increased thyroid stimulation. A recent study, demonstrating a direct correlation between the increased hCG levels in hyperemesis and thyroid stimulation *in vitro*, lends support to this theory.[25] In most cases the hyperthyroidism in this condition is mild and resolves spontaneously before the second trimester.[26]

Clinical features

Many women in pregnancy experience symptoms that in a non-pregnant woman would lead to a suspicion of hyperthyroidism. These symptoms include changes in appetite, weight and bowel function, tremor, palpitations, heat intolerance, mood changes, anxiety and tiredness.

The possibility of thyroid dysfunction should not be discounted in pregnancy, particularly in women with a past or family history of thyroid disease.

Diagnosis

This is confirmed biochemically by the detection of suppressed TSH and elevated T4 levels in maternal serum. In borderline cases it is sometimes useful to repeat the blood tests after 3–4 weeks in order to confirm or exclude the diagnosis. TSH is the single best indicator of thyroid function in pregnancy,[27,28] the diagnosis of hyperthyroidism being based on its low levels. T4 may be normal and T3 levels elevated in isolation.

Since Graves' disease is such a common cause of hyperthyroidism in pregnancy, the thyroid-stimulating antibodies should be measured in all cases in order to assess the risks to the fetus and neonate.

Effects of hyperthyroidism on pregnancy

Maternal. Although oligo- or amenorrhea and anovulation are associated with thyrotoxicosis,[29] mild hyperthyroidism has not been found to significantly affect fertility.[11] A rare but serious complication of thyrotoxicosis is congestive cardiac failure. Women with long-standing untreated disease and those remaining thyrotoxic despite treatment are most at risk of developing this problem.[30]

Fetal. Maternal thyrotoxicosis in pregnancy is associated with considerable risks to the fetus. The incidence of miscarriage, stillbirth, intrauterine growth retardation (IUGR), premature delivery and neonatal death are all greater than in normal pregnancy.[30–33] An increase in the number of babies with structural and chromosomal abnormalities, including Down's syndrome, has also been reported,[33–35] but the cause of this is not clear.

Antithyroid drugs have also been implicated, but recent evidence suggests that poor control of thyrotoxicosis is more likely to account for congenital defects.[34] Thyroid autoimmunity is thought to be a risk factor both for chromosomal abnormality[36] and for miscarriage.[37,38] Higher titers of TSH receptor antibody increase the fetal risks.[32]

Treatment

The maternal and fetal complications are significantly reduced if the disease is diagnosed and treated promptly.

Drug therapy. Thionamides are the most common agents used for the treatment of thyrotoxicosis in pregnancy. They include carbimazole, methimazole and propylthyrouracil (PTU). Carbimazole is rapidly metabolized to methimazole. These drugs have two

actions. First, they inhibit thyroid hormone synthesis. This is achieved by the competitive blocking of the peroxidase enzyme, preventing the release of iodine from circulating iodides. The enzymes responsible for the iodination of tyrosine and the coupling of iodothyronine molecules are also inhibited. The second action is to cause a reduction in the levels of circulating thyroid autoantibodies. PTU has the additional effect of inhibiting the peripheral conversion of T4 to the more active T3. The release of thyroid hormones is not prevented, so it may be at least a week before a response is detectable and up to 6 weeks before a patient becomes euthyroid.

Although all the thionamide drugs cross the placenta, PTU does so more slowly than carbimazole and methimazole.[39] This has resulted in PTU becoming the treatment of first choice in pregnancy. There is ongoing concern that there may be a link between the use of methimazole and the development of a rare skin condition in the fetus, aplasia cutis congenita; although a direct causal relationship has not been confirmed, this has further decreased the popularity of this drug.[40] Despite its advantages, PTU is not without risks to the fetus. It is slowly metabolized by the fetus, and is present in higher concentrations in the fetal than the maternal circulation.[41] The resulting suppression of fetal thyroid function by this drug can lead to the development of fetal goiter,[42,43] or neonatal hypothyroidism.[44]

The treatment regimen commonly used in non-pregnant women with Graves' disease involves complete suppression of thyroid function with high doses of antithyroid drugs and T4 replacement. This treatment cannot be used in pregnancy because of the poor placental transfer of T4 compared to the thiourea drugs.

The aim of treatment should be to rapidly control the thyrotoxicosis and then to reduce the dose of drug to maintain the T4 level toward the upper limit of the normal range, or at mildly hyperthyroid levels.[40,45] Treatment should be monitored by measuring maternal free T4, which generally correlates well with fetal levels; TSH measurement is less useful in these patients.

Up to 5% of women experience mild side effects with thionamides. These include gastrointestinal upset, rashes, joint pains, pruritus, a metallic taste and nausea. More serious side effects such as bronchospasm, hepatitis and a lupus-like syndrome can also occur. Some patients will, however, be able to tolerate a different agent from the group. The most dangerous side effect, agranulo-cytosis, occurs in only 0.1% of patients. It tends to occur in women older than 40 years of age; it is dose related and reversible on stopping treatment.[46] It is a contraindication to further treatment with any thionamide agents.

Side effects are usually apparent within 2 months after commencing treatment. All women should have regular assessment of liver function and blood count, and be advised to report any problems.

β-Blockers may be used in the short term to control severe symptoms such as palpitations. They do not, however, treat the underlying condition. Prolonged use has been associated with a number of fetal side effects including IUGR, fetal bradycardia, hypoglycemia, a poor response to anoxic stress and respiratory depression at birth.[47,48]

Surgery. This is only indicated in pregnancy for those women who cannot tolerate antithyroid drugs, those in whom biochemical control is poor and in rare cases of suspected malignancy. It is best performed during the second trimester. The complications are the same as for non-pregnant patients and include hypothyroidism, recurrent hyperthyroidism, hypoparathyroidism and vocal cord paralysis.

Radioactive iodine therapy. This form of treatment is contraindicated in pregnancy and during breast feeding.[49] Termination of pregnancy should be offered to women inadvertently treated during early pregnancy, due to the risks of teratogenesis.

Maternal hypothyroidism

Incidence

Hypothyroidism is more common than hyperthyroidism, occurring in between 6 and 9 per 1000 women in pregnancy.[50]

Etiology

Autoimmune disorders. Most cases of hypothyroidism in women of child-bearing age have an autoimmune etiology. These conditions tend to reduce fertility and are unlikely to develop during pregnancy, thus most women will have been diagnosed, and treatment instituted, before the onset of pregnancy. The commonest cause in this group of women is Hashimoto's thyroiditis. Spontaneous atrophic hypothyroidism and treated Graves' disease with inadequate thyroxine replacement are other autoimmune conditions that should be considered.

Iatrogenic. Hypothyroidism may also be the consequence of thyroidectomy, radio-iodine ablation or excessive dosage with antithyroid drugs.

Iodine deficiency. During pregnancy the uptake of iodine is increased in order to maintain normal thyroid function. This is of little significance in developed countries, but in areas of the Third World where iodine deficiency is endemic it is a major health problem.

Clinical features. The symptoms of hypothyroidism including tiredness, poor concentration and weight gain with poor appetite, dry skin, hair loss and cold

intolerance often occur only in severe cases. Physical signs including bradycardia, delayed relaxation of tendon reflexes and goiter are, likewise, not invariably present.[9]

Diagnosis

In hypothyroidism the serum concentration of TSH is significantly increased. Free T4 and T3 may be reduced; however, due to the increase in TBG found in pregnancy the total serum levels of these hormones may remain within the normal range, and are not useful in the diagnosis. Testing for maternal thyroid autoantibodies should be performed routinely.

Effects of hypothyroidism on pregnancy

Maternal. It is well recognized that the incidence of menstrual irregularity and anovulation are high in hypothyroid women. Pregnancy is uncommon in severe cases. Gestational hypertension is much more common in hypothyroid women than in the general obstetric population, even in those with subclinical disease.[51]

Fetal. In the past, hypothyroidism has been associated with high rates of miscarriage, stillbirth, neonatal death and congenital abnormality.[52–55] More recent evidence has been more reassuring, indicating that pregnancy outcome is usually good in these women.[56]

Treatment

Many women with hypothyroidism will already be taking T4 replacement therapy before becoming pregnant. Those in whom the diagnosis is made during pregnancy should be started immediately on T4. Adequate dosage should be confirmed by monitoring maternal TSH levels. It has been reported that the requirements for T4 are increased during pregnancy;[57] however, for women who are established on treatment, it is probably sufficient to check TSH and free T4 levels once in the first trimester, and to alter the dose at this point if necessary.[58] Subsequent adjustments can be made if the patient becomes symptomatic.

As with the treatment of hyperthyroidism, the serum free T4 levels should be kept in the upper normal or lower hyperthyroid range. This will allow adequate production of T3 via the peripheral conversion of T4. It is perfectly safe for mothers to breastfeed while taking thyroxine.

Abnormalities of fetal and neonatal thyroid function

Hyperthyroidism

Incidence

This is a rare condition affecting less than 1 in 4000 pregnancies.[59]

Etiology

Fetal and neonatal thyrotoxicosis generally occurs as a result of transplacental transfer of thyroid autoantibodies from the maternal circulation. All women with a history of autoimmune thyroid disorder (most commonly Graves' disease or Hashimoto's thyroiditis) may, even after successful treatment, pass antibodies to the fetus during pregnancy.

The risk to the fetus can be determined by measuring the maternal antibody levels. If the levels are low, the fetus is not at risk; if they are high, more careful monitoring is required.[60,61] However, it is only after 22–24 weeks' gestation that the fetus is at risk of developing thyrotoxicosis.[62] All women with a past or current history of thyroid disease should be monitored carefully during the second half of pregnancy. Increased thyroid activity has also been demonstrated in fetuses anemic as a result of rhesus isoimmunization.[63]

Clinical features

Fetal. The rates of preterm delivery and stillbirth are considerably higher for thyrotoxic fetuses.[64] Careful postmortem in cases of stillbirth may reveal features including thyromegaly, cardiomegaly, congestive visceromegaly, generalized adenopathy, reduction in subcutaneous fat and signs of pulmonary hypertension.[65]

Neonatal. A number of clinical signs may lead to a suspicion of thyrotoxicosis in the fetus at risk of this condition. These include poor feeding and failure to gain weight, irritability, tachypnea, tachycardia and sometimes the development of cardiac failure. Goiter may also be seen.[9]

Diagnosis

Fetal. Serial ultrasound scanning from 28 weeks' gestation is useful for the detection of IUGR, fetal tachycardia, hyperactivity and goiter. The characteristic findings of advanced bone age and craniosynostosis have also been described on ultrasound.[11] Polyhydramnios, which may be due to esophageal obstruction by fetal goiter and fetal hydrops from cardiac failure, can also be excluded.

Fetal thyroid function can be abnormal regardless of maternal thyroid status and occasionally a direct assessment of fetal thyroid function can be undertaken by performing fetal blood sampling. The results can be compared with established normal ranges.[7]

Neonatal. Cord blood should be taken at the time of delivery to check for thyroid autoantibodies, TSH, T4 and T3 in all at-risk cases. It is important to remember that autoantibodies will last longer in the neonatal circulation than antithyroid medication transferred from the maternal circulation. Therefore, if the mother has been taking antithyroid drugs the neonate

may not present with features of thyrotoxicosis until 5–10 days of age. Untreated neonatal thyrotoxicosis has a mortality rate of up to 25%.[66] It is important to maintain a high index of suspicion, to make an early diagnosis and to institute treatment promptly.

Treatment

Fetal. If the diagnosis of fetal thyrotoxicosis is made, the mother should be treated with antithyroid medication in the same way as for maternal hyperthyroidism. PTU is the drug of choice, as already described.

The fetal condition can be closely monitored with cardiotocography (CTG) and ultrasound assessment. These should initially be performed weekly, but the frequency can be decreased as the condition stabilizes.

Neonatal. When the diagnosis is made in the neonate the thionamide agents are still the first-line choice of treatment. Other drugs such as propranolol for tachycardia, digoxin and diuretics for cardiac failure and sedatives can be used as appropriate.

Maternal autoantibodies will disappear from the neonatal circulation over the first 3–4 months, leading to spontaneous resolution of the hyperthyroidism, allowing gradual withdrawal of medication.

Hypothyroidism

Incidence

Screening programs performed in the USA have found the incidence of permanent abnormalities leading to hypothyroidism to be between 1 in 3500 and 4000 live births. Transient functional abnormalities occur in 1–2% of newborn babies, with premature infants being most commonly affected.[67–69]

Etiology

Thyroid dysgenesis. This term covers the spectrum of disorders from ectopic or hypoplastic thyroid gland tissue to complete agenesis. It is the most common cause of permanent hypothyroidism. Babies tend to be asymptomatic and are diagnosed by routine screening. The cause is unknown.

Dyshormonogenesis. Several defects in thyroid hormone synthesis and metabolism have been described. Most have an autosomal recessive inheritance. Goiter may be present at birth, but usually develops postnatally over a period of months or years.[6]

Secondary and tertiary hypothyroidism. Abnormal synthesis or metabolism of TSH and TRH are extremely rare. They may occur either as isolated abnormalities or in association with other hypothalamic or pituitary abnormality.[70] These conditions will not be detected by routine screening.

Transient primary hypothyroidism. This may result from passage across the placenta of antithyroid drugs or other drugs such as amiodarone or lithium.[71,72] It can also be caused by the transfer of maternal thyroid autoantibodies or high concentrations of iodine from excessive maternal intake.

Prematurity. Serum T4 concentration increases with gestational age, as the hypothalamic function matures.[6] All premature infants thus have low T4 levels at birth, which are physiological. TSH levels remain within the normal range. Sick premature infants may have lower levels of T4 than those who are well, and lower T3 levels due to reduced peripheral conversion of T4.[73] Thyroid function returns to normal as the babies recover.

Hypoxia and IUGR. Hypothyroidism has been found to be a feature of hypoxic growth retardation due to uteroplacental insufficiency. TSH is higher and T4 lower in these babies as compared to normally grown babies of the same gestation. The severity of the hypothyroidism reflects the severity of the hypoxia.[74] It is thought that this may be a result either of reduced supply of nutrients across the placenta due to impaired placental blood flow, or of hypoxia affecting the thyroid function itself.

Chromosomal abnormalities. More than 50% of adults with Down's syndrome suffer from hypothyroidism.[75] These patients have been found to have a greater degree of intellectual impairment than euthyroid Down's syndrome patients.[76]

It is only recently that the thyroid function of fetuses with chromosomal abnormalities has been investigated *in utero*.[77] It has been found that even though their thyroid hormones remain within the normal range, TSH levels are elevated. This may be an early sign of developing hypothyroidism. It has been suggested that this may contribute to the development of mental and neurological handicap in chromosomally abnormal patients.

Iodine deficiency. Around 800 million people live in areas of severe iodine deficiency and are thus at risk of developing related disorders.[78] This includes the development of cretinism, which is a major problem, commonly leading to irreversible mental deficiency, deaf-mutism and spastic diplegia.[9] In these countries the situation may be worsened by the high intake of foodstuffs such as cassava, which inhibit thyroid function. The condition can be prevented by the administration of iodine supplementation.

Clinical features

Fetal. IUGR, bradycardia, delayed skeletal development and goiter have all been identified in severely hypothyroid fetuses.[79] Goiter may cause polyhydramnios

by mechanical obstruction of the esophagus, thus increasing the risk of preterm labor.

Neonatal. Often there are no obvious clinical features at birth in these babies. Depending on the cause and severity of the condition the classical features may take several weeks or months to become apparent. These features include poor feeding, constipation, respiratory problems, umbilical hernia, prolonged jaundice, dry skin, 'cretinoid facies' and an enlarged fontanelle.

Neurological development. Babies born with severe congenital hypothyroidism, even if treated promptly after birth, have been shown to have lower scores on intelligence testing than their normal siblings and moderately hypothyroid infants.[80] There seems to be a threshold level of T4 below which impaired brain development occurs.[81]

Screening

In the UK all babies are screened routinely for hypothyroidism at between 5 and 8 days of age. A blood sample is obtained from the baby by heel prick. Spots of blood are applied directly on to special filter papers and TSH measured. Similar programs are in operation in Europe, USA and Japan. These screening programs allow early diagnosis and treatment of affected babies, thus preventing the development of neurological and mental impairment.[82.]

Babies born to mothers with a history of autoimmune disease or other babies thought to be particularly at risk can be investigated in more detail by obtaining cord blood at the time of delivery.

Diagnosis

Fetal. Fetal hypothyroidism may be suspected because of maternal history, or in the presence of the abnormal scan findings described earlier. Investigation of the mother is helpful to assess the thyroid hormone and autoantibody status. As mentioned previously, fetal thyroid function can only be measured directly by obtaining a fetal blood sample. A raised TSH will confirm the diagnosis.[83]

Neonatal. Screening programs will allow the detection of most cases in the first week of life. Further investigation, including measurement of autoantibodies and thyroglobulin or even radioisotope scanning, may be necessary in order to determine the cause. In the rare cases of secondary or tertiary hypothyroidism the TSH will not be increased, and thus these conditions will not be detected by normal screening.

Treatment

Careful assessment of maternal thyroid function and autoantibody levels is essential. In those women taking antithyroid medication or T4, the treatment dosage should be adjusted to keep the maternal thyroid function in the upper normal or low hyperthyroid range.

Unfortunately very little T4 crosses the placenta after the first trimester of pregnancy. If the fetus were to be adequately treated by maternal administration of T4, the doses required would result in the mother developing significant hyperthyroidism.[2] Treatment of the fetus by intra-amniotic administration of T4 at intervals of 7–10 days has been described by several authors.[83–85] Fetal blood sampling for assessment of thyroid function has been described in the management of thyrotoxicosis.[86] This technique is equally suitable for the management of hypothyroidism cases where the response to intra-amniotic treatment was poor.

There are many advantages of early treatment. These include the prevention of neurological sequelae of antenatal fetal hypothyroidism and also reduction of the polyhydramnios associated with fetal goiter, thereby decreasing the risk of preterm delivery and its complications.

Postpartum maternal thyroid dysfunction

Incidence

The reported incidence of postpartum thyroiditis varies widely between different studies, but is probably somewhere around 4.9%.[87]

Etiology

A mild state of immunosuppression exists in pregnancy, which results in the temporary remission of many autoimmune diseases. This is often followed by a relapse in the postnatal period as the autoimmune activity increases. Graves' disease is one condition that follows this pattern.[21]

Both Graves' disease and Hashimoto's thyroiditis may also present for the first time after pregnancy. There is another form of autoimmune thyroiditis that occurs specifically in postpartum women. This condition, known as postpartum thyroiditis, is characterized by its transient nature, and was first described by Amino and colleagues in 1976.[88] The classical picture of this disease comprises an initial hyperthyroid phase typically occurring 2–3 months after delivery. This is caused by a destructive process involving the thyroid gland and resulting in the release of thyroid hormones into the circulation. This phase is followed 2–6 months later by a hypothyroid phase. This phase generally resolves spontaneously within 3–5 months; however, it may be severe enough to require treatment and often results in goiter formation. It has also been associated with postnatal depression.[89]

The presentation of this condition may vary from the sequence of events described. Patients may experience transient hypothyroidism without the preceding hyperthyroid phase or an isolated transient hyperthyroidism. Interestingly, it has been found to occur more commonly in women giving birth to girls.[90]

Women developing postpartum thyroiditis are significantly more likely than those not affected to develop permanent hypothyroidism.[91]

Diagnosis

Levels of T4, T3 and TSH are different during the various phases of the disease. Thyroid antibodies, including microsomal antibodies, are present in high concentrations.[92] Measurement of microsomal antibodies during the first trimester may predict the development and degree of transient postpartum hypothyroidism.[93] If the mother is not breast-feeding, radioisotope scanning can be performed and will demonstrate decreased uptake, which is consistent with thyroiditis and the associated reduction in thyroid hormone synthesis.

Cytological examination of specimens obtained by fine-needle aspiration from the thyroid glands of women with this condition shows a lymphocytic infiltration consistent with an autoimmune diagnosis.[94]

Treatment

The hyperthyroid phase tends to be mild and of short duration, so that treatment is seldom indicated. If the symptoms are severe they should be treated with β-blockers or mild sedatives. Antithyroid medication is not indicated as the high levels of thyroid hormones result from destruction of the gland and release of stored hormone rather than increased production or secretion.

T4 therapy is, however, indicated for all women developing symptoms during the hypothyroid phase of the illness. This can be continued for up to 1 year. The thyroid function should be monitored carefully after stopping treatment to exclude the development of permanent hypothyroidism. The risk of recurrence in future pregnancies means that follow-up is particularly important at this time.

The effect of thyroid hormones on fetal lung maturation

Background

Thyroid hormones are among the many factors involved in the development and maturation of fetal lung function. This is important due to the high incidence of respiratory morbidity and mortality occurring in preterm infants. These complications of prematurity have been greatly reduced but not abolished by the introduction of maternal corticosteroid administration to women at risk of preterm labor.

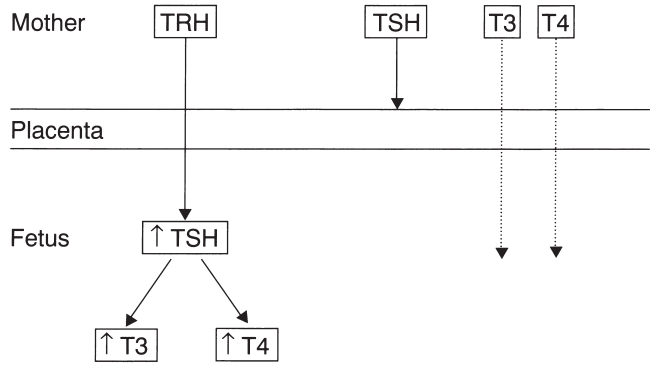

Figure 197.1 Placental transfer of thyroid-stimulating hormone (TSH), thyroid-releasing hormone (TRH), triiodothyronine (T3) and thyroxine (T4).

It has been known for some time that infants with respiratory distress syndrome (RDS) have lower levels of T3 and T4 than normal infants.[95] This has led to the investigation of the potential benefit of the antenatal use of thyroid hormones in an attempt to prevent the development of RDS.[96]

As already discussed TSH does not cross the placenta, and T3 and T4 cross only in small amounts. The maternal dose of T4 required to obtain satisfactory fetal levels is unacceptably high for the mother.[2] Both intra-amniotic and fetal intramuscular administration of T4 have therefore been attempted.[96,97] These routes are invasive and thus carry risks for the fetus. Another problem with the intra-amniotic route is that the volume of amniotic fluid, and hence the concentration of the hormones, is variable and fetal absorption may be different in different fetuses. These considerations have limited the adoption of this policy.

The safest and most effective way to stimulate fetal thyroid function is by the maternal administration of TRH. This small tripeptide molecule rapidly crosses the placenta and stimulates fetal production of TSH with the subsequent release of thyroid hormones (Figure 197.1).

Mechanism of action of TRH

There is no evidence to suggest that TRH alone, without corticosteroids, is of any benefit in promoting lung maturity. However, there is believed to be a synergistic effect when TRH and corticosteroids are used in combination.

Many mechanisms have been hypothesized. These include effects on increasing surfactant production;[98] effects on pulmonary fluid production and absorption;[99] stimulation of fetal breathing;[100] accelerated structural development, possibly mediated by prolactin secretion[101] and stimulation of the sympathetic nervous system via the neurotransmitter properties of TRH.[102] Despite these theories the exact mechanism has not yet been defined.[103]

Clinical trials

A number of randomized controlled trials comparing the outcome in women and their babies given TRH and corticosteroids antenatally to those given corticosteroids alone have now been conducted.[104–109] A meta-analysis of these trials has also been published.[110] These studies have used different dosages, dose intervals and number of doses of TRH. Various gestational ages have been used to qualify for entry into the trials.

Different subgroup analysis has also been performed, with a number of the trials reporting outcomes only for the 'optimally treated' infants, this being defined as those having received a complete course of treatment and then delivered within a certain time period. Even optimal treatment is defined differently in different papers. These discrepancies make direct comparison of the results of these trials quite difficult. So far, the combined results show few significant differences between the treatment and control groups. These differences are a reduction in the incidence of severe RDS and an increase in maternal side effects. There is no significant effect on the incidence of either chronic lung disease or perinatal mortality.

Further work is currently in progress to investigate the issue of antenatal TRH treatment. Long-term follow-up of the infants delivered after their mothers have received this therapy will also be necessary to address the question of pituitary–thyroid and neurodevelopmental effects.

Conclusion

Maternal thyroid disease in pregnancy may have important implications for both mother and fetus. Prompt diagnosis and treatment are therefore imperative. It is also important to remember that the babies of women with thyroid disease may be at risk despite normal maternal thyroid function throughout pregnancy. These pregnancies should thus be monitored carefully.

Antenatal TRH therapy is currently being investigated as a potentially useful addition to corticosteroids in reducing morbidity and mortality in preterm infants. The definitive results of this work are awaited.

198 Management of severe pre-eclampsia and eclampsia

C. Sen

Introduction

Hypertension is a common problem occurring in around 12–15% of all pregnancies.[1] It remains one of the major causes of maternal mortality.[2] Because of the difficulty in deciding who has a problem and who does not, obstetricians often admit a patient to hospital for closer observation. This approach can cause much inconvenience to the patient and her family. In-patient management may vary between different hospitals but the cornerstone is hospitalization in order to maintain close monitoring.

The outcome of pre-eclampsia changes depends on severity. Maternal and perinatal mortality and morbidity in the hospitalized case with mild pre-eclampsia are extremely low and approach those of normotensive pregnancies. In contrast, in the case of severe pre-eclampsia, maternal and perinatal mortality is very high. Sibai and colleagues[3] reported that the corrected perinatal mortality rate in severe pre-eclampsia is 135 in 1000. In this study, the perinatal survival rate was zero in those cases up to 28 weeks' gestation, but rose to 100% after 36 weeks' gestation, especially in cases of pre-eclampsia with hemolysis, elevated liver enzymes and low platelet (HELLP) syndrome when the perinatal mortality ranged from 77 to 600 per 1000 and maternal mortality from 0% to 24%. Based on this experience, prompt delivery was recommended after stabilizing the maternal condition.[4,5]

Doppler studies on uterine artery and fibronectin measurements in maternal blood have been predictive methods for pre-eclampsia with 77% and 90% sensitivity, respectively.[6,7] In these high-risk patients low-dose aspirin can be given as a prophylaxis, but recent studies have shown that there is no apparent beneficial effect on clinical outcome.[8,9] At the present time there is no effective method that can prevent the complications of pre-eclampsia, and clinical management of severe cases is becoming an important issue.

The most important therapy for severe pre-eclampsia and eclampsia is delivery of the fetus and placenta and there is universal agreement that all such patients should be delivered at or after 32–34 weeks' gestation and, in cases of severe pre-eclampsia, delivery has to be taken into account between 28 and 32 weeks' gestation, depending on the situation. At this stage, the neonatal mortality rate is not very high depending on the ability and experience of the neonatal intensive care unit.[10] Timing the delivery in cases of severe pre-eclampsia at a gestational age of less than 28 weeks is a difficult decision for the mother and obstetrician to make. Aggressive management with immediate delivery will result in extremely high neonatal mortality and morbidity. In contrast, attempts to prolong pregnancy may result in fetal demise and high maternal morbidity and mortality. The perinatal survival rate is poor when the disease develops before 24 weeks' gestation (2%); however, after that stage the survival rate is good (50%).[11]

In a study with 252 cases of hypertension in pregnancy, the maternal mortality rate was 0.4% (eclamptic case with cesarean section). Overall perinatal mortality in those cases with hypertension in pregnancy was 182/1000, which is 2.5-fold higher compared to the perinatal mortality at this hospital.[12] In those cases of severe pre-eclampsia, the perinatal mortality was about 300/1000. Most of the cases had not received any antenatal care nor were referred patients who had received conservative management with antihypertensive therapy over a long period. In this study, the perinatal mortality was 116/1000 in those cases after 32 weeks' gestation and 686/1000 in those of less than 32 weeks' gestation. The rate of intrauterine growth retardation (IUGR) in patients with severe pre-eclampsia was 92.3% for those cases below 32 weeks' gestation and 40% in those cases above 32 weeks' gestation. The average rate of IUGR was 54.2% in the severe pre-eclamptic cases. For this reason maximum attention should be paid to the fetus [e.g. non-stress test (NST), Doppler assessment]. In addition, there was no beneficial effect of cesarean delivery on perinatal mortality in case of pre-eclampsia and eclampsia.

