Oxford Textbook of Medicine 4th edition (March 2003): by David A. Warrell (Editor), Timothy M. Cox (Editor), John D. Firth (Editor), Edward J., J R., M.D. Benz (Editor) By Oxford Press;

By OkDoKeY

Oxford Textbook of Medicine

TABLE OF CONTENTS

Volume 1

Geoffrey L. Smith

7.10.5 Mumps: epidemic parotitis
B. K. Rima

7.10.6 Measles
H.C. Whittle and P. Aaby

7.10.6.1 Nipah and Hendra viruses
James G. Olson

7.10.7 Enterovirus infections
Ulrich Desselberger and Philip Minor

7.10.8 Virus infections causing diarrhoea and vomiting
Ulrich Desselberger

7.10.9 Rhabdoviruses: rabies and rabies-related viruses
M. J. Warrell and D.A. Warrell

7.10.10 Colorado tick fever and other arthropod-borne reoviruses
M.J. Warrell and D.A. Warrell

7.10.11 Alphaviruses
L. R. Petersen and D. J. Gubler

7.10.12 Rubella
P. A. Tookey and S. Logan

7.10.13 Flaviviruses
L. R. Petersen and D. J. Gubler

7.10.14 Bunyaviridae
J. W. LeDuc and J. S. Porterfield

7.10.15 Arenaviruses
Susan Fisher-Hoch and Joseph McCormick

7.10.16 Filoviruses
Susan Fisher-Hoch and Joseph McCormick

7.10.17 Papovaviruses
K. V. Shah

7.10.18 Parvovirus B19
B. J. Cohen

7.10.19 Hepatitis viruses (including TTV)
N. V. Naoumov

7.10.20 Hepatitis C virus
D. L. Thomas

7.10.21 HIV and AIDS
G. A. Luzzi, T. E. A. Peto, R. A. Weiss, and C. P. Conlon

7.10.22 HIV in the developing world
Charles F. Gilks

7.10.23 HTLV-I and II and associated diseases
C. R. M. Bangham, M. Osame, and S. Nightingale

7.10.24 Viruses and cancer
R.A. Weiss

7.10.25 Orf
N. Jones

7.10.26 Molluscum contagiosum
N. Jones

7.11 Bacteria

7.11.1 Diphtheria
Delia Bethell and Tran Tin Hien

7.11.2 Streptococci and enterococci
S. J. Eykyn

7.11.3 Pneumococcal diseases
Keith P. Klugman and Brian M. Greenwood

7.11.4 Staphylococci
S. J. Eykyn

7.11.5 Meningococcal infections
P. Brandtzaeg

7.11.6 Neisseria gonorrhoeae
D. Barlow and C. Ison

7.11.7 Enterobacteria, campylobacter, and miscellaneous food-poisoning bacteria
G. T. Keusch and M. B. Skirrow

7.11.8 Typhoid and paratyphoid fevers

J. Richens and C. Parry

7.11.9 Intracellular Klebsiella infections
J. Richens

7.11.10 Anaerobic bacteria
S. J. Eykyn

7.11.11 Cholera
Michael L. Bennish

7.11.12 Haemophilus influenzae
E. R. Moxon

7.11.13 *Haemophilus ducreyi* and chancroid
Allan R. Ronald

7.11.14 Bordetella
Calvin C. Linnemann, Jr

7.11.15 Melioidosis and glanders
D. A. B. Dance

7.11.16 Plague
T. Butler

7.11.17 Yersinia, Pasteurella, and Francisella
David Lalloo

7.11.18 Anthrax
Thira Sirisanthana

7.11.19 Brucellosis
M. Monir Madkour

7.11.20 Tetanus
F. E. Udwadia

7.11.21 Botulism, gas gangrene, and clostridial gastrointestinal infections
H. E. Larson

7.11.22 Tuberculosis
Richard E. Chaisson and Jean Nachega

7.11.23 Disease caused by environmental mycobacteria
J. M. Grange and P. D. O. Davies

7.11.24 Leprosy (Hansen's disease)
Diana N. J. Lockwood

7.11.25 Buruli ulcer: *Mycobacterium ulcerans* infection
Wayne M. Meyers and Francoise Portaels

7.11.26 Actinomycosis
K. P. Schaal

7.11.27 Nocardiosis
R. J. Hay

7.11.28 Rat bite fevers
D. A. Warrell

7.11.29 Lyme borreliosis
John Nowakowski, Robert B. Nadelman, and Gary P. Wormser

7.11.30 Other borrelia infections
D. A. Warrell

7.11.31 Leptospirosis
George Watt

7.11.32 Non-venereal treponematoses: yaws, endemic syphilis (bejel), and pinta
P.L. Perine and D. A. Warrell

7.11.33 Syphilis
D. J. M. Wright and S. E. Jones

7.11.34 Listeriosis
P. J. Wilkinson

7.11.35 Legionellosis and legionnaires' disease
J. B. Kurtz and J.T. Macfarlane

7.11.36 Rickettsial diseases including ehrlichiosis
D. H. Walker

7.11.37 Scrub typhus
George Watt

7.11.38 *Coxiella burnetii* infections (Q fever)
T. J. Marrie

7.11.39 Bartonelloses, excluding *Bartonella bacilliformis* infections
James G. Olson

7.11.39.1 *Bartonella bacilliformis* infection

A. Llanos Cuentas

7.11.40 Chlamydial infections including lymphogranuloma venerum
D. Taylor-Robinson and D. C. W. Mabey

7.11.41 Mycoplasmas
D. Taylor-Robinson

7.11.42 Newly identified and lesser-known bacteria
J. Paul

7.12 Fungal infections (mycoses)

7.12.1 Fungal infections
R.J. Hay

7.12.2 Cryptococcosis
William G. Powderly

7.12.3 Coccidioidomycosis
John R. Graybill

7.12.4 Paracoccidioidomycosis
M. A. S. Yasuda

7.12.5 Pneumocystis carinii
Robert F. Miller and Ann E. Wakefield

7.12.6 Infection due to Penicillium marneffei
Thira Sirisanthana

7.13 Protozoa

7.13.1 Amoebic infections
R. Knight

7.13.2 Malaria
D. J. Bradley and D. A. Warrell

7.13.3 Babesia
P. Brasseur

7.13.4 Toxoplasmosis
J. Couvreur and Ph. Thulliez

7.13.5 Cryptosporidium and cryptosporidiosis
D.P. Casemore and D.A. Warrell

7.13.6 Cyclospora
D. P. Casemore

7.13.7 Sarcocystosis
V. Zaman

7.13.8 Giardiasis, balantidiasis, isosporiasis, and microsporidiosis
Martin F. Heyworth

7.13.9 *Blastocystis hominis* infection
R. Knight

7.13.10 Human African trypanosomiasis
August Stich

7.13.11 Chagas' disease
Michael Miles

7.13.12 Leishmaniasis
A. D. M. Bryceson

7.13.13 Trichomoniasis
J. P. Ackers

7.14 Nematodes (roundworms)

7.14.1 Cutaneous filariasis
G. M. Burnham

7.14.2 Lymphatic filariasis
R. Knight

7.14.3 Guinea-worm disease: dracunculiasis
R. Knight

7.14.4 Strongyloidiasis, hookworm, and other gut strongyloid nematodes
R. Knight

7.14.5 Nematode infections of lesser importance
D. Grove

7.14.6 Other gut nematodes
V. Zaman

7.14.7 Toxocariasis and visceral larva migrans
V. Zaman

John Dent and Richard H. Holloway

14.7 Peptic ulcer diseases
John Calam

14.8 Hormones and the gastrointestinal tract
P. J. Hammond, S. R. Bloom, A. E. Bishop, and J.M. Polak

14.9 Malabsorption

14.9.1 Differential diagnosis and investigation of malabsorption
Julian R. F. Walters

14.9.2 Small bowel bacterial overgrowth
P. P. Toskes

14.9.3 Coeliac disease
D. P. Jewell

14.9.4 Gastrointestinal lymphoma
P. G. Isaacson

14.9.5 Disaccharidase deficiency
T. M. Cox

14.9.6 Whipple's disease
H. J. F. Hodgson

14.9.7 Effects of massive small bowel resection
R. J. Playford

14.9.8 Malabsorption syndromes in the tropics
V. I. Mathan

14.10 Crohn's disease
D. P. Jewell

14.11 Ulcerative colitis
D. P. Jewell

14.12 Functional bowel disorders and irritable bowel syndrome
D. G. Thompson

14.13 Colonic diverticular disease
N. J. McC. Mortensen and M. G. W. Kettlewell

14.14 Congenital abnormalities of the gastrointestinal tract
V. M. Wright and J. A. Walker-Smith

14.15 Tumours of the gastrointestinal tract
A. F. Markham, I. C. Talbot, and C. B. Williams

14.16 Vascular and collagen disorders
Graham Neale

14.17 Gastrointestinal infections
Davidson H. Hamer and Sherwood L. Gorbach

14.18 Liver, pancreas, and biliary tree

14.18.1 Structure and function of the liver, biliary tract, and pancreas
A. E. S. Gimson

14.18.2 Computed tomography and magnetic resonance imaging of the liver and pancreas
C. S. Ng, D.J. Lomas, and A.K. Dixon

14.18.3 Diseases of the pancreas

14.18.3.1 Acute pancreatitis
C. W. Imrie

14.18.3.2 Chronic pancreatitis
P. P. Toskes

14.18.3.3 Tumours of the pancreas
Julian Britton

14.19 Disease of the gallbladder and biliary tree

14.19.1 Congenital disorders of the liver, biliary tract, and pancreas
J. A. Summerfield

14.19.2 Diseases of the gallbladder and biliary tree
J. A. Summerfield

14.19.3 Jaundice
R. P. H. Thompson

14.20 Hepatitis and autoimmune liver disease

14.20.1 Viral hepatitis - clinical aspects
H. J. F. Hodgson

14.20.2 Autoimmune liver disease

William MacNee

17.7 Chronic respiratory failure
P. M. A. Calverley

17.8 The upper respiratory tract

17.8.1 Upper airways obstruction
J. R. Stradling

17.8.2 Sleep-related disorders of breathing
J. R. Stradling

17.9 Bronchiectasis
D. Bilton

17.10 Cystic fibrosis
Duncan Geddes and Andy Bush

17.11 Diffuse parenchymal lung disease

17.11.1 Diffuse parenchymal lung disease: an introduction
R. M. du Bois

17.11.2 Cryptogenic fibrosing alveolitis
R. M. du Bois

17.11.3 Bronchiolitis obliterans and organizing pneumonia
R. M. du Bois

17.11.4 The lungs and rheumatological diseases
R. M. du Bois and A. K. Wells

17.11.5 The lung in vasculitis
R. M. du Bois

17.11.6 Sarcoidosis
Robert P. Baughman and Elyse E. Lower

17.11.7 Pneumoconioses
A. Seaton

17.11.8 Pulmonary haemorrhagic disorders
D. J. Hendrick G. P. Spickett

17.11.9 Eosinophilic pneumonia
D. J. Hendrick and G. P. Spickett

17.11.10 Lymphocytic infiltrations of the lung
D. J. Hendrick

17.11.11 Extrinsic allergic alveolitis
D. J. Hendrick and G. P. Spickett

17.11.12 Eosinophilic granuloma of the lung and pulmonary lymphangiomyomatosis
D. J. Hendrick

17.11.13 Pulmonary alveolar proteinosis
D. J. Hendrick

17.11.14 Pulmonary amyloidosis
D. J. Hendrick

17.11.15 Lipoid (lipid) pneumonia
D. J. Hendrick

17.11.16 Pulmonary alveolar microlithiasis
D. J. Hendrick

17.11.17 Toxic gases and fumes
D. J. Hendrick

17.11.18 Radiation pneumonitis
D. J. Hendrick

17.11.19 Drug-induced lung disease
D. J. Hendrick and G. P. Spickett

17.12 Pleural disease
M. K. Benson

17.13 Disorders of the thoracic cage and diaphragm
J. M. Shneerson

17.14 Neoplastic disorders

17.14.1 Lung cancer
S. G. Spiro

17.14.2 Pulmonary metastases
S. G. Spiro

17.14.3 Pleural tumours
M. K. Benson

19 Diseases of the skeleton

20 Nephrology

Foreword

by Professor Sir David Weatherall, FRS

It is now 20 years since the first edition of the *Oxford Textbook of Medicine* appeared on the scene, a time when the concept of the all-encompassing textbook of medicine was being questioned. Its predecessor, *Price's Textbook of the Practice of Medicine,* first published in 1922 and by then in its twelfth edition, had come under considerable criticism. One of its most voluble critics, the late J.R.A. Mitchell, had even gone to the trouble of weighing the book, after which he suggested that, because dinosaurs became extinct because of their sheer bulk, medical textbooks would suffer the same fate. In addition, he and many other reviewers suggested that large textbooks are out of date before they are published and hence are of extremely limited value. Notwithstanding Professor Mitchell's outdated views on the extinction of dinosaurs, we thought that he had a point.