Maternal mortality in the case of eclampsia is usually associated with mismanaged or complicated cases. Maternal morbidity is greater in multigravidae than in primigravidae. This difference may be due to a higher incidence of chronic hypertension and underlying renal disease in multigravidae. The complication rate is also higher in patients who have had no antenatal care. The fetus of the eclamptic woman is particularly at risk from abruptio placentae, preterm delivery, IUGR and fetal distress during seizure. In a study from Turkey,[13] the rate of maternal mortality in cases of hypertension in pregnancy varied in the different regions, while the rate of maternal mortality was about 0.52–1.20% in urban areas; in the rural areas, where antenatal care is not satisfactory, the perinatal mortality was 2.90–5.20%.

The clinical course of patients with severe pre-eclampsia may be associated with progressive deterioration in maternal and fetal condition. In the case of severe pre-eclampsia, both the mother and the fetus are at risk for morbidity and mortality. Some clinical signs and symptoms, such as hypertension, proteinuria, edema or other parameters, might indicate the level of pathophysiology in relation to the severity of the disease and endothelial cell damage. With regard to endothelial cell damage and vascular pathology, the risk of vascular damage for the mother would appear to increase after the diastolic blood pressure had reached 110 mmHg, whereas an increased risk to the baby has been shown to correlate with a diastolic blood pressure above 95 mmHg.[14] There is universal agreement that all such patients should be delivered at or after 32–34 weeks' gestation or if there is any evidence of premature rupture of membranes, IUGR, oligohydramnios or fetal and/or maternal distress, at any gestational age. However, there is disagreement on the management of patients with severe pre-eclampsia before 32 weeks' gestation. Some authors consider delivery as a definitive therapy for all patients with severe pre-eclampsia regardless of gestational age; others recommend expectant management.[3,15] In the literature it is not always possible to compare the studies because their design differs in definition, clinical decision and follow-up and studies are retrospective. There is also no agreement on the classification of hypertension in pregnancy. The classifications of the American College of Obstetricians and Gynecologists and the International Society for the Study of Hypertension in Pregnancy are mostly used, but both are not clinically well applicable. The outcome of severe pre-eclamptic cases differs depending on definition and clinical management. If the pathology is severe enough in the case of severe pre-eclampsia, the maternal morbidity and mortality are very high. In some cases with severe pre-eclampsia where the blood pressure is high but the other clinical parameters are not severe, the pathophysiology may not be severe enough to put the mother at risk of severe morbidity or mortality. We need to differentiate therefore between which patient should have expectant management and induction of labor and which criteria we should apply to make a decision for delivery in the case of expectant management with severe pre-eclampsia.

Expectant management in severe pre-eclampsia

There is no controversy on the management of the cases with chronic hypertension, gestational hypertension and mild pre-eclampsia at any gestational age. These cases consist of a mild group and maternal–perinatal mortality and morbidity (mild pre-eclampsia has high perinatal morbidity) are not high and patients are delivered at term. In severe cases, because the maternal–perinatal morbidity and mortality are very high, delivery should be after 32 weeks' gestation, when fetal lung maturity is complete. However, there is controversy in the literature on management of cases with severe pre-eclampsia at a gestational age of less than 32 weeks because of high perinatal mortality. While delivery has long been felt to be the best therapeutic regimen for the mother with severe pre-eclampsia, in certain cases remote from term it may not be the best for the fetus. As methods for monitoring both maternal and fetal well-being have been improved, expectant management in an attempt to prolong gestation is an alternative option.

When the extent of the maternal antenatal management is compared with the costs of neonatal intensive care, it is obvious that intensive care for prolonged periods of time is more complicated and also therefore more costly. For developing countries with limited resources available for sophisticated treatment, expectant management is recommended providing that the level of care is adequate to detect any maternal complications early. The expectant management can be beneficial to the fetus without exposing the mother to severe risks.

In a study,[16] a randomized clinical trial was conducted in which patients with severe pre-eclampsia between 26 and 36 weeks' gestation were assigned to be treated with either nifedipine or hydralazine. The authors found better control of blood pressure and a lower incidence of fetal distress in the group managed with nifedipine. In addition, the group managed with nifedipine had a better perinatal outcome than those receiving hydralazine. They concluded that nifedipine is a safe and effective drug in the management of patients with severe pre-eclampsia remote from term.

Odendaal and colleagues[17] described the results of conservative management in 129 patients with severe pre-eclampsia before 34 weeks' gestation. The patients were managed with bed rest, antihypertensive therapy and frequent evaluation of maternal and fetal well-being. These pregnancies were prolonged for an

average of 11 days. The overall perinatal mortality was 326/1000.

Moderate and severe pre-eclampsia

Some authors suggest that severe pre-eclampsia cases at a gestational age of between 26 and 32 weeks can be managed conservatively in a close follow-up at the hospital, but in the literature there is no clear definition of which case is suitable for expectant management.

In order to evaluate and properly manage the cases with hypertension in pregnancy we should identify which case is at high risk. In our practice we classify cases with hypertension in pregnancy as follows:

(1) Chronic hypertension;
(2) Gestational hypertension (hypertension in pregnancy without proteinuria);
(3) Mild pre-eclampsia (hypertension < 10 mmHg diastolic pressure and proteinuria > 0.5 g/l and < 5 g/l);
(4) Moderate pre-eclampsia (hypertension ≥ 10 mmHg diastolic pressure and proteinuria < 5 g/l, no other clinical/laboratory signs for severity);
(5) Severe pre-eclampsia (hypertension ≥ 110 mmHg and/or proteinuria > 5 g/l, and/or clinical/laboratory sign for severity such as oliguria, scotomata, headache, confusion, epigastric pain, retinal hemorrhage, pulmonary edema, HELLP syndrome) or a moderate pre-eclampsia that cannot be controlled by antihypertensive therapy;
(6) Superimposed pre-eclampsia and
(7) Eclampsia.

The cases with moderate pre-eclampsia, as classified above, can be managed with expectant management. At this stage of the pathophysiology the blood supply from mother to the placenta and hence to the fetus can be achieved by increased blood pressure. The pathophysiology is not generally systemic and the organ systems of the mother are not compromised. There is no increased risk for the mother but fetal morbidity and mortality are very high. The method of assessment for the fetus at risk will be discussed later (NST, Doppler and fetal blood sampling). Another important point is that the expectantly managed pregnant woman should be hospitalized and followed intensively for the probability of a severe form of pre-eclampsia that can cause severe maternal morbidity and mortality.

For this purpose the patients are hospitalized and given special care in the hospital. For moderate pre-eclampsia, proteinuria should not be higher than 5 g/l with no other clinical/laboratory sign for severity. After bed rest in the hospital, the diastolic blood pressure might be decreased to less than 110 mmHg without any medication. If not, an antihypertensive drug such as nifedipine can be given to keep the diastolic pressure level between 90 and 100 mmHg. If the patient is treated by antihypertensive therapy, it may cause relatively decreased blood flow in the uterine artery and fetal hypoxia. Also, fetal demise should be expected if the blood pressure is prominently decreased. We should remember that in both moderate and severe cases, perinatal morbidity such as IUGR (45.8%) is higher than in mild cases (10.2%).[12] The evidence of IUGR and oligohydramnios is an indication for induction of labor in the case of moderate pre-eclampsia.

If any of the following signs is becoming evident, the case should be categorized as severe pre-eclampsia and labor should be induced: diastolic pressure more than 110 mmHg in spite of antihypertensive therapy, increase in proteinuria to 5 g/l or more, any clinical/laboratory sign for severity during follow-up in the hospital. In that case, delivery should be the recommended approach to the patient because of high maternal morbidity and mortality as well as high perinatal mortality.

The aim of expectant management for cases with moderate pre-eclampsia is to gain more time for the fetus to mature. It is possible to prolong the pregnancy by approximately 7–10 days but usually no longer. It should be expected that the patient with expectant management may move to the severe category at any time. Daily NST and Doppler assessment should be carried out. Biochemical parameters for severe pre-eclampsia (uric acid, platelets, Hb, bilirubin, transaminases and fundoscopic evaluation) should be checked at least every other day. Close clinical follow-up and blood pressure monitoring at least four times a day are essential clinical workup. These moderate cases should be managed by a person who has experience of these cases, preferably at a tertiary center.

Fetal surveillance

The NST is a useful test, and has 88% specificity and 50% sensitivity for fetal well-being.[18,19] The oxytocin challenge test (OCT) has no extra value compared to the NST and also can be hazardous. Doppler study and NST are both more accurate in IUGR and oligohydramnios cases. In a study[20,21] of IUGR cases with oligohydramnios, 90% of the cases with abnormal Doppler findings were acidemic. In cases of oligohydramnios without IUGR with normal findings, both Doppler and NST were 20% acidemic. We should remember that in the case of IUGR, the risk for fetal hypoxemia is very high and delivery is mandatory. In the case of oligohydramnios there is a high risk of fetal hypoxemia, which remains at 20%. Fetal blood sampling may help to rule out the risk of fetal hypoxia or acidemia in a tertiary center. Fetal biophysical profile (FBP) may also help in high-risk cases but is time-consuming. Meanwhile the combination of NST and amniotic fluid volume measurement (AFV) is a reliable

and time-saving method with similar sensitivity and specificity rates as FBP.[22] In any category of pre-eclampsia, any case with IUGR and oligohydramnios should be delivered. Some cases with moderate pre-eclampsia and borderline IUGR without oligohydramnios at a gestational age of less than 28 weeks, if NST and Doppler findings are normal, can be managed conservatively. Recently, it has been shown[23] that monitoring of the fetal venous circulation represents a more accurate method of determining the optimum time of delivery and also can predict fetal compromise earlier than antenatal cardiotocography. Another important factor to be taken into consideration in moderate pre-eclampsia managed expectantly is the risk of abruptio placentae and eclampsia.

Antihypertensive therapy in moderate/severe pre-eclampsia

In severe pre-eclampsia, a blood pressure more than 180/110 mmHg, mainly a diastolic pressure of more than 110 mmHg, is a risk factor for intracerebral bleeding, tissue hypoxia and abruptio placentae, which can cause maternal or fetal morbidity and mortality. In this situation, to control the blood pressure, antihypertensive medications should be given to the mother until delivery.

Pre-eclampsia might be better explained and defined as a platelet/endothelial cell disorder rather than a primary hypertensive disease. For that reason using antihypertensive drugs is not the best treatment for the disease. The clinical manifestations of moderate or severe pre-eclampsia are consistent with a systemic disorder in which severe hypertension is only one aspect of the pathophysiology. Patients presenting with such multiorgan disease are often both a diagnostic and a therapeutic challenge. For that reason treating the mother by antihypertensive medications should not be the main therapeutic approach. The control of hypertension may prevent some complications such as intracerebral hemorrhage and cardiac failure in which severe proteinuria and other compromised systemic organ functions are not evident. The aim of antihypertensive therapy in the case of moderate pre-eclampsia at less than 32 weeks' gestation is to gain more time and to reduce the risk of respiratory distress syndrome. If there is IUGR and oligohydramnios, the fetus is probably at risk as well as the mother. For that reason there is no indication for using antihypertensive therapy and in that situation the best option is delivery at any gestational age.

Different types of antihypertensive agents have been used for the long- or short-term treatment of hypertension in pregnancy.[24] Methyldopa is one of the antihypertensive agents whose long-term safety for both the mother and the fetus has been adequately assessed. It reduces systemic vascular resistance without significant physiological changes in heart or cardiac output, while renal blood flow is maintained. Plasma half-life and also peak plasma levels after oral administration are approximately 2 h. However, decrease in arterial pressure is maximal about 4–8 h after an oral dose of methyldopa. The usual dose is 1–2 g/day given in four divided doses although sometimes 4 g/day is needed.

Clonidine is a potent a_2 receptor to central stimulator and has some side effects such as sedation, dry mouth and rebound hypertension following an abrupt discontinuation. The usual oral dose is 0.1–0.3 mg/day given in two divided doses and up to a maximum of 1.2 mg/day as needed. Horvath and coworkers[25] studied this drug and concluded that clonidine was a safe and effective antihypertensive agent.

Sodium nitroprusside is a potent arterial and venous dilator, which is used extensively in the treatment of cases with malignant hypertension in non-pregnant patients. It has a rapid onset and a short duration of action. This agent should be used only in extreme emergencies in pregnancy because of the potential risks of fetal cyanide poisoning and metabolic acidosis.[26]

β-Blockers (propanolol, metropolol and atenolol) have different hemodynamic effects that depend on their receptor selectivity. The type of action of β-blockers is competitive inhibition of catecholamines at β_1 (heart) and β_2 (peripheral circulation, bronchi and uterus) adrenoreceptors. Side effects are bronchial spasm, hypoglycemia, cold extremities and a disturbance in lipid metabolism, neonatal bradycardia, neonatal hyperglycemia, fetal growth retardation and neonatal respiratory depression.[27] Because of the concern regarding side effects such as fetal growth retardation, the use of this drug should be limited.

Labetalol is a combined α- and β-adrenoreceptor blocker. The additional property of α-blockade induces vasodilatation improving the primary vasospasm in this disorder. The usual dose is 33 mg daily up to 2400 mg/day as required. It appears to be safe like methyldopa for short-term use in the third trimester, but it has an increased incidence of fetal growth retardation in the case of long-term use.[28]

Diuretics decrease the blood pressure by decreasing the intravascular volume and cardiac output. The most commonly used diuretics of the non-pregnant hypertensives are the thiazide diuretics. However, the use of diuretics in case of pre-eclampsia should be restricted to the patients whose pregnancy is complicated by pulmonary edema or excessive fluid retention or to certain patients with renal disease.

Hydralazine has a direct relaxation effect on arterial smooth muscle and is associated with stimulation of the sympathetic nervous system resulting in an increased heart rate and contractility. Maternal side effects are headache, flushing, palpitations, nausea and vomiting. Drug-induced lupus syndrome is generally observed only after long-term oral use. Uteroplacental blood flow may decrease following parenteral administration, which can cause fetal distress. Hydralazine

may accumulate after continuous intravenous infusion resulting in hypertension and therefore it should be administered in small intravenous amounts of 5–10 g at intervals because the onset of the effect may be delayed for 15–20 min.

Comparative trials between hydralazine, nifedipine and labetalol have not shown one agent to be superior in the acute management of severe hypertension.[16,28,29] Calcium channel blockers (such as nifedipine, nicardipine, isradipine, nimodipine and verapamil) are potent antihypertensive agents that depress the myogenic tone of precapillary arterioles. The most frequent side effects associated with these drugs are secondary to the acute vasodilatation.

Nicardipine has been studied[30] and demonstrated to reduce maternal blood pressure without increasing neonatal morbidity. Additionally, Doppler flow studies of the umbilical artery were not significantly affected by nicardipine therapy. Long-term therapy was well tolerated by the mother with no adverse fetal/neonatal side effects.

Intravenous isradipine studied by Ingemarsson and associates[31] was found to normalize blood pressure 15–30 min after injection. There was no change in Doppler velocimetry of the umbilical arteries. Wide-Swensson and coworkers[32] performed a randomized placebo-controlled trial of a slow-release form of isradipine in women with gestational hypertension. Again, they demonstrated the effect of isradipine on decreasing maternal blood pressure without demonstrating an effect on vascular flow.

Belfort and colleagues[33] studied the hemodynamic effects of verapamil administration in nine women with proteinuric hypertension. These patients had an intravenous infusion of verapamil, after plasma volume expansion with dextran-70, until a 20% reduction in mean arterial pressure was obtained. They concluded that verapamil is a good antihypertensive agent to be used in hypertension in pregnancy but deemed that caution was indicated when it was used in combination with magnesium sulfate.

Nifedipine was found to be extremely effective in the acute treatment of severe hypertension in pregnancy. In patients treated with daily nifedipine and serially followed by maternal blood pressure and fetal Doppler studies, it was demonstrated that a significant decrease occurred in maternal blood pressure without any change in resistance index in the umbilical and uterine arteries or in the fetal aorta. The Apgar scores and arterial blood gases were not consistent with fetal compromise. In a retrospective study, Sibai and colleagues[34] studied the effect of nifedipine on 200 women between 26 and 36 weeks' gestation. Nifedipine was associated with significantly lower blood pressure and good perinatal outcome.

Many of the calcium channel blocker agents have been found to inhibit platelet aggregation, both *in vivo* and *in vitro*. Rubin and colleagues[35] studied 10 women with proteinuric gestational hypertension and noted a statistically significant increase in the mean platelet count, which they attributed to nifedipine. They concluded that nifedipine reversed thrombocytopenia and controlled blood pressure in patients with gestational hypertension.

In conclusion, calcium channel blockers such as nifedipine have been used for many years in pregnant women with good effect. In many cases, they are effective and safe for the mother and the fetus when used carefully and are inexpensive. Additional benefits may be derived from vasodilator and antiaggregational effects. In the acute situation, calcium channel blockers such as nifedipine can be given sublingually 10 mg two or three times at 15-min intervals. Blood pressure decreases slowly to an appropriate level and then is maintained with 10 mg three or four times a day at 6–8-h intervals. The onset of action occurs within 10 min of administration and the peak action occurs after 30 min, with the blood pressure control maintained for approximately 4 h. It should be remembered that the daily maximum dose should not exceed 120 mg/day because of maternal side effects. Mild side effects and a short half-life, plus a rapid but not very deep response, make this drug preferable to others. In moderate pre-eclampsia there is no need to add any alternative antihypertensive agent. In this situation the case should be classified as severe pre-eclampsia and be delivered after stabilization of the mother.

Maternal volume expansion

The clinical consequences of vasodilatation without volume expansion include precipitous falls in blood pressure as well as the onset of peripheral ischemia, most clearly evident as a fall in renal output and the development of fetal distress.[36] Preloading the patient prior to vasodilatation is known to prevent these complications and also facilitates subsequent vasodilatation.

Fluid therapy in pre-eclampsia has traditionally been monitored by the use of central venous pressure (CVP) lines, but CVP readings, while acting as a good index of overall intravascular volume, do not give any indication of the left ventricular response to acute volume expansion. Central monitoring, to be meaningful, requires right heart catheterization in order to measure pulmonary capillary wedge pressure. In practice, in these severe cases, patients should never be exposed to acute plasma volume expansion of more than 30 ml of fluid.

Eclampsia

Eclampsia is associated with multiple organ dysfunction. The question of whether or not eclampsia is a preventable complication is controversial. Campbell and coworkers[37] studied factors leading to the development of eclampsia in 66 women and concluded that convulsions were not preventable in 42% of the cases.

The first action should be to control convulsions. As a first line, 10 mg intravenous diazepam can be given as a bolus and then 3–4 mg of magnesium sulfate administered as a bolus. After convulsions have been abolished, the magnesium sulfate perfusion should be maintained at 1–1.5 g/h for at least 24 h. Arterial blood gas measurements, magnesium level in the blood and a chest radiograph should be obtained to ensure adequate maternal oxygenation and to avoid overperfusion of magnesium. Hypoxemia and acidemia should be corrected. Hydralazine or labetalol can be intravenously administered, or sublingual/oral calcium channel blockers can be used to control the blood pressure. Intensive care of the patient is necessary. Occasionally, it is not possible to control the convulsions. In that situation the woman should be cared for in the intensive care unit under the perfusion of sodium thiopental. The seizures can be prevented with this therapeutic approach.

In some cases, fetal bradycardia or signs of fetal distress can be seen during or just after seizures. In this situation, there is no hurry to perform immediate cesarean section. Because of maternal distress, the placental flow is not in the optimum condition and temporary fetoplacental insufficiency is present. After abolishing the seizures, maternal oxygenation and hemodynamic condition recover. At this stage, any sign of fetal distress disappears and fetal well-being returns. Immediate maternal oxygenation and control of seizures and blood pressure are significant steps for fetal well-being. Fetal heart rate usually returns to normal once convulsions cease. If the bradycardia persists or the uterus is hypertonic, placental abruption should be suspected. Following stabilization of maternal conditions, the next step should be delivery of the fetus. Induction of labor with oxytocin is often successful. The fetal heart rate and uterine activity must be closely monitored. Eclampsia is not an indication for cesarean section. Cesarean section solely for this indication should be avoided. In the case of seizure or just after convulsion, it can cause harmful effects on the maternal system and increase maternal morbidity and the heart rate.

Magnesium sulfate prophylaxis in severe pre-eclampsia

Considerable conflict exists regarding the need for seizure prophylaxis, the optimal anticonvulsant for this purpose and the type of hypertension in pregnancy that increases the patient's risk. The recommendations from the literature state that the essential management of pre-eclampsia includes preventing convulsions, which involves the use of parenteral magnesium sulfate.[38] Magnesium sulfate is the drug of choice in the United States, while it is less frequently used in other countries. Instead, standard anticonvulsants such as phenytoin, diazepam and phenobarbital are used frequently for the treatment of seizures. In Turkey, magnesium sulfate is the most preferred and used anticonvulsant for the treatment of convulsions and also for the prophylaxis of convulsions in the case of severe pre-eclampsia.[39]

Moodley and Moodley[40] addressed the necessity of anticonvulsant therapy in hypertension in pregnancy. They randomized 228 women with severe pre-eclampsia to receive magnesium sulfate with antihypertensive therapy vs. antihypertensive therapy alone. There was no significant difference in the number of convulsions, birth weight, Apgar score or maternal complications between these two groups. In 1993, Friedman and associates[41] performed a randomized clinical trial on the use of phenytoin vs. magnesium sulfate in 105 patients with severe pre-eclampsia or eclampsia. They found that patients receiving phenytoin had a more rapid cervical dilatation and a decreased incidence of postpartum anemia. There were no seizures in either group after initiation of therapy.

In 1995 the Eclampsia Trial Collaborative Group published data[42] on the anticonvulsant medication for the treatment of eclampsia and compared the efficacy of magnesium sulfate, phenytoin and diazepam with respect to reduction of seizures in women with eclampsia. They concluded that magnesium sulfate is a more effective agent than either of the other two medications in the prevention of further seizures, as well as being equally safe. The use of magnesium sulfate for the prevention of eclamptic seizures is not entirely without risk. Magnesium toxicity can culminate in cardio-respiratory arrest if it is not prevented or treated immediately. In addition, some studies have reported low Apgar scores, respiratory depression and hyperflexia in preterm neonates of mothers receiving magnesium sulfate.[43]

Recently, Odendaal and Hall[44] performed a study on maternal and perinatal outcomes by using prophylactic administration of magnesium sulfate to patients with early severe pre-eclampsia. They concluded that the prophylactic use of magnesium sulfate in patients with severe pre-eclampsia, especially when they are not in labor, is questionable, and that, although the use of magnesium sulfate did not cause severe morbidity, it is a potentially harmful drug that should be reserved for specific indications.

Cases with severe pre-eclampsia or eclampsia that present with cerebral or visual disturbances, right quadrant abdominal pain, severe headache, unconsciousness, acute exacerbation in blood pressure or uncontrolled blood pressure should have prophylatic therapy because of high seizure risk. Also, in the case of severe pre-eclampsia or eclampsia during labor or on the first day of the postpartum period, prophylactic therapy should be initiated. This prophylactic therapy can be administered as 3–4 g magnesium sulfate intravenously given as a bolus, with a caution about side effects, and then perfused 1.5 g/h for 24 h. Under these circumstances there is no evidence or

reason for continuing prophylactic therapy for more than 24 h.

Intrapartum and postpartum management

Pre-eclampsia or eclampsia alone should not be an indication for cesarean section. All women with severe pre-eclampsia should receive anticonvulsant prophylaxis during labor or postpartum. In our institute, magnesium sulfate is administered by controlled intravenous infusion with a loading dose of 3 or 4 g over 20 min, followed by a maintenance dose of 1.5 g/h. The infusion is continued throughout labor and delivery, and at least 12 h postpartum. All patients should be monitored very closely, with special attention given to fluid intake and output. Patients with severe pre-eclampsia and eclampsia, particularly uncontrolled, or those remote from term and those with the HELLP syndrome are at increased risk for the development of pulmonary edema and acute renal failure.[4]

199 Maternal mortality in developing countries

J. A. Fortney, J. B. Smith and P. E. Bailey

Levels of maternal mortality and the public health discrepancy

Overall mortality in developing countries has declined rapidly during the last half of the 20th century. Much of this decline is attributable to nearly universal immunization against childhood diseases, public health measures such as improved water and sanitation, and some economic development allowing higher living standards.[1] Differences between rich and poor countries in expectation of life at birth have narrowed, although discrepancies in various public health indices remain.[2]

Maternal mortality has failed to keep up with this progress in public health. Maternal mortality ratios (MMRs) in developing countries are about 20-fold greater than in the developed world.[3] By contrast, infant mortality is only ninefold greater, and life expectancy at birth is 20% lower in developing countries than in developed countries (24% lower if China is excluded).[4]

Maternal mortality is fundamentally different from other public health challenges in that curative services are more important than preventive services and in that a package of interventions is needed to address it. About 80% of maternal deaths are attributable to five direct obstetric complications, which can, for the most part, be neither predicted nor prevented. They are hemorrhage, sepsis, hypertensive disorders of pregnancy, prolonged or obstructed labor, and unsafe abortion.

While it is generally true that direct obstetric complications are not predictable or preventable, some complications can be prevented some of the time. Recent studies have now provided good evidence that active management of the third stage of labor has the potential to prevent a significant proportion of postpartum hemorrhage (PPH), perhaps in the range of 40% if well and widely implemented.[5–7] Evidence to date, however, requires that deliveries take place in the presence of an attendant trained and equipped to practice active management of the third stage. Research regarding the use of uterotonics (especially misoprostol) with less skilled attendants is under development.[8] It is important to note that even if active management of the third stage of labor is fully and perfectly implemented, some PPH will still occur and will require treatment by skilled attendants in a facility equipped to provide such care.

While prevention of sepsis in domiciliary deliveries attended by traditional birth attendants (TBAs) has been disappointing,[9] sepsis is preventable when deliveries are supervised by skilled attendants properly trained and equipped.[10] Preventing sepsis in cesarean deliveries is eminently possible.[11] Evidence for the ability to prevent hypertensive diseases of pregnancy is not compelling at the present time, but may be accumulating.[12–14]

Complications of abortion, either spontaneous or induced, typically include sepsis and/or blood loss. In places with good access to care for these complications, abortion mortality is extremely low. In places where access to care for abortion complications is poor (for either resource or policy reasons), abortion complications can account for as much as 20% of maternal mortality.[15] Of course, abortion complications can be prevented by making safe abortion available and accessible; and the need for abortion can be reduced (but not eliminated) by affordable, acceptable, and accessible family planning programs.

While the direct obstetric complications themselves may not usually be preventable, death resulting from them can usually be prevented if appropriate medical care is available. As we shall see, this is a big 'if'.

Developing countries today

The countries with the highest MMR today are in Africa. (The sole exception to this is Afghanistan.) Table 199.1 shows MMRs estimated by UN agencies.[16] While the developing world as a whole has MMRs 22 times greater than the developed world, the range among individual countries is vastly greater. Some developed countries may go for long periods (i.e. more than 1 year) without any maternal death and therefore

Table 199.1 UN estimates of maternal mortality in 2000* (adapted from AbouZahr and Wardlaw[16])

Region	MMR*	Number of maternal deaths	Lifetime risk of maternal death (1 in)
World total	400	529,000	74
Developed regions	20	2,500	2800
Developing regions	440	527,000	61
Northern Africa	130	4,600	210
Sub-Saharan Africa	920	247,000	16
Eastern Asia	55	11,000	840
South Central Asia	520	207,000	46
South Eastern Asia	210	25,000	140
Western Asia	190	9,800	120
Latin America and the Caribbean	190	22,000	160
Oceania	240	530	83

*Maternal deaths per 100,000 live births

Table 199.2 Maternal mortality ratios in 1920 in developed countries (adapted from Woodbury RM. *Maternal Mortality*. Washington, DC: Children's Bureau Publications, No. 15, 1926; quoted in Loudon[17])

Europe		Other developed countries	
Country	MMR	Country	MMR
Denmark	235	Uruguay	338
Netherlands	242	Japan	353
Sweden (1918)	258	South Africa*	410
Norway (1919)	297	Australia	501
Finland	360	New Zealand	648
Italy	367	Chile	748
England and Wales	433	United States	799
Spain	501		
Germany (1919)	515		
Ireland	553		
Belgium	609		
Scotland	615		
France	664		

*Probably (but not so specified) whites only

have an MMR of 0 for that year (e.g. Iceland). Other countries (e.g. Afghanistan, Sierra Leone) have MMRs in excess of 2000 deaths per 100,000 live births. In many countries, national estimates may mask wide subnational variations in MMRs – especially in remote or geographically challenging areas where MMRs may be considerably higher than the national ratio.

Considering the absolute number of deaths rather than the MMRs, the magnitude of the problem becomes even more apparent. The number of deaths in Asia (combined) is approximately equal to those in Africa. This is because the generally lower MMRs in Asia are applied to a larger population base. Certain countries account for large numbers of maternal deaths. India, alone, accounts for 136,000 – a staggering quarter of all the world's maternal deaths. Nigeria is a distant second with 37,000, and Pakistan is third with 26,000. China, on the other hand, has 'only' 11,000 in spite of having a population more or less the same as India's.

Developed countries historically

Historically, the countries currently labeled as developed had MMRs not very different from the developing world today.[17] Table 199.2 shows MMRs from the early 20th century for 21 of today's developed countries. Given the level of sophistication with regard to measurement at that time, these numbers should be interpreted with caution, and experience tells us that they are probably underestimates. It should also be noted that some of the countries at the high end had some remote (and therefore difficult to reach) populations, but so did Norway and Finland.

Table 199.3 Decline in MMRs from 1920 to 1960 in the United States, England and Wales, and the Netherlands (adapted from Loudon[17])

	1920	1940	1960
United States	799	376	37
England and Wales	433	261	39
The Netherlands	242	235	37

High as these 1920s numbers are, some had already declined substantially. Loudon graphs the decline in several of these countries showing in Scandinavia, the Netherlands, Belgium, and Paris a sharp decline from around 1880 to around 1910. He attributes this to acceptance of new aseptic techniques during this period and, to a lesser extent, the emergence of anesthesia. In other countries (England and Wales, Scotland, Australia, New Zealand, and the United States), there was no comparable decline in 1880–1920.

Table 199.3 shows how rapidly three disparate countries converged during the first half of the last century. Again, readers should view the numbers as indicative rather than completely accurate.

Maternal mortality in the developed world began its rapid decline to current levels in the 1930s (Table 199.3) following the widespread introduction of new drugs (sulfa drugs in the late 1930s, then antibiotics in the mid-1940s[18]) for management of infections,[19] blood transfusion technologies,[20,21] and improved surgical techniques developed during World War II. Cesarean sections, for example, carried a high risk of dying before the availability of antibiotics and blood transfusion. There was a further decline in the 1960s and 1970s, though far less spectacular, as many countries both legalized abortion and introduced safer techniques of pregnancy termination. Probably, the increasing proportion of deliveries taking place in medical facilities also contributed to the decline in many (but not all) countries.

Developed countries today

Developed countries today account for 2500 deaths or 0.005% of the world's total. Their combined MMR is 20. A score of countries have MMRs in the single digits, including some well-resourced Middle Eastern ones. The United States and the United Kingdom, both countries with pockets of poverty and/or substantial immigrant populations, are in the midteens. Developed countries with higher MMRs are most likely to be located in Eastern Europe where access to high-quality care may be limited in some areas.

Issues in measuring maternal mortality

Three measures of maternal mortality are used.*

(a) *Maternal mortality ratio*: The MMR is the most commonly used measure. It is defined as the number of maternal deaths per 100,000 live births. (Unfortunately, many people still refer to this by its old name – maternal mortality rate, which means something else.) There are issues related to both the numerator and the denominator.

  (1) *Numerator*: Should only direct obstetric deaths be included? What about indirect obstetric deaths, and non-obstetric deaths? The trend is to be more inclusive. One reason for this is that it is increasingly recognized that it is not always simple to determine whether the death is related to pregnancy. The most glaring example of this is deaths related to domestic violence, homicide, suicide, and accidents.[23] One author reports that 40% of maternal deaths in New York City are due to injury, mostly homicide and suicide.[24] Furthermore, it seems likely that pregnancy contributes to the likelihood of violence.[25]

  (2) What time frame should be used – 42 days, 3 months, 12 months?[26] Again, the trend is to be more inclusive for several reasons. In developed countries, where extreme measures are sometimes taken, women may survive well beyond the 42-day limit only to eventually succumb to a direct obstetric complication (for example, kidney failure due to eclampsia). Postpartum depression may lead to suicide more than 3 months after delivery. The advantage of 12 months is that maternal mortality would then be equivalent to infant death (deaths to infants under 12 months due to any cause per 1000 live births). The disadvantage, of course, is that the ratio would be inflated with deaths unrelated to pregnancy or childbirth.

  (3) *Denominator*: Some writers prefer using 10,000 or even 1000. Smaller denominators turn the low levels of MMR in developed countries into an awkward statistic – the mean is 2 per 10,000 live births or 0.2 per 1000. Some writers have argued that the denominator should include all pregnancies, not just live births. This is a matter of convenience. National statistical offices report live births reasonably accurately; stillbirths are reported less completely, and data

* Calculations may be found in Fortney.[22]

on abortions (whether spontaneous or induced) are invariably underreported.

(b) *Maternal mortality rate*: This is defined as the number of maternal deaths per 100,000 women of reproductive age (15–45 years). It is a measure of both obstetric risk and the frequency with which women are exposed to the risk. If you wish to measure the impact of family planning on maternal mortality, this is the measure to use.[22]

(c) *Lifetime risk*: This is the risk of dying in childbirth for a woman in a specific country and is stated as a 1 in *X* risk. For example, it was recently reported that a girl in Sudan is more likely to die in childbirth than to finish primary school. The likelihood that she will finish primary school is 1 in 100, while her lifetime risk of death in childbirth is 1 in 9.[27] This, too, is a measure of the average number of births combined with the risk of dying at each birth.[22]

Why measure?

Maternal mortality is measured either to assess the magnitude of the problem or to evaluate the impact of improved services. However, all methods of measurement have significant shortcomings or are costly to implement. Furthermore, one commonly used method (sisterhood) refers to a period of time beginning 10 years (or so) before the measurement is taken, which has implications for its current usefulness for policy makers. Because of its cost and its lack of precision, it is recommended to undertake measurements of maternal mortality only rarely, i.e. not more than once every 10 years.[28] Whichever method is used, it is important to calculate 95% confidence limits as these are typically quite wide. This is especially important in making comparisons as confidence limits may overlap even though point estimates seem quite different.

Types of measurement

There are several ways of measuring maternal mortality. These are discussed below in approximate order of their appearance over time.

Hospital death rate: This is defined as the number of maternal deaths divided by the number of obstetric patients admitted. While most hospitals calculate this, it is of value only to that hospital and reflects the mix of patients and their condition on admission as well as the quality of care they receive. Conceivably, a hospital's death rate could increase as the quality of care improves and more patients come from ever greater distances. The case fatality rate (obstetric deaths per 100 obstetric complications admitted) is a better measure of quality of care, but this too is affected by the condition of patients at admission. The more inaccessible[†] the area served by the health facility the less informative the hospital death rate could be.

Vital statistics: Even in countries where reporting of death is complete, maternal deaths are underestimated in vital statistics.[29–31] There are several reasons for this, including the skills of the physician signing the death certificate and that of the person assigning the code for cause of death. Vital statistics should not be used as a measure of maternal death.

RAMOS: RAMOS stands for reproductive age mortality survey, and was developed in the late 1970s. It consists of determining (usually by verbal autopsy[32] through interviews with family members and health care workers) the cause of death in women of reproductive age (15–45 years). This generates a percentage that can be attributed to each of the major causes of death ('proportional mortality'). In developing countries, maternal deaths are typically between 20% and 25% of all deaths during the reproductive life span, but can be much higher for the prime child-bearing years.[33] RAMOS studies have fallen into some disfavor because of challenges in locating all deaths to women of reproductive age (usually in the absence of systematic death reports), but one was done in 2002 in four provinces of Afghanistan.[34]

Sisterhood: The limitations of the methods described above led to the development, in the 1980s of a method of estimating maternal mortality by asking people (both men and women) how many sisters they have ever had, how many are still living, the age at death of those who died, and their cause of death.[35] There is now very wide experience with this method; it is used in the demographic and health surveys that are implemented in many developing countries on a continuing basis. The sisterhood method tends to consistently underestimate maternal mortality by about one-third.[28] There are several reasons for this built-in bias.[36] In spite of its limitations, this method is currently the best there is and will continue to be used until newer methods are developed and refined. The IMMPACT program at the University of Aberdeen[‡] is currently developing methods to assess the effectiveness and cost-effectiveness of maternal mortality reduction intervention strategies.[37]

Modeling: The continuing difficulty in arriving at good – and not too expensive – estimates of maternal mortality led WHO, in the 1990s, to collaborate with scholars at the Johns Hopkins University School of Public Health to develop estimates by using a computer model. This method has been used successfully to estimate infant mortality.[38] The maternal mortality estimates are updated regularly by the UN agencies

[†]Inaccessibility includes distance, lack of transport, cost, cultural avoidance of medical facilities, and beliefs in causes of complications that are at odds with medical science.

[‡]Funded by the Bill and Melinda Gates Foundation, the European Union, DfID (UK's Department for International Development), and United States Agency for International Development.

Table 199.4 The UN process indicators (from United Nations[38])

Process indicator	Definition
Availability of EmOC	Number of facilities that provide EmOC per 500,000 population
Percentage of all births in EmOC facilities	Percentage of all births in EmOC facilities
Met need	Proportion of women estimated to have complications who are treated in EmOC facilities
Cesarean deliveries as a percentage of all births	Cesarean deliveries as a percentage of all births
Case fatality rate	Proportion of women with obstetric complications admitted to a facility who die

* Emergency obstetric care.

using this model.[16] This method has the advantage that it uses secondary data, the collection of which is less time-consuming and costs less than collecting new data in the field.

Monitoring progress

Progress in reducing maternal mortality can be assessed either through the use of a direct indicator (i.e. the MMR) or through changes in proxy indicators that are known (or strongly believed) to have a strong and *direct* association with maternal mortality. Indicators such as education or the status of women are strongly associated with maternal mortality, but the relationship is indirect – better educated women are more likely to seek care *if it is available*. Countries with a relatively high status of women are more likely to make maternity care available.

It is important to recognize that whether a woman survives an obstetric complication depends on many factors. A failure in one part of the health system can lead to death even when all the other parts are functioning correctly. If the MMR is used as the measure of success or failure, the measure will not identify which element is lacking or has failed to improve. The use of a package of proxy indicators can identify some of the elements in need of improvement.

UN indicators

The UN agencies with a mandate to address maternal mortality (WHO, UNICEF, and UNFPA) developed such a set of proxy indicators – described in the 'UN Guidelines' (Table 199.4).[39] The guidelines identify eight 'signal functions', which are deemed necessary to manage obstetric complications. Each should have been provided to at least one patient in the last 3 months for the facility to be considered able to provide it. The functions are provision of parenteral antibiotics, oxytocics, and antihypertensives; removal of retained products (preferably manual vacuum aspiration rather than D&C); manual removal of placenta; assisted vaginal delivery; cesarean section; and blood transfusion. If a medical facility can provide only the first six it is considered able to provide basic emergency obstetric care (EmOC). If it can provide all eight it is considered to provide comprehensive EmOC.

The UN Guidelines further note that there should be at least one comprehensive and at least four basic EmOC facilities per 500,000 population. Because approximately 15% of women will experience a potentially life-threatening complication during pregnancy or delivery, at least 15% of women should deliver in a medical facility able to provide EmOC, and 100% of women with complications should deliver in a medical facility. Cesarean section rates should be between 5% and 15%, and case fatality rates should not exceed 1% of women presenting with complications.

The UN indicators have now been used in many needs assessments in all regions of the world and have proven to be useful in national and regional planning.[40–45] It is probable they will be reviewed in the near future in the light of accumulated experience, and they may undergo minor modifications. The signal function that is least likely to be available is assisted vaginal delivery. Some countries no longer train midwives (or even doctors) to do this, preferring instead for women to proceed directly to cesarean section.[46] While most countries have an adequate number of comprehensive EmOC facilities (though not necessarily well located), most have far too few facilities providing basic EmOC. This means that women must travel further to seek care, causing them to be in poorer condition on arrival at the hospital. This may also cause an overload in the comprehensive EmOC facilities.

The theoretical framework

The three-delay model[47] describes the three points in time at which delay contributes to maternal death: the delay in deciding to seek care, the delay in reaching an adequate facility, and the delay in receiving adequate care once at the facility.

When a woman experiences an obstetric complication during a home delivery she and her family decide whether to seek help. First, they must decide whom they will ask to help – other family members, TBAs, staff at a health center nearby, or staff at a more distant hospital. Often all of these are consulted in roughly that order. Seeking care from the formal health system requires traveling there whether on foot, on human-powered devices, or on motorized

transport of various types, public or private. This may or may not require the presence of roads and/or money.

When she arrives at the medical facility (sometimes after hours or even days of travel), her family may be required to provide a certain amount of money, which they may need time to get, or they may be asked to go outside the hospital to buy drugs. In addition, staff may not be there, drugs and equipment may not be available, or there may be no operating room or blood for transfusion. All may be present, but the staff may be unwilling or unable to do what is needed. It is obvious that many things need to be *simultaneously* in place and functioning before medical care of adequate quality is administered. Interventions may target any one or more of these opportunities in the pursuit of medical attention. Some of the more common interventions are described later.

Training TBAs

Training TBAs has long been a priority in many developing countries, but its effectiveness is being questioned. Typically, training lasts several weeks and covers the 'three cleans' (hands, delivery surface, cord care), management of a normal delivery, recognition of complications, and referral. Note the assumption that there is an appropriate place to which women can be referred if needed.

Evaluating the work of TBAs is not easy. Evaluations most often consist of the number of TBAs trained. Sometimes TBAs are given oral examinations asking about their knowledge, attitude, and practice. Rarely are they observed practicing their trade, and if they are, the presence of the observer may change the practice. Goodburn and colleagues[9] found that training in asepsis and antisepsis neither improved practice nor reduced infections. Smith and Fortney, comparing outcomes of pregnancy among women delivered by trained or untrained TBAs in Ghana, found a small improvement in management of the placenta and postpartum fever, but a tendency to wait longer before referral.[48] Bailey found that TBAs in Quetzaltenango, Guatemala, were actually less likely to detect women with complications after they were trained.[49] A recent meta-analysis of studies with quasi-experimental design[50] found small but significant benefits for neonatal morbidity and mortality, but no evidence of either cost-effectiveness or benefits for mothers.

There is anecdotal evidence that TBA effectiveness is enhanced when they are incorporated into the larger health system, accorded respect, and allowed to remain with their patients even when they are admitted to hospital. Payment is a crucial factor; if TBAs lose their fee when their patients are delivered elsewhere, then the motivation to refer is reduced. To address this issue, hospitals sometimes pay a small fee to TBAs for the referrals (anecdotal evidence only).

Antenatal care

The purpose of antenatal care is to improve women's health and nutrition during pregnancy, to detect the early signs of what could develop into a complication and potentially prevent it, to educate women to recognize symptoms of complications, and to help women make decisions about where to deliver (and 'birth preparedness'). Unfortunately, antenatal care in many resource-poor settings is little more than an injection of tetanus toxoid, and weighing and measuring the woman's height. Often, even when potential complications are detected (hypertension, for example), no further action is taken. In spite of their shortcomings, antenatal clinics are often overcrowded so that most women spend no more than 5 min with a physician during their entire pregnancy. Blood pressure machines often do not function and vitamins and iron supplements are inadequately supplied. Nonetheless, widespread use of tetanus toxoid has greatly reduced both neonatal and maternal mortality due to tetanus.

In fact, antenatal care has only a limited ability to reduce maternal mortality. Consider the five main causes of maternal death: complications of abortion, prolonged or obstructed labor, PPH, puerperal infection, and hypertensive disorder of pregnancy. Only the last can logically be affected by antenatal care. Some of its effectiveness depends on the availability of a not-too-distant referral hospital. A program in an area of Gambia provided high-quality antenatal care (and nutritional support) to pregnant women; nevertheless until the 24 h-a-day availability of a physician or qualified midwife, maternal mortality did not decline.[51]

The risk approach and risk assessment

Every obstetrician considers the risks to which each patient is subject. Some programs, however, calculate a score based on several factors. Many of these have been developed, some complex, others simple. Often the factors are demographic (age, parity), physical (height), and obstetric history (previous pregnancy loss, or previous complications).[52]

The paramount difficulty with any risk scoring system is that both sensitivity and specificity are low. In other words, many complications occur in 'low-risk' mothers, and most of the mothers defined as 'high risk' will deliver normally. As long as most women deliver in a medical facility, this presents little difficulty. However, it is when most women deliver at home, and only those 'at risk' deliver in medical facilities that difficulties arise. Being labeled as 'low risk' gives mothers and their families a false sense of security and reduces their 'birth preparedness'. The

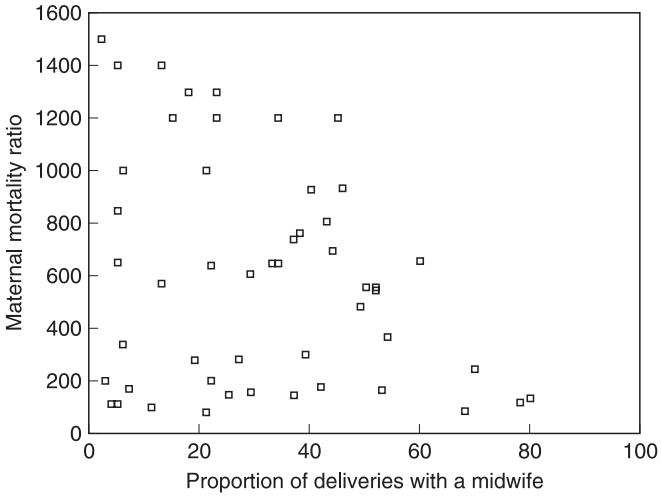

Figure 199.1 Proportion of deliveries with midwives and the maternal mortality ratio for 50 developing countries. Adapted from Graham *et al*.[57] with permission.

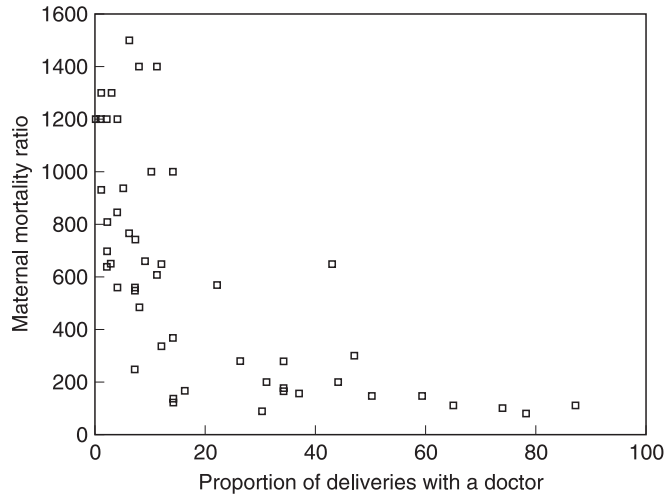

Figure 199.2 Proportion of deliveries with doctors and the maternal mortality ratio for 50 developing countries, 1990. Adapted from McCord *et al*.[56] with permission.

fact is that all women are at risk and should be prepared to seek medical help.[53]

Having said that, at least one country – Malaysia – used the risk approach to dramatically change its maternal health program.[54] Using a system of colored cards and careful follow-up with home visits if needed, 'high-risk' women were encouraged *and helped* to deliver in medical facilities. Definitions of risk were very broad and included geographic reasons – living a long way from the hospital. Furthermore, the number of risk factors was gradually expanded until a large proportion of women were included – acknowledging, tacitly, that indeed all women are at risk. Delivery in a medical facility increased from about 15% in 1950 to more than 80% in 1995, and maternal mortality plummeted from 534 to 19.[55] It is sometimes said that the disadvantage of a risk assessment approach is that medical facilities are 'flooded' with women who, although labeled as high risk, in fact have uncomplicated deliveries. The other side of this coin is that, as Malaysia found, increasing the proportion of deliveries in medical facilities is often desirable.

Note that even if accurate risk assessment were feasible, any program based on this approach would require the availability of high-quality maternity care, including EmOC, to manage those women who do develop complications – regardless of whether they were labeled high or low risk.

Institutional deliveries

We have said above that increasing the proportion of deliveries in medical facilities is often desirable. Institutional deliveries are more likely to be aseptic, to include active management of the third stage of labor, to use the partogram for early identification of obstructed labor, and to have rapid access to the drugs and equipment needed in case obstetric emergencies do arise. It is important to note, however, that not all medical facilities meet these standards.

An assessment of several hospitals in a country of medium development found clinical staff disregarded their training, ignored management protocols, and treated patients with little regard for their comfort and dignity.[55] Maternal and perinatal mortality were higher than might be expected despite the high rate of delivery by a skilled attendant. An analysis of the situation points to weak leadership and management, a lack of accountability in the health system, and women who are unaware of their rights to higher quality of care. Nevertheless, women defend their decisions to deliver in these facilities; they believe (probably correctly) this is where the highest quality of care is to be found.

In most developed countries virtually all deliveries take place in institutions, usually those able to provide a full range of life-saving services. The Netherlands is an exception to this rule (MMR = 16) but hospitals are always in close proximity. Among developing countries, there is a very wide range of institutional deliveries. Often the problem is the inaccessibility of quality obstetric care when it is needed. McCord and his colleagues in southern India[56] have shown that, given confidence in the quality of medical services provided, women and their families do a good job of knowing when to seek care. Furthermore, they are willing to pay for it. Thus, we can see that, while increasing the proportion of births in institutions certainly facilitates a rapid decline in maternal mortality, it is neither necessary nor sufficient.

Figures 199.1 and 199.2 show scattergrams of MMRs with the percentage of births attended by

midwives and doctors, respectively. Figure 199.1 (midwives) shows no clear pattern, while Figure 199.2 shows a clear relationship between physician-assisted delivery and lowered maternal mortality. While, in general, doctors practice in hospitals, midwives may practice in either communities or hospitals.

There is a building momentum within the donor community for increasing the availability of *skilled* (not merely trained) attendance at delivery. Skilled attendance is defined as a skilled attendant in an environment that enables referral to higher levels of skill as needed. While the rigorous evidence needed to support the claim that skilled attendance reduces maternal mortality is lacking, less rigorous evidence does support this claim.[56] Note that the effects of skilled attendance and those of institutional deliveries overlap to a considerable degree. Note also that the concept of skilled attendance includes access to EmOC and the two are highly complementary.

Community involvement

Community involvement, as a program, typically includes one or more of the following: community facilitation of transport to a medical institution, community-implemented insurance schemes, community education on the need for nurturing pregnant women, education on recognition of symptoms of complications,[58] community involvement in building a health center or maternity waiting home[59] and/or providing a welcoming environment for health workers in rural areas. A welcoming environment might include, for example, a cultural acceptance of single women (doctors, nurses, or midwives) living apart from their families, or the building of living quarters suitable for health professionals.

While community involvement often costs relatively little, sustainability is difficult and many programs fold when program support is withdrawn. Homegrown programs have greater viability. In the absence of accessible medical care, community involvement in maternity care is necessarily of limited effectiveness. At the end of the day, however, community involvement is an essential ingredient to enhance the utilization of obstetric services.

Emergency obstetric care

Accessible, acceptable, and affordable EmOC is the ingredient that is critical to the success of all other approaches. Implicit in almost all interventions designed to reduce maternal mortality is the intention to increase the proportion of women who are able to seek care when they need it. Surprisingly, this was not made explicit until relatively recently.[60] Nor were the components of EmOC defined until relatively recently. They include the following:

- availability of EmOC 24 h a day, 7 days a week (24/7)
- training of staff (at all levels) in the clinical and support skills needed for EmOC
- management protocols for each complication
- reliable and accessible supply of drugs and functioning equipment
- renovation of buildings to provide dedicated labor and delivery rooms and operating rooms that can be kept clean
- infection prevention measures
- laboratory support
- a functioning system of collecting and transfusing blood
- sensible management and logistics
- quality assurance including regular self-assessment (audits)[61]
- supportive supervision and mechanisms of quality improvement.

A recent program at Columbia University[§] has been elaborating the necessary components and implements programs through two UN agencies (UNICEF and UNFPA) and two non-governmental organizations (Care and Save the Children).[62] This program is now at the point where an assessment of impact can be made. The program met many challenges that had to be overcome – nonfunctioning equipment, drugs that remained in warehouses or on the docks, surgeons working in hospitals with no anesthetists or functioning operating room, staff untrained in obstetric procedures, low staff morale, no budgets for maintenance and repair, national policies against necessary practices, unwillingness to innovate, among others. The good news is that many of the problems could be solved with relatively little money simply by improving logistics and management practices.

Few of the interventions described above have been adequately evaluated. As we have stressed earlier, whether a woman survives an obstetric complication depends on many factors. If one element fails, others cannot function, as they should. Thus, no matter how well TBAs might recognize complications and understand the need for referral, if they cannot refer because there is nowhere to refer to, their training will have little impact on maternal mortality. A community may collaborate on developing means of transport, but if there is no medical facility to transport women to, their efforts are wasted.

There are well-established guidelines for evaluating individual interventions – such as active management of the third stage of labor.[5] But there is – as yet – no recognized hierarchy of evidence to support programs (which are, in essence, packages of interventions). While this is beginning to be developed for EmOC it remains at an early stage[63] and others would contest this.[64] It is important for researchers in this field to develop imaginative ways to provide evidence for the effectiveness of program interventions.

Causes of maternal death

There are many causes of maternal death. In Fathalla's now famous 'Why did Mrs X die?' he describes the many off-ramps from the road to death.[65] In addition to PPH, Mrs X was high parity, without access to contraception, and the hospital to which she was taken had no blood available for transfusion. It is important to address the multiple causes of maternal death and this requires the attention of many in the government and the private sectors, not only those concerned with health.

Clinical causes

All obstetricians are familiar with the clinical causes of maternal death. In addition to the five main direct causes (abortion complications, hemorrhage, sepsis, obstructed/prolonged labor, hypertensive diseases of pregnancy) there are less frequent ones such as ectopic pregnancy, amniotic fluid embolism among others. Indirect and non-obstetric causes can be difficult to separate. In developing countries, malaria, tuberculosis, and AIDS all make a significant contribution. HIV/AIDS-associated disease is the leading cause of maternal death in some settings.[66] Anemia, while rarely a cause by itself, makes women less resistant to other complications. Violence is increasingly getting attention as a cause of maternal death, though it may not always come to the attention of maternal health workers.

Social causes

The low status of women contributes greatly to women's inability to obtain the medical care they need. It limits their access to money needed to pay for transport or for medical care, and it makes them less likely to demand high-quality care provided humanely and with dignity. Low levels of education and high rates of illiteracy in some developing countries make women less likely to know the symptoms of complications, less likely to understand the need for certain interventions, and less likely to be told the reason for treatment. Some widespread cultural beliefs (for example, obstructed labor is caused by adultery) mean that women and their families do not seek appropriate care for some complications. Many hospitals ignore women's preferences for such things as companions during labor, delivery position, or means of placenta disposal; this adds to women's reluctance to deliver in hospital. The social distance between women (especially, rural women) and medical staff means women may be reluctant to speak (and therefore to provide necessary information) to their doctors and midwives. Often they have no language in common, and even if they do, medical professionals often fail to state things in simple, non-medical terms.

Geographic and logistic causes

Many countries must contend with populations living in remote or difficult areas (curfews, mountains, deserts, rivers, floods). In developed countries, the solutions are often high-tech (such as telemedicine) or expensive – medical 'flying squads' that fly women to medical centers 2 or more weeks before the expected date of delivery. In low-resource countries, these solutions are usually out of the question. But there are maternity waiting homes in many countries that provide a convenient place to stay for a week or more prior to delivery. Because these populations are often quite small (and out of sight), and the solutions are difficult, they are seldom given high priority. Indeed, it is difficult to provide any kind of service to such populations and preventive health services are more easily given than curative ones. Lack of infrastructure – roads, transport, communication, security – presents further barriers to those seeking medical care.

Management and quality of obstetric services

Experience has shown us a multitude of ways in which poor management can jeopardize quality of care. All aspects of clinical care and support functions are compromised by poor management, from failure to replace light bulbs to assigning surgeons to hospitals with no operating room or anesthetist. It is difficult to overestimate the contribution made by poor management to maternal mortality, or indeed mortality from any cause. Poor management is the leading contributor to the 'third delay' (failure to receive prompt and appropriate care once in the medical facility).