After considering these arguments carefully we came to the conclusion that there was still a place for at least one major British work of reference which attempted to cover the whole field of internal medicine. This decision was based largely on the view that, because of the enormous breadth of the subject and the increasing tendency to overspecialization, very few students and practitioners could have immediate access to smaller monographs on every branch of the field; even when they are available they are not always written by those who evaluate their patients in a general medical setting. And if this is true of clinicians in the richer countries, it must apply even more to those in the developing world, where access to libraries and review articles may be limited. Furthermore, although we were well aware that textbooks rapidly become out of date, few advances in medicine lead to major changes in patient care, and those that do often require many years of critical evaluation before they become an integral part of routine clinical practice. For this reason we decided to try to produce a wide-ranging medical textbook which would have a particular emphasis on the global aspects of disease, rather than focus simply on the day-to-day medical problems of the developed world.

Since the *Oxford Textbook of Medicine* first appeared there have been profound changes, both in the practice of medicine and in the problems of the provision of medical care. None of the richer countries has been able to solve the problem of the spiralling costs of health care, which have resulted in part from the introduction of new technology but, even more importantly, from the remarkable increase in the age of their patient populations. If anything, the gap between the quality of the provision of health care between the richer and poorer countries has widened, and although some of the poorer countries have made the epidemiological transition from high death rates due to infection and malnutrition towards a more westernized pattern of illness, particularly in sub-Saharan Africa infectious disease, notably respiratory infection, AIDS, tuberculosis, and malaria, remain the major causes of death; a review of over 11 million childhood deaths in 1998 disclosed, disgracefully, that over 4 million were due to diseases for which adequate vaccines or other forms of prevention already exist. The phenomena of 'globalization', and increasing corporate dominance, are also tending to exacerbate the divide between the rich and poor nations.

Another profound change which has occurred over the last 20 years is the emphasis on the study of disease at the molecular and cellular levels and the increasing role of what is still rather optimistically called 'molecular medicine'. But while this remarkable field promises much for the health of mankind for the future, so far it has had little place in day-to-day clinical practice. Thus, while the fruits of the human genome project offer enormous potential for the better understanding, prevention, and management of the common killers of middle life and old age in richer societies, and the pathogen genome projects offer equal hope for controlling the infectious killers of the developing countries, it is still far from clear when the rich promises of these fields will come to fruition for preventative medicine and clinical care. And there is the danger that when they do, because many of them are likely to be expensive, the gap between the provision of health care in the poorer and richer countries will become even wider. Although many of the solutions to these problems depend on a complete change of attitude of governments and industry in the richer countries, there is no doubt that there will be a rapidly increasing role for their medical schools and doctors to develop collaborative programmes with those of the developing countries and, in general, to take a much more global view of disease, both in medical education and research.

The other major change in the medical field over the last 20 years has been the increasing disquiet about the pattern of medical practice. In many countries doctors have come under increasing criticism for their lack of ability to communicate adequately with patients, for their quality of patient care and, overall, for their lack of humanity. The patient community has become much more sophisticated and demanding, and in most countries there has been a rapid increase in the number of medico-legal actions taken against doctors. This trend has already had wide-ranging repercussions. There has been a major rethink about the pattern of medical education, placing less emphasis on its scientific basis and more on communication skills, ethics, and the social aspects of medicine. The remarkable revolution in the basic biological sciences that underlie medical practice, particularly in the field of genomics, is also raising new ethical issues which would have been undreamed of at the time of the first edition of this book.

In short, medical practice has entered the new millennium in a state of considerable uncertainty. The whole ethos of clinical practice is being questioned, none of the richer countries has got to grips with how to finance the increasing demands of medical care, and many of the poorer countries still have completely dysfunctional health care systems. It is very pleasing therefore to see that the new edition of the *Oxford Textbook of Medicine* reflects so many of these changing issues, as they affect internal medicine. In particular, the textbook has maintained and expanded the aspirations of its original editors towards providing a genuinely global picture of disease, not just as it affects the populations of the richer countries but as it involves the lives of all of those in the poorer countries of the world. As well as continuing to describe the major causes of ill-health and death in the populations of the poorer countries, it includes new sections on screening and the costs of health care, and has greatly increased its coverage of some of the major infectious killers, particularly HIV/AIDS. At the other end of the spectrum it has expanded its sections on the molecular mechanisms of disease and tried to put molecular medicine into perspective by defining its limits. And it has not ignored the remarkable advances in medicine which relate to the richer countries, particularly in its coverage of the problems of the aged. In doing so it has focused on the major killers of Western society, notably cancer, heart disease, and stroke, and has greatly increased the coverage of critical care and emergency medicine. This extensive revision has required the recruitment of many new authors, reflecting a change of over one-third of those from the last edition.

After the publication of the last edition of the *Oxford Textbook of Medicine* my colleague John Ledingham and I decided that it was time to stand aside and pass on our editorial roles to a younger team of editors who are still very active in the fields of medical research and practice. We are delighted to see that our younger colleagues have maintained the tradition of producing a broad-ranging medical textbook which emphasizes the pastoral, scientific, and global aspects of medical care. Despite all its problems medical practice is entering the most exciting and challenging period of its development, and we believe that it still offers the most exciting and enriching of careers for its practitioners. We trust that the 'OTM' will remain their guide and friend for many years to come.

Preface

Textbooks of medicine: *raison d'etre*

Now, in the third millennium, is there any need for a textbook of medicine? Never before has so much information on medical matters been so readily available to so many: physicians are inundated, as are their patients and everyone else. The media seem to carry more and more medical stories in more and more detail every day. The genome has been sequenced. Articulate teenagers speak of stem cells. The internet brings widespread and virtually unlimited access to biomedical information (and misinformation) of a sort: one click of a mouse, and it's all anyone's. A plethora of organizations besieges physicians with guidelines and protocols on every aspect of the practice of medicine. Traditional values are being challenged in all facets of life, including medicine, and there is an unprecedented and entirely appropriate demand for supportive evidence, not just weight of experience, to justify medical interventions.

In these circumstances, some might argue that textbooks of medicine were irrelevant, inappropriate, or even redundant. We strongly refute this. Amidst the maelstrom of 'information' in which physicians now work there is, more than ever, a need for a fixed point of reference, something by which the new, the exciting, and the fashionable can be judged. We make the bold claim that the *Oxford Textbook of Medicine* is just such a fixed point. We argue, unashamedly, that a clinical textbook in the Oslerian tradition is not only required but is essential, to provide expert review, evaluation, and recommendation.

Clinical medicine: changes, challenges, and reconsiderations

This fourth edition of the *Oxford Textbook of Medicine* emerges at a time when discoveries in molecular sciences and advances in technology provide an unprecedented range of diagnostic reagents, drugs, and bioinformatics. Yet, at the same time, there is a widespread recognition that the outcome of treatment for many patients falls short of ideal standards. Microbial resistance to antibiotics, adverse consequences of drugs, and the fallibility of doctors all contribute to failures; and we now realize how dangerous hospitals and clinics can be. Besides this, many contemporary high-tech procedures cannot cure chronic illnesses, and we lack effective weapons to influence the powerful social and behavioural factors that underlie so much illness. The advent of predictive DNA testing also poses complex ethical questions for practitioners, for which few answers are available.

Advances in biomedical science crucially drive innovation and improvement in medical practice. These are not neglected in this book, but the practice of medicine (except in dire emergency) is initiated by a patient talking with a physician and proceeds (as appropriate) through physical examination and investigation to discussion of diagnosis, prognosis, and treatment. These are the core issues of clinical medicine which form the bulk of this textbook.

A culture of public mistrust: the physician-patient relationship

Our political masters in much of the developed world, long tired of being marginalized by old-established networks within the professions, have introduced a new accountability distilled from the concept of audit. This has been exported from the world of finance to embrace the scrutiny of non-financial processes in health care and has created a political climate obsessed with cost effectiveness. The degree of central control often leads to impossible conflicts in the expectations of the public and those entrusted with provision of health care. Baroness O'Neil in her BBC Reith Lectures of 2002 * has pointed out that there is often an inconsistency in the demands raised by such control, providing, as it does, perverse incentives for the specious goals and 'output measures' determined by central bodies. While it is true that much better standards of health care delivery are required and careful surveillance of clinical activities is desirable, the *Oxford Textbook of Medicine* presents an affirmation of the physician-patient relationship in the fight against illness, debility, and suffering: for this relationship should remain sacrosanct, based on professional integrity, knowledge, and human feeling.

Aims and emphases: Sir Archibald Garrod's legacy

Garrod first understood the unique interactions between heredity and environment in the genesis of human disease and asked the question: 'Why did this particular person develop this particular illness in this particular environment?' - a question that we are only just beginning to answer in an era of almost naïve enthusiasm for genetics. While the study of the invariant factors in human genetics is almost intoxicating in its simplicity, we now face the formidable challenge of identifying the contribution of the environment, with all its attendant variables, to the generation of the clinical phenotype we define as illness.

This is the background to this edition of the *Oxford Textbook of Medicine*: its remit stretches from disease as it presents to physicians at the bedside, to the attendant disturbances of cellular, tissue, and organ function, all occurring within an individual, inevitably a part of the turmoil of society. To have a complete description of all these aspects of any medical complaint would not be possible, but we recognize that many readers will not have ready access to the latest sources of scientific information. The book is therefore designed to be a proper reference point for both scientific and clinical aspects of medical practice and bears the fingerprints of Osler, Garrod, Doll, and Weatherall, all Regius Professors of Medicine in Oxford.

Limitations and strengths

The bitter practicalities of writing, editing, and producing any book, especially a work of this size, prevent its referring to the last edition of *The Lancet, Quarterly Journal of Medicine, New England Journal of Medicine,* or any other periodical. But this book can and does provide the medical background against which new information should be assessed and understood. Grounded in the principles that have made the first three editions standard reference textbooks, the new edition has, like medicine itself, evolved to bring all contemporary resources to focus on the teaching and interpretation of medicine. Many new approaches and topics are included and we have incorporated the skill, experience, and perspectives of a truly international complement of highly distinguished authors, including the recently honoured Nobel Laureate in Medicine, Dr Sydney Brenner.

This fourth edition includes, for the first time, an editorial adviser based in the United States (EJB) and a greatly increased and broadened representation of North American authors. By adopting this approach, we hope we have been able to integrate and synthesize in this edition the perspectives on shared medical issues as they confront physicians and medical scientists in different countries.