Accountability for how professional staff perform and behave is likely to contribute to whether women receive the care they need.[67] Too often key staff are absent and sometimes for understandable reasons – public salaries are so low that medical professionals must maintain more than one job. Thus, management at the policy level must also be held accountable.

Quality of care is compromised by a very long list of factors including – but not limited to – lack of accountability, poor preservice training, lack of ongoing in-service training, lack of up-to-date skills, lack of clinical management protocols, lack of equipment and drugs, low morale of health workers, lack of concern for patients, poor condition of hospital buildings, and a policy environment that is not supportive of the needs of either health workers or their patients. Nevertheless, some hospitals are able to function well and provide high-quality care in spite of these many obstacles, which may help explain why some poor countries despite their limited financial resources have lower mortality than others with a similar level of poverty.

Prospects for the future

The Nairobi Conference on Safe Motherhood in 1987 set the goal of halving maternal mortality by 2000 and this goal was adopted by national governments and other international conferences including the International Conference on Population and Development in Cairo (1994) and the Fourth World Conference on Women in Beijing (1995). But the goal was not met. The international development community is currently using the Millennium Development Goals (MDGs) as a roadmap to reducing poverty. It includes only eight goals, one of which is to improve maternal health; its indicator target is to reduce maternal mortality by 3/4 by 2015 from the 1990 levels (whether the MMR or actual numbers is not specified). National governments and donor agencies are also adopting these goals. From a political perspective, keeping maternal mortality reduction at the center of long-term planning is critical.

While MMRs have declined, the population base has increased leading to an increase in the number of deaths. Several donors – multilateral agencies, national aid agencies, and private foundations – have provided several hundred million US dollars toward achievement of the goal. Much of the effort has, however, been directed to projects that were, and still are, small relative to the size of the target population. Few countries have embraced the challenge and moved beyond statements of goodwill and good intentions.

A significant barrier has been the perception that real progress would require a great deal of money and reform of health systems; the former was not forthcoming and the latter seemed too great a challenge. Many projects therefore remained small in scale and went around the health system rather than attempting wider reform.

Recently, it has been realized that revitalizing maternity services can lead to improvements in hospital services beyond obstetric departments. Functioning operating rooms and blood transfusion services benefit those needing surgery as well as obstetric emergencies. The same is true for training anesthetists and laboratory technicians, or renovating operating rooms. Improved drug logistics benefit far more patients than just those in the obstetric ward. Better infection prevention benefits medical staff, patients, and the community at large. Enabling people to do their jobs as they were trained to do them (through the components listed in 'Emergency Obstetric Care') improves morale, performance, and accountability. Thus, it appears that a focus on EmOC can lead to significant improvements in the way the broader health system functions.

As countries move from externally funded projects in limited geographic areas to nationwide programs, two questions dominate. First, how should a country 'scale up'? Second, how can we ensure sustainability when donors withdraw their technical and financial assistance?

Improvement in health services is incremental but successful expansion to a national level will undoubtedly require that the specific goal of reducing maternal mortality and the general goal of improving health systems be widely internalized. The increasing profile of the MDGs should reinforce these goals as countries must report to the UN their progress on the MDGs. Not only must all personnel in the health sector – from the Minister of Health down – understand what needs to be done, but so must counterparts in other sectors. Nevertheless, significant progress can be made with the involvement of only the health sector. And while improvement is facilitated by economic development, Sri Lanka and Malaysia have demonstrated that low mortality can be achieved even in low-resource countries.

The precise route to national expansion will vary with circumstances. Determining factors include whether the health sector (among others) is centralized, decentralized, or devolved; the geographic barriers that exist; the size of the population and whether the country (or regions of it) is densely or sparsely populated; whether services are free or fee-for-service; the mix of public and private services; and the commitment of the relevant professional organizations.

Similarly, there are many routes to expansion of health sector improvements that are sustainable when donors withdraw. The reader is referred to publications of the World Bank on this topic. Two important factors, though, are first, widespread commitment to health outside the health sector and second, widespread technical competence within the health sector. The latter includes competence in public health, management, awareness of international norms and standards of practice, and problem-solving skills. These skills are needed at the district level as well as at the central level, and the more so in devolved or decentralized systems.

200 Developing countries: the goals of safe motherhood

G. Benagiano and B. Thomas

Introduction

The 20th century witnessed a dramatic drop in maternal mortality throughout the western, industrialized world. For example, maternal death rates in England and Wales, between 1935 and 1978 dropped from 341 to 10 per 100,000[1] and in 1990 there were no deaths attributable to pregnancy and delivery in Iceland, Luxembourg and Malta.[2] Unfortunately, similar results were not achieved in the developing world and in most countries of the so-called 'south' deaths attributable to pregnancy, labor, delivery and the immediate postpartum continued to be unacceptably high throughout the second part of the 20th century.[2]

This means that most obstetricians practicing in developed countries end their professional careers without witnessing a single maternal death, whereas for obstetricians in the South of the world, "maternal deaths are real people, human faces seen in agony and distress: they have names, and continue to live in their memories. Indeed, for an obstetrician, there is no more tragic event than a maternal death".[3]

Because of the failure of the international community to effectively tackle the plight of so many young women and their children, it was not until the 1980s that the right to safe motherhood was recognized as an important health goal. The turning point in creating a global awareness about maternal mortality was achieved with the convening of the International Conference on Safe Motherhood, in Nairobi in 1987. The sponsors of the Conference then created an *Inter-Agency Group for Safe Motherhood*, whose members included the World Health Organization (WHO), the United Nation Population Fund (UNFPA), the World Bank, the United Nations Children Fund (UNICEF), the International Planned Parenthood Federation (IPPF) and The Population Council amongst others; the secretariat of Family Care International acted as secretariat.[4]

It must be pointed out that obstetricians were conspicuously absent in this initiative, because, at the time, their relevance was in doubt; there was a feeling that obstetricians were part of the problem, rather than a part of the solution. In fact, initially, there were many misconceptions about the role of obstetricians, with their professional privileges, their alleged obsession for high technology and inability to play the constructive role of team leaders.[3]

Fortunately, this attitude changed and – in the 1990s – the international community recognized that obstetricians in the South and North were very much concerned about this neglected tragedy, and that they had the know-how to alleviate this unnecessary suffering. Proof of this recognition was the invitation extended to the International Federation of Gynecology and Obstetrics (FIGO) to join the Inter-Agency Group.

The work to bring maternal morbidity and mortality to the forefront of the international agenda for development climaxed in the year 2000, when the largest-ever gathering of heads of state at the United Nations in New York, adopted the *UN Millennium Declaration*, made up of eight critical goals to fight poverty and accelerate development, named *Millennium Development Goals* (MDGs). Two of the eight MDGs deal with improving maternal health and reducing child mortality, thereby recognizing the importance of these health goals in promoting global development and in fighting poverty.[5] The target is to reduce by three-quarters, between 1990 and 2015, the maternal mortality ratio. As an indicator to measure progress toward the goal of reducing maternal and under-five mortalities, the MDGs selected the proportion of births attended by a skilled attendant. Targets were agreed for countries with high rates of both maternal mortality and under-five mortality. Thanks to the existence of these MDGs, today's policy-makers must, not only acknowledge that for the world's poor, pregnancy and delivery still carry an unacceptably high risk of morbidity and mortality, but also actively engage themselves to improve the situation.

Unfortunately, 5 years after the Declaration, the available data on reported proportion of births attended by a skilled attendant show poor progress in a number of countries, particularly in Asia and sub-Saharan Africa, the very places where maternal

mortality is highest. At the same time, in spite of a slow start and of many obstacles, today, 25 years after the founding of the safe motherhood movement and many failed attempts, the international community seems ready to launch a unified struggle to reduce mortality related to pregnancy, including that due to unsafe abortion. Indeed, the beginning of a new era was marked in September of 2003, when all major organizations active in the field of maternal health, joined forces and launched, in Kuala Lumpur, the Partnership for Maternal and Neonatal Health.

Thanks to the new partnership, a global consensus has now been reached on what should be done to eliminate the menace of maternal deaths and disabilities hanging over so many women of the developing world.

Four major strategies have been identified to reach the MDGs of safer pregnancies and deliveries:

- Skilled attendance at all births,
- Basic emergency obstetric care (BEOC) in peripheral units,
- Comprehensive emergency obstetric care (CEOC) in referral hospitals, and
- Rapid transport of women in need of special care.

Ways to achieve these goals will be illustrated in this chapter.

Skilled attendance at birth

The first and most important strategy to reduce maternal mortality involves the presence – during childbirth – of a health professional who can manage a normal delivery as well as detect and manage complications such as hemorrhage, shock and infection. Skilled attendants should have access to a functioning emergency and transport system so that they can refer women to an appropriate health facility for higher level medical care (such as cesarean delivery or blood transfusion) when necessary.[6] Skilled attendants include doctors, nurses, midwives and other health workers with midwifery skills who can diagnose and manage complications during childbirth, as well as assist normal deliveries.

Already in 1999, a joint statement by several international organizations called on countries to 'ensure that all women and newborns have skilled care during pregnancy, childbirth and the immediate postnatal period'.[7]

According to a document jointly published by the WHO, FIGO and the International Confederation of Midwives (ICM),[8] 'Skilled care refers to the care provided to a woman (and her newborn) during pregnancy, childbirth or immediately after birth by an accredited and competent health care provider who has at her/his disposal the necessary equipment and the support of a functioning health system, including transport and referral facilities for emergency obstetric care'. Around the world skilled care can be provided by a range of health professionals, whose titles may vary according to specific countries. For this reason it has been agreed to refer to this health care provider as the 'skilled birth attendant' (SBA), so as to avoid confusion over titles.

Therefore, an SBA is 'an accredited health professional – such as a midwife, doctor or nurse – who has been educated and trained to proficiency in the skills needed to manage normal, uncomplicated pregnancies, childbirth and the immediate postnatal period, and in the identification, management or referral of complications in women and newborns'.[8]

The unique role of SBAs becomes clear when we realize that, at the community level, she/he will often be the only qualified and accredited health care worker who can take care of women during pregnancy, child birth and the immediate postpartum period. Unfortunately, communities in many developing countries often still lack sufficient numbers of skilled attendants and rely on unskilled personnel, such as the Traditional Birth Attendants (TBAs).

All skilled attendants must have the core midwifery skills. The additional skills required will vary from country to country, and possibly even within a country, to take account of local differences such as urban and rural settings. As detailed in the joint WHO, ICM, FIGO document,[8] the core functions must include:

- Communicate effectively cross-culturally in order to be able to provide holistic 'women-centered' care. To provide such care skilled attendants will need to cultivate effective interpersonal communication skills and an attitude of respect for the woman's right to be a full partner in the management of her pregnancy, childbirth and the postnatal period.
- In pregnancy care, take a detailed history by asking relevant questions, assess individual needs, give appropriate advice and guidance, calculate the expected date of delivery and perform specific screening tests as required, including voluntary counseling and testing for HIV.
- Assist pregnant women and their families in making a plan for birth (i.e. where the delivery will take place, who will be present and, in case of a complication, how timely referral will be arranged).
- Educate women (and their families and others supporting pregnant women) in self-care during pregnancy, childbirth and the postnatal period.
- Identify illnesses and conditions detrimental to health during pregnancy, perform first-line management (including performance of life-saving procedures when needed) and make arrangements for effective referral.
- Perform vaginal examination, ensuring the woman's and her/his own safety (by using gloves).
- Identify the onset of labor.
- Monitor maternal and fetal well-being during labor and provide supportive care.

- Record maternal and fetal well-being on a partograph and identify maternal and fetal distress and take appropriate action, including referral where required.
- Identify delayed progress in labor and take appropriate action, including referral where appropriate.
- Manage a normal vaginal delivery.
- Manage the third stage of labor actively, including using oxytocic drugs.
- Assess the newborn at birth and give immediate care.
- Identify any life-threatening conditions in the newborn and take essential life-saving measures, including, where necessary, active resuscitation as a component of the management of birth asphyxia, and referral where appropriate.
- Identify hemorrhage and hypertension in labor, provide first-line management (including life-saving skills where needed) and, if required, make an effective referral.
- Provide postnatal care to women and their newborn infants and post-abortion care where necessary.
- Assist women and their newborns in initiating and establishing exclusive breastfeeding, including educating women and their families and other helpers in maintaining successful breastfeeding.
- Identify illnesses and conditions detrimental to the health of women and/or their newborns in the postnatal period, apply first-line management (including the performance of life-saving procedures when needed) and, if required, make arrangements for effective referral.
- Supervise non-skilled attendants, including TBAs where they exist, in order to ensure that the care they provide during pregnancy, childbirth and early postpartum period is of sound quality and ensure continuous training of non-skilled attendants.
- Provide advice on postpartum family planning and birth spacing.
- Educate women (and their families) on how to prevent sexually transmitted infections including HIV.
- Collect and report relevant data and collaborate in data analysis and case audits.
- Promote an ethos of shared responsibility and partnership with individual women, their family members/supporters and the community for the care of women and newborns throughout pregnancy, childbirth and the postnatal period.

Obviously, depending on the setting and the availability of referral centers, additional and advanced skills should be identified and agreed upon by individual countries.

As part of the new, ongoing collaboration promoted and supported by the Partnership for Maternal and Newborn Health (and its predecessor, the Inter Agency Group for Safe Motherhood), WHO-UNICEF-UNFPA-the World Bank, with the endorsement of ICM, FIGO and the International Pediatric Association (IPA) have produced a Manual for the integrated management of pregnancy and child birth[9] that details essential practices for the management of pregnancy, childbirth and the postpartum and for proper neonatal care.

Emergency obstetric care

Contrary to common belief – most obstetric complications cannot be predicted or prevented,[10,11] but they can be treated and a woman's life saved in most cases. Therefore, the second pillar of safe motherhood is represented by the widespread availability of centers capable to provide BEOC. This involves the provision of antibiotics, oxytocics, anticonvulsants, the manual removal of placenta and – if necessary – of retained products and assisted vaginal delivery.[12]

The presence of skilled attendants at all home births should be sufficient to ensure an early identification of those complications requiring referral of the woman to a center where can BEOC be provided. It must be pointed out that, in a majority of developing countries, centers supposed to provide BEOC already exist, although – for a variety of reasons – the posts may not be equipped. It seems therefore that basic emergency care could be provided in most countries and that a modest financial input would be sufficient to enable skilled attendants to provide basic services to most women.

In the effort to provide BEOC, it is vital to ensure their proper distribution throughout a territory, taking care of studying the geography, the presence of roads, or the existence of natural barriers (rivers, mountains, etc.) that can make difficult the access to a health post. Under normal conditions, it should be sufficient to have one BEOC center for every 100,000–150,000 inhabitants.

Comprehensive obstetric care

A facility providing BEOC can perform a majority, but not all, emergency obstetric functions. There is therefore a need to ensure that, for each territory of 500,000 inhabitants or so (again, depending on the geography and overall easiness of access) a CEOC facility exists. Such a center must be able to provide all BEOC functions plus the possibility to perform cesarean sections and blood transfusions.[12]

All district hospitals are, in theory, capable of carrying out CEOC, although this is often not the case because existing equipment is not functioning, spare parts are not available, or the skills needed for repair do not exist. Given this situation, any attempt at ensuring CEOC for a given area must focus on upgrading existing facilities, not creating new ones. Monitoring the functioning of a facility providing comprehensive care is essential to ensure that lives will be saved. Experience has taught that efforts aimed at improving

the situation in the developing world are often not sustainable, that once a project or a model intervention has been completed, because of lack of funding, personnel turnover or equipment break down, slowly but steadily the situation reverts to the *status quo ante*. This is probably the biggest danger that all safe motherhood programs run into; it is therefore fundamental that – when improving a CEOC facility – the self-sustainability of the effort be properly evaluated and measures to ensure it be undertaken.

Another major problem is that local physicians may not be adequately trained, or that they, as well as other auxiliary health personnel may not be available on a 24 h basis, or that drugs or blood supplies do not exist. In this respect, skills in surgery and anesthesiology are critical for the management of complications in pregnancy and childbirth. It is therefore essential that skilled attendants in the field or at primary health facilities who do not themselves have these skills, be able to refer women to centers where these skills are available. In such cases, skilled attendants must work closely with these professionals in order to ensure that speedy action is taken soon after the need for surgery has been established.

Countries that are facing a severe shortage of physicians trained in surgery and/or anesthesiology have successfully trained nurses, midwives and other cadres of health workers to perform or assist in cesarean sections. This however can pose problems, since if people with these skills are health care workers who are not skilled attendants, then the need to operate must be identified by the skilled attendant working in the field or at the BEOC unit; furthermore the skilled attendants must be able to provide ongoing and follow-up midwifery care.

Rapid transport

A safe pregnancy and a safe delivery require the provision of a continuum of care, which – in turn – necessitates, not only a functioning health care system, but also the necessary infrastructure, including transport between the primary level of health care and referral clinics and hospitals. It also needs effective, efficient and proactive collaboration between all those involved in the provision of care to pregnant women and newborns.

For this reason, improving facilities and ensuring their presence in a territory does not *per se* ensure that all women will reach a post in time for their lives to be saved. Often transportation, to be effective must be *rapid,* since conditions like intrapartum hemorrhage, must be dealt with within a very short time. Unfortunately, the rapid transport of patients in need involves complex interactions between the pregnant woman and the community in which she lives and this may be problematic.

In an effort to contribute to the solution of this problem, the Mailman School of Public Health at Columbia University in New York, has recommended a scheme focused on delays that could lead to maternal mortality, with the aim of identifying solutions to the causes of such delays[12,13] and to possible solutions.

The 'three delays' are defined as:

- Delay in deciding to seek care,
- Delay in reaching a treatment facility, and
- Delay in receiving adequate treatment at the facility.

It must be stressed that in many cases, a decision to seek care to resolve a labor complication occurring at the pregnant woman's home – where most deliveries still occur in the developing world – is often neither quick nor easy.

In societies where a long, painful labor is considered part of the process of giving birth, family members may not recognize a 'true' complication. Often, TBAs, who still assist a majority of home deliveries, may delay a decision to seek skilled care by days, because referral may be seen as a 'failure' on their part, especially if – once the woman has reached the facility – health center personnel will exclude the TBA from any further involvement. Furthermore, the lack of autonomy of women in many societies may necessitate a decision by the husband to seek help and the cost of transportation may negatively influence his decision.

Even when a decision has been made, a health post may be days away, especially if it can only be reached by foot. This is why the proper distribution of centers providing emergency obstetric care is so important in the fight for safe motherhood. For instance, if a woman has reached a BEOC facility and it is determined that she needs a cesarean section, the ability to immediately communicate with the referral CEOC center to request the ambulance needed for a speedy transport of the woman, may be the most important ring in the chain to save her life.

Finally, statistics show that many maternal deaths take place at a health post or hospital; this is why the delay in receiving care once reaching a center is still an important factor to be considered in attempting to achieve safe motherhood.

Implementing programs: the FIGO Save the Mothers Initiative

Over the last two decades many international, governmental or non-governmental organizations have created programs aimed at promoting safe motherhood, both in terms of decreasing mortality and morbidity. Only one program however, was promoted and implemented by obstetricians – gynecologists. For this reason, it was felt important – in providing an example of field activities – to single out the work carried out by the FIGO, the only organization capable

of combining the experience of doctors in the industrialized world with the local knowledge of their colleagues in the developing world to combat the scourge of maternal mortality and morbidity. With this initiative, obstetricians–gynecologists all over the world provided clear proof that they are part of the solution, rather than being part of the problem.

FIGO's activities, named the FIGO Save the Mothers Initiative, have been ongoing since 1998 with funding from UNFPA, the World Bank and Pharmacia Corporation and FIGO's own resources and today span over several fields: prevention of maternal mortality, treatment of disabilities (vescico-vaginal fistulae) and prevention of hemorrhage during labor, delivery and the postpartum. These are the areas where obstetrician/gynecologists can contribute most and, at the same time, acknowledge the roots of the problem and the need for other interventions. The overall objective of the project was – and continues to be – to mobilize the obstetric/gynecological community in both the developed and developing world to work in partnership to reduce maternal mortality, and to show the feasibility and effectiveness of integrated essential and/or comprehensive obstetric services.

Reports of individual projects,[14–17] as well as a comprehensive summary[18] have already been published. The following is therefore an overview aimed at illustrating the uniqueness of FIGO's interventions.

The twinning system

From the outset, FIGO's initiative was confronted with an overwhelming demand for assistance that could not possibly be satisfied in full. For this reason, the number of partnerships to be created had to be limited to five, as follows:

- The Society of Obstetricians and Gynecologists of Canada (SOGC) was twinned with the Association of Obstetricians and Gynecologists of Uganda (AOGU).
- The American College of Obstetrics and Gynecology (ACOG) was twinned with the Central American Federation of Associations and Societies of Obstetrics and Gynecology (FECASOG).
- The Swedish Society of Obstetrics and Gynecology was twinned with the Ethiopian Society of Obstetricians & Gynecologists.
- The Royal College of Obstetricians and Gynaecologists was twinned with the Pakistani Society of Obstetricians and Gynaecologists.
- The Italian Society of Gynecology and Obstetrics was asked to work directly with the Government of Mozambique, since that country does not, as yet, have a dedicated society of obstetricians and gynecologists.

The countries in which activities took place were chosen on the basis of their high maternal mortality, the desire of the local society of obstetrics and gynecology to work with FIGO, the demonstration of government interest and commitment to improving women's health and an expression of interest from a FIGO member society of obstetricians and gynecologists in a developed country to work in the chosen region. Dedicated 'Country Teams' were established for each geographical area identified. Each team consisted of international experts and of local obstetricians–gynecologists, in a developing country together with representatives from both the 'developed' and the 'developing' country.

For each Country Team a Coordinator was selected to participate in the initial situational analysis and needs assessment visits to the developing country with a view to defining how maternity services can best be organized within the available and potentially available resources, and to work with the other members of the Country Team to evaluate the feasibility, impact and cost-effectiveness of the proposals made as a result of the assessment carried out.

Evaluating the situation

The first step in the implementation phase consisted of carrying out a situation analysis to assess the accessibility and efficiency of the existing health infrastructure for essential obstetric functions, the availability of facilities, equipment, supplies, training needs and personnel to provide easy access to obstetric functions. As part of the assessment, each Team evaluated the optimal allocation and redeployment of available resources, so that the ensuing demonstration project could be properly customized to meet the needs of the area selected in each country.

Particular attention was paid to ways to measure the success of the project. In the end, it was decided that only really measurable output would be the number of cases of life-threatening complications admitted to the health facilities and the outcome of their management.

In carrying out the needs assessment the Guidelines issued by the United Nations were used.[19] These Guidelines focus on process indicators of CEOC – in other words, the treatment of serious obstetric complications. Three key indicators are laid out in the Guidelines:

(1) *Coverage of services:* The Guidelines specify that for every 500,000 population there should be at least one facility providing CEOC and four facilities providing BEOC.
(2) *Unmet need for emergency obstetric care:* An estimated 15% of pregnant women will require medical treatment for obstetric complications. Unmet need is the proportion of these women who do not receive care in a medical facility.
(3) *Cesarean section rate:* At least 5% of women giving birth will require a cesarean section. (Note

that this is population-based rate and not a hospital-based rate.) By counting the number of cesarean sections performed in health facilities, the deficit in this life-saving service can be estimated (the recommended maximum for the cesarean section rate is 15% and care must be taken that all procedures are indicated).

When the teams conducted needs assessments, they found striking deficits. Not surprisingly, the greatest deficits were in the poorest countries. In the study areas of Ethiopia and Mozambique, for example, the unmet need for emergency obstetric care was over 98% and the cesarean section rate for the population was less than 1%. Even in Central America, serious shortages were discovered. While there were enough hospitals in the study areas of the four countries in this region, there were no lower level facilities (such as health centers) providing BEOC. The lack of basic care, often caused by shortages of trained staff, equipment and drugs, presents serious access problems for poor women in rural areas, where transportation is scarce and expensive.

The field projects

Each project carried out in partnership is different and therefore their characteristics have been unique, although they have all achieved the basic goal of helping to save mothers' lives. For this reason they represent useful examples of how, with limited resources, obstetricians–gynecologists can move out of their hospital natural setting and provide unique support to the fight for safe motherhood. For this reason, the main feature of all five projects will be briefly described here.

Central America

The Central America–USA demonstration projects took place in one rural province of El Salvador, Guatemala, Honduras, and Nicaragua. They focused on interventions aimed at implementing training courses in the management of BEOC and CEOC on the one hand and at improving relationships between the National Obstetric and Gynecology societies and the Ministries of Health, on the other.

The starting point was the realization that high maternal mortality rates were a common medical, social, as well as human problem and that no reliable information on maternal mortality was available in the four Central American countries. It was recognized that, notwithstanding the fact that properly trained obstetricians–gynecologists existed in all four countries, at rural level the capacity to render basic care for obstetric emergencies was virtually nonexistent. Almost all of the institutions rendering total care were located in urban areas and were private facilities. As a result, the indigent population, which comprises the majority of the rural population, had very limited access to obstetric care during pregnancy and at delivery, since adequately trained health care personnel capable of managing obstetric emergencies at peripheral public hospitals and at health centers and offices were lacking and communication between health centers and regional hospitals was deficient.

Given this reality, activities centered around assessing and improving obstetric emergency care, establishing monitoring systems and committees at community and district hospital levels, properly carrying out audits of cases of maternal deaths and identifying strategies to effectively prevent these deaths.

A series of interventions were therefore planned and implemented, including:

- Training of field coordinators in the management of emergency obstetric care, including the development of *ad hoc* Instructors and Course Manuals with Updates in Obstetric Emergency Care.[20] These coordinators then trained the remainder of the staff in the entire province thereby ensuring that all health care personnel would be adequately trained.
- Introducing a routine protocol for the active management with oxytocin during the third period of labor in all the institutions providing childbirth services.
- Establishing a prospective and systematic data gathering system, including a detailed study of all maternal deaths with 'verbal autopsies' (interviews with family and community members), thereby determining a more realistic maternal mortality rate.
- Creating provincial maternal mortality committees to better understand causes and factors related to each death, with the aim of providing education to ensure better prevention.
- Training health providers in the manual endometrial vacuum aspiration for incomplete abortions.
- Installing radiotelephones at health centers and tertiary hospitals to ensure proper communication with tertiary hospitals.
- Establishing evaluation meetings to brief local and national health authorities and Obstetrics/Gynecology Society representatives.

In all areas, the *unmet need* for emergency obstetric care was in the order of 80%. When, after 3 years, results started to be evaluated, a slight decrease was observed to approximately 70%. However, one worrying feature emerged: no significant reduction in the number of maternal deaths was evident, contrary to the strong belief of everyone involved who had originally expected positive results within a 3-year time frame. However, looking more carefully at the situation, it became apparent that, as a result of the improved surveillance system, more maternal deaths were being identified. Indeed, the surveillance system developed by the project clearly demonstrated that the majority of maternal deaths were not being

reported. This made any comparison with historical data impossible and forced the realization that the intervention would need to continue for a longer period in order to demonstrate a decrease in the real maternal mortality rate. An important finding, with very practical repercussions was that 74% of maternal deaths – approximately two-thirds of which due to postpartum hemorrhage – occur following delivery at home and only 22% occur in hospitals, pointing out to serious delays in transporting women to medical facilities.

The most important achievement of the activities in Central America was the training of almost all health care providers in the targeted provinces. Overall, 929 health care personnel received initial training and 502 follow-up training. Today, all health care facilities in each of the four provinces can provide BEOC.

Ethiopia

Maternal mortality in Ethiopia is one of the highest in the world, with a ratio of 1800 deaths per 100,000 live births and the prospect for a rapid decline in this rate is poor because of the limited availability of health services. In addition, in Ethiopia there is a substantial number of women who die because of complications caused by illegal abortions.

The FIGO project dealt with an area approximately 250 km from the capital, where a zonal hospital and two health centers are located. The area is among those with the lowest obstetric indicators for the entire country and emergency obstetric care services deemed below an acceptable standard and not provided around the clock, even at the zonal hospital. Coverage of emergency obstetric care in the targeted area was very low, at slightly more than 6% in 1999, raising to some 7.5% in 2001. This indicates an unmet need for emergency obstetric care of 91% and for Caesarean sections of 97%. In the area there was an acute shortage or absence of trained manpower at all levels; a poor administrative system and a lack of accountability by bureaucrats; non-conducive working environments for medical and paramedical personnel; shortages of essential drugs, supplies and medical equipment; absence of blood transfusion services and of an effective referral system.