At a time when there is a tendency for physicians in some parts of the world to be more and more proficient about less and less, this book is a means of their grasping what is happening and what is important in all areas of medical practice. When the movement of people, diseases, and doctors around the world is greater than ever, there is a need for a truly global perspective, which this book provides.

Acknowledgements

This edition contains much that is entirely new, but we wish here to acknowledge that it is built on the firm foundations established by the distinguished co-editors of the previous editions, Professor Sir David Weatherall and Professor John Ledingham. No work of this kind can be produced without the engagement of dedicated professionals who believe in publishing and commit themselves way beyond healthy expectations to see the task through. Mrs Alison Langton has provided guidance and discipline throughout the production and we are enormously grateful to her and her staff at Oxford University Press for their confidence, commitment, and friendship. We are particularly indebted to Dr Irene Butcher who has worked indefatigably to help us realize our aims and at every level has contributed to the organization of the final text and its complex illustrative material. Her experience, knowledge, and uncompromising attention to detail must surely be unique; her forbearance with the editors and, on rare occasions, errant contributors, has been nothing short of miraculous. We thank our contributors for their patience in delivering their sections and review of proofs for which they are responsible. Ultimately, however, the book and any errors it might contain remain the responsibility of the editors.

Finally we thank Mary, Sue, Helen, and Peggy, our constant, supportive, and forgiving wives; Professor Sir David Weatherall, Professor Alastair Compston, Dr Graham Neale, Professor Michael de Swiet, and Dr Michael Sharpe our section advisers; Professor David Lomas, Professor Julian Hopkin, Professor Michael Doherty, Professor David Isenberg, and Dr Christopher Winearls who gave advice and comment for which the editors are very grateful; and our personal secretaries, Eunice Berry (a veteran of four editions), Joan Grantham, Janet Cameron, Naoe Suzuki, and Beverly Comegys for their exceptional dedication.

15.3.3 Echocardiography. 15.14.1 Thoracic aortic dissection

D. J. P. Barker Director, MRC Environmental Epidemiology Unit, University of Southampton, UK.
15.4.1.1 Influences acting *in utero* and early childhood

Roger Barker University Lecturer and Honorary Consultant in Neurology, Department of Neurology, Addenbrooke's Hospital, Cambridge, UK.
24.13.11 Disorders of movement (excluding Parkinson's disease)

D. Barlow Consultant Physician, Department of Genitourinary Medicine, St Thomas's Hospital, London, UK.
7.11.6 Neisseria gonorrhoeae

M. P. Barnes Professor of Neurological Rehabilitation, Hunters Moor Regional Rehabilitation Centre, Newcastle upon Tyne, UK.
24.13.17 Spinal cord injury and its management

John G. Bartlett Chief, Division of Infectious Diseases, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA.
17.5.2.1 Pneumonia - normal host. 17.5.2.2 Nosocomial pneumonia

Christopher Bass Consultant in Liaison Psychiatry, Department of Psychological Medicine, John Radcliffe Hospital, Oxford, UK.
26.5.3 Medically unexplained symptoms in patients attending medical clinics

M. F. Bassendine Professor of Hepatology, Centre for Liver Research, The Medical School, University of Newcastle upon Tyne, UK.
14.20.2.2 Primary biliary cirrhosis

David Bates Professor of Clinical Neurology, Department of Neurology, University of Newcastle upon Tyne, UK.
24.9 Brainstem syndromes. 24.13.1 The unconscious patient

Robert P. Baughman University of Cincinnati Medical Centre, Ohio, USA.
17.11.6 Sarcoidosis

Peter J. Baxter Consultant Physician, Occupational and Environmental Medicine, University of Cambridge, UK.
8.5.12 Disasters: earthquakes, volcanic eruptions, hurricanes, and floods

Peter H. Baylis Provost and Dean of Faculty of Medical Sciences, University of Newcastle upon Tyne, UK.

20.2.1 Water and sodium homeostasis and their disorders

D. Gareth Beevers Professor of Medicine, City Hospital, Birmingham, UK.
15.16.3 Hypertensive emergencies and urgencies

Michael L. Bennish Director, Africa Centre for Health and Population Studies, Mtubatuba, South Africa.
7.11.11 Cholera

M. K. Benson Consultant Physician, Oxford Centre for Respiratory Medicine, Churchill Hospital, Oxford, UK.
17.12 Pleural disease. 17.14.3 Pleural tumours. 17.14.4 Mediastinal tumours and cysts

V. Beral Head, Cancer Research UK Epidemiology Unit, Radcliffe Infirmary, Oxford, UK.
21.6 Cervical cancer and other cancers caused by sexually transmitted infections

Anthony R. Berendt Consultant Physician-in-Charge, Bone Infection Unit, Nuffield Orthopaedic Centre, Oxford, UK.
18.7.1 Pyogenic arthritis. 19.3 Osteomyelitis

Nancy Berliner Professor of Medicine and Genetics, Yale School of Medicine, New Haven, Connecticut, USA.
22.4.1 Leucocytes in health and disease. 22.4.2 Introduction to the lymphoproliferative disorders

Michael Besser Professor of Medicine Emeritus, Bart's and The London School of Medicine and Dentistry, Queen Mary College, London, UK.
12.2 Disorders of the anterior pituitary. 12.3 Disorders of the posterior pituitary

Delia B. Bethell Specialist Registrar in Paediatrics, Department of Paediatrics, John Radcliffe Hospital, Oxford, UK.
7.11.1 Diphtheria

Ernest Beutler Chairman, Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, California, USA.
22.5.11 Erythrocyte enzymopathies

P. C. L. Beverley Professor and Scientific Head, Edward Jenner Institute for Vaccine Research, Compton, Berkshire, UK.
6.5 Tumour immunology

R. W. Bilous Professor of Clinical Medicine, James Cook University Hospital, Middlesbrough, Cleveland, UK.
20.10.1 Diabetes mellitus and the kidney

D. Bilton Consultant in Respiratory Medicine, Papworth Hospital, Cambridge, UK.
17.9 Bronchiectasis

A. E. Bishop Senior Lecturer, Tissue Engineering and Regenerative Medicine Centre, Chelsea and Westminster Hospital, London, UK.
14.8 Hormones and the gastrointestinal tract

Carol M. Black President of the Royal College of Physicians of London and Professor of Rheumatology, Royal Free and University College Medical School, Royal Free Campus, London, UK.
18.10.3 Systemic sclerosis

S. R. Bloom Professor of Medicine and Head, Division of Investigative Science, Imperial College Faculty of Medicine, Hammersmith Campus, London, UK.
12.10 Non-diabetic pancreatic endocrine disorders and multiple endocrine neoplasia. 14.8 Hormones and the gastrointestinal tract

L. D. Blumhardt Emeritus Professor of Clinical Neurology, University of Nottingham, UK.
24.13.5 Syncope. 24.13.16 Diseases of the spinal cord

N. Boon Consultant Cardiologist, Royal Infirmary of Edinburgh, UK.
15.10.4 Cardiac disease in HIV infection

D. R. Booth Senior Hospital Scientist, Institute for Immunology and Allergy Research, Westmead Millennium Institute, Sydney, New South Wales, Australia.
11.12.3 Familial Mediterranean fever and other inherited periodic fever syndromes

Richard T. Booth Professor, Health and Safety Unit, Aston University, Birmingham, UK.
8.4.2 Occupational safety

Leszek K. Borysiewicz Professor and Principal of the Faculty of Medicine, University of Wales, Cardiff, UK.
7.4 The host response to infection

I. C. J. W. Bowler Consultant Microbiologist, Department of Microbiology, John Radcliffe Hospital, Oxford, UK.
7.9 Nosocomial infections

D. J. Bradley Ross Professor of Tropical Hygiene, London School of Hygiene and Tropical Medicine, UK.
7.13.2 Malaria

Thomas Brandt Klinikum Groshadern, Munich, Germany.
24.12.1 Eye movements and balance

P. Brandtzaeg Professor of Paediatrics, Ullevål University Hospital, University of Oslo, Norway.
7.11.5 Meningococcal infections

P. Brasseur Professor and Head of Department of Parasitology, Faculty of Medicine, Rouen, France.
7.13.3 Babesia

J. Braun Professor and Medical Director, Rheumazentrum Ruhrgebiet, Herne, Germany.
18.6 Spondyloarthritides and related arthritides

Sidney Brenner Research Professor, Salk Institute, La Jolla, California, USA, and Honorary Professor of Genetic Medicine, University of Cambridge, UK.
4.2 The human genome sequence

D. P. Brenton Sub Dean (Curriculum), Royal Free and University College Medical School, London, UK.
11.2 Inborn errors of amino acid and organic acid metabolism

Paul H. Brion Rheumatologist in Private Practice, Vista, California, USA.

18.8 Osteoarthritis

Julian Britton Consultant Surgeon, John Radcliffe Hospital, Oxford, UK.
14.3.1 The acute abdomen. 14.18.3.3 Tumours of the pancreas

Anthony F. T. Brown Associate Professor and Senior Staff Specialist, Department of Emergency Medicine, Royal Brisbane Hospital, Queensland, Australia.
16.4 Anaphylaxis

M. J. Brown Professor of Clinical Pharmacology, University of Cambridge and Honorary Consultant Physician, Addenbrooke's Hospital NHS Trust, Cambridge, UK.
15.16.2.3 Primary hyperaldosteronism (Conn's syndrome). 15.16.2.4 Phaeochromocytoma

A. D. M. Bryceson Emeritus Professor of Tropical Medicine, London School of Hygiene and Tropical Medicine, UK.
7.13.12 Leishmaniasis

Philip J. Burke Johns Hopkins Oncology Center, Baltimore, Maryland, USA.
22.3.3 Acute lymphoblastic leukaemia. 22.3.4 Acute myeloblastic leukaemia

G. M. Burnham Associate Professor of International Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, USA.
7.14.1 Cutaneous filariasis

Jacky Burrin Professor of Experimental Endocrinology, Bart's and The London School of Medicine and Dentistry, St Bartholomew's Hospital, London, UK.
12.1 Principles of hormone action

Andy Bush Reader in Paediatric Respirology, London, UK.
17.10 Cystic fibrosis

K. Bushby Professor of Neuromuscular Genetics, Institute of Human Genetics, Newcastle upon Tyne, UK.
24.22.2 Muscular dystrophy

Anthony Busuttil Regius Professor of Forensic Medicine, Forensic Medicine Section, Edinburgh University Medical School, UK.
27 Forensic medicine and the practising doctor

T. Butler Professor of Internal Medicine and Chief of Infectious Diseases, Texas Technical University Health Sciences Center, Lubbock, Texas, USA.
7.11.16 Plague

W. F. Bynum Professor of History of Medicine, Wellcome Trust Centre for the History of Medicine at University College London, UK.
2.1 Science in medicine: when, how, and what

I. Byren Consultant in Infectious Diseases and Genito-Urinary Medicine, John Radcliffe Hospital, Oxford, UK.
15.10.3 Cardiovascular syphilis

John Calam* Professor of Medicine, Imperial College London, UK.
14.7 Peptic ulcer diseases

Donald B. Calne Professor Emeritus, University of British Columbia, Vancouver, Canada.
24.13.10 Parkinsonism and other extrapyramidal disorders

P. M. A. Calverley Professor of Medicine (Pulmonary and Rehabilitation), Clinical Science Centre, University Hospital Aintree, Liverpool, UK.
17.7 Chronic respiratory failure

Giovambattista Capasso Professor of Nephrology, Second University of Naples, Italy.
20.13 Urinary stones, nephrocalcinosis, and renal tubular acidosis

Jonathan R. Carapetis Senior Lecturer, Research Fellow, and Consultant in Infectious Diseases, Centre for International Child Health, University of Melbourne Department of Paediatrics, Royal Children's Hospital, Melbourne, Australia.
15.10.1 Acute rheumatic fever

Simon Carette Head, Division of Rheumatology, Toronto Western Hospital, Ontario, Canada.
18.4 Back pain and regional disorders

D. J. S. Carmichael Consultant Renal Physician, Southend Hospital, Westcliffeon-Sea, Essex, UK.
20.16 Drugs and the kidney

D. P. Casemore Senior Research Fellow, CREH, University of Wales, St Asaph, Denbighshire, UK.
7.13.5 Cryptosporidium and cryptosporidiosis. 7.13.6 Cyclospora

D. Catovsky Professor of Haematology, Royal Marsden Hospital and Institute of Cancer Research, London, UK.
22.3.2 The classification of leukaemia. 22.3.5 Chronic lymphocytic leukaemia and other leukaemias of mature B and T cells

Bruce A. Chabner Professor of Medicine, Harvard Medical School and Massachusetts General Hospital, Boston, USA.
6.7 Cancer chemotherapy and radiation therapy

Richard E. Chaisson Professor of Medicine, Epidemiology and International Health, Johns Hopkins University Schools of Medicine and Public Health, Baltimore, Maryland, USA.
7.11.22 Tuberculosis

R. W. Chapman Consultant Gastroenterologist/Hepatologist, John Radcliffe Hospital, Oxford, UK.
14.20.2.3 Primary sclerosing cholangitis

V. Krishna K. Chatterjee Professor of Endocrinology, University of Cambridge, Addenbrooke's Hospital, Cambridge, UK.
12.1 Principles of hormone action

Dominique Chauveau Consultant Nephrologist, Department of Nephrology, Hôpital Necker, Paris, France.
20.9.1 Acute interstitial nephritis

P. F. Chinnery Senior Lecturer in Neurogenetics and Honorary Consultant Neurologist, University of Newcastle upon Tyne and Newcastle upon Tyne Hospitals NHS Trust, UK.
24.22.5 Mitochondrial encephalomyopathies

Seung-Yull Cho Professor, Section of Molecular Parasitology, Sungkyunkwan University School of Medicine, Suwon, Korea.
7.15.4 Pseudophyllidean tapeworms: diphyllobothriasis and sparganosis

Kirpal S. Chugh Professor Emeritus, Department of Nephrology, Postgraduate Institute of Medical Education and Research, Chandigarh, India.
20.7.10 Glomerular disease in the tropics

L. Chwastiak Acting Assistant Professor, Department of Psychiatry, University of Washington, Seattle, USA.
26.5.4 Anxiety and depression

C. M. Clothier Queen's Counsel (retired), London, UK.
1 On being a patient

Andrew J. S. Coats Viscount Royston Professor of Cardiology, Imperial College London and Honorary Consultant Cardiologist, Royal Brompton Hospital, London, UK.
15.2.2 The syndrome of heart failure. 15.5.3 Cardiac rehabilitation

S. M. Cobbe Walton Professor of Medical Cardiology, University of Glasgow, Glasgow Royal Infirmary, UK.
15.2.3 Syncope and palpitation. 15.6 Cardiac arrhythmias

B. J. Cohen Clinical Scientist, Central Public Health Laboratory, London, UK.
7.10.18 Parvovirus B19

J. Cohen Dean and Professor of Infectious Diseases, Brighton and Sussex Medical School, UK.
7.20 Infection in the immunocompromised host

R. D. Cohen Emeritus Professor of Medicine, Bart's and The London School of Medicine and Dentistry, Queen Mary College, University of London, UK.
11.11 Disturbances of acid-base homeostasis

Francis S. Collins Director, National Human Genome Research Institute, Bethesda, Maryland, USA.
4.1 The genomic basis of medicine

R. Collins British Heart Foundation Professor of Medicine and Epidemiology, Clinical Trial Service Unit and Epidemiological Studies Unit, University of Oxford, UK.
2.4.3 Large-scale randomized evidence: trials and overviews

Alastair Compston Professor of Neurology, University of Cambridge, UK.
24.1 Introduction and approach to the patient with neurological disease . 24.16 Demyelinating disorders of the central nervous system

Juliet Compston Reader in Metabolic Bone Diseases and Honorary Consultant Physician, Addenbrooke's Hospital, Cambridge, UK.
19.4 Osteoporosis

C. P. Conlon Consultant Physician in Infectious Diseases, Nuffield Department of Medicine, John Radcliffe Hospital, Oxford, UK.
7.8 Travel and expedition medicine. 7.10.21 HIV and AIDS

Andrew Coop Duke University Medical Center, Durham, North Carolina, USA.
6.2 The nature and development of cancer. 6.3 The genetics of inherited cancers

M. R. Cooper Freelance Science Writer, CAB International, Wallingford, Oxfordshire, UK.
8.3 Poisonous plants and fungi

Susan Copley Consultant Radiologist, Hammersmith Hospital, London, UK.
17.3.1 Thoracic imaging

Fernando F. Costa Professor of Haematology, School of Medical Sciences, Unicamp, Campinas, Brazil.
22.5.10 Disorders of the red cell membrane

J. Couvreur Professeur Associé, Laboratoire de la Toxoplasmose, Institut de Puericulture, Paris, France.
7.13.4 Toxoplasmosis

P. J. Cowen Professor of Psychopharmacology, Warneford Hospital, Oxford, UK.
26.6.1 Psychopharmacology in medical practice

T. M. Cox Professor of Medicine, University of Cambridge, and Honorary Consultant Physician, Addenbrooke's Hospital, Cambridge, UK.
11.3.1 Glycogen storage diseases. 11.3.2 Inborn errors of fructose metabolism. 11.3.3 Disorders of galactose, pentose, and pyruvate metabolism. 11.5 The porphyrias. 11.7.1 Hereditary Haemochromatosis. 11.8 Lysosomal storage diseases. 12.13 The pineal gland and melatonin. 14.9.5 Disaccharidase deficiency. 22.5.4 Iron metabolism and its disorders. 33 Emergency Medicine

Dorothy H. Crawford Professor of Medical Microbiology, Centre for Infectious Diseases, University of Edinburgh, UK.
7.10.3 The Epstein-Barr virus

Robin A. F. Crawford Consultant Gynaecological Oncologist, Addenbrooke's Hospital, Cambridge, UK.
13.17 Malignant disease in pregnancy

A. J. Crisp Consultant Rheumatologist, Addenbrooke's Hospital, Cambridge, UK.
19.5 Avascular necrosis and related topics

D. W. M. Crook Consultant Microbiologist/Infectious Diseases, John Radcliffe Hospital, Oxford, UK.
24.14.1 Bacterial meningitis

J. Cunningham Professor of Renal and Metabolic Medicine, The Royal London Hospital and Queen Mary's School of Medicine and Dentistry, London, UK.
20.8 Renal tubular disorders

Patrick C. D'Haese Associate Professor, Department of Nephrology and Hypertension, University of Antwerp, Belgium.
20.9.2 Chronic tubulointerstitial nephritis

Tim Dalgleish Research Scientist, MRC Cognitions and Brain Sciences Unit, Cambridge, UK.
26.5.1 Grief, stress, and post-traumatic stress disorder

D. A. B. Dance Director/Consultant Microbiologist, Public Health Laboratory, Derriford Hospital, Plymouth, UK.

7.11.15 Melioidosis and glanders

Chi V. Dang Professor of Medicine and Chief, Hematology Division, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA.
22.3.7 Myelodysplasia

C. J. Danpure Professor of Molecular Cell Biology, Department of Biology, University College London, UK.
11.10 Disorders of oxalate metabolism

John H. Dark Professor of Cardiothoracic Surgery, Freeman Hospital, Newcastle upon Tyne, UK.
15.5.4 Cardiac transplantation and mechanical circulatory support

A. Davenport Consultant Renal Physician/Honorary Senior Lecturer, Centre for Nephrology, Royal Free Hospital, London, UK.
20.3.2 Clinical investigation of renal disease

G. Davey Smith Professor of Clinical Epidemiology, University of Bristol, UK.
15.4.1.2 The epidemiology of ischaemic heart disease

Alun Davies Reader and Honorary Consultant Surgeon, Department of Vascular Surgery, Faculty of Medicine, Imperial College School of Medicine, Charing Cross Hospital, London, UK.
15.14.2 Peripheral arterial disease

P. D. O. Davies Consultant Physician, Fazakerley Hospital, Liverpool, UK.
7.11.23 Disease caused by environmental mycobacteria

Alex M. Davison Professor and Consultant Renal Physician, St James's University Hospital, Leeds, UK.
20.3.1 The clinical presentation of renal disease

Marc E. De Broe Professor in Medicine, Department of Nephrology, University of Antwerp, Belgium.
20.9.2 Chronic tubulointerstitial nephritis

P. de la Motte Hall Professor, Division of Anatomical Pathology, Faculty of Health Sciences, University of Cape Town, South Africa.
14.21.6 Hepatic granulomas

M. de Swiet Professor of Obstetric Medicine, Queeen Charlotte's and Chelsea Hospital, London, UK.
13.7 Thromboembolism in pregnancy. 13.8 Chest diseases in pregnancy

Barbara A. Degar Yale School of Medicine, New Haven, Connecticut, USA.
22.4.2 Introduction to the lymphoproliferative disorders

Eric Demoncheaux Research Associate, Medical School, University of Sheffield, UK.
15.15.1 The pulmonary circulation and its influence on gas exchange

D. M. Denison Emeritus Professor of Clinical Physiology, Royal Brompton Hospital, London, UK.
8.5.5 Aerospace medicine. 8.5.6 Diving medicine

John Dent Director, Department of Gastroenterology, Hepatology and General Medicine and Clinical Professor of Medicine, Royal Adelaide Hospital/Adelaide University, Australia.
14.6 Diseases of the oesophagus

Christopher P. Denton Senior Lecturer/Consultant Rheumatologist, Centre for Rheumatology, Royal Free Hospital, London, UK.
18.10.3 Systemic sclerosis

Ulrich Desselberger Consultant Virologist and Director, Clinical Microbiology and Public Health Laboratory, Addenbrooke's Hospital, Cambridge, UK.
7.10.7 Enterovirus infections. 7.10.8 Virus infections causing diarrhoea and vomiting

Charles A. Dinarello Professor of Medicine, University of Colorado, Denver, Colorado, USA.
4.4 Cytokines: interleukin-1 and tumor necrosis factor in inflammation

A. K. Dixon Professor of Radiology and Honorary Consultant Radiologist, University of Cambridge and Addenbrooke's Hospital, Cambridge, UK.
14.18.2 Computed tomography and magnetic resonance imaging of the liver and pancreas

Michael Doherty Professor of Rheumatology, University of Nottingham Medical School, UK.
18.3 Clinical investigation. 18.9 Crystal-related arthropathies

R. Doll Emeritus Professor of Medicine and Honorary Member, Cancer Studies Unit, Nuffield Department of Medicine, Radcliffe Infirmary, Oxford, UK.
6.1 Epidemiology of cancer

Michael Donaghy Reader in Clinical Neurology, University of Oxford, Honorary Consultant Neurologist, Radcliffe Infirmary, and Honorary Civilian Consultant in Neurology to the Army, Oxford, UK.
24.13.13 The motor neurone diseases

Dominique Droz Unite de Pathologie Renale, Hôpital Necker, Paris, France.
20.9.1 Acute interstitial nephritis

R. M. du Bois Professor of Respiratory Medicine, National Heart and Lung Institute, University College London and Consultant Physician, Royal Brompton Hospital, London, UK.
17.11.1 Diffuse parenchymal lung disease: an introduction. 17.11.2 Cryptogenic fibrosing alveolitis. 17.11.3 Bronchiolitis obliterans and organizing pneumonia. 17.11.4 The lungs and rheumatological diseases. 17.11.5 The lung in vasculitis