Given this reality, the main aim of the intervention was to increase coverage in emergency obstetric care through training, accurate record keeping, securing adequate staff and creating cost-effective, community-based, integrated emergency obstetric care services. This was accomplished by upgrading existing facilities through the provision of equipment, supplies and materials.

The intervention included training physicians and other service providers from the Hospital and the health centers in emergency obstetric care; providing new equipment, materials and supplies; entering into agreements with the Ethiopian Red Cross Society for a regular supply of blood for transfusion in Ambo Hospital; securing a dependable supply of water and electricity to a new block for obstetric and gynecological services that had been built at the zonal hospital prior to the intervention, and had been standing idle for over 2 years. During the intervention period, all the obstetric and gynecological services – including the operating theatre were moved to the new block; encouraging community participation through a regular dialogue with community leaders and extending invitations to the local population to attend graduation ceremonies of trainees.

Specific care was given to training and motivating staff; this led to an improvement in record keeping already after the first round of training not only in the zonal hospital, but also in the two health centers. Midwives were assigned this responsibility in all facilities, and this activity has also been strengthened by regular supervision. Before the intervention, obstetric performance at the target Hospital was very poor, as documented by the number of referrals to Hospitals in the Capital. However, as soon as the implementation phase began, the total number of deliveries at the Hospital increased from a baseline of 709 in 1998 to 991 in 2001 (an increase of almost 40%). Particularly significant was the increase in cases with obstetric complications – from 128 in 1998 to 432 in 2001 (an increase of approximately 238%). The leading cause of hospitalization in the area is obstructed labor, accounting for 39% of all complications. Obstetric hemorrhage comes next, accounting for 24% of all admissions. Instrumental deliveries also increased from 6% in 1998 to 23% in 2001. Particularly noteworthy was the almost sixfold increase in the Caesarean section rate at the zonal hospital, from a base line level of 3.8% in 1998 to 17.3% in 2001. Case fatality rates, calculated taking into account direct maternal deaths, decreased from 7.2% in 1998 to 4.6% in 2001. The two health centers in the intervention area have been upgraded in terms of training of staff members, and provision of equipment and supplies. Regular supervision has been undertaken to ensure that the community in these areas has access to BEOC services.

The availability of high-quality emergency obstetric care in the hospital and in the sites involved in the project is shown by a significant decline in referrals to Addis Ababa. Annual deliveries at one of the health centers have increased from 38 in 1999 to 76 in 2001 and at the other from 206 in 1999 to 362 in 2001.

Mozambique

Mozambique is another African country where maternal mortality rates are very high, ranging – in 1997 – between 500 and 1500 per 100,000 live births. A recent analysis of 90 in-hospital maternal deaths in seven provinces during the period of January 1, 1997 and June 30, 1998 was conducted by the Ministry of Health in order to try to identify the principal determinants of maternal mortality; the results indicated

that more than 80% of these deaths were attributed to direct obstetric causes.

One of the major determinants was obstructed labor: with a caesarean section rate of 2.7% and a range of 7.3% in urban areas and of 1.4% in rural areas, clearly the majority of cases of obstructed labor went untreated.

The FIGO project focused on six Rural Hospitals and two General Hospitals in the area around the capital, where a number of reasons were identified that accounted for a general inability to provide CEOC. These included: low number of trained personnel; scarcity of drugs and lack of surgical materials and equipment. When trying to design strategies to improve the situation, it soon was recognized that the major obstacle to improvement was the almost complete lack of trained medical practitioners qualified to provide obstetric care. Therefore, improving the country's ability to train physicians in general and obstetricians in particular, became a top long-term priority.

Although the floods that devastated Mozambique in 2000 affected the project areas and completely disturbed the normal activities at the country level, interventions went on aimed at upgrading three selected hospitals to allow them to become CEOC units. This was obtained through training of non-physicians (surgical technicians); supplementing the equipment of the BEOC and CEOC units in the selected Districts; improving the diagnosis and management of obstetric complications; improving the interpersonal communication and counseling skills of health providers; and improving data collection systems.

As a result of the interventions the number of centers offering BEOC in the project area doubled in 2 years and the number of units offering BEOC increased, during the same period from one to five. Within the first 3 years, emergency obstetric care had become available 24 h a day in one site, for part of the day in another and intermittently at the third site, with the aim of 24-h provision in all three centers by the end of the project activities. This resulted in an increase in the number of complications treated at the project hospitals where, globally, total deliveries decreased between 1998 and 2000, from 4289 to 3822, but concomitantly complications rose from 1816 to 2065 and the number of caesarean sections increased from 14 to 39.

An important result of the FIGO project was that the model of intervention used was adopted as a model for basic and comprehensive emergency care at the national level. As a result, a 5-year plan was developed for Mozambique, taking into account the difficulties, mistakes and problems that had arisen during the demonstration project. All the lessons learned have been incorporated into the national strategy for the reduction of maternal and perinatal mortality in the country, which essentially means the concepts utilized in the FIGO project have now been applied throughout the country. Work continues to ensure sustainability of the effort even in the difficult situation faced by Mozambique.

Pakistan

The FIGO-supported intervention took place in a rural district which was believed to be representative of the semi-urban and rural nature of many of the country's communities. Although the area would not rank as 'very poor' by Pakistani standards, it was considered representative of the country, as, prior to the commencement of activities, the provision of emergency obstetric care was virtually non-existent. Three Rural Health Centers (RHCs) – essentially 'cottage hospitals' with only modest inpatient facilities – each serving about six Basic Health Units (BHUs) – primary care facilities – were targeted. Once operational, the registers of all three RHCs were audited both for normal deliveries and for all interventions (including caesarean sections) carried out in the presence of complications, to evaluate which were potentially life-threatening if untreated. Specific attention was given to an evaluation of the impact that the new services might have throughout the area. Therefore, the village of origin of all women presenting themselves for delivery, or treatment of a pregnancy-related emergency, at hospitals in Lahore was also recorded. This ensured that, for the population of the study area, the total number of deliveries, treated complications and caesarean sections were recorded irrespective of whether they had taken place within and outside the area.

The interventions aimed at restoring structural facilities and upgrading the operating and delivery rooms within the RHCs, at ensuring that RHC ambulances were functional and that blood transfusion equipment became available. An important component of the project involved negotiating the filling of established health personnel positions, and offering in-service training in emergency obstetric care to existing medical and paramedical staff. Another specific feature dealt with the creation of a comprehensive educational program for local people, including males and civic dignitaries (customarily the decision makers) and 'dayas' (TBAs).

As a result of the intervention, the number of births in the project facilities increased in 1 year by almost 71%; caesarean sections increased in the same period by 48% and that of complications treated by almost 10%. By the middle of 2002, over 80% of all women living in the area of intervention who required a caesarean section, received it at the targeted centers. Good liaison and interaction with government authorities was established at all levels and the traditional cultural resistance shown by women to the idea of being examined or treated by male doctors has all but disappeared.

Uganda

Uganda is unquestionably one of the poorest countries in the world. Maternal mortality in Uganda

is estimated at 510 per 100,000 live births. Only 38% of all births are attended by trained health personnel (skilled attendants), making the country perfectly eligible for a FIGO project.

The rural district selected for the intervention was of the appropriate size, with no other ongoing public health projects and one hospital with the capacity to become a referral hospital. Maternal mortality rates in the district had been estimated at 650 per 100,000 live births, even higher than the national average.

The main challenges to the provision of emergency obstetric care services identified in the district were: delays in transportation for women trying to reach a health center; lack of radio or telephone communication between the community dispensaries and the referral hospital; lack of trained midwives; lack of community health workers; and lack of basic equipment and supplies in some community dispensaries.

A number of interventions were planned to make emergency obstetric services available to the women of the District and reduce maternal morbidity and mortality. Among them prominent was increasing the skilled attendants' coverage and capabilities related to basic and CEOC. This was achieved by opening eight new Dispensary Maternity Units; recruiting 14 midwives to ensure 24-h coverage; recruiting a midwife-coordinator to coordinate the project's seminar series for midwives, collect the project data and organize the bimonthly visits of local or foreign volunteer obstetricians.

Another important task was upgrading health facilities by providing basic equipment, supplies and medication; identifying and addressing social and cultural barriers to maternal care by educating, through a partnership with the Department of Women and Gender Studies at Makerere University, women and their families on issues related to pregnancy, delivery and possible complications during birth; addressing the lack of emergency communication and transportation facilities in the district to ensure the timely transfer of women to health facilities.

Already after the first 18 months of continuing work, a number of improvements were noticed: one CEOC facility became fully functional, with two other facilities providing basic care; the number of births in the project's health facilities increased from 17% in 1998, to 23% in 1999, although it decreased slightly to 21% in 2000. The ability to treat all women with obstetric complications (the so-called 'met need'), in emergency obstetric care facilities increased from 8.5% in 1998, to 34% in 1999 and 38% in the year 2000.

Caesarean section rates increased from 1.3% in 1998 to 2.2% in 1999 and to 2.7% in the year 2000 and the number of antenatal cases seen and treated by midwives increased by more than 40%.

More work lies ahead: the number of births in all the BEOC centers and Dispensary Maternity Units has consistently remained less than 10% of women attending antenatal clinics, with the majority of deliveries taking place in the home. Overall 'unmet need' for general obstetrics services remains more than 60% and the cesarean section rate still needs to raise to the optimum calculated at around 12%.

Lessons from the FIGO Initiative

The Save the Mothers activities in all five areas have been quite different, although they have all achieved varying degrees of success. It must be stressed that FIGO set out to try to show that one of the direst medico-social problems affecting the lives of women in the developing world, could be addressed and resolved even under some of the worst logistic conditions and with very limited financial resources. It is fair to state that the results document that this approach is feasible and should be replicated.

A number of lessons can be drawn: first, although activities had been designed using the same basic parameters, as the work progressed, it became clear that each project was unique, reflecting the needs of the countries and regions concerned. Perhaps more importantly, it also became apparent that individual projects could easily be replicated wherever a set of similar circumstances prevailed, as it was the case in each of the countries where the Initiative was conducted. In many ways, whereas FIGO had expected to see one solution that could be applied across the board, it got five. All five projects developed findings that, whilst specific to their area, could also provide lessons for not just other similar interventions, but also for health care workers in developing nations worldwide.

In Central America, training of field coordinators who then trained the remainder of the staff of the entire province ensured better training for all health care personnel involved in delivering obstetric services. In Ethiopia, strengthening existing programs improved the availability of Emergency obstetric care services, and simple modification of routine practices produced startling results: adequate supplies of blood for transfusions at Ambo Hospital were obtained by simply discussing the matter with the local Red Cross. In Mozambique, the simple interventions advocated by the Initiative were adopted as a model for basic and comprehensive emergency care at the national level and a 5-year plan based on the project's template was developed. In Pakistan, the activities undertaken in a rural area, close to a large city, highlighted a number of interesting points that, whilst not anticipated, should be noted. For example, voluntary Lady Health Workers, who became major contributors particularly insofar as immunization and family planning aspects were concerned, facilitated the collection of data. Of particular note is the fact that a 300% increase over 5 years in the uptake of general (i.e. non-pregnancy-related) medical services was seen at the 'flagship' RHC, without any increase in

costs or staffing. Finally, in Uganda, those working in the field noted that less than 20% of the relatively large number of women who attended antenatal classes returned to the same facility to deliver their baby, a fact which strongly suggested the existence of cultural barriers against delivery outside the home environment. In addition, although the number of women with obstetric complications referred to the hospital increased over the period of the interventions, between 40% and 60% of those who had been instructed to attend the hospital for treatment did not subsequently go. Up to 10% of the women referred to the hospital returned home to seek care from relatives or other community providers; unfortunately, some of these women died.

Conclusions

The work of the international community has begun to show that even an extremely difficult and logistically complex problem such as that of ensuring safe motherhood for all women of the planet can be attacked and eventually resolved: if there is a will, there is a way. What is needed today in a sustained effort capable of producing results over the long period in all the areas where women die unnecessarily.

Thanks to this work today we know that, not only progress is possible with modest resources, but improving emergency obstetric care is a cost-effective approach to reducing maternal mortality. At the same time, the effort must be global; in other words, success depends on strengthening the full range of existing reproductive health programs, of which availability of Emergency Obstetric Care services is a key component.

Success however, is also linked to modifications of existing routine practices; even minor modifications can result in startling improvements, as it is the case with the many solutions found across the developing world to the non-availability of adequate supplies of blood for transfusions. These are areas where the Community, if properly mobilized, can take a leading role.

More complex to resolve is the lack of trained professionals – particularly acute in some countries. This suggests that one of the top priorities in creating emergency obstetric centers is the need to develop human resources and to place trained personnel in areas where women are dying. A sustained 'cascading' of knowledge through training at the local level could allow replication of the results achieved in one area or country to another. All this means that success will not be achieved without the development of local capacity for support, supervision and monitoring. In this respect, the partnership of midwives, general practitioners and an obstetrician can have a significant impact on the availability of emergency obstetric care in rural districts.

The role of local communities, their sense of pride and 'ownership' in the fight to improve the health of women is also essential. In this respect, upgrading facilities can lead to a global better utilization of a health center for purposes that go well beyond safe motherhood. When a center 'belongs' to a community, even the age old and widespread reticence to deliver in medical facilities – a result of culture and tradition which requires an intensive effort to modify – may eventually be resolved. At a higher level, since Ministries of Health are the most important players in the struggle to resolve their countries' problems, involving Ministry officials becomes a primary objective.

In conclusion, there is one inescapable conclusion of all the efforts we have recently witnessed: with determination and a sustained effort, the lives of mothers and their babies can be saved with very little real financial outlay.

The real outlay is one, not of money, but of a will by doctors, nurses, midwives and all other arms of the medical profession to become a part of the solution rather than remain part of the problem, and by government to recognize that by diverting a comparatively modest part of their national budgets to providing, at a modest cost, CEOC, they will be helping to save countless thousands of lives.

Acknowledgments

The section of this chapter dealing with the FIGO Project is based on material originally supplied and written by the members of the country teams concerned, to whom due acknowledgment must be made.

201 Vesico-vaginal fistulas in developing countries

P. Hilton

Introduction

Although it is likely that vesico-vaginal fistula (VVF) of obstetric etiology was known to the physicians of ancient Egypt, the association with difficult labor was not made until 1000 AD when it was described by the Perso-Arab physician Avicenna (Ibn Sinna) in his text 'Al Kanoun'.

Since then the literature on this subject has been extensive, although largely based on anecdote, small retrospective case series, and opinions rather than facts. As a result, much of our knowledge and practice in this area is based on the experience of a small number of individuals working in areas of high fistula prevalence, rather than firm scientific evidence.

Etiology and epidemiology

Urogenital fistulas may occur congenitally, but are most often acquired from obstetric, surgical, radiation, malignant, and miscellaneous causes. In much of the developing world over 90% of fistulae are of obstetric etiology,[1–4] whereas in the UK and USA over 70% follow pelvic surgery.[5]

Obstetric fistulas

The basic physical factors responsible for obstetric fistula include obstructed labor, accidental injury at the time of caesarean section, forceps delivery, craniotomy, symphysiotomy, traditional surgical practices including circumcision and gishiri, and complications of criminal abortion.

The overwhelming proportion of cases are complications of neglected obstructed labor. During normal labor the bladder is displaced upwards and the anterior vaginal wall, bladder base, and urethra are compressed between the fetal head and the posterior surface of the pubis. No harm results if compression lasts for a short time, but in prolonged obstructed labor the intervening tissues are devitalized by ischemia. Usually the anterior vaginal wall and underlying bladder neck are affected, although sometimes the area of necrosis is higher, in which case the anterior lip of the cervix and underlying trigone are involved. The devitalized area separates as a slough, usually between the third and 10th day of the puerperium, with resulting fistula formation and incontinence (see Figures 201.1 and 201.2).

In other instances accidental injury to the vaginal wall occurs during a difficult operative delivery and may involve damage to the underlying bladder wall, particularly if the tissues are devitalized by prolonged pressure. Forcible rotation of the head with Kielland's

Figure 201.1 Area of slough on anterior vaginal wall 5 days following delivery.

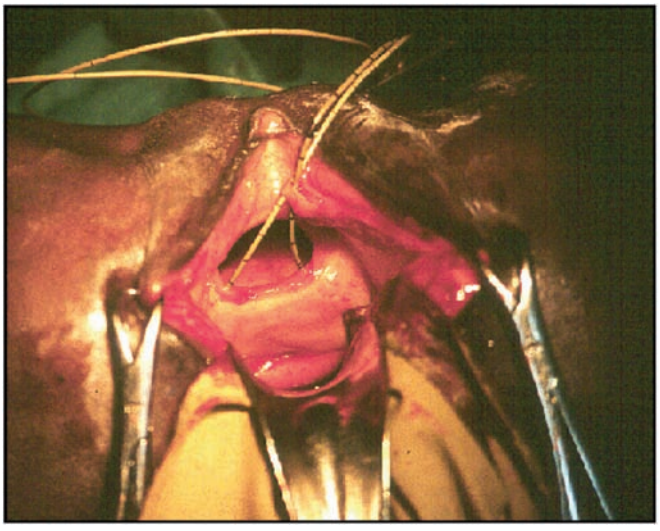

Figure 201.2 Large obstetric fistula involving the whole urethra and bladder base, up to the level of the ureteric orifices.

forceps is particularly liable to produce such an injury by shearing stresses. The bladder is exposed to injury following symphysiotomy if the pubic bones are too widely separated by forced abduction of the thighs. In these circumstances the unsupported bladder neck is very likely to be damaged especially if the head is rotated and extracted with forceps. The posterior wall of the bladder may be accidentally incised during lower segment cesarean section or repair of ruptured uterus, particularly if the bladder is not reflected sufficiently far downwards before the lower uterine segment is opened. Alternatively, sutures may be passed through the posterior bladder wall during repair of the uterine incision. The appearance of urinary incontinence in such cases is delayed until the intervening bladder tissue is caught up in the suture sloughs.

Traditional surgical practices play a significant role in the etiology of obstetric fistulas in several parts of Africa. The practice of yankan gishiri is still commonly employed among the Hausa, Fulani and Kanuri tribes of northern Nigeria. The traditional cut made with a razor blade or knife through the vaginal introitus is sometimes superficial, but still may result in fistula formation. Since the procedure is usually made by linear incision into healthy tissues, repair is often much easier than those fistulas which result from pressure necrosis (see Figure 201.3).

Female circumcision is practiced in various forms in much of North Africa, and is widespread in Sudan and other Moslem cultures. The most extreme form, pharaonic circumcision, involves removal of the labia minora, most of the labia majora, the mons veneris, and often the clitoris, the introitus being reduced to pinhole size. Coitus itself may result in perineal rupture and may be a primary cause of fistula formation. Delivery will often necessitate wide episiotomy, often with an anterior incision. Intuitively one might expect this to contribute to the development of both VVF, and recto-vaginal fistulas or third-degree tears, particularly where skilled obstetric care is not available; however, the exact relevance of female circumcision to obstetric VVF remains unclear. Tahzib reported on the epidemiological determinants of VVF in women and children in northern Nigeria.[6,7] In over 80% of cases obstructed labor was the major etiological factor; one-third of the total had undergone gishiri, and in 15% this was felt to be the main etiological factor.

In considering obstetric fistulas, however, it is equally relevant to consider the social, cultural and geographical influences of this condition. Obstructed labor is most often due to a contracted pelvis. This usually results from stunting of growth by malnutrition and untreated infections in childhood and adolescence. Where women retain a subservient role in society, and standards of education are limited, early marriage and the absence of family planning results in early childbearing. First pregnancies occur soon after menarche, before growth of the pelvis is complete, accentuating this risk. It is however important to recognize that whilst fistula are of high prevalence in areas where the educational and nutritional status of women is poor, where traditional surgical practices abound, and where early marriage, early childbearing and poor access to health care are the norm, these factors are not necessarily in themselves causative. In a case–control series from northern Nigeria it was found that whilst VVF patients had a lower educational and socioeconomic status than control women, age at marriage and first pregnancy, and uptake of antenatal care were not different.[8]

Surgical fistulas

Genital fistula may occur following a wide range of surgical procedures within the pelvis. The contribution of surgical fistulas to the total fistula prevalence in developing countries is small, however. It is often supposed that this complication results from direct injury to the lower urinary tract at the time of operation but this is certainly not always the result of careless, hurried, or rough surgical technique. Of the 165 urogenital fistulas referred to the author over the last 12 years, 117 have been associated with pelvic surgery, and 91 followed hysterectomies; of these only four (4%) presented with leakage of urine on the first day postoperatively. In the other cases it was presumed that tissue devascularization during dissection, inadvertent suture placement, or pelvic hematoma formation or infection developing postoperatively resulted in tissue necrosis with leakage usually developing 5–14 days later. Overdistension of the bladder postoperatively may be an additional factor in many of these latter cases.[9] It is likely that patients with a habit of infrequent voiding, or those with inefficient detrusor contractility, may be at increased risk of postoperative urinary retention; if this is not recognized early and managed appropriately, the risk of

Figure 201.3 Urethro-vaginal fistula following 'gishiri cut'.

fistula formation may be increased. The use of prophylactic catheterization in the first 24–48 h might be expected to reduce the risk of postoperative fistula formation, but this has never been proven.

Radiation fistulas

The obliterative endarteritis associated with ionizing radiation in therapeutic dosage proceeds over many years and may result in a fistula long after the primary malignancy has been treated. Of the 19 radiation fistulas in the author's series, leakage developed at intervals between 1 and 30 years following radiotherapy. The associated devascularization in the adjacent tissues means that ordinary surgical repair has a high likelihood of failure,[10] and modified surgical techniques are required.

Malignant fistulas

Excluding the effects of treatment, malignant disease itself may result in genital tract fistula, particularly in areas where primary health care and screening programs are absent or ineffective. Carcinoma of cervix, vagina and rectum are the most common malignancies to present in this manner. It is relatively unusual for urothelial tumors to present with fistula formation, other than following surgery or radiotherapy. Although the development of a fistula may be a distressing aspect of the terminal phase of malignant disease, it is nevertheless deserving of a full consideration of the therapeutic or palliative possibilities rather than simply compassion.

Miscellaneous causes

Miscellaneous causes of fistulas in the genital tract include infection (lymphogranuloma venereum, schistosomiasis, tuberculosis, actinomycosis, measles, noma vaginae), trauma (penetrating trauma, coital injury, neglected pessary, or other foreign bodies), and catheter-related injuries.

Prevalence

The prevalence of genital fistulas varies from country to country and continent to continent, just as the main causative factors vary. In the developing world, many fistula cases never come to medical attention, as these women are separated from their husbands and ostracized from society. Although the true prevalence in the developing world is unknown, high prevalence rates have been reported from Sudan,[11] Ethiopia,[12] Chad,[13] Ghana,[3] and Nigeria.[6] An incidence of 1–2 per 1000 deliveries has been estimated worldwide, with an annual incidence of 50,000–100,000 and a prevalence of untreated fistulas of 500,000–2,000,000.[14] The incidence of fistulas clearly relates to the level of maternity care. Areas with high maternal mortality also tend to have high fistula rates. Danso *et al.* have suggested that a more realistic estimate of the incidence of fistulas in any community might be that it approaches the maternal mortality rate.[3] If this were true the annual incidence worldwide might approach 500,000.

The rate of fistula formation following hysterectomy has been calculated as between 1 per 642 (from the author's fistula cases) and 1 per 1330 operations in the UK (J. B. Lawson, 1990, personal communication). Figures of between 1% and 4% fistulas have been reported following radical hysterectomy,[15,16] with a similar incidence following radiation for gynecological malignancies.[17] The incidence of fistula formation following pelvic exenteration may be as high as 10%.[18]

Investigation

The four cardinal principles of investigation are simple: (1) confirm that the discharge is urinary; (2) confirm that leakage is extra-urethral; (3) identify site of leakage; and (4) identify or exclude multiple or complex fistulous tracks.

Investigation has traditionally been undertaken by dye testing, examination under anesthesia, cystourethroscopy, and intravenous urography. Phenazopyridine may be used orally or indigo carmine intravenously to stain the urine and hence confirm the presence of a fistula. The identification of the fistula site is best carried out by the instillation of colored dye (usually methylene blue) into the bladder with the patient in the lithotomy position. The traditional 'three swab test' has limitations and is not recommended; examination is best carried out with direct inspection. If leakage of clear fluid continues after dye instillation a ureteric fistula is likely, and this is most easily confirmed by a 'two dye test', using phenazopyridine to stain the renal urine, and methylene blue to stain bladder contents.[19]

Although intravenous urography is a particularly insensitive investigation for the diagnosis of VVF, assessment of upper urinary tract status may have a significant influence on treatment measures applied (see Figure 201.4). Where x-ray facilities are available, this test should be viewed as an essential part of the investigation. Some authorities would go so far as to advocate bilateral retrograde pyelography in the assessment of all VVFs. Compromise to ureteric function is a particularly common finding when a fistula occurs in relation to malignant disease or its treatment. Whilst this recommendation is not possible in much of the world, it remains underutilized where facilities are available.

Management

Immediate management by catheter drainage

An abnormal communication between viscera will tend to close spontaneously before epithelialization is complete, provided that the natural outflow is unobstructed. Bypassing the urethral sphincter mechanisms by catheterization may encourage early closure, especially in cases where the fistula is small. Obstetric fistulas developing after obstructed labor should be treated initially by continuous bladder drainage, combined with antibiotics to limit tissue damage from infection. Indeed, if a patient is known to have been in obstructed labor for any significant length of time, or is recognized to have areas of slough on the vaginal walls during the puerperium, prophylactic catheterization should be undertaken before the development of a fistula. This should be maintained for 6–8 weeks, since spontaneous closure in both surgical and obstetric cases may occur within this period.[14,20,21] Indeed, spontaneous closure of obstetric fistulas has been reported in up to 28% of cases where catheterization has been employed.[22]

Palliation and skin care

The vulvar skin is at considerable risk from ammoniacal dermatitis in fistula patients, and liberal use of barrier creams should be encouraged (see Figure 201.5). Steroid therapy was advocated in the past as a means of reducing tissue edema and fibrosis, although these benefits have been refuted more recently, and there may be a risk of compromise to subsequent healing. Local estrogen cream has been recommended by some authors, and whilst empirically one might expect benefit in postmenopausal women or those obstetric fistula patients with prolonged amenorrhea, the evidence for this is lacking.

Nutrition

Because of social ostracism and the effects of prolonged sepsis, patients with obstetric fistulas may also suffer from malnutrition and anemia. In order to maximize the prospects for postoperative healing, it is essential to optimize the general health of the patient. The admission of fistula patients to preoperative hostel facilities is encouraged by several of the larger third world fistula units. Where nursing staffs are

Figure 201.5 Ammoniacal dermatitis.

limited, family members may be required to help with cooking and general support.

Physiotherapy

Early involvement of the physiotherapist in preoperative management and rehabilitation of such patients is essential, as obstetric fistulas are commonly associated with lower limb weakness, foot drop and limb contracture. In a group of 479 patients studied prospectively, 27% had signs of peroneal nerve weakness at presentation, and a further 38% gave a history of relevant symptoms.

Antimicrobial therapy

Opinions differ on the desirability of prophylactic antibiotics at the time of surgery. Some authors avoid their use except for the treatment of specific infection; others advocate broad-spectrum treatment in all cases. One randomized trial of antibiotic prophylaxis in obstetric fistula patients from West Africa failed to show benefit.[23] The author's current practice is single-dose prophylaxis in urinary fistulas, and 5-day coverage for intestinal fistulas.

Counseling

Confident but realistic counseling by the surgeon is essential. Of equal importance is the involvement of nursing staff or counselors with experience of fistula patients. In addition, support from previously treated patients can be of immense value in maintaining patient morale, especially where a delay prior to definitive treatment is required.

General principles of surgical treatment

Timing of repair

The timing of surgical repair is perhaps the single most contentious aspect of fistula management. Whilst shortening the waiting period is of both social and psychological benefit, one must not compromise surgical success. The benefit of delay is to allow slough to separate and the inflammatory changes to resolve. Considerable sloughing of tissues occurs in both obstetric and radiation fistulas and it is imperative that this should have ceased before repair is undertaken. Most authorities suggest that a minimum of 3 months should be allowed to elapse in obstetric cases, although others advocate surgery as soon as the slough is separated.[14] It may be necessary to wait 12 months or more in radiation fistulas.