C. R. K. Dudley Consultant Renal Physician, The Richard Bright Renal Unit Southmead Hospital, North Bristol NHS Trust, Bristol, UK.
15.14.3 Cholesterol emboli

D. W. Dunne Reader in Immunoparasitology, Department of Pathology, University of Cambridge, UK.
7.16.1 Schistosomiasis

David T. Durack Consulting Professor of Medicine, Duke University, Durham, North Carolina and Vice-President, Corporate Medical Affairs, Becton Dickinson & Co., Franklin Lakes, New Jersey, USA.
7.2 Fever of unknown origin

S. R. Durham Professor of Allergy and Respiratory Medicine, Imperial College Faculty of Medicine, National Heart and Lung Hospital, and Royal Brompton Hospital, London, UK.
17.4.2 Allergic rhinitis ('hay fever')

P. N. Durrington Professor of Medicine, University of Manchester Department of Medicine, Manchester Royal Infirmary, UK.
11.6 Lipid and lipoprotein disorders

M. Eastwood Post-Retirement Honorary Fellow, Department of Medical Sciences, Western General Hospital, Edinburgh, UK.
10.3 Vitamins and trace elements

Jonathan C. W. Edwards Professor in Connective Tissue Medicine, University College London, UK.
18.1 Joints and connective tissue: introduction

Richard Edwards Emeritus Professor of Medicine, University of Liverpool, UK.
24.22.4 Metabolic and endocrine disorders

M. Elia Professor of Clinical Nutrition and Metabolism, Institute of Human Nutrition, University of Southampton, UK.
10.6 Special nutritional problems and the use of enteral and parenteral nutrition

Matthew J. Ellis Associate Professor of Medicine and Director, Breast Cancer Program, Duke University Medical Center, Durham, North Carolina, USA.
6.2 The nature and development of cancer. 6.3 The genetics of inherited cancers

Monique M. Elseviers Department of Nephrology-Hypertension, University Hospital Antwerp, Belgium.
20.9.2 Chronic tubulointerstitial nephritis

M. A. Epstein Emeritus Professor of Pathology, University of Bristol, UK.
7.10.3 The Epstein-Barr virus

E. Ernst Professor and Director, Department of Complementary Medicine, University of Exeter, UK.
2.5 Complementary and alternative medicine

David Eschenbach Professor, Department of Obstetrics and Gynecology, University of Washington, Seattle, USA.
21.4 Pelvic inflammatory disease

S. M. Evans Specialist Registrar in Gastroenterology, Royal Sussex County Hospital, Brighton, UK.
8.5.8 Podoconiosis

S. J. Eykyn Professor (and Honorary Consultant) in Clinical Microbiology, St Thomas' Hospital, London, UK.
7.11.2 Streptococci and enterococci. 7.11.4 Staphylococci. 7.11.10 Anaerobic bacteria. 15.10.2 Infective endocarditis

C. A. Eynon Director of Neurosciences Intensive Care, Southampton University Hospital NHS Trust, UK.
16.3 Cardiac arrest. 33 Emergency Medicine

Christopher G. Fairburn Wellcome Principal Research Fellow and Professor of Psychiatry, Oxford University Department of Psychiatry, Warneford Hospital, Oxford, UK.
26.5.5 Eating disorders

J. J. Farrar Senior Fellow, Wellcome Trust, University of Oxford Clinical Research Unit, The Hospital for Tropical Diseases, Ho Chi Minh, Vietnam.
24.14.1 Bacterial meningitis. 24.14.2 Viral infections of the central nervous system

Ken Farrington Consultant Nephrologist, Lister Hospital, Stevenage, Hertfordshire, UK.
20.6.1 Haemodialysis

D. T. Fearon Wellcome Trust Professor of Medicine, University of Cambridge, UK.
5.5 Innate immune system

John Feehally Professor of Renal Medicine, Leicester General Hospital, UK.
20.7.2 IgA nephropathy and Henoch-Schonlein purpura. 20.7.3 Thin membrane nephropathy

Alvan R. Feinstein* Professor, Yale University School of Medicine, New Haven, Connecticut, USA.
2.4.2 Evidence-based medicine

Eleanor Feldman Consultant Liaison Psychiatrist and Honorary Senior Lecturer, University of Oxford, John Radcliffe Hospital, Oxford, UK.
26.2 Taking a psychiatric history from a medical patient. 26.4 Acute behavioural emergencies

Peter J. Fenner Associate Professor, Schools of Medicine and Health Sciences, James Cook University and National Medical Officer, Surf Life Saving Association of Australia, Mackay, North Queensland, Australia.
8.5.3 Drowning

Robert Ferrari Clinical Assistant Professor, University of Alberta Hospital, Edmonton, Canada.
18.2 Clinical presentation and diagnosis of rheumatic disease

C. ffrench-Constant Professor of Neurological Genetics, University of Cambridge, UK.
24.21 Developmental abnormalities of the nervous system

R. G. Finch Professor of Infectious Diseases, City Hospital and University of Nottingham, UK.
7.6 Antimicrobial chemotherapy

H. Firth Consultant in Medical Genetics, Department of Medical Genetics, Addenbrooke's Hospital, Cambridge, UK.
24.21 Developmental abnormalities of the nervous system

J. Firth Consultant Physician and Nephrologist, Addenbrooke's Hospital, Cambridge, UK.
13.5 Renal disease in pregnancy. 15.15.2.2 Pulmonary oedema. 15.15.3.1 Deep venous thrombosis and pulmonary embolism. 15.18 Idiopathic oedema of women. 16.1 The clinical approach to the patient who is very ill . 20.2.2 Disorders of potassium homeostasis. 20.4 Acute renal failure. 33 Emergency Medicine

Susan Fisher-Hoch Professor, University of Texas School of Public Health at Brownsville, USA.
7.10.15 Arenaviruses. 7.10.16 Filoviruses

Robert A. Fishman Professor of Neurology Emeritus, University of California San Francisco School of Medicine, USA.
24.7 Lumbar puncture

Edward D. Folland Associate Director of Cardiology and Professor of Medicine, UMass Memorial Medical Center/University of Massachusetts Medical School, Worcester, Maryland, USA.
15.3.6 Cardiac catheterization and angiography . 15.4.2.4 Percutaneous interventional cardiac procedures

J. C. Forfar Consultant Cardiologist, John Radcliffe Hospital, Oxford and Honorary Senior Lecturer, University of Oxford, UK.
13.6 Heart disease in pregnancy

I. S. Foulds Consultant Dermatologist, City Hospital, Birmingham, UK.
8.4.1 Occupational and environmental health and safety

Keith A. A. Fox Professor of Cardiology, Royal Infirmary and University of Edinburgh, UK.
15.4.2.3 Management of acute coronary syndromes: unstable angina and myocardial infarction

Richard Frackowiak Vice Provost (Biomedicine), University College London, Institute of Neurology, London, UK.
24.3 Brain and mind: functional neuroimaging

T. J. R. Francis Consultant in Diving Medicine, Tintagel, Cornwall, UK.
8.5.6 Diving medicine

Keith N. Frayn Professor of Human Metabolism, Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, UK.
10.2 Nutrition: biochemical background

Alan Freeman Consultant Radiologist, Addenbrooke's Hospital, Cambridge, UK.
14.2.3 Radiology of the gastrointestinal tract

Peggy Frith Consultant Ophthalmic Physician, The Eye Hospital, Radcliffe Infirmary, Oxford and University College London Hospital, UK.
25 The eye in general medicine

Patrick G. Gallagher Associate Professor, Department of Pediatrics, Yale University School of Medicine, New Haven, Connecticut, USA.
22.5.10 Disorders of the red cell membrane

Clare J. Galton Specialist Registrar in Neurology, Neurology Department, Addenbrooke's Hospital, Cambridge, UK.
24.13.8 Alzheimer's disease and other dementias

Hector H. Garcia Associate Professor, Department of Microbiology, Universidad Peruana Cayetano Heredia and Head, Cysticercosis Unit, Department of Transmissible Diseases, Instituto de Ciencias Neurologicas, Lima, Peru.
7.15.1 Cystic hydatid disease (Echinococcus granulosus) . 7.15.3 Cysticercosis

K. Gardiner Professor and Managing Director, International Occupational Health Ltd., Birmingham, UK.
8.4.1 Occupational and environmental health and safety

Lawrence B. Gardner Assistant Professor of Medicine, Johns Hopkins University school of Medicine, Baltimore, Maryland, USA.
22.3.7 Myelodysplasia

Christopher S. Garrard Consultant Physician in Intensive Care, John Radcliffe Hospital, Oxford, UK.
16.5.2 The management of respiratory failure

J. S. H. Gaston Professor of Rheumatology, University of Cambridge School of Medicine, Addenbrooke's Hospital, Cambridge, UK.
18.7.2 Reactive arthritis

Duncan Geddes Professor of Respiratory Medicine, Royal Brompton Hospital, London, UK.
17.10 Cystic fibrosis

D. G. Gibson Consultant Cardiologist, Royal Brompton Hospital, London, UK.
15.7 Valve disease. 15.9 Pericardial disease

G. J. Gibson Professor of Respiratory Medicine/Consultant Physician, Freeman Hospital, Newcastle upon Tyne, UK.
17.3.2 Respiratory function tests

A. M. Giles Scientific Officer, Health Systems, Oxford, UK.
32 Reference intervals for biochemical data

I. P. Giles ARC Research Fellow, Bloomsbury Rheumatology Unit, London, UK.
18.10.1 Autoimmune rheumatic disorders and vasculitis

Charles F. Gilks Professor of Tropical Medicine and Senior Adviser on Care, HIV/AIDS Department, World Health Organization, Geneva, Switzerland.
7.10.22 HIV in the developing world

Michael D. J. Gillmer Consultant Obstetrician and Gynaecologist, Women's Centre, John Radcliffe Hospital, Oxford, UK.
13.10 Diabetes in pregnancy

Robert H. Gilman Professor, Department of International Health, Johns Hopkins School of Public Health, Baltimore, Maryland, USA and Research Professor, Universidad Peruana Cayetano Heredia, Lima, Peru.
7.15.3 Cysticercosis

A. E. S. Gimson Consultant Physician and Hepatologist, Cambridge Liver Transplantation Unit, Addenbrooke's Hospital, Cambridge, UK.
13.9 Liver and gastrointestinal diseases during pregnancy . 14.18.1 Structure and function of the liver, biliary tract, and pancreas

P. Glasziou Huntington Centre for Risk Analysis, Boston, Massachusetts, USA.
2.4.1 Bringing the best evidence to the point of care

Peter J. Goadsby Professor of Clinical Neurology, Institute of Neurology, University College and The National Hospital for Neurology and Neurosurgery, London, UK.
24.13.2 Headache

D. Goldblatt Reader in Immunology and Consultant Paediatric Immunologist, Institute of Child Health, Great Ormond Hospital for Children NHS Trust, London, UK.

7.7 Immunization

John M. Goldman Professor of Leukaemia Biology and Chairman, Department of Haematology, Imperial College School of Medicine, London, UK.
22.3.6 Chronic myeloid leukaemia

Irwin Goldstein Director, Institute for Sexual Medicine and Professor of Urology and Gynecology, Boston University School of Medicine, Massachusetts, USA.
12.8.4 Sexual dysfunction

Armando E. Gonzalez Department of Public Health, School of Veterinary Medicine, Universidad Nacional Mayor de San Marcos, Lima, Peru.
7.15.1 Cystic hydatid disease (Echinococcus granulosus)

Timothy H. J. Goodship Reader in Nephrology, University of Newcastle upon Tyne and Consultant Nephrologist, Royal Victoria Infirmary, Newcastle upon Tyne, UK.
20.10.6 Haemolytic uraemic syndrome

Sherwood L. Gorbach Department of Community Health and Medicine, TUFTS University School of Medicine, Boston, Massachusetts, USA.
14.17 Gastrointestinal infections

E. C. Gordon-Smith Professor of Haematology, St George's Hospital Medical School, London, UK.
22.3.11 Aplastic anaemia and other causes of bone marrow failure . 22.8.2 Haemopoietic stem cell transplantation

J. M. Grange Visiting Professor, University College London, Centre for Infectious Diseases and International Health, Royal Free and University College Medical School, London, UK.
7.11.23 Disease caused by environmental mycobacteria

R. Gray Professor of Medical Statistics and Director, University of Birmingham Clinical Trials Unit, UK.
2.4.3 Large-scale randomized evidence: trials and overviews

John R. Graybill Professor, University of Texas Health Science Center, San Antonio, Texas, USA.
7.12.3 Coccidioidomycosis

Jackie Green Director, Centre for Health Promotion Research, Leeds Metropolitan University, Leeds, UK.
3.5 Health promotion

Brian M. Greenwood Professor of Clinical Tropical Medicine, London School of Hygiene and Tropical Medicine, London, UK.
7.11.3 Pneumococcal diseases

Roger Greenwood Consultant Nephrologist and Lead Clinician, Lister Hospital, Stevenage, Hertfordshire, UK.
20.6.1 Haemodialysis

B. Gribbin Honorary Consultant Cardiologist, John Radcliffe Hospital, Oxford, UK.
15.10.3 Cardiovascular syphilis . 15.14.1 Thoracic aortic dissection

John Grimley Evans Professor Emeritus of Clinical Geratology, Green College, Oxford, UK.
30.1 Medicine in old age

Michael L. Grossbard Chief, Hematology/Oncology, St Luke's-Roosevelt Hospital and Beth Israel Medical Center, New York, USA.
6.7 Cancer chemotherapy and radiation therapy

David I. Grove Professor and Director, Clinical Microbiology and Infectious Diseases, The Queen Elizabeth Hospital, Adelaide, Australia.
7.14.5 Nematode infections of lesser importance . 7.16.2 Liver fluke infections . 7.16.4 Intestinal trematode infections

J. P. Grünfeld Professor of Nephrology, Université Paris V - René Descartes and Head of Nephrology, Hôpital Necker, Paris, France.
20.11 Renal involvement in genetic disease

D. J. Gubler Director, Division of Vector-Borne Infectious Diseases, Centers for Disease Control and Prevention, Fort Collins, Colorado, USA.
7.10.11 Alphaviruses . 7.10.13 Flaviviruses

Mark Gurnell Specialist Registrar and Research Fellow, Department of Medicine, Division of Endocrinology and Metabolism, Addenbrooke's Hospital, Cambridge, UK.
12.1 Principles of hormone action

David M. Gustin Section of Hematology-Oncology, University of Chicago, Illinois, USA.
22.3.8 The polycythaemias . 22.3.10 Thrombocytosis

M. R. Haeney Consultant Immunologist, Salford Royal Hospitals NHS Trust, Salford, Manchester, UK.
14.4 Immune disorders of the gastrointestinal tract

Davidson H. Hamer Director, Traveler's Health Service, Tufts-New England Medical Center and Assistant Professor of Medicine and Nutrition, Tufts University, Boston, Massachusetts, USA.
14.17 Gastrointestinal infections

P. J. Hammond Consultant Physician and Endocrinologist, Harrogate District Hospital, Yorkshire, UK.
12.10 Non-diabetic pancreatic endocrine disorders and multiple endocrine neoplasia . 14.8 Hormones and the gastrointestinal tract

J. R. Hampton Professor of Cardiology, Queen's Medical Centre, Nottingham, UK.
15.2.1 Chest pain . 15.2.4 Physical examination of the cardiovascular system

M. Hanna Consultant Neurologist and Reader in Clinical Neurology, National Hospital for Neurology and Neurosurgery and Institute of Neurology, University College London, UK.
24.22.1 Introduction: structure and function

David M. Hansell Professor of Thoracic Imaging, Royal Brompton Hospital, London, UK.
17.3.1 Thoracic imaging

P. Harnden Consultant Urological Pathologist, Cancer Research UK Clinical Centre, St James's University Hospital, Leeds, UK.
20.15 Tumours of the urinary tract

J. M. Harrington Emeritus Professor of Occupational Health, University of Birmingham, UK.

8.4.1 Occupational and environmental health and safety

Anthony Harrison Fellow in Health Systems, King's Fund, London, UK.
3.3 The pattern of care: hospital and community

J. R. Harrison Force Medical Adviser, Sussex Police Authority, Lewes, UK.
8.5.9 Radiation

C. Haslett Professor of Respiratory Medicine, Royal Infirmary, Edinburgh, UK.
16.5.1 Pathophysiology and pathogenesis of acute respiratory distress syndrome . 17.1.3 'First line' defence mechanisms of the lung

Adrian R. W. Hatfield Consultant Gastroenterologist, The Middlesex Hospital, London, UK.
14.2.2 Upper gastrointestinal endoscopy

P. N. Hawkins Professor of Medicine, Royal Free and University College Medical School, London, UK.
11.12.3 Familial Mediterranean fever and other inherited periodic fever syndromes . 11.12.4 Amyloidosis

Keith Hawton Professor of Psychiatry, University Department of Psychiatry and Director and Consultant Psychiatrist, Centre for Suicide Research, Warneford Hospital, Oxford, UK.
26.5.2 The patient who has attempted suicide

R. J. Hay Professor and Dean, Faculty of Medicine and Health Sciences, Queens University, Belfast, UK.
7.11.27 Nocardiosis. 7.12.1 Fungal infections

B. Hazleman Consultant Rheumatologist, Rheumatology Department, Addenbrooke's Hospital, Cambridge, UK.
18.11 Miscellaneous conditions presenting to the rheumatologist

Nick Heather Consultant Clinical Psychologist and Director, Centre for Alcohol and Drug Studies, Newcastle, North Tyneside, and Northumberland Mental Health NHS Trust, Newcastle upon Tyne, UK.
26.7.2 Brief interventions against excessive alcohol consumption

David B. Hellmann Professor, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA.
18.10.7 Polymyositis and dermatomyositis

D. J. Hendrick Consultant Physician and Professor of Occupational Respiratory Medicine, Royal Victoria Infirmary, University of Newcastle upon Tyne, UK.
17.11.8 Pulmonary haemorrhagic disorders. 17.11.9 Eosinophilic pneumonia. 17.11.10 Lymphocytic infiltrations of the lung . 17.11.11 Extrinsic allergic alveolitis . 17.11.12 Eosinophilic granuloma of the lung and pulmonary lymphangiomyomatosis. 17.11.13 Pulmonary alveolar proteinosis. 17.11.14 Pulmonary amyloidosis. 17.11.15 Lipoid (lipid) pneumonia. 17.11.16 Pulmonary alveolar microlithiasis. 17.11.17 Toxic gases and fumes. 17.11.18 Radiation pneumonitis. 17.11.19 Drug-induced lung disease

Mark Herbert Clinical Lecturer in Neonatal Paediatrics, Department of Paediatrics, University of Oxford, UK.
13.15 Infections in pregnancy

Andrew Herxheimer Emeritus Fellow, UK Cochrane Centre, London, UK.
9 Principles of clinical pharmacology and drug therapy

Martin F. Heyworth Chief of Staff and Clinical Professor of Medicine, VA Medical Center and University of Pennsylvania, Philadelphia, USA.
7.13.8 Giardiasis, balantidiasis, isosporiasis, and microsporidiosis

Tim Higenbottam Global Clinical Expert, Astra-Zeneca, Charnwood, Leicestershire and Visiting Professor of Medicine, University of Sheffield, UK.
15.15.1 The pulmonary circulation and its influence on gas exchange . 15.15.2.1 Primary pulmonary hypertension

Katherine A. High William H. Bennett Professor of Pediatrics, University of Pennsylvania School of Medicine and The Children's Hospital of Philadelphia, Pennsylvania, USA.
22.6.4 Genetic disorders of coagulation

S. L. Hillier Research Associate Professor of Obstetrics and Gynecology, University of Washington, Seattle, USA.
21.3 Vaginal discharge

David Hilton-Jones Clinical Director, Oxford MDC Muscle and Nerve Centre, Radcliffe Infirmary, Oxford, UK.
24.17 Diseases of the neuromuscular junction. 24.22.3 Myotonia. 24.22.4 Metabolic and endocrine disorders

John R. Hodges Professor of Behavioural Neurology, MRC Cognition and Brain Sciences Unit and Department of Neurology, Addenbrooke's Hospital, Cambridge, UK.
24.8 Disturbances of higher cerebral function . 24.13.8 Alzheimer's disease and other dementias

H. J. F. Hodgson Sheila Sherlock Professor of Medicine and Director, Centre for Hepatology, Royal Free and University College Medical School, London, UK.
14.9.6 Whipple's disease . 14.20.1 Viral hepatitis - clinical aspects . 14.20.2.1 Autoimmune hepatitis

A. V. Hoffbrand Emeritus Professor of Haematology, Royal Free and University College School of Medicine, London, UK.
22.5.6 Megaloblastic anaemia and miscellaneous deficiency anaemias

Ronald Hoffman Professor, Hematology-Oncology Section University of Illinois College of Medicine, Chicago, USA.
22.3.8 The polycythaemias. 22.3.10 Thrombocytosis

P. A. H. Holloway Consultant Chemical Pathologist in Intensive Care and Honorary Reader in Medicine, John Radcliffe Hospital, Oxford, UK.
32 Reference intervals for biochemical data

Richard H. Holloway Associate Professor of Medicine and Senior Consultant Gastroenterologist, Department of Gastroenterology, Hepatology and General Medicine, Royal Adelaide Hospital, Australia.
14.6 Diseases of the oesophagus

J. M. Hopkin Professor, Experimental Medicine Unit, Swansea Clinical School, University of Wales, Swansea, UK.
17.4.1 Asthma: genetic effects. 17.15 The genetics of lung diseases

Carol Ann Huff Assistant Professor of Oncology, Sidney Kimmel Comprehensive Cancer Care at Johns Hopkins, Baltimore, Maryland, USA.
26.7.3 Problems of alcohol and drug users in the hospital

I. A. Hughes Professor of Paediatrics and Honorary Consultant Paediatric Enterologist, Department of Paediatrics, University of Cambridge, UK.