The same principles should apply with surgical fistulas. Here, although the extent of sloughing is limited, extravasation of urine into the pelvic tissues invariably sets up some inflammatory response. Although several authors advocate early repair most would agree that 10–12 weeks after the inciting event is the earliest appropriate time for repair.

Route of repair

Arguments continue as to whether the abdominal or vaginal route is most appropriate for fistula repair. Two recent small and uncontrolled studies suggested advantage from the abdominal transvesical[24] and transperitoneal[25] approaches. Recognizing that other authorities recommend the vaginal route,[2,26] these two series acknowledge the need for individualized management based upon anatomical relationships, extent of injury, and comorbidities. Larger series of obstetric[1,2] and surgical[5] fistulas indicate high success rates with the vaginal approach.

Regardless of personal preferences, surgeons involved in fistula management should be capable of all approaches, and must have the versatility to modify their techniques in order to select that most appropriate to the individual case. When access is good and vaginal tissues are sufficiently mobile, the vaginal route is usually most appropriate. If access is poor and the fistula cannot be brought down, on the contrary, the abdominal approach should be used. Overall more surgical than obstetric fistulas are likely to require an abdominal repair, although in the author's series of cases from the UK,[5] and those reviewed from Nigeria,[2] two-thirds of cases were satisfactorily treated by the vaginal route regardless of etiology.

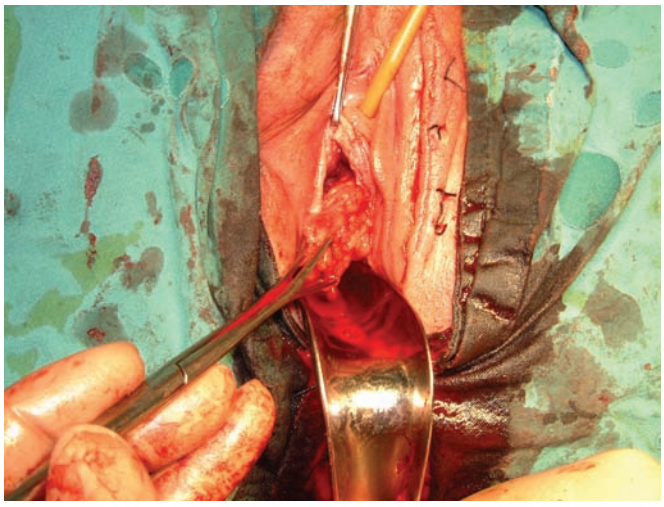

Figure 201.6 Martius bulbocavernous muscle/fat graft passed subcutaneously from left labium majus to overlie fistula repair.

Interposition grafts

Several techniques have been described to support fistula repair in different sites. In each instance, the interposed tissue serves to create an additional layer in the repair, to fill dead space, and to bring in new blood supply to the area. As such, interposition grafts have been most commonly in use in the repair of radiation fistulas, or to limit scarring and reduce postfistula repair stress incontinence in patients with urethral and bladder neck fistulas. The tissues used include: (a) labial fat and bulbocavernosus muscle passed subcutaneously to cover a vaginal repair (Martius graft)[27] (see Figure 201.6); (b) gracilis muscle, either passed via the obturator foramen[28] or subcutaneously[29] or rectus abdominis muscle[30] – both used in repairs by the vaginal route; (c) omental pedicle grafts[31,32] from the greater curve of the stomach and rotated into the pelvis on the right gastroepiploic artery (these may be used at any transperitoneal procedure, but have greatest advantage in postradiation fistulae); (d) peritoneal flap grafts[33] provide an additional layer for transperitoneal repair procedures by taking a flap of peritoneum from any available surface, most usually the paravesical area; (e) a pedicled flap of vaginal wall[34] (although the results were good in this case, concern exists over the risk of subvaginal cyst formation in the buried vaginal tissue); and (f) free bladder mucosal grafting.[35]

The role of interposition flaps in transabdominal repair procedures has recently reviewed by Evans *et al.*[36] These authors reported 37 patients with fistulas of largely surgical etiology. All of the 12 treated employing an omental or peritoneal interposition flap were cured, compared with 16 cures among 25 managed without interposition (64%). This finding was consistent for fistulas of both benign and malignant etiology. The authors acknowledge that their overall cure rate (75%) is lower than many series. Despite this, they recommend an interposition flap regardless of fistula etiology when a transabdominal repair is undertaken, particularly when the repair is performed by a surgeon without extensive prior experience.

Rangnekar *et al.* evaluated the role of the Martius graft in vaginal repair procedures in a series of mainly obstetric fistulas from Mumbai, India.[37] Forty-six cases were reviewed retrospectively, of which 12 were urethro-vaginal and 34 vesico-vaginal; a Martius graft was employed in 21 instances. Overall, 95% of those treated with a graft were cured, compared with 72% of those with simple anatomic repair. Despite small numbers, the authors of this series recommend the use of an interposition graft, particularly for urethro-vaginal fistulas and in patients with recurrent or multiple fistulas.

The difficulty with case series such as those cited here is that the use of grafting has not been randomized, and reflects the personal prejudices of the surgeon as to which patients are most likely to benefit form the procedure. In the author's practice, it has been standard for the last 15 years, to use a labial fat graft in all urethral and bladder neck fistulas, and an omental graft in VVFs treated by the transperitoneal approach, but not in those treated by either the vaginal or abdominal transvesical routes. With this approach, the cure rate at first operation has been 95% for those cases treated with a graft, and 97% for those where a graft has not been used. There were also no significant differences in cure rate between the urethral and bladder fistulas, or between primary and recurrent fistulas.

Urinary diversion

The acceptability of permanent urinary diversion in most developing countries is extremely limited, and the need is infrequent. In the series of cases from southeast Nigeria cited previously, only 0.6% of 2484 patients required diversion.[2] In a review of 55 cases from Denmark, Langkilde *et al.* report 90% success using either vaginal or transvesical approaches in postsurgical fistulas, but only 14% success in postradiation fistulas.[10] As a consequence, they advocate ileal conduit urinary diversion as the method of choice for the latter cases. Although currently 12% of patients with VVF undergo a diversionary procedure in the UK,[38] the requirement for urinary diversion in fistula patients should be very uncommon, and in series of both surgical[5] and obstetric[2] cases is less than 3%.

Specific repair techniques

Vaginal procedures

Dissection and repair in layers. Two main types of closure are applied to the vaginal repair of urinary fistulas, the classical saucerization technique described in 1852 by Sims (see below),[39] and the much more commonly used dissection and repair in layers. In this latter procedure sutures must be placed

with meticulous accuracy in the bladder wall, care being taken not to penetrate the mucosa which should be inverted as far as possible. The repair should be started at either end, working toward the midline, so that the least accessible aspects are sutured first. Interrupted sutures are preferred and should be placed approximately 3 mm apart, taking as large a bite of tissue as feasible. Stitches that are too close together, or the use of continuous or purse-string sutures, tend to impair blood supply and interfere with healing. Knots must be secure with three hitches, so that they can be cut short, leaving the minimum amount of material within the body of the repair. With dissection and repair in layers the first layer of sutures in the bladder should invert the edges; the second adds bulk to the repair by taking a wide bite of bladder wall, but also closes off dead space by catching the back of the vaginal flaps. After testing the repair, a third layer of interrupted mattress sutures is used to evert and close the vaginal wall, consolidating the repair by picking up the underlying bladder wall.

Saucerization. The saucerization technique described by Sims involves converting the track into a shallow crater, which is closed without dissection of bladder from vagina using a single row of interrupted sutures. The method is only applicable to small fistulas and perhaps residual fistulas after closure of a larger defect; in other situations the technique does not allow secure closure without tension.

Vaginal repair procedures in specific circumstances

The conventional dissection and repair in layers described above is entirely appropriate for the majority of mid-vaginal fistulas, although modifications may be necessary in specific circumstances. In juxta-cervical fistulas in the anterior fornix vaginal repair may be feasible if the cervix can be drawn down to provide access. Dissection should include mobilization of the bladder from the cervix. The repair must be undertaken transversely to reconstruct the underlying trigone and prevent distortion of the ureteric orifices.

Vault fistulas, particularly those following hysterectomy, can again usually be managed vaginally. The vault is incised transversely and mobilization of the fistula is often aided by deliberate opening of the Pouch of Douglas.[40] The peritoneal opening does not require to be closed separately, but is incorporated into the vaginal closure.

Tissue loss may be extensive with subsymphyseal fistulas involving the bladder neck and proximal urethra as a consequence of obstructed labor, and fixity to underlying bone is a common problem. The lateral aspects of the fistula require careful mobilization to overcome disproportion between the defect in the bladder and the urethral stump. A racquet shape extension of the incision facilitates exposure of the proximal urethra. Although transverse repair is often necessary, longitudinal closure gives better prospects for urethral competence.

Where there is substantial urethral loss, reconstruction may be undertaken using the method described by Chassar Moir,[41] or Hamlin and Nicholson.[29] A strip of anterior vaginal wall is constructed into a tube over a catheter. Plication behind the bladder neck is probably important if continence is to be achieved. The interposition of a labial fat or muscle graft not only fills up the potential dead space, but provides additional bladder neck support and improves continence by reducing scarring between bladder neck and vagina.

The extensive dissection required with very large fistulas extending from the bladder neck to the vault may produce considerable bleeding. The main surgical difficulty is to avoid the ureters. They are usually situated close to the supero-lateral angles of the fistula, and if they can be identified they should be catheterized. Straight ureteric catheters passed transurethrally, or double pigtail catheters may both be useful in directing the intramural portion of the ureters internally.

Radiation fistulas present particular problems in that the area of devitalized tissue is usually considerably larger than the fistula itself. Mobilization is often impossible, and the flaps are likely to slough if repair in layers is attempted. Closure by colpocleisis is usually required. Some authors advocate total closure of the vagina although it is preferable to avoid dissection in the devitalized tissue entirely and to perform a lower partial colpocleisis converting the upper vagina into a diverticulum of the bladder. It is usually necessary to fill the dead space below this with an interposition graft.

Abdominal procedures

Transvesical repair. Repair by the abdominal route is indicated when high fistulas are fixed in the vault and are inaccessible *per vaginam*. Transvesical repair has the advantage of being entirely extraperitoneal. It is often helpful to elevate the fistula site by a vaginal pack, and the ureters should be catheterized under direct vision. The technique of closure is similar to that of the transvaginal flap-splitting repair except that for hemostasis the bladder mucosa is closed with a continuous suture.

Transperitoneal repair. It is often said that there is little place for a simple transperitoneal repair, although a combined transperitoneal and transvesical procedure is favored by urologists and is particularly useful for VVF following cesarean section. A midline split is made in the vault of the bladder; this is extended downward in a racquet shape around the fistula. The fistulous track is excised and the vaginal or cervical defect closed in a single layer. The bladder is then closed in two layers.

Results

It is difficult to compare the results of treatment in different series, since the lesions involved and the techniques of repair vary so greatly. Cure rates should be considered in terms of closure at first operation; these vary from 60% to 98%. Of the 165 patients in the author's series managed in the UK, 12 (7.2%) healed without operation, nine declined surgery, one (with coexistent detrusor instability) was asymptomatic on medical treatment, three underwent primary urinary diversion, and two patients with radiotherapy fistulae died without being operated upon (one from recurrent disease and one from cachexia without recurrence). Of the remaining 138 who underwent repair surgery, 133 (96%) were cured by the first operation. Of the 71 fistulas occurring after simple hysterectomy, 99% were cured at their first operation.

As in many other forms of surgery a law of diminishing returns is evident in fistula repair. Although repeat operations are certainly justified, the success rate decreases progressively with increasing numbers of previous unsuccessful procedures. Unfortunately, individual surgical series are rarely large enough for this fact to be evident. In one series of 2484 largely obstetric fistulas, the success rate fell from 81% for first procedures to 65% for those requiring two or more procedures.[2]

Postfistula stress incontinence

The occurrence of stress incontinence in patients following successful repair of obstetric VVF is well known, and estimated to range from 10% to 12%. Waaldijk documented the occurrence of postfistula stress incontinence in fistulas of varying type in a Nigerian population, describing 1% incidence where there was no sphincter involvement in the fistula, 13% incidence where there was sphincter involvement without tissue loss, and 16% incidence where there was both sphincter involvement and tissue loss.[1] Because of concern over the possible incidence of functional abnormalities of the lower urinary tract following fistula repair in the UK and the need to appropriately counsel patients prior to repair, Hilton undertook a series of urodynamic investigations in 30 patients with urogenital fistulas prior to repair.[9] Only one in six had normal findings, with 47% showing urodynamic stress incontinence, 40% detrusor instability, and 50% voiding dysfunction; those with urethral or bladder neck fistulas had the highest incidence of abnormality. Following repair of the fistulas in this small group of patients, stress incontinence persisted in 11%, and detrusor overactivity in 50% of those urethral fistula patients who had had these diagnoses prior to repair. In another series of urodynamic investigations in 30 women with persistent incontinence following anatomically successful repair of obstetric fistulas from Ethiopia, 31% had urodynamic stress incontinence, 4% detrusor overactivity, and 20% mixed incontinence.[42] In a long-term 'quality of life' follow-up of previously treated fistula patients in the UK, whilst seriously bothersome residual urinary symptoms were most uncommon, mildly bothersome symptoms were reported by 75% of patients.[43] Whilst the extrapolation of outcomes from patients with surgical fistulas in the UK to those with obstetric fistulas in the developing world might be questioned, it is unlikely that functional outcomes in the latter group would be better.

There have been a number of recent reports describing techniques for the management of postfistula repair stress incontinence. These range from the relatively minimally invasive peri-urethral injection of autologous fat,[44] to a combined retropubic urethrolysis, fascial sling, and omental graft.[45] Most recently Browning has reported on the use of a sling procedure at the time of fistula for prophylaxis against postoperative stress incontinence, in women felt to be at particular risk for this complication.[46]

Subsequent pregnancy

Although many patients with obstetric VVF experience amenorrhea for 2 years or more after the causative pregnancy,[2] hypothalamic function often returns to normal immediately after successful repair if tissue loss is not great, and fertility may be relatively normal. The need for cesarean section in any subsequent pregnancy has been emphasized.[47] Kelly, however, reported 33 patients who became pregnant within 1 year of fistula repair, 12 of whom were delivered vaginally without damage to the repair.[48] The criteria he used for attempting vaginal delivery were that the fistula arose from a non-recurring cause (i.e. malpresentation as opposed to absolute pelvic contraction), that an interposition graft had been utilized in the repair, and that the labor is conducted under skilled supervision in hospital.

National and international strategies

The World Health Organization estimates that approximately 500,000 maternal deaths occur each year worldwide. It is clear that the prevalence of obstetric fistulas and maternal mortality rates are closely related. Indeed, one might consider the VVF patient as being the 'near miss' maternal death. In recognition of this fact, WHO established, through their 'Safe Motherhood Initiative', a technical working group to investigate the problems of prevention and management of obstetric fistulas. The recommendations from this working group included the extension of antenatal and intrapartum care, the transfer of women in prolonged labor for delivery by skilled personnel, the identification of areas where fistulas are still

prevalent, so that resources could be mobilized to deal with fistulas more effectively, and the creation of specialized centers for management, training and research.[49]

Certainly obstetric fistulas would disappear if early intervention in obstructed labor were available and acceptable throughout the world. It has been pointed out, however, that this would require the establishment of some 75,000 obstetric units throughout Africa.[50] In addition to the provision of services for fistula management however, the achievement of the WHO's aims and recommendations is critically dependent on major social changes in areas where fistulas are most prevalent. These changes must include government recognition of fistulas as a major public health concern, improvement in the status of women in society, the extension of primary education for girls, deferment of marriage and childbearing, the abolition of female genital mutilation, improved nutritional status and contraceptive services, and affordable, accessible and acceptable services for all pregnant women.[51] These socio-political issues were the main concerns of an international workshop on fistula management and prevention in Abuja.[52]

202 Traditional birth attendant training

P. Buekens

Introduction

The training of traditional birth attendants (TBAs) was a priority strategy to reduce maternal and newborn mortality and morbidity in the late 1970s and throughout the 1980s, but its effectiveness is now questioned by many. Yet, little scientific evidence is available to support the enthusiasm of the past and the criticisms of today.[1] In many developing countries, the majority of the deliveries are not performed by health professionals.[2] Training TBAs seems thus a logical thing to do.

The term 'TBA' was coined by the international health development community and includes the vast array of birth attendants throughout the world who have not received formal Western medical training.[3] A shortcoming of the term is that it gives the impression that TBAs are one unified body of birth attendants and that health professionals have a choice of whether or not to collaborate with them. In fact, TBAs are quite heterogeneous and play such a central role in many societies that ignoring them does not seem realistic.

The role of TBAs varies across communities. In some cultures, TBAs only attend a few deliveries a year among family members, while in others they have a broader role.[1] On average, 24% of births were attended by TBAs in countries where data from 1995–2002 Demographic and Health Surveys were available, but the frequency varied from less than 1% to over 90%.[4] In most countries, TBAs do not provide prenatal care, with the exception of Guatemala, Honduras and Mexico.[5,6]

TBAs are an important source of social and cultural support to women, and the role of TBAs in providing support during childbirth is potentially important.[1] Support provided by TBAs could be compared with the support provided by 'doulas' or other accompanying persons during labor. A meta-analysis of 15 randomized trials concluded that continuous support for women during childbirth was associated with a reduction in the length of labor, better Apgar scores, increased women's satisfaction and increased breast feeding at 4–6 weeks.[7]

Clean delivery kits

The goal of TBA training is to improve each individual's skills and to strengthen links within the health care system.[1] Training programs put emphasis on infection prevention and include such approaches as the promotion of the 'three cleans' (Table 202.1) and the provision of clean delivery kits (CDKs).[8,9] CDKs generally include soap, a plastic sheet (1×1 m), a new razor blade and clean cord ties. A CDK that is packed in a sturdy plastic bag and includes pictorial instructions is available from UNFPA Procurement Services, and the kits can be produced locally as well (Figure 202.1).[8,9] In Nepal, the rate of cord infections found in deliveries that utilized CDKs was less than half of the infection rate among non-users who did not use a new or boiled razor blade and a clean cutting surface.[10] However, more than 90% of non-users did in fact use a new or boiled blade to cut the cord. Another study from Nepal suggests that CDKs have a limited influence on hygiene practices, as the majority of the respondents were not aware that the soap provided in the kit was intended for washing their hands during the delivery rather than for bathing the infant after delivery.[11] In rural Bangladesh, training TBAs in clean delivery did not prevent postpartum infection.[12] Furthermore, although a clean delivery should decrease the risk of maternal and neonatal tetanus, immunization with tetanus toxoid is overwhelmingly superior.[1]

Table 202.1 'Three cleans' and clean delivery kits[8,9]

'Three cleans'	clean delivery kit
1. Clean hands	Soap
2. Clean delivery surface	Plastic sheet
3. Clean cord cutting	New razor blade
	Clean cord ties

Figure courtesy of Program for Appropriate Technology in Health.[9] Step 1: Measuring string for cord ties; Step 2: Cutting string; Step 3: Wrapping cord ties and razor blade into paper packet; Step 4: Cutting soap pieces; Step 5: Cutting sheets of papers into squares; Step 6: Placing wrapped components into kit plastic bag; Step 7: Placing the pictorial instruction sheet into kit plastic bag; Step 8: Sealing kit plastic bag with candle flame; Step 9: Placing delivery kits in large plastic bags for storage.

Prevention and treatment of postpartum hemorrhage

Postpartum hemorrhage is a major cause of maternal mortality, and TBAs should refer bleeding women to an essential obstetric care facility.[1] Unfortunately, timely referrals are not always feasible, as transportation is difficult to obtain and essential obstetric care facilities are often unavailable. This is a major limitation in the role of TBAs. Early suckling and nipple stimulation have been proposed as simple alternatives to uterotonics, but a trial randomizing 23 TBAs to an early suckling intervention group and 26 TBAs to a control group did not show any difference in blood loss between the groups.[13] One alternative currently under study is the potential postpartum use of misoprostol.[14–16] A prostaglandin E_1 analog with strong uterotonic effects, misoprostol can be taken orally or administered rectally, does not require refrigeration and is not contraindicated for hypertensive patients.[16] However, for active management of the third stage of labor, oral misoprostol 600 μg has been shown to be less effective than injectable uterotonics, and trials comparing misoprostol vs. no uterotonics or a placebo were inconclusive.[17] Shivering, pyrexia, nausea and vomiting are common but not severe side-effects of misoprostol. Potential misuse of misoprostol during the first and second stage of labor is a concern.[18] However, a field demonstration project conducted in Indonesia suggests that self-administration of misoprostol is feasible.[15] Community health workers distributed misoprostol and counseling material to women for self-administration after delivery. Additionally, the use of misoprostol for managing postpartum hemorrhage rather than preventing it is promising and is under study.[15,16] A Tanzania study is examining the use of 1000 μg of misoprosotol administered rectally by TBAs when blood loss is greater than 500 ml.[15] It is too early to recommend making misoprostol widely available to TBAs until studies in the community show that it is both safe and effective.

Referral

A key element of TBA training should be the identification of obstetric complications and their referral. The

author's experience in Burkina Faso suggests that TBAs can indeed detect complications and refer women.[19] However, a meta-analysis of 16 studies showed that the effect of TBA training on the referral of women with obstetric complications is relatively small.[4] Another meta-analysis suggested that TBAs may play a role in referring women to professional prenatal care during pregnancy.[20] The availability of an essential obstetric care unit to which the women can be referred is a necessary condition for TBAs to be effective.[1,21]

Impact on health outcomes

Evaluating the impact of TBA training on health outcomes is difficult. One of the challenges is that very large sample sizes are needed to study an impact on maternal mortality, which is a relatively rare event. Many evaluations have thus been focused on process rather than on outcome. A meta-analysis recently published by Sibley and Sipe summarized the results of 60 studies of the effectiveness of TBA training.[22,23] The data suggest that TBA training is associated with substantial improvement in TBA's 'knowledge, attitudes, behavior and advice'. There was also a small (8%) decrease in perinatal or neonatal mortality associated with training. Two studies included data on maternal mortality, and the meta-analysis concluded that there were 8% fewer deaths among women cared for or living in areas served by trained TBAs. However, the studies were not randomized controlled trials, and thus were not rigorous enough to firmly establish a causal relationship between TBA training and improved health outcomes. The results of this meta-analysis suggest that the impact of TBA training should not be expected to be large.

Conclusion

In addition to having a limited impact, TBA training programs are expensive and are difficult to sustain if not funded by international donors.[1] Thus, TBA training should not be given a high priority. While there is no single magic solution that will make pregnancy safer in developing countries, programs need to be multifaceted and improve every level of health care. As such, TBAs should not be ignored and should be trained and linked to the health system whenever possible.

Acknowledgments

The author thanks Jose Belizan, Richard Derman and Lynn Sibley for their comments and suggestions.

203 Collaborative perinatal neonatal networking in the Eastern Mediterranean Region

K. A. Yunis, G. Mumtaz, H. Tamim and A. Adra

Introduction

Maternal and perinatal health remain major contributors to the global burden of disease, on a par with HIV, tuberculosis, and malaria. The annual global burden of neonatal deaths is estimated at about four million, 98% of which occur in the developing countries.[1] In the Eastern Mediterranean Region (EMR) maternal and perinatal conditions rank second among the leading causes of death, as they account for 8.8% of all deaths.[2] About 99% of the half million women who die annually from pregnancy or childbirth complications occur in low- and middle-income countries.[3]

While developing countries suffer from the greatest load of the world's health burden, they have the least capacity to carry out quality research and to generate nation-specific data that will allow them the identification of their own health problems and priorities.[4] The first recommendation by the Commission on Macroeconomics and Health[5] is that 'Developing countries should begin to map out a path to universal access for essential health services based on epidemiological evidence and the health priorities of the poor', stressing the importance of scientific research in identifying national priorities.

Furthermore, most developing countries lack high-quality routine statistics that provide a consistent and continuous system of assessment that constitutes the first step in planning appropriate health strategies. Poverty, the lack of health care infrastructure and the limited resources are enormous barriers faced by governments trying to implement such systems. Statistics are mostly based on models or *ad hoc* surveys, with minimal training of personnel on interpretation of findings and few follow-up interventions. The sample sizes of *ad hoc* studies are often too small to allow decentralized problem identification and planning. In such settings with fragmented care and weak government regulation and capacity, research networks are likely to be one of the few successful approaches to building an infrastructure for evidence-based decision and policy making.

The multidimensional nature of the medical field makes networking in medicine very attractive and efficient. Practice, policy, education, and research are different facets of the domain. As a result, the relationships between these factors cannot be ignored and cannot be considered as separate items. The combination of resources from all dimensions and the collaboration of all persons within these dimensions are necessary to accomplish strength and productivity.

International experience has proven that building up regional networks among academic, research and health care institutions allows an accurate and continuous assessment of the population health status and is an efficient approach to respond to growing economic constraints faced by developing countries. Identification of common problems, pooling of resources and addressing solutions collectively increase the problem-solving potential of these countries. These South–South alliances contribute significantly to capacity building and are the basis for sustainable development. In this chapter, we present the experience of a perinatal neonatal network established in Lebanon as a model for a successful approach to research in the EMR.

Defining networks

A network is an infrastructure where individuals, institutions or organizations that have similar issues, aspirations or problems join their efforts to collaborate, share information and expertise, find solutions

and as a result improve the quality of their services to reach higher standards in their quest for excellence. Flexibility and collaboration alongside with having a systematic structure and a long-term perspective are crucial concepts in insuring a network's scientific self-sufficiency and, most importantly, sustainablitiy.[6]

At the core of their activities, networks maintain databases. Collaborative databases provide a rich and functional resource for analysis and constitute a solid infrastructure to assess the impact of maternal and neonatal health care over time, carry out intervention programs aiming at improving perinatal health and health care, conduct multicenter randomized controlled research trials, efficiently practice continuous quality improvement, help member institutions reach national and international accreditation standards and most importantly, it helps in defining and implementing national health care policies based on accurate primary data.

Examples of existing networks in the world

Networking in research is not a novel approach. It has been applied in both developed and developing parts of the world and has proven successful. Examples of perinatal neonatal networks include the Vermont Oxford Neonatal Network (VON) which includes over 450 neonatal intensive care units across the world, the Latin American Center for Perinatology and Human development (CLAP) whose database covers information on more than one million births from hospitals in 19 Latin American and Caribbean countries and The National Institute of Child Health and Human Development (NICHD) Neonatal Research Network in the USA specialized in conducting clinical trials. The European Neonatal Network (Euro Neo Net) is a similar European-level initiative whose database was developed to meet the specific needs of the very-low-birthweight infants.

Introducing the National Collaborative Perinatal Neonatal Network

Lebanon, with relatively high fertility and perinatal mortality rates is in great need for vital and routine health statistics. Unfortunately similar to other developing countries, many obstacles, related mainly to the lack of a structured health care system and a restricted budget the government is allocating for scientific research, are impeding the way to generating accurate health statistics and to setting national priorities and programs. These problems are widespread in the region; the latest United Nations Development Programme (UNDP) Arab Human Development report identifies the region as suffering from a paucity of investment in research and information gathering.[7]

In such an environment, the National Collaborative Perinatal Neonatal Network (NCPNN) was created in 1998 by a group of investigators working in different private health care institutions in Beirut. Partially funded by grants from the World Health Organization (WHO), the Network is a voluntary collaborative effort of professionals from different disciplines including pediatrics, obstetrics, family medicine, nursing, epidemiology and public health. The primary objective of the NCPNN is to improve the health of the pregnant woman and her offspring through scientific research and the establishment of an integrated maternal and perinatal neonatal database.

Mission statement of the Network: The Network is a non-profit collaboration created to conduct scientific research, gather scientific and sociodemographic data, and maintain the database regarding the quality, utilization, costs, outcomes and effectiveness of medical treatments and health care practices as related to perinatal and neonatal elements.

Methodology of the NCPNN

Data covering all deliveries are collected prospectively at participating health care centers in the capital Beirut and its suburbs. With so far nine member hospitals in Beirut, the NCPNN has achieved a good coverage of the population of pregnant women and their newborns in the capital and its suburbs where 35% of the Lebanese population resides. The NCPNN is currently expanding to the rural more underprivileged areas of Lebanon where maternal and child health problems are of greater magnitude. Eight centers in different areas of Lebanon have joined the network so far and efforts are made in planning the regional expansion of the network to neighboring countries. The NCPNN database gathers data on over 60,000 newborns and their mothers.