12.7.2 Congenital adrenal hyperplasia

Lawrence Impey Consultant in Fetal Medicine, The Women's Centre, John Radcliffe Hospital, Oxford, UK.
13.15 Infections in pregnancy

C. W. Imrie Consultant Surgeon and Honorary Professor, Lister Department of Surgery, Royal Infirmary, Glasgow, UK.
14.18.3.1 Acute pancreatitis

H. Irving Consultant Radiologist, St James's University Hospital, Leeds, UK.
20.15 Tumours of the urinary tract

P. G. Isaacson Professor of Histopathology, Royal Free and University College Medical School, London, UK.
14.9.4 Gastrointestinal lymphoma

D. A. Isenberg The Arthritis Research Campaign Professor of Rheumatology at University College London, Centre for Rheumatology, London, UK.
18.10.1 Autoimmune rheumatic disorders and vasculitis. 18.10.2 Systemic lupus erythematosus and related disorders

C. G. Isles Consultant Physician, Medical Unit, Dumfries and Galloway Royal Infirmary, Dumfries, UK.
15.16.1.1 Prevalence, epidemiology, and pathophysiology of hypertension

C. Ison Reader in Medical Microbiology, Department of Infectious Diseases and Microbiology, Faculty of Medicine, Imperial College, St Mary's Campus, London, UK.
7.11.6 Neisseria gonorrhoeae

Alan A. Jackson Professor and Director, Institute of Human Nutrition, University of Southampton, UK.
10.4 Severe malnutrition

H. S. Jacobs Emeritus Professor of Reproductive Endocrinology, University College London Medical School, UK.
12.8.1 Ovarian disorders. 12.8.3 The breast

Robin Jacoby Professor of Old Age Psychiatry, University of Oxford Department of Psychiatry, Warneford Hospital, Oxford, UK.
30.2 Mental disorders of old age

O. F. W. James Head of Clinical Medical Sciences, Medical School, University of Newcastle upon Tyne, UK.
14.21.1 Alcoholic liver disease and non-alcoholic steatosis hepatitis

Paul J. Jenkins Senior Lecturer in Endocrinology, St Bartholomew's Hospital, London, UK.
12.2 Disorders of the anterior pituitary

B. Jennett Emeritus Professor of Neurosurgery, Institute of Neurological Sciences, University of Glasgow, UK.
24.13.6 Brain death and the vegetative state

D. P. Jewell Professor of Gastroenterology, John Radcliffe Hospital, Oxford, UK.
14.9.3 Coeliac disease. 14.10 Crohn's disease. 14.11 Ulcerative colitis. 14.22 Miscellaneous disorders of gastrointestinal tract and liver

Vivekanand Jha Associate Professor of Nephrology, Postgraduate Institute of Medical Education and Research, Chandigarh, India.
20.7.10 Glomerular disease in the tropics

Anne M. Johnson Professor of Infectious Disease Epidemiology and Head, Department of Primary Care and Population Sciences, University College London, UK.
21.2 Sexual behaviour

A. W. Johnson CAB International, Wallingford, Oxfordshire, UK.
8.3 Poisonous plants and fungi

E. Anthony Jones Chief of Hepatology, Academic Medical Centre, Amsterdam, The Netherlands.
14.21.3 Hepatocellular failure

N. Jones Department of Virology, John Radcliffe Hospital, Oxford, UK.
7.10.25 Orf. 7.10.26 Molluscum contagiosum

S. E. Jones Research Associate, Department of Biology, Imperial College of Science, Technology and Medicine, London, UK.
7.11.33 Syphilis

Kenneth C. Kalunian Professor of Medicine, UCLA School of Medicine, Los Angeles, California, USA.
18.8 Osteoarthritis

Eileen Kaner NHS Primary Care Career Scientist, School of Population and Health Sciences, University of Newcastle upon Tyne, UK.
26.7.2 Brief interventions against excessive alcohol consumption

W. Katon Professor and Vice Chair, Director of Division of Health Services and Psychiatric Epidemiology, University of Washington, Seattle, Washington, USA.
26.5.4 Anxiety and depression

Tomisaku Kawasaki Professor and Director, Japan Kawasaki Disease Research Center, Tokyo, Japan.
18.10.8 Kawasaki syndrome

David Keeling Consultant Haematologist and Director, Oxford Haemophilia Centre and Thrombosis Unit, Churchill Hospital, Oxford, UK.
15.5.2 Therapeutic anticoagulation in atrial fibrillation and heart failure . 15.15.3.2 Therapeutic anticoagulation in deep venous thrombosis and pulmonary embolism

David P. Kelsell Non-Clinical Senior Lecturer, Centre for Cutaneous Research, Barts and The London, Queen Mary's School of Medicine and Dentistry, London, UK.
23.2 Molecular basis of inherited skin disease

John G. Kelton Dean and Vice-President, Faculty of Health Sciences, McMaster University, Hamilton, Ontario, Canada.
22.6.3 Disorders of platelet number and function

Christopher Kennard Professor and Head, Division of Neuroscience and Psychological Medicine, Imperial College London, Charing Cross Campus, London, UK.
24.11 Visual pathways

Rose Anne Kenny Professor of Cardiovascular Research, Institute of Ageing and Health, University of Newcastle upon Tyne, UK.
24.13.5.1 Head-up tilt-table testing in the diagnosis of vasovagal syncope and related disorders

M. G. W. Kettlewell Consultant Surgeon, Oxford Radcliffe Trust, UK.
14.13 Colonic diverticular disease

G. T. Keusch Associate Director for International Research, National Institutes of Health, Bethesda, Maryland, and Professor of Medicine, Tufts-New England Medical Center, Boston, Massachusetts, USA.
7.11.7 Enterobacteria, campylobacter, and miscellaneous food-poisoning bacteria

Munther A. Khamashta Senior Lecturer and Consultant Physician, Lupus Research Unit, The Rayne Institute, St Thomas' Hospital, London, UK.
13.14 Autoimmune rheumatic disorders and vasculitis in pregnancy

Maurice King Honorary Research Fellow, University of Leeds, UK.
3.7.2 Health in a fragile future

Keith P. Klugman Professor of International Health, Rollins School of Public Health and Division of Infectious Diseases, School of Medicine, Emory University, Atlanta, Georgia, USA.
7.11.3 Pneumococcal diseases

R. Knight Associate Specialist in General Medicine, Royal Sussex County Hospital, Brighton, UK.
7.13.1 Amoebic infections. 7.13.9 *Blastocystis hominis* infection. 7.14.2 Lymphatic filariasis. 7.14.3 Guinea-worm disease: dracunculiasis. 7.14.4 Strongyloidiasis, hookworm, and other gut strongyloid nematodes. 7.14.8 Angiostrongyliasis. 7.15.2 Gut cestodes

Michael D. Kopelman Professor of Clinical Medicine and Deputy Warden, Bart's and The London, Queen Mary's School of Medicine and Dentistry, University of London, UK.
26.3 Neuropsychiatric disorders

Peter G. Kopelman Professor of Clinical Medicine, Bart's and The London Queen Mary's School of Medicine and Dentistry, London, UK.
10.5 Obesity

Christian Krarup Professor, Department of Clinical Neurophysiology, Rigshospitalet, Copenhagen, Denmark.
24.2 Electrophysiology of the central and peripheral nervous systems

J. B. Kurtz Consultant Virologist (retired), Public Health Laboratory, Birmingham Heartlands Hospital, UK.
7.11.35 Legionellosis and legionnaires' disease

Robert A. Kyle Professor of Medicine and Laboratory Medicine, Mayo Clinic, Rochester, Minnesota, USA.
22.4.5 Myeloma and paraproteinaemias

David Lalloo Senior Lecturer in Tropical Medicine, Liverpool School of Tropical Medicine, UK.
7.11.17 Yersinia, Pasteurella, and Francisella

D. J. Lane Consultant Chest Physician (Retired), Oxford Radcliffe Hospital, UK.
17.2 The clinical presentation of chest diseases

Peter Lanyon Consultant Rheumatologist, University Hospital, Queen's Medical Centre, Nottingham, UK.
18.3 Clinical investigation

H. E. Larson Private Practice in Infectious Diseases, Marlborough, Massachusetts, USA.
7.11.21 Botulism, gas gangrene, and clostridial gastrointestinal infections

S. Lawrie Senior Clinical Research Fellow, University Department of Psychiatry, Royal Edinburgh Hospital, UK.
26.5.6 Schizophrenia, bipolar disorder, obsessive-compulsive disorder, and personality disorder

N. F. Lawton Consultant Neurologist, Wessex Neurological Centre, Southampton General Hospital and Honorary Senior Lecturer, University of Southampton, UK.
24.13.19 Intracranial hypertension

John H, Lazarus Professor of Clinical Endocrinology, University of Wales College of Medicine, Cardiff, UK.
13.11 Endocrine disease in pregnancy

J. W. LeDuc Director, Division of Viral and Rickettsial Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia, USA.
7.10.14 Bunyaviridae

P. J. Lee Consultant in Metabolic Medicine, Metabolic Unit, National Hospital for Neurology and Neurosurgery, London, UK.
11.2 Inborn errors of amino acid and organic acid metabolism

Tak H. Lee Professor of Allergy and Respiratory Medicine, Guy's, King's and St Thomas' School of Medicine, Guy's Hospital, London, UK.
17.4.3 Basic mechanisms and pathophysiology of asthma

William M. F. Lee Department of Medicine, School of Medicine, University of Pennsylvania, Philadelphia, USA.
4.3 Molecular cell biology

T. Lehner Professor of Basic and Applied Immunology, Department of Immunobiology, Guy's, King's and St Thomas' School of Medicine, London, UK.
14.5 The mouth and salivary glands. 18.10.5 Behcet's disease

Irene M. Leigh Professor of Cellular and Molecular Medicine, Bart's and The London Queen Mary's School of Medicine and Dentistry, University of London, UK.
23.2 Molecular basis of inherited skin disease

G. G. Lennox Consultant Neurologist, Addenbrooke's Hospital, Cambridge, UK.
13.12 Neurological disease in pregnancy

E. A. Letsky Consultant Perinatal Haematologist, Queen Charlotte's and Chelsea Hospital, London, UK.
13.16 Blood disorders in pregnancy

Jeremy Levy Consultant Nephrologist, Imperial College, Hammersmith Hospital, London, UK.
20.7.7 Antiglomerular basement membrane disease

L. M. Lichtenstein Professor of Medicine and Director, Asthma and Allergy Center, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA.
5.2 Allergy

D. C. Linch Professor and Head of Haematology, University College London, UK.
22.2.2 Stem-cell disorders

M. J. Lindop Consultant, Anaesthesia/Intensive Care, Addenbrooke's Hospital, Cambridge, UK.
16.6.3 Brainstem death and organ donation. 16.6.4 The patient without hope

Calvin C. Linnemann, Jr Professor and Director, Infectious Diseases Division, University of Cincinnati Medical Center, Ohio, USA.
7.11.14 Bordetella

Gregory Y. H. Lip Professor of Cardiovascular Medicine, University Department of Medicine, City Hospital, Birmingham, UK.
15.16.3 Hypertensive emergencies and urgencies

P. Little Professor of Primary Care Research, Community Clinical Sciences Division, University of Southampton, UK.
17.5.1 Upper respiratory tract infections

Roderick A. Little Honorary Professor of Surgical Science, University of Manchester, UK.
11.12.2 Metabolic response to accidental and surgical injury

W. Littler Medical Director, University Hospital NHS Trust, Birmingham, UK.
15.10.2 Infective endocarditis

A. Llanos Cuentas Principal Professor, Facultad de Salud Publica y Administracion, Universidad Peruana Cayetano Heredia, Lima, Peru.
7.11.39.1 *Bartonella bacilliformis* infection

Diana N. J. Lockwood Consultant Leprologist and Senior Lecturer, Hospital for Tropical Diseases and London School of Hygiene and Tropical Medicine, UK.
7.11.24 Leprosy (Hansen's disease)

S. Logan Senior Lecturer in Paediatric Epidemiology, Institute of Child Health, London, UK.
7.10.12 Rubella

D. J. Lomas Professor of Clinical MRI, University Department of Radiology, Addenbrooke's Hospital, Cambridge, UK.
14.18.2 Computed tomography and magnetic resonance imaging of the liver and pancreas

David A. Lomas Professor of Respiratory Biology and Honorary Consultant Physician, Department of Medicine, University of Cambridge Institute for Medical Research, UK.
11.13 a_1-Antitrypsin deficiency and the serpinopathies

Thomas Look Professor of Pediatrics, Harvard Medical School and Vice-Chair for Research, Pediatric Oncology Department, Dana-Farber Institute, Boston, Massachusetts, USA.
22.3.1 Cell and molecular biology of human leukaemias

A. D. Lopez Senior Science Adviser, World Health Organization, Geneva, Switzerland.
3.1 The Global Burden of Disease Study

Elyse E. Lower Professor of Medicine, University of Cincinnati, Ohio, USA.
17.11.6 Sarcoidosis