Currently, the coordinating center of the NCPNN lies at the American University of Beirut Medical Center. It is composed of a project director (neonatologist), three co-investigators (a PhD epidemiologist and biostatistician and a family medicine professor and an obstetrician), one network coordinator, two data analysts (MSc Epidemiology and Biostatistics), five research assistants and several data entry persons. Obstetricians working in the different network centers are also close collaborators and key investigators in the network's integrated activities. A primary investigator (attending physician) is assigned in each member hospital to supervise the implementation of the system. Meetings are held on regular basis with the investigators for updates and discussions of current and future matters pertaining to the network. Data are collected daily at each participating hospital by a local nurse, midwife or research assistant. Data collectors undergo an extensive training on the questionnaire and on retrieval of the data from the medical charts of the mother and newborn. Training is done by

the network coordinator in the locals of the participating hospital to insure applicability to the available medical charts. Two standardized instruments have been developed: one for the Normal Nursery and one more detailed version for the Neonatal Intensive Care Unit. These questionnaires are modified and updated as the need arises, depending on observations and experiences from current collection. The collected data is transported at the end of each month to the coordinating center where it is entered into the computerized database. Continuous auditing of data collection and entry is performed. The data are highly protected and access to the data is restricted to insure confidentiality of both patients and providers. One general annual report covering data on the entire network and individual reports for each center are generated and distributed to the member hospitals. Newsletters are issued and distributed periodically.

Projects by the NCPNN

In addition to the ongoing database, the NCPNN carried on several research projects that took advantage from the existing database for the identification of study objectives, data collection, access to medical records from hospitals, identification of cases and many other logistics. One example is the 'The study on morbidity and mortality among newborn babies, infants and under 5-year-old children in Greater Beirut' also known as the follow-up (FUP) study. This was the first cohort study of its kind in the region whereby 1320 newborns were recruited and followed up prospectively with the collaboration of over 117 pediatricians. The NCPNN has completed the first phase of the study, which is the first year of life follow-up.

The FUP study met its primary objective in identifying the causes of morbidity and mortality during the first year of life in our population. Among all morbidity outcomes, the overall infection rate till the age of 15 months was the highest. Of the entire cohort, 71.8% have had at least one infection episode during their first year of life. Upper respiratory tract infections were the most common type of infections (49.9%). High prevalence of otitis and bronchiolitis was also noted (26.5% and 20.1%, respectively). On the contrary, the cumulative hospital readmission rate during the first year of life was 15%, being highest at the age of 1–2 months. The high rate of antibiotic use identified in the analysis warrants further research into the reasons behind such a high rate and the extent of accompanying antibiotic resistance. The rate of antibiotic use during the first year was over 42%. Although not recommended during the first months of life, 4.3% of the infants received oral antibiotics at the age of 1–2 months.

In addition to morbidity patterns, the FUP study looked into behavioral and preventive practices such as breast feeding, vaccination patterns, car seat use and others. Low breast feeding rates at 4 months were noticed in our sample (24.7%) and a negative correlation was found between breast feeding and socioeconomic status. On the contrary, by the end of the first year of life, there was an almost complete coverage for the three doses of polio, diphtheria-tetanus-pertussis (DTP), and hemophilus influenza (Hib) vaccines, with a noticeable decrease in the third dose (87.7%) of Hib vaccination rate. The vast majority of the children received the cellular type of DTP. Although WHO recommends the exclusive use of oral poliovirus vaccine, the injectable form of polio was administered to more than 65.5% of the children.

The above-mentioned results have been published in the monograph summarizing results of the first year of life FUP[8] and that was distributed during the national dissemination workshop held in Beirut in February 2004. Results derived from the study carry several implications for further analysis, research and interventions.

Another project by the NCPNN is 'Group B streptococcal colonization of pregnant women and neonates in Beirut'. This is the first study conducted in Lebanon, whereby the prevalence of group B streptococcus (GBS) and its risk of infection are determined in attempt to assess the magnitude of the problem in our population. The study is still ongoing. However, preliminary results indicate relatively high rates of GBS colonization among pregnant women and among newborns. Predictors of GBS colonization are also looked at. The generated data would thus provide the guidelines for recommending and implementing appropriate policies regarding screening and prevention of neonatal GBS disease in the country.

Currently, the NCPNN is in the data collection phase of a study entitled 'Consanguinity and congenital malformations: a study of prevalence and association in the Lebanese population'. This projects looks into the health consequences of consanguinity. Consanguinity has been associated with increased morbidity and mortality in offsprings of consanguineous parents. Research by the NCPNN has already found significant association between consanguinity and congenital health disease,[9] apnea of prematurity[10] and intrauterine growth restriction (unpublished data, Mumtaz G, Tamim H, Khawaja M *et al.*)[11] in Beirut. Despite the adverse health consequences of consanguineous marriages, this practice is still common in the Lebanese community. The NCPNN data indicates a consanguinity rate of 12.8% in the Capital Beirut and its suburbs. Preliminary analyses on the data collected from the newly recruited hospitals in the rural areas shows significantly higher rates reaching up to 40% in some remote areas of Lebanon. The inclusion, in the sample, of hospitals located outside the capital Beirut, including the most underprivileged areas of the country, represents indeed a major feature of this study, as local research is usually confined to the capital Beirut. Results of this project will provide solid grounds for public health programs concerning the implications of consanguinity.

Achievements of the NCPNN

Research conducted by the NCPNN has identified health and health care problems and as such, has set the grounds for conducting intervention studies of public health significance. One of the most important observations is the high cesarean-section rate in most member centers of the NCPNN, reaching more than 30% in some hospitals. In addition to other adverse outcomes identified in the literature, a significant double-fold risk of hyaline membrane disease was found in babies delivered via cesarean route in the NCPNN newborn population.[12] Accordingly, the NCPNN is about to start a multicenter intervention study based on the implementation of practice guidelines and on auditing, in an attempt to reduce the cesarean-section rate.

Among the other major issues that pertain to the pregnant women, the indiscriminate use of oxytocin, the high rate of general anesthesia administered during cesarean delivery, postpartum depression and cigarette and/or hubble-bubble smoking during pregnancy were some of the major concerns identified. The NCPNN has also identified several problems that pertain to the care of the newborn, such as nosocomial infections, the abuse of antibiotics during the first months of life and the lack of long-term follow-up for premature infants.

In the absence of any published birthweight for gestational age growth charts for the Lebanese newborn population, a major achievement by the NCPNN was the development of its own fetal growth charts based on the NCPNN newborn population.[13] In Lebanon, the absence of a governmental entity responsible for the production and dissemination of perinatal health statistics has precluded data collection on a large scale and the generation of national standards for intrauterine growth. The availability of the NCPNN database allowed the development of our own population fetal growth charts based on 24,767 single live births delivered between 28 and 42 weeks of gestation. To our knowledge, this is the first attempt at devising intrauterine growth standards that are specific to a developing country in the EMR and thus they are useful tools for assessing the health of newborn infants delivered at sea level in the urban areas of Lebanon and other countries having a similar socioeconomic profile.

From our experience at the NCPNN, the establishment of research networks of collaborative nature has a considerable impact on the health care system. The NCPNN annual reports presented to each of the participating hospitals, and the NCPNN newsletters distributed to pediatricians, nurses, hospital administrators, and other health care providers have been instrumental in the ongoing self-evaluation and thus improvement of hospital services and pediatricians' practices. Furthermore, there has been a steady improvement in medical records documentation at the participating hospitals as per NCPNN recommendations. Some hospitals have even incorporated a questionnaire in their medical charts similar to that of the NCPNN. The NCPNN has also played a role in educating women about health issues related to the different stages of pregnancy such as breast feeding, postpartum follow-up, pap smear performance and newborn vaccination.

NCPNN, the future

So far, the main achievements of the NCPNN were in the capital Beirut where the network was created and maintained for the past few years. During the past two years, the NCPNN has initiated its local expansion in the different regions of Lebanon and new health centers have already joined the network successfully. The NCPNN near objectives are the consolidation of the perinatal care system in Lebanon, with more centers from the rural underprivileged areas joining the network, so as to insure a national coverage of the Lebanese population. However, the regional expansion of the network to neighboring countries remains the primary objective of the NCPNN. The NCPNN infrastructure provides a solid base for the network to be a model for a successful approach to medicine and public health research in these countries that share similar population characteristics, similar environmental and geographical features as well as similar challenges.

Consolidation and expansion of the network will not be feasible without lesson-learning from other multinational networks (e.g. CLAP) and links with governmental and international agencies, the network is anticipating to collaborate with. In that respect, the NCPNN is planning to initiate ties with professional/institutions having expertise in networking methodology such as the National Institute of Child Health neonatal network and Development and the Vermont-Oxford network. These North–South alliances will help strengthening the research capacity of the network member countries by providing expertise and knowledge. In addition, the NCPNN anticipates establishing links with regional groupings such as Pediatric and Obstetric Societies, with academic or research institutions that can be of help in issues of analysis and with professionals with expertise in the field of perinatal and neonatal network as well as in electronic data management and other technicalities.

Conclusion

The NCPNN has pioneered a unique system/model in Lebanon and the region. With over 88% of the deliveries in Lebanon occurring in hospitals,[14] hospital-based networks are effective and insure a good coverage of the population of pregnant women. However, financial constraints and the unavailability of adequate funding for planning and organizing have been the major limitation to the rapid expansion

of the NCPNN in Lebanon and other neighboring countries. In developing countries with a low level of expenditure on health research, the input of the private sector (academic institutions, non-governmental agencies and private hospitals) is crucial. Inter- and intra-organizational arrangements, as well as partnership and collaboration among professionals can provide such settings with a productive, reliable and sustainable model/system where epidemiological evidence is gathered, the health priorities of the population under study are set and effective interventions are designed.

Funding remains the major challenge for the sustainability and evolution of such systems, but experience with this voluntary approach to date and projected estimates of the costs per patient entered in the database suggest that the anticipated cost is affordable in the settings concerned, making the proposed system appealing for governments to support and collaborate with.

204 Perinatal genetics: preliminary experience from a developing country

P. Zalloua and A. Adra

Introduction

Being located in the Eastern Mediterranean Basin, Lebanon has been a crossroads between Europe, Asia and Africa, allowing the settlement and intermingling of successive different ethnic groups throughout history. Consequently, a melting pot of over three million people comprising 17 religious groups resides in Lebanon, contributing to its particular genetic heterogeneity. Intercommunity marriages are rare but consanguineous marriages exceed 25% in certain groups,[1] increasing the incidence of genetic diseases, particularly autosomal recessive diseases, such as hemoglobinopathies, cystic fibrosis (CF) and congenital sensorineural deafness.[2] For example, beta-thalassemia (β-thalassemia), an autosomal recessive disorder characterized by reduced (β^+) or absent (β^0) beta-globin chain synthesis, is the most predominant genetic defect and the most common hemoglobin disorder in Lebanon[3] and throughout the Middle East region. The challenges in diagnosis, treatment and prevention of this disease, as discussed in this chapter, are indicative of the difficulties in the management and prevention of genetic diseases in developing countries.

The early identification of genetic diseases could aid health care providers: obstetricians, neonatalogists and pediatricians, in treating the affected individuals and in providing support to their families. In addition, a comprehensive approach to early diagnosis as well as the creation of a centralized data bank concerning epidemiological characteristics could aid in planning and implementing the appropriate preventive measures.[4]

Furthermore, the comprehensive approach is never complete without the presence of genetic counselors who have a primordial role in discussing the medical aspects of the disorder, its mode of inheritance, the available diagnostic and treatment options as well as possible preventive measures.[5]

The role of genetic counseling in a developing country

Genetic counseling addresses the medical and psychosocial impact of a genetic disease on the individuals and their families who are either undergoing molecular genetic testing or who are afflicted with such a disease. Genetic counseling is an integral part of any genetic testing, screening or prevention programs and should be optimally offered before and after the genetic testing.[6]

In addition, it should be offered by medically trained clinical geneticists or trained genetic counselors.[6] These criteria are not always easy to implement in Lebanon. There are two genetic counseling programs available and they usually handle postdiagnostic counseling, often having difficulty in follow-up counseling. Education of the medical community and the population at large concerning the importance of the prediagnostic counseling is essential.

Furthermore, while one of the goals of prenatal genetic counseling and diagnosis is patient reassurance to foster reproduction in parents with genetic problems, the prenatal diagnosis of a genetic disorder may be followed by abortion of the affected fetus for many reasons, including the obvious monetary cost/benefit ratios in an economically struggling developing country.[5] A comprehensive genetic counseling program, in addition to counseling couples with a child afflicted with a genetic disease, should also support couples who have decided to abort their fetus, as these couples are at risk for depression or marital separation.[5]

The implementation of a good prevention program with one of its main axis based on prenatal diagnosis requires clear laws concerning abortion. This has to be kept in mind in any country where religion plays a major role in societal life.

Prenatal diagnosis and population screening in a developing country

Many prenatal diagnosis techniques have been incorporated into routine antenatal care in Lebanon. The request for prenatal diagnosis is most commonly made for aneuploidy testing and for disorders with onset in early childhood, associated with severe symptoms and/or with no treatment available. Individuals seeking prenatal diagnosis for a genetic disease are usually couples who already have an affected child, who have had a positive history of miscarriages or because of advanced maternal age.[5] In addition, there is a proportional relationship between the demand for genetic testing and the perceived individual and familial burden of a genetic disease.[7] The request for prenatal diagnosis may be made not only for the selective abortion of the affected fetus, but also for better preparation for an affected child.[6]

In Lebanon, prenatal diagnosis has rapidly been accepted in concordance with a changing cultural climate consisting of a reluctance to accept physical handicap and a struggle to balance the independent rights of the unborn fetus with limiting the perceived suffering of the unborn child. Prenatal diagnosis has an increasingly recognized role in confirming normality, optimizing antenatal management and providing the opportunity for intrauterine treatment.[8]

Furthermore, in order to decrease the incidence of genetic disease in Lebanon, carrier testing and prenatal diagnosis are very important.[5] Some limitations do occur and include the lack of social acceptability of genetic testing in some populations because of the fear of being labeled as 'abnormal', the lack of adequate genetic counseling and the cost-effectiveness in detecting heterozygous couples. More importantly, governmental support or subsidy for genetic testing is still limited and the cost/benefit ratio for public testing still needs to be adequately studied when considering funding carrier screening or prenatal diagnosis programs.

The new approach: preimplantation genetic diagnosis

Preimplantation genetic diagnosis (PGD) is used to detect many single gene disorders including β-thalassemia, CF and others.[9] It allows for the selection and transfers of unaffected embryos in high-risk couples[10] and thus may be used as an alternative to prenatal diagnosis in a country where abortion is not always preferred or even illegal. Furthermore, some patients undergoing *in vitro* fertilization (IVF) for male infertility factor may be CF male carriers having a congenital absence of their vas deferens. These patients could benefit from PDG.[9] Nevertheless today, because of the prohibitive cost of the test, PGD is mainly recommended for patients with a specific chromosomal abnormality.[11]

In order to perform PGD, couples need to undergo IVF.[11] To diagnose single gene defects, genetic testing centers need to biopsy one to two cells from an 8- to 10-cell embryo and use polymerase chain reaction (PCR) technology to detect the gene defect.[10] Embryo biopsy for PGD is usually performed on the morning of day 3 after egg collection. PGD only tests for one specific disease so it is important for IVF couples to consider prenatal diagnosis for other diseases.[9]

In Lebanon, efforts are being made to develop a comprehensive PGD program. The lack of advanced training in the field and the absence of adequate training in the procedure of embryo biopsy are hindering the rapid development of such a program.

Furthermore, in Lebanon and elsewhere, PGD is still considered an experimental procedure rather than a form of medical treatment or an extension of IVF, and health insurers do not have PGD as part of their coverage policy.[12] In Lebanon, patients would be required to cover the entire cost of PGD, without governmental subsidy or insurance coverage. Legislation is required to address and regulate genetic testing as well as PGD.

Thalassemia: a case study of perinatal genetics in a developing country

β-Thalassemia is an autosomal recessive disorder of hemoglobin metabolism in which there is a genetic defect in one of two or more genes which results in reduced synthesis of β-globin chains.[13] The disorder is manifested by a severe hemolytic anemia, requiring regular blood transfusions and iron chelating therapy. β-Thalassemia occurs with high frequency in areas endemic for malaria such as the Mediterranean countries, Africa and Southeast Asia, where carriers of the disease are genetically protected against malaria and therefore selectively advantaged.[14] It is the most common hemoglobin disorder in Lebanon and there is an estimated carrier frequency rate between 2% and 3%.[15] Based on the patients' registry of the 'Chronic Care Center (CCC)', a non-governmental, non-profit medico-social center that specializes in the treatment and care of patients with thalassemia and childhood diabetes, there are about 600 registered patients in Lebanon with hemoglobinopathies (86% β-thalassemia major and intermedia, 5% α-thalassemia, 4% sickle cell-thalassemia and 5% sickle cell disease).

Though non-curable, thalassemia is a preventable disease as learned from Cyprus and Sardinia, Italy. In a country like Lebanon, thalassemia prevention is desperately needed since treatment costs are a healthcare burden to a society where the health care system is private and medical expenses are very high. Prevention strategies have been implemented since

1994 and focus mainly on premarital testing, population screening and more recently prenatal diagnosis programs accompanied by public awareness and education campaigns. However, success has been limited due to a number of barriers including (1) limited individual education, (2) culture and religion obstacles mostly with regard to abortion issues, and (3) genetic test costs that are not included under any national health insurance coverage. All these factors limit the success of prevention and comprehensive screening programs.

Premarital testing

The law for premarital testing for β-thalassemia was implemented in 1994. This law helped tremendously in identifying couples at risk of having a child with this hemoglobinopathy, especially since around 25% of marriages in Lebanon are consanguineous, reaching 61% in some areas of Lebanon, as reported in a 1993 study done by the Lebanese Ministry of Public Health and UNICEF in underserved areas. Analysis of the percentage distribution of thalassemic patients from CCC by geographic area of origin (Figure 204.1), showed that the majority is from the North and South regions of Lebanon (49.7%) followed by the Bekaa region (17.7%). Since malaria was reported to have spread mostly in these marshy regions,[16,17] sparing Beirut, the central parts of the country and the mountains, these results might also explain the high prevalence of thalassemia among Muslims (Figure 204.2) who resided in these areas, corroborating the fact that malaria-infested regions exhibit the highest incidences of β-thalassemia with the Muslim Sunnis showing evidence of 16 different mutations (Figure 204.3). This high mutational heterogeneity may be partly explained by their interaction with neighboring Muslim countries for centuries, resulting in a genetic admixture.

Nevertheless, despite the goals of premarital screening, two major problems were encountered that hampered its success. On one hand, the primary laboratory screening test performed consists mainly of determining the mean corpuscular volume (MCV). Blood samples with an MCV value of $< 70\,\mu m^3$ were considered as having microcytosis and electrophoresis was then performed to determine the presence of a thalassemia trait. However, with a cut-off point of $70\,\mu m^3$ and the occurrence of errors in testing, some carriers of thalassemia are missed. On the other hand, couples identified at risk are offered very basic counseling by the laboratory technician or physician where the test was performed or by their referring physician. This type of genetic counseling seems insufficient because of the currently registered thalassemic patients at the CCC, 27.2% remain under the age of 10. The need for professional genetic counseling is evident.

Population screening

Screening patients' siblings is currently being conducted in order to identify those carrying the disease trait and thus make them or their parents aware of any future risk they might have in giving birth to a thalassemic child. Furthermore, a 'Thalassemia Youth Screening Project' was initiated in 2002 in schools, universities and other youth's clubs. This project was launched by a collaborative effort between the CCC and the Ministry of Social Affairs in Lebanon. Due to limited resources, the progress is unfortunately slow with no preliminary data available yet.

Genetic testing and prenatal diagnosis

β-Thalassemia mutations may be identified using the Amplification Refractory Mutation System (ARMS) PCR or direct gene sequencing. Haplotype analysis of a subset of the Lebanese population shows that the observed genetic diversity originates from both new mutational events and gene flow from population migration. Identification of both common and rare

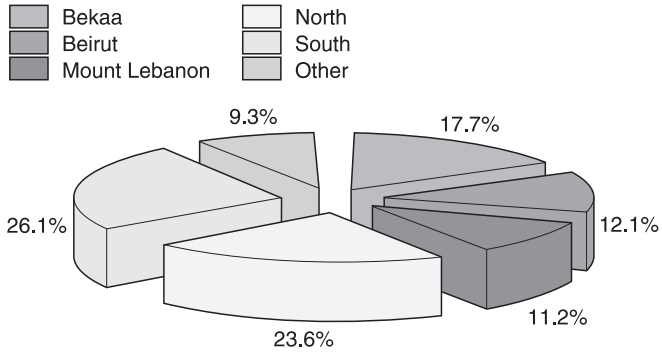

Figure 204.1 Geographic distribution of thalassemia patients.

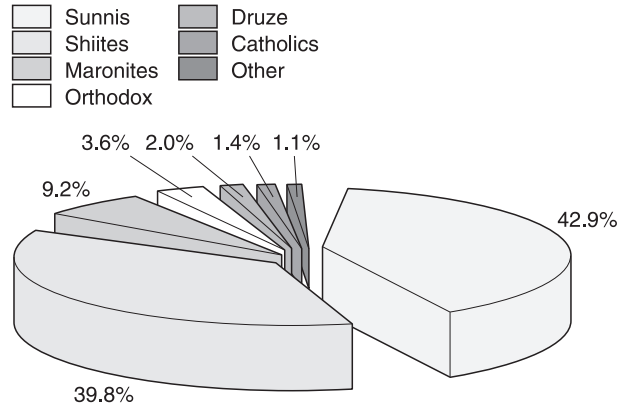

Figure 204.2 Distribution of thalassemia patients by religious groups.

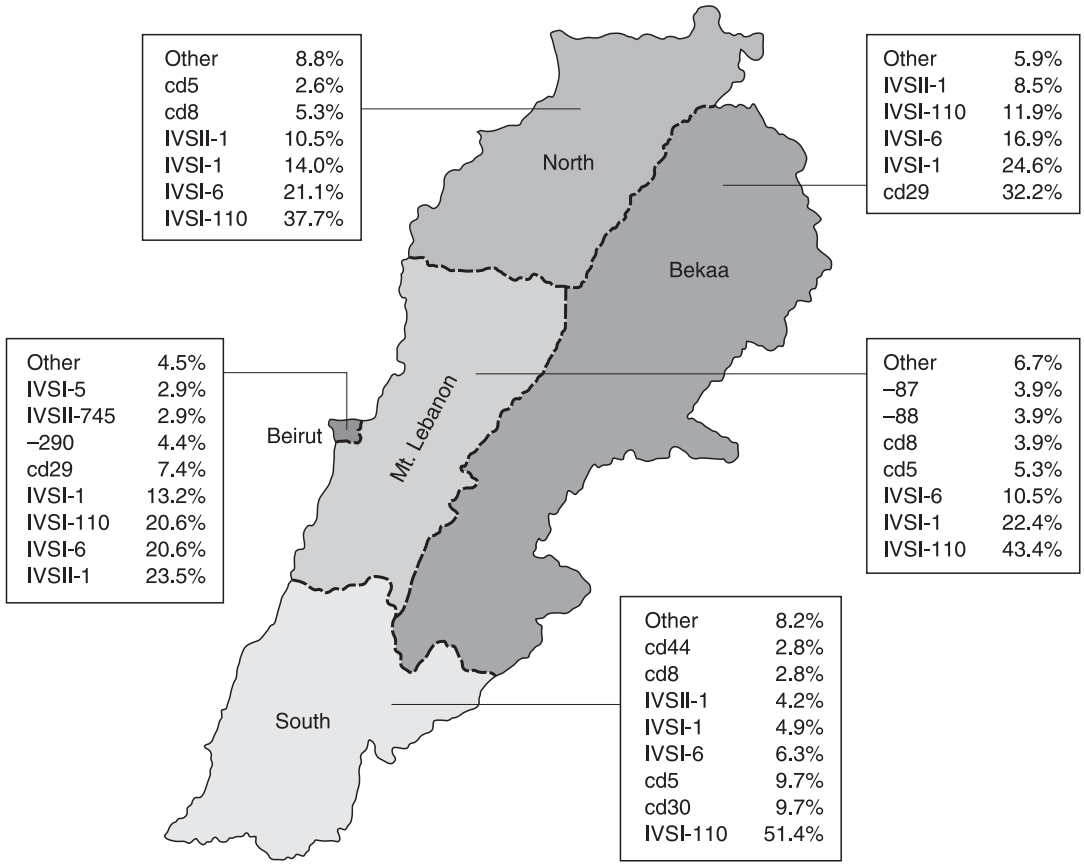

Figure 204.3 The relative frequencies and distribution of β-thalassemia mutations within five main geographic regions in Lebanon.

β-thalassemia mutations is essential for the implementation of screening and prenatal diagnosis programs.

In 1982, chorionic villous tissue was used for the first time to provide fetal DNA in order to diagnose fetal hemoglobinopathies. This procedure was not used in Lebanon for the detection of β-thalassemia until 1999 because of test costs, ignorance of the procedure, cultural and religious beliefs.[18] Furthermore, the required genetic testing procedure was exclusively performed abroad in Cyprus, the UK or the USA, which exacerbated the costs and made the actual testing more cumbersome and complicated. Local genetic prenatal diagnosis for thalassemia in Lebanon was started in 1999 at the Genetics Research Laboratory of the CCC. Diagnosis is based on mutation detection using ARMS PCR[19,20] and DNA sequencing on DNA from chorionic villi and in some cases fetal amniocytes. Most individuals (90%) who are referred for prenatal diagnosis in Lebanon already have an affected child or family member. Today, an increasing number of couples, suspected or confirmed to be β-thalassemia carriers, seek prenatal diagnosis, mostly encouraged by their obstetrician, family doctor or hematologist. The families are given limited genetic counseling at the CCC. Since most couples seeking prenatal diagnosis for thalassemia already have an affected child, they most often choose to terminate the pregnancy in the event of an affected fetus.

All these prevention strategies, though encouraging, seem insufficient. Recent data from the CCC shows that only 12% of thalassemia cases are being prevented each year! Several barriers need to be overcome in order to achieve a concrete success with existing and future prevention strategies.

Barriers: education

Education is the key ingredient to promoting awareness. Most families with thalassemia come from low socioeconomic backgrounds with limited schooling or university education. Many a times parents do not come to terms that their child is affected when there has never been any affected member of the family before. Furthermore, the mother is often blamed for the condition of her child. The notion that the genetic makeup of a child is determined by the genetic makeup of both the father and the mother is rarely accepted. To promote awareness and understanding of thalassemia as a genetic disease, parents of children afflicted with the disease are invited to attend seminars at the CCC given by nurses, doctors and/or members of thalassemic parents association. Educational material is distributed during these

meetings and the language is simple and understandable to all.

Unfortunately, however, public awareness of the disease is limited. Some TV talk shows are presented each year on the International Thalassemia Day (May 8) but these remain insufficient since the focus is on patients, their families and how the disease is affecting them rather than on the different ways to prevent and treat thalassemia. Awareness campaigns at the national level involving the media, schools and universities are primordial.

Barriers: culture and religion

Sometimes, parents with an affected child, from both a legal and religious perspective, are found with no alternatives but to continue with the pregnancy. Despite these barriers, abortions are sometimes performed on affected fetuses.

Barriers: financial

The costs of amniocentesis and chorionic villous sampling procedures for genetic diagnosis as well the diagnostic laboratory testing itself are almost equivalent to the minimum monthly wage set by the government. These procedures and genetic tests are not covered by the National Social Security Foundation. Private health insurance companies still do not include genetic testing in their premium. In any public health policies, cost/benefit ratios need to be determined and funding provided if the problem is considered important.

Other barriers

Geographic and psychological factors also influence the success of prevention and awareness programs. Even though Lebanon is a small country, reaching remote villages and towns in order to promote knowledge on thalassemia and its prevention is very difficult. Residents of these villages are sometimes illiterate, they visit a doctor for emergencies only and may seek late or erratic prenatal care. Psychological fear from being labeled as 'outside the norms' is quite frequent and results in denial of the diagnosis or refusal to seek prenatal testing.

Steps toward improvement

In neighboring Cyprus, where the frequency of β-thalassemia carriers is highest (one in seven) among East Mediterranean countries, control programs have achieved close to 100% prevention of new thalassemia cases and specialized clinics and centers deliver the best treatment and management for affected individuals.[21] Successful screening programs were also implemented and encouraged by the Greek Orthodox Church who refused marriages unless the couple's carrier status for thalassemia was determined. Furthermore, although sanctioned by the church, abortion in Cyprus is legal for affected fetuses.[21,22]

In 1994, the WHO working group on hemoglobinopathies, in its publication 'Guidelines for the Control of Hemoglobin Disorders',[23] outlined the steps required for successful control programs implementation. In Lebanon, while management of thalassemia patients is optimized, the need for more extensive prevention programs is urgent. A collaborative effort between governmental, religious and legal sectors as well as healthcare institutions is necessary in order to create a national work task force for the prevention of hemoglobin disorders.

Obstetric and laboratory facilities are already available but not extensively exploited. Population screening programs and mutation detection are not very expensive when compared with the healthcare costs incurred during the treatment of thalassemia and thus they constitute the next step in the program. In addition, genetic counseling should be offered to families by trained genetic counselors and specialists who can properly explain the mode of inheritance, risk and treatment/diagnostic tools available to families. Of particular importance is the discussion, revision and resolution of important abortion laws, bioethical and religious issues.

The control program has to be carefully monitored by an expert program coordinator who would overlook the progress by continuous research. The establishment of a national birth registry, like in other Arab countries,[24] and a national reference center would allow the exact evaluation of the health and economic burden.[25]

Other genetic diseases

Congenital sensorineural hearing loss

Hearing loss in humans is not uncommon. In fact, one in 1000 children are hearing impaired and half of these cases appear to have a genetic cause.[2] The incidence of hearing loss in Lebanon is unknown, due to the lack of a national registry, but could be high because of the high rate of consanguineous marriages.

The congenital sensorineural hearing loss is a 'hearing impairment due to disorders of the cochlear division of the ninth cranial nerve (auditory nerve), the cochlea, or the retro cochlear nerve tracts'.[13] The major mode of inheritance is autosomal recessive.[26] As such, prelingual deafness is highly genetically heterogeneous.[26] Mutations in the Connexin 26 gene, producing a defunct gap junction protein, represent a major cause of the deafness.[26] In particular, the 30delG mutation is one of the most frequent mutations and was found to occur with a carrier frequency

of 1/43 in one study of the Lebanese population, with no excess in any particular ethno-religious community.[2] This high prevalence is due to a 'hot spot' rather than from an ancestral mutation in the Lebanese population.[2,26]

In Lebanon and elsewhere, genetic counseling for patients with congenital sensorineural hearing loss and their families is limited because physicians are currently unable to distinguish between genetic non-syndromic and non-genetic deafness.[26] Based on recent findings of the prevalence of the Connexin 26 mutation, the possibility of developing a simple molecular test to distinguish between genetic and non-genetic deafness would greatly improve genetic counseling opportunities for affected families. Furthermore, early screening for the 30delG mutation would allow for the early detection of about one-third of non-syndromic autosomal recessive deafness cases in Lebanon.[2]

Cystic fibrosis

Cystic fibrosis is the most common lethal autosomal recessive disorder in Caucasians[27], yet its prevalence in Lebanon is unknown. It is an autosomal recessive congenital metabolic disorder characterized by chronic pulmonary disease, pancreatic exocrine insufficiency and increased sodium chloride composition of sweat.[13,28] Genetic allelic heterogeneity is associated with clinical heterogeneity.[28]

Cystic fibrosis results from a mutation in the gene encoding the cystic fibrosis transmembrane regulator (CFTR) involved in the transport of ions across the cell membrane.[28] It is imperative for the genetic counselor/genetic scientist to be aware of the relative frequency of the most common CFTR gene mutations among their respective patient population. Mutations of the CF gene are detected using ARMS PCR and Allele-Specific Oligonucleotide technology.[27] For at-risk families or consanguineous couples, linkage analysis based on the family's particular genetic markers may also be used to detect the mutation.[27,28] In addition, an amniocentesis may be performed for fetuses found to have a fetal meconium ileus with an unknown risk of CF.[28] To definitively diagnose a patient postnatally, a sweat and pancreatic sufficiency test is needed.[27]

Cystic fibrosis is thought to be rare among the Arab populations from the Middle East and little data have been reported so far. A recent study have been performed on several families living in Lebanon for several generations and who have at least one child with CF. The study found that there was a 50% rate of consanguineous marriage among these families, independent of the community of origin. Mutational analysis have been performed and a total of 10 different mutations accounting for 87.5% of 32 unrelated CF alleles were identified, including two novel putative mutations (E672del and IVS21-28G→A). Three mutations, delta F508 (37.5%), W1282X (15.6%), and N1303K (9.4%) accounted for 62.5% of CF alleles.

Treatment for CF requires long-term medical care, managing respiratory complications and replacing pancreatic enzymes. The disease is often fatal by the fourth decade.[28] Newborn CF screening in Lebanon could make a large difference in the quality of life of CF patients, allowing for early diagnosis or prophylactic treatment. Screening could prevent chronic malnutrition, allow for improved growth of patients, improved pulmonary function and reduce the number of hospital admissions.[29,30] In the future, genetic counseling could also allow parents to avoid having a second child with CF.[29]

Duchenne muscular dystrophy

Duchenne muscular dystrophy (DMD) is the most common childhood muscular dystrophy and is characterized by symmetrical weakness and muscle wasting.[13] It is an X-linked recessive disease with an incidence of 1/3000 male births in most parts of the world. It is caused by a mutation in the dystrophin gene resulting in grossly reduced or absent levels of dystrophin in muscles. Without dystrophin, muscle degeneration occurs. Fetuses with a positive family history for DMD may be tested using Southern Blotting or PCR analysis.[28]

Conclusion/future plans

In the future development of the field of genetics in Lebanon, it is imperative to develop an interconnected network of professionals consisting of genetic counselors, laboratory researchers, clinicians and nurses, in addition to establishing a comprehensive patient and family support system. In particular, fertility centers and clinical genetic scientists as well as neonatologists need to develop an interconnected perinatal network to provide more opportunities for couples with a positive family history for a genetic disease or who are themselves afflicted with a genetic disease. It is equally important to consider the development of graduate programs in the field of genetics and genetic counseling at universities within Lebanon and the Middle East.

Furthermore, the development of a national registry for genetic disorders is essential. In fact, in Lebanon, the National Collaborative Perinatal Neonatal Network is aiming at improving the lives of mothers and newborn infants. One of its goals is to establish a Lebanese National Birth Registry that would help in following the prevalence of certain diseases in the country and hopefully measure the success of future genetic counseling programs and PGD programs in Lebanon.

205 Surgical management of postpartum hemorrhage: lessons learned

M. Seoud and A. Adra

Introduction

Postpartum hemorrhage (PPH) remains a leading cause of maternal morbidity and mortality in developing and developed countries. Maternal mortality varies from 1000 per 100,000 live births in countries like Mozambique to 11.8 per 100,000 live births in the USA.[1] PPH remains a leading cause of death accounting for around one-third of maternal deaths in USA and other developing countries.[1] The most frequent causes of death due to hemorrhage are abruptio placenta, uterine atony, uterine rupture and lacerations of the birth canal. The frequency of each of these causes varies depending on various risk factors including age, parity, place of delivery, presence and type of birth attendant, prior incidence of PPH, type of delivery, prior cesarean birth, as well as other maternal and fetal complications that are beyond the scope of discussion of this chapter.[2]

The definition of PPH is arbitrary. It is often defined as a blood loss of more than 500 cm^3 following a normal vaginal delivery and 1000 cm^3 following a cesarean delivery. In practical terms, however, it is very difficult to quantitate the amount of bleeding and it is left to the birth attendant to subjectively assess the amount of blood loss that is frequently underestimated. Blood loss estimate at cesarean section is even more difficult to assess since one cannot visualize the amount of blood loss until is has spilled over the table and onto the floor. Objectively, the American College of Obstetricians and Gynecologists (ACOG) defines PPH as a drop in hematocrit of more than 10% or a need for blood transfusion.[3]

The predictable increase in the red cell mass of 33% and blood volume of around 45% and the compensatory venous adaptation in pregnancy allows the pregnant women to tolerate moderate amount of blood loss with no significant hemodynamic compromise. However, with excessive blood loss, compensatory mechanisms fail and hypovolemic shock sets in resulting in hypoperfusion and its consequences on vital organs especially the kidneys. The birth attendant should be aware of the hemodynamics of the patient while trying to control PPH. He should call for the appropriate expert help to assist him both in the surgical and supportive management of the patient.

Practical approach to the initial evaluation and management of PPH

The management of PPH starts with steps taken before, during and after its occurrence. It is important to identify high-risk factors which increase the risk of a pregnant patient to develop PPH. This will ensure the right set up and support team to be available at delivery. In some situations, it may involve the early transfer of the patient to a better-equipped center. The presence of skilled and experienced obstetricians, anesthesiologists, intensive care unit, and blood bank are all necessary to ensure a good outcome.

It is beyond the scope of this chapter to discuss high-risk factors and their identification. It is also beyond our scope to discuss various medical and non-surgical means of management of PPH.

When all medical and supportive measures fail to control PPH, the obstetrician must intervene surgically to identify and control the source of bleeding. During surgery, the obstetrician must continue to assess the hemodynamic status of the patient and try to avoid hypovolemic shock with its deleterious effects on organ perfusion. In general, the patient should have two large-bore intravenous (i.v.) accesses. Dilute Pitocin should be infused continuously. A Foley catheter should be in place and continuous monitoring of urine output performed. An adequate urine output of more than 25–30 cm^3 per hour usually indicates an appropriate renal perfusion and avoids postpartum acute tubular necrosis. Although difficult,

an estimate of the amount of blood loss should be promptly made in order to prepare the appropriate amount and type of blood products. Crystalloids are preferred solutions, however, in cases of sudden and excessive blood loss and while waiting for blood to be transfused, plasma expanders may be used with supervision of accurate input and output to avoid cardiac overload and pulmonary edema.

The most difficult decision to make is usually when to start packed red blood cells (RBCs) and blood component replacement. At the present time, blood is the best volume expander and ensures the best oxygenation and blood pressure support. Yet it has several potential disadvantages ranging from unavailability especially in unpredictable situations, possible untoward reactions, and blood born infections. Nonetheless, with massive hemorrhage, blood replacement is life-saving and should be available. Moreover, the use of clotting factors, especially fresh frozen plasma (FFP), is usually needed in cases of massive blood loss. A quick assessment of the bed-side-clotting time (wall clot) may indicate the need for FFP. However, the exact timing of the use of the FFP is often not clear and is arbitrary. The preparation of packed RBCs and FFP may take up to 30–60 min depending on their availability and the closeness of the blood bank. It is important for the obstetrician to anticipate the need for blood component replacement ahead of time and to ask for its preparation. The presence of a skilled anesthesiologist, familiar with the hemodynamics of pregnancy, may relieve the pressure on the obstetrician who subsequently can concentrate on the surgical management of PPH. Most of the time, placement of central monitoring (central venous line, arterial line, and pulmonary capillary pressure catheter) is left to the anesthesiologist, the maternal fetal medicine specialist, or intensive care specialist.

When medical management fails and surgery is contemplated, it is important for the obstetrician to formulate a differential diagnosis and proceed accordingly. Conditions requiring surgical intervention include: lacerations of maternal soft tissues, uterine atony, placental conditions (retained placenta, placenta accreta), uterine rupture, and uterine inversion.

Differential diagnosis and management of PPH

Faced with PPH, the birth attendant should immediately ask for additional help. This should include a senior experienced obstetrician, a skilled anesthesiologist and a high-risk nursing staff. An additional i.v. access should be inserted and continuous vital signs monitoring initiated including blood pressure, pulse, oxygen saturation, and urine output. The patient should be carefully inspected including assessment of the birth canal for lacerations, uterine tone for atony and the abdomen for blood collection.

Cervico-vaginal lacerations

With appropriate anesthesia (general is preferred to regional to avoid worsening of the hypotension), the birth canal should be carefully and gently inspected. Various risk factors may guide toward certain potential sites of bleeding. A vaginal birth after cesarean may necessitate a careful inspection of the prior uterine incision. A difficult vaginal delivery especially if associated with an operative delivery (vacuum or forceps) or if complicated by a macrosomic newborn or shoulder dystocia may result in a cervical or vaginal laceration. Inspection should start with the episiotomy especially the apex, even if it involves reopening the episiotomy. A rectal examination may also reveal the presence of a hematoma which should be evacuated, the bleeder identified if possible and ligated and, if one cannot be seen, a drain should be left in the episiotomy bed. The cervix should be examined and sutured if bleeding lacerations are noted, securing the base of the laceration. In referred cases of vaginal laceration, especially if previously inspected and manipulated, the vagina is often very edematous, eroded and individual bleeders are often difficult to identify. In these cases, careful packing of the vagina may be necessary. If bleeding from vaginal laceration continues despite these efforts, then one may resort to selective artery embolization as noted in the next section. Recently however, Hebisch and Huch described a method of vaginal uterine artery ligation which in their experience avoided other procedures.[4] If no cervico-vaginal lacerations are found, then one has to concentrate on the uterus as a source of bleeding. Sterile manual digital exploration of the uterine cavity is mandatory in order to identify uterine laceration, dehiscence/rupture of prior scar, or retained placental tissues. In case of dehiscence of a uterine scar or uterine laceration associated with brisk vaginal bleeding, an emergency exploratory laparotomy is usually needed as detailed in the following section.

If a vaginal pack is left in place for few hours, the patient should be frequently assessed for collection of blood behind the pack. A Foley catheter is left to asses the urine output and may be removed following removal of the pack if the patient vital signs are stable. Management of lacerations of the uterus and or uterine artery will be discussed later.

Placental conditions

Case 1

Mrs A.S. was undergoing a quaternary cesarean section at a small community hospital. Following the delivery of the newborn, the placenta was noted to be complete previa and attempt at its separation resulted in the avulsion of the lower uterine segment. This left a large crater with subsequent massive bleeding. Following a short attempt to control bleeding, the defect was packed and the abdomen closed. The

patient was transferred immediately to our hospital and directly to the operating room (OR). In the OR, following dissection of the bladder from the remaining lower uterine segment, exposing the broad ligament, and identifying the uterine arteries and the ureters, an abdominal hysterectomy was performed. The patient was transfused with packed RBCs. The bleeding continued despite the hysterectomy and the whole surgical bed was oozing, with no specific major bleeder. Following careful revision of all pedicles, bilateral hypogastric artery ligation was performed with significant decrease in the bleeding. A drain was left in place and the abdomen closed. Post-op, the patient initially did well. However, 12 h later, she became hypotensive with progressive decrease in the hematocrit. Computerized tomographic scan of abdomen and pelvis revealed a pelvic hematoma. Uterine artery embolization was arranged, however the vital signs stabilized and the hematocrit as well. The patient was transfused with a total of 30 units of blood and FFP. She was discharged on the fifth post-op day, and remains well 1 year after the surgery.

Most cases of retained placenta can be managed conservatively. One can usually wait for the placenta to separate spontaneously. In the presence of heavy bleeding manual separation and removal are needed. Piece-meal removal of the placenta should be followed by curetting of the cavity. Inspection of the placenta may identify one or more missing cotyledons. In rare cases, careful uterine inspection may identify the presence of a succenturiate placental lobe. Inspection of the cavity with a large oval forceps and/or a gauze wrapped around the fingers, may be needed to remove large placental tissue followed by gentle curetting of the cavity with a blunt curette to avoid uterine synechiae in the future. In the majority of patients, this is enough to control the bleeding. In rare cases, it may reveal the presence of an adherent placenta or accreta.

The incidence of placenta accreta has increased 10 times in the last 50 years reaching an incidence of 1/2500 deliveries.[5] This increase is attributed to the increase in the cesarean section rate. Women who have two or more cesarean sections have a 40% risk of developing placenta accreta.[5,6] The use of ultrasonography, color Doppler and magnetic resonance imaging have improved our ability to diagnose abnormal placentation antenatally.[7] The ACOG advocates in cases where the diagnosis is strongly suspected to be prepared by properly counseling the patient, preparing blood products, timing and properly locating the delivery with the obstetric anesthesiologist on alert.[5] When attempts fail to control vaginal bleeding from a retained placenta the obstetrician usually resorts to a laparotomy to control the bleeding. Recently however, some have recommended the use of selective uterine artery embolization to control bleeding from a placenta accreta.[8,9] Others have left the placenta in place after ligating and cutting the umbilical cord, followed by the use of methotrexate. Others have combined this with the use of internal iliac balloon catheterization with limited success.[10] When a small segment of placenta is firmly adherent to the endometrium, segmental resection of the piece with the underlying myometrium can be attempted.[11] In case of profuse bleeding from a low lying or placenta previa/accreta, we and others have successfully sutured the lower uterine segment *en masse* or segmentaly.[11,12] When all conservative measures fail, a hysterectomy should be performed.

Uterine atony

Case 2

Mrs M.A. was a 28-year-old primigravida who failed tocolysis at 31 weeks and was undergoing a primary cesarean delivery for breech presentation. Following the delivery, the uterus was atonic with continued bleeding. All conservative measures, including ligation of the uterine and utero-ovarian ligaments, and hemostatic sutures failed. Bilateral hypogastric artery ligation also failed. News of the newborn not faring well only prolonged the attempt at preserving the uterus. Finally, an abdominal hysterectomy was performed. However, continuous oozing from the surgical bed was noted. In the end, multiple surgical pads were tied together, left in place and extruded through the vagina and slowly removed over the next 48 h. She was transfused with a total of 60 units of packed RBCs, FFPs, and platelets. She survived with bilateral moderate atrophy of her gluteal muscles.

Postpartum uterine atony is the most common cause of PPH. The birth attendant should be aware of the various risk factors in order to anticipate the occurrence of uterine atony. Various preventive measures have been found to be effective in significantly reducing the incidence and magnitude of PPH from atony. These include the prophylactic use of various uterotonic agents, in addition to the routine practice of manual uterine massage with gentle cord traction to assist in spontaneous placental separation.

When the medical management of uterine atony fails and the uterus remains hypotonic and continuously bleeding, one can resort to uterine packing while preparing the patient for the operating room. Traditionally, this involves packing the uterus with a long sterile pack while applying continuous pressure on the uterine fundus. Prior to surgical exploration the pack can be gently removed and the bleeding and uterine tone observed. In case the bleeding recurs, a ring forceps is placed on the anterior and posterior lips of the cervix to help identifying the cervix if an abdominal hysterectomy is later needed. This is especially useful when the patient is fully dilated and the cervico-vaginal junction cannot be easily palpated abdominally. Others have tried various devices to tamponade the uterus, such as using a 30–50 ml

intrauterine Foley catheter balloon or a 75 ml ovoid fluted Foley catheter which will allow the drainage of blood as well as tamponading the uterus.[13]

If uterine atony is encountered during a cesarean section, uterine massage with a warm pack may be helpful. Compressing the anterior and posterior abdominal wall is important to decrease the amount of bleeding while preparing prostaglandin medications such as intra-myometrial 15-methyl-$F_{2\alpha}$.[14] Success of this preliminary maneuver may be also useful in identifying those patients who will benefit from placement of hemostatic sutures in the uterine wall. Various techniques have been tried in placing these compressing sutures, however, the most popular being the B-lynch using a 36 inch 0-vicryl through the uterine wall in the lower uterine segment, over the uterine fundus and across to the other side.[14–16] Some authors have reported serious complications from such procedures such as the development of pyometra.[17]

If all these methods fail, one may resort to the ligation of the various blood supply to the uterus including the uterine vessels, the utero-ovarian vessels, and the internal iliac vessels. In cases of uterine atony, however, these may not be as useful as in cases of uterine laceration or accreta, and they are more difficult to perform by a general obstetrician (especially ligation of the internal iliac arteries). These may also take precious time that is best spent on proceeding with a hysterectomy. In our part of the world, we have witnessed on numerous occasions significant morbidity and mortality when time is wasted while attempting to safeguard the uterus especially if the patient is young, nulliparous, of low parity, and/or the newborn is not in a viable condition.

Uterine lacerations

Case 3

Mrs I.S. is a 31-year-old G3 P2 woman at 38 weeks who was undergoing a trial of labor following a vaginal delivery and a cesarean section for a non-reassuring fetal heart. The patient was expecting her third female newborn. She progressed smoothly to full dilatation and pushed for 2 h with arrest of dilatation. During the repeat cesarean section, and following the extraction, a lateral downward extension of the uterine scar was noted. Massive bleeding ensued. Careful dissection of the bladder off the cervix revealed a laceration of the descending branch of the uterine artery. The ureter on that site was carefully dissected and the uterine branch ligated effectively controlling the bleeding. The family was adamantly opposing a hysterectomy citing the need for a future male progeny. The patient subsequently had two more female children by repeat cesarean sections and still wants to continue conceiving.

Uterine laceration may be encountered during a vaginal delivery, such as during a trial of labor for a patient with a prior uterine scar, during operative vaginal delivery (much less these days), during an intrauterine rotation (much less common), or with extension of a cesarean incision.

Lacerations following a trial of labor with a prior cesarean section or during a primary or repeat cesarean section most often result from the extension of the incision toward the uterine vessels, at times leading to massive hemorrhage. Occasionally, the extension is toward the cervix and or vagina, where the bleeding is more difficult to see. The blood flow of the uterine artery at term may reach 500 cm^3/min, hence the urgency in rapidly controlling the bleeding. If the uterus has been exteriorized outside the abdomen, the vessels may retract and constrict, and hence be more difficult to identify. Replacing the uterus in the abdomen may reveal the source of bleeding. In controlling the bleeding from such extension, one should be aware of the path of the ureter and the position of the bladder, especially in patients with a prior cesarean section when the cervix is fully dilated and/or the bladder is adherent to the lower segment. In all cases, the bladder should be identified and sharply dissected as low as possible from the lower uterine segment. The broad ligament on the side of the laceration should be opened, and the ureter identified on its medial leaf. If suturing the edge of the uterus at the site of laceration does not control the bleeding, then one should ligate the uterine vessels at the site of the laceration. This suture, as originally described by O' Leary, is performed using number 1 or 0-vicryl suture placed above and below the laceration perpendicular to the uterine artery and in the uterine wall thus ligating the ascending branch of the uterine vessels.[18] In addition, occlusion of the utero-ovarian ligament on that side by a vascular clamp may further decrease the amount of bleeding. If bleeding decreases, the utero-ovarian vessels may be permanently ligated.

In cases where the bleeding results from more extensive lacerations in the lower uterine segment, such as in placenta previa/accreta, especially in repeat cesarean section, when the lower uterine segment cannot be identified, some advocate ligation of the hypogastric vessels. It is a rather easy procedure, but with which many obstetricians are not familiar. If not familiar with it, this is not the time to learn it and one should not waste precious time trying to perform it. If expertise is available, the dissection should start with opening the broad ligament at the level of the round ligament. The external iliac artery is easy to identify. The index finger is placed over it and used to dissect the tissues cephalad toward the bifurcation of common iliac arteries. The ureter passes over them and is followed caudally to identify the internal iliac vessels. The vessel is ligated using 2-0 silk sutures by passing a right-angle clamp starting laterally toward the midline below the artery and beyond the posterior division to avoid ligation of the superior gluteal artery. Occlusion of both hypogastric vessels may be needed to drop the pulse pressure enough to decrease

the bleeding. The presence of extensive pelvic anastomosis is a mixed blessing. While it makes the uterus the best incubator for the fetus and makes it hard to control PPH, it also helps the uterus survive ligation of many of its blood supply with subsequent successful pregnancies.[7] Recently, however, identification and embolization of pelvic bleeders have been performed radiologically under fluoroscopy. In patients who are relatively more stable, this procedure in expert hands has helped avoid many surgeries.

When all measures fail to control PPH, hysterectomy is then indicated. Often, however, precious time is lost trying to preserve the uterus for future fertility. It is important to proceed with the hysterectomy before the onset of disseminated intravascular coagulopathy when all measures may fail to control the bleeding. It is the precise timing of the hysterectomy that helps avoiding many of the long-term complications. Hysterectomy on a pregnant uterus with a non-dilated cervix is relatively simple and quick. When the cervix is fully dilated, it becomes more difficult to identify the cervico-vaginal junction. Placing ring forceps on the anterior and posterior cervical lips will make it easier. However, if the cervix is difficult to identify, one should not waste time looking for it, but rather proceed with a supracervical hysterectomy, unless the bleeding is from the cervix or upper vagina. In many cases, oozing is noted from the surgical bed. If it is minimal, and the patient is not hypotensive, one can leave a drain, exteriorize it from the vagina, and close the peritoneum over it.

In cases of a complete previa/accreta, especially after repeat cesarean sections, a large defect may be left in the lower uterine segment and pelvis. Bleeding in these cases may neither be controlled with ligation of the hypogastric arteries nor following hysterectomy. One should avoid the non-discriminate use of clamping as well the placement of blind sutures. This will not control bleeding and may injure vital organs such as ureters and veins. Applying pressure with pads exteriorized through the vagina or placed in a nylon bag and placed in the pelvis, exteriorized through vagina and placed under tension by attaching it to 1 l of an i.v. bag over the edge of the bed, may be life-saving. One may go back 24–48 h later to remove the pack, or slowly remove them from the vagina, when the patient is stable, and blood products made available.[19,20] The use of hemostatic powder over the area prior to the application of pressure may also be useful.

Selective embolization of the uterine artery

When medical management of PPH fails, and if the patient is clinically stable, selective embolization of the uterine artery, in the proper hands, may be attempted. It is becoming an increasingly popular alternative to hysterectomy or myomectomy for uterine fibroids.[21] It was originally used successfully to control intractable PPH.[22] A recent review indicated a high success rate (91%) when properly used by expert interventional radiologists.[23] Nevertheless, numerous complications have been reported, including uterine necrosis, labial necrosis, ovarian artery necrosis, and other serious complications.[24]

Conclusions

(1) The management of PPH starts with steps taken before (recognizing high-risk factors), during and after its occurrence.
(2) The obstetrician must continue to assess the hemodynamic status of the patient and try to avoid hypovolemic shock with its deleterious effects on organ perfusion.
(3) Faced with PPH, the birth attendant should immediately ask for additional help.
(4) In referred cases of vaginal laceration, because the vaginal mucosa is often very edematous, eroded and individual bleeders are often difficult to identify, careful packing of the vagina may be necessary.
(5) Most cases of retained placenta can be managed conservatively.
(6) Postpartum uterine atony is the most common cause of PPH. Various preventive measures including the use of pharmacologic agents have been found to be effective in significantly reducing the incidence and magnitude of PPH from atony.
(7) If hemorrhage secondary to uterine atony fails to respond to conventional methods and available pharmacologic agents, the obstetrician should proceed with surgical management starting with ligation of the uterine and ovarian arteries.
(8) When vascular ligation fails to control the bleeding, it is important to proceed with hysterectomy before the onset of disseminated intravascular coagulopathy. It is the precise timing of the hysterectomy that helps avoiding many of the long-term morbidity.
(9) Proceed with a supracervical hysterectomy to shorten operative time and reduce blood loss, unless the bleeding is from the cervix or upper vagina.
(10) Selective uterine artery embolization should be considered in women of low parity with persistent hemorrhage and stable vital signs, where preservation of the uterus is contemplated for future fertility.

Textbook of
Perinatal Medicine

Second Edition

Pregnancy, childbirth and being a newborn are special periods in human life when the risk of death, illness or disability can be high. The last decade has brought enormous progress of science and technology in improving maternal and newborn health - the treatment of genetic diseases, intra-uterine surgery, and improved knowledge about the human genome. Yet perinatal disease and disability worldwide remains very high. It is vitally important for those working in the field to maintain a focus on what can and should be done, and to ensure that best practice is disseminated.

This second edition, authored by a prestigious international cast of practitioners and researchers, is fully revised and updated, now in color with over 1000 illustrations.

With contributions from 380 specialists, this authoritative book, published under the auspices of the World Association of Perinatal Medicine, is a gold-standard summary of modern clinical practice and will be welcomed by all who work in this important field of medicine.

Asim Kurjak MD - Department of Obstetrics & Gynecology, University of Zagreb Medical School, Sveti Duh Hospital, Zagreb, Croatia

Frank A Chervenak MD - Given Foundation Professor & Chairman, Department of Obstetrics & Gynecology, New York Presbyterian Hospital, New York, NY, USA