Linda M. Luxon Professor of Audiological Medicine, University of London, Institute of Child Health, London, UK and Director, National Institute for Cancer Research, Genova, Italy.
24.12.2 Disorders of hearing

Lucio Luzzatto Professor, Department of Human Genetics, Memorial Sloan- Kettering Cancer Center, New York, USA.
22.3.12 Paroxysmal nocturnal haemoglobinuria. 22.5.12 Glucose-6-phosphate-dehydrogenase (G6PD) deficiency

G. A. Luzzi Consultant in Genitourinary/HIV Medicine, South Buckinghamshire NHS Trust, Wycombe Hospital, High Wycombe, Buckinghamshire, UK.
7.10.21 HIV and AIDS

D. C. W. Mabey Professor of Communicable Diseases, London School of Hygiene and Tropical Medicine, London, UK.
7.11.40 Chlamydial infections including lymphogranuloma venerum

P. K. MacCallum Senior Lecturer in Haematology, Barts and The London, Queen Mary's School of Medicine and Dentistry, London, UK.
15.1.2.2 The haemostatic system in arterial disease

J. T. Macfarlane Consultant Physician, Nottingham City Hospital, UK.
7.11.35 Legionellosis and legionnaires' disease

K. T. MacLeod Reader in Cardiac Physiology, Cardiac Medicine, NHLI, Faculty of Medicine, Imperial College London, UK.
15.1.3.1 Physical considerations: biochemistry and cellular physiology of heart muscle

William MacNee Professor of Respiratory and Environmental Medicine, University of Edinburgh, and Honorary Consultant Physician, Lothian University NHS Trust, Edinburgh, UK.
17.6 Chronic obstructive pulmonary disease

M. Monir Madkour Consultant Physician, Military Hospital, Riyadh, Saudi Arabia.
7.11.19 Brucellosis

R. N. Maini Professor of Rheumatology in the University of London, Head of the Kennedy Institute of Rheumatology Division, Faculty of Medicine, Imperial College London, and Honorary Consultant Physician, Charing Cross Hospital, London, UK.
18.5 Rheumatoid arthritis

Hadi Manji Consultant Neurologist, National Hospital for Neurology, London and Ipswich Hospital, Suffolk, UK.
24.14.4 Neurosyphilis and neuroAIDS

J. I. Mann Professor in Human Nutrition and Medicine, University of Otago, Dunedin, New Zealand.
10.1 Diseases of overnourished societies and the need for dietary change

D. Mant Professor of General Practice, Department of Primary Health Care, University of Oxford, UK.

3.4 Preventive medicine

Victor J. Marder Orthopedic Hospital/UCLA Vascular Medicine Program, Los Angeles, California, USA.
22.6.2 Evaluation of the patient with a bleeding diathesis

A. F. Markham Professor of Medicine, St James's University Hospital, Leeds, UK.
14.15 Tumours of the gastrointestinal tract

V. Marks Professor of Clinical Biochemistry Emeritus, Post-Graduate Medical School, University of Surrey, Guildford, UK.
12.11.3 Hypoglycaemia

T. J. Marrie Professor and Chair, Department of Medicine, University of Alberta, Edmonton, Canada.
7.11.38 *Coxiella burneti*i infections (Q fever)

Helen Marriott Research Associate, Department of Respiratory Medicine, University of Shefffield, UK.
15.15.2.1 Primary pulmonary hypertension

C. D. Marsden* Professor of Neurology, National Hospital for Neurology and Neurosurgery, London, UK.
24.15 Metabolic disorders and the nervous system

Jay W. Mason Professor and Chair, Department of Medicine, University of Kentucky College of Medicine, Lexington, USA.
15.8.1 Myocarditis

V. I. Mathan Professor, ICDDR, Dhaka, Bangladesh.
14.9.8 Malabsorption syndromes in the tropics

Christopher J. Mathias Professor of Neurovascular Medicine and Consultant Physician, Imperial College of Science, Technology and Medicine at St Mary's and National Hospital for Neurology and Neurosurgery, Institute of Neurology, University College London, UK.
24.13.14 Disorders of the autonomic nervous system

Peter W. Mathiesen Professor of Renal Medicine, Academic Renal Unit, University of Bristol, Southmead Hospital, Bristol, UK.
20.7.5 Proliferative glomerulonephritis . 20.7.6 Mesangiocapillary glomerulonephritis

R. McCaig Head, Human Factors Unit, Health Directorate, Health and Safety Executive, Bootle, UK.
8.5.10 Noise. 8.5.11 Vibration

Mary E. McCaul Professor, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA.
26.7.1 Alcohol and drug dependence

Joseph McCormick Regional Dean, University of Texas School of Public Health at Brownsville, USA.
7.10.15 Arenaviruses. 7.10.16 Filoviruses

William J. McKenna BHF Professor of Molecular Cardiovascular Sciences, Department of Cardiological Sciences, St George's Hospital Medical School, London, UK.
15.8.2 The cardiomyopathies: hypertrophic, dilated, restrictive, and right ventricular . 15.8.3 Specific heart muscle disorders

A. J. McMichael Professor and Director, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK.
5.1 Principles of immunology.

A. J. McMichael Professor and Director, National Centre for Epidemiology and Population Health, Australian National University, Canberra, Australia.
3.2 Human population size, environment, and health

A. McMillan Consultant Physician, Department of Genito-urinary Medicine, Edinburgh Royal Infirmary, UK.
21.5 Infections and other medical problems in homosexual men

Martin McNally Consultant in Limb Reconstruction and Honorary Senior Lecturer in Orthopaedic Surgery, Bone Infection Unit, Nuffield Orthopaedic Centre, Oxford, UK.
19.3 Osteomyelitis

K. McNeil Director of Transplant Services, The Prince Charles Hospital, Brisbane, Australia.
17.16 Lung and heart-lung transplantation

T. W. Meade Emeritus Professor of Epidemiology, London School of Hygiene and Tropical Medicine, UK.
15.1.2.2 The haemostatic system in arterial disease

A. Meheus Professor, University of Antwerp, Belgium.
21.1 Epidemiology

David K. Menon Professor of Anaesthesia, University of Cambridge, Addenbrooke's Hospital, Cambridge, UK.
16.6.2 Management of raised intracranial pressure

Wayne M. Meyers Chief, Mycobacteriology, Armed Forces Institute of Pathology, Washington DC, USA.
7.11.25 Buruli ulcer: *Mycobacterium ulcerans* infection

Anna Rita Migliaccio Dirigente de Ricerca in Transfusion Medicine, Laboratory of Clinical Biochemistry, Istituto Superiore dei Sanità, Rome, Italy.
22.5.1 Erythropoiesis and the normal red cell

M. A. Miles Professor, London School of Hygiene and Tropical Medicine, UK.
7.13.11 Chagas' disease

G. J. Miller Professor of Epidemiology, Barts and The London, Queen Mary's School of Medicine and Dentistry, London, UK.
15.1.2.2 The haemostatic system in arterial disease

Mary Miller Consultant in Palliative Medicine, Sir Michael Sobell House, Churchill Hospital, Oxford, UK.
31 Palliative care

Robert F. Miller Reader in Clinical Infection and Consultant Physician, Royal Free and University College Medical School, London, UK.
7.12.5 Pneumocystis carinii

K. R. Mills Professor of Clinical Neurophysiology, King's College Hospital, London, UK.

24.4 Investigation of central motor pathways: magnetic brain stimulation

Philip Minor Public Health and Clinical Microbiology Laboratory, Addenbrooke's Hospital, Cambridge, UK.
7.10.7 Enterovirus infections

Raad H. Mohiaddin Consultant and Honorary Senior Lecturer, Royal Brompton and Harefield NHS Trust, London, JK.
15.3.5 Cardiovascular magnetic resonance and computed X-ray tomography

Andrew J. Molyneux Consultant Neuroradiologist, Radcliffe Infirmary, Oxford, UK.
24.5 Neuroimaging in neurological diseases

Kevin Moore Senior Lecturer, Centre for Hepatology, Royal Free ospital and University College Medical School, London, UK.
14.21.2 Cirrhosis, portal hypertension and ascites

Pedro L. Moro Fellow, Vaccine Safety Division, National Immunization Program, Centers for Disease Control and Prevention, Baltimore, Maryland, USA.
7.15.1 Cystic hydatid disease (Echinococcus granulosus)

N. J. McC. Mortensen Professor of Colorectal Surgery, Department of Colorectal Surgery, John Radcliffe Hospital, Oxford, UK.
14.13 Colonic diverticular disease

Peter S. Mortimer Professor of Dermatological Medicine and Consultant Skin Physician, St George's Hospital Medical School, Division of Physiological Medicine, London, UK.
15.17 Lymphoedema

Alastair G. Mowat Clinical Lecturer in Rheumatology, Department of Rheumatology, Nuffield Orthopaedic Centre, Oxford, UK.
18.10.4 Polymyalgia rheumatica and giant cell arteritis

E. R. Moxon Head, Oxford University Department of Paediatrics, John Radcliffe Hospital, Oxford, UK.
7.11.12 Haemophilus influenzae

M. F. Muers Consultant Physician, Respiratory Medicine, The General Infirmary at Leeds, UK.
17.3.4 Diagnostic bronchoscopy, thoracoscopy, and tissue biopsy

Tariq I. Mughal Consultant Haematologist and Medical Oncologist and Senior Lecturer in Oncology, Lancashire Teaching Hospitals NHS Trust and Preston and Christie Hospital NHS Trust, Manchester, UK.
22.3.6 Chronic myeloid leukaemia

J. A. Muir Gray Director of the UK National Screening Committee, Institute of Health Sciences, Oxford, UK.
3.6 Screening

P. A. Murphy Professor of Medicine and Microbiology, Johns Hopkins University and Chief, Infectious Diseases Division, Johns Hopkins Bayview Hospital, Baltimore, Maryland, USA.
7.5 Physiological changes in infected patients

C. J. L. Murray Global Programme on Evidence for Health Policy, World Health Organization, Geneva, Switzerland.
3.1 The Global Burden of Disease Study

Iain M. Murray-Lyon Consultant Physician and Gastroenterologist, Charing Cross Hospital and Chelsea and Westminster Hospital, London, UK.
14.21.5 Primary and secondary liver tumours

Jean Nachega Assistant Scientist, Johns Hopkins University, Baltimore, Maryland, USA.
7.11.22 Tuberculosis

Robert B. Nadelman Professor of Medicine, Division of Infectious Diseases, New York Medical College, USA.
7.11.29 Lyme borreliosis

N. V. Naoumov Reader in Hepatology/Honorary Consultant Physician, Institute of Hepatology, University College London, UK.
7.10.19 Hepatitis viruses (including TTV)

R. P. Naoumova MRC Senior Clinical Scientist/Honorary Consultant Physician, MRC Clinical Sciences Centre, Hammersmith Hospital, London, UK.
15.1.2.1 The pathogenesis of atherosclerosis

D. G. Nathan President, Dana-Farber Cancer Institute, Boston, Massachusetts, USA.
22.2.1 Stem cells and haemotopoiesis

Graham Neale Research Fellow, Clinical Risk Unit, University College London, UK.
14.1 Introduction to gastroenterology. 14.1.1.2 Symptomatology of gastrointestinal disease. 14.16 Vascular and collagen disorders

Catherine Nelson-Piercy Consultant Obstetric Physician, Guy's and St Thomas' Hospitals Trust, London, UK.
13.14 Autoimmune rheumatic disorders and vasculitis in pregnancy

A. R. Ness Senior Lecturer in Epidemiology, Department of Social Medicine, University of Bristol, UK.
15.4.1.2 The epidemiology of ischaemic heart disease

Peter Nestor Neurologist, University of Cambridge Neurology Unit, UK.
24.8 Disturbances of higher cerebral function

J. Neuberger Professor of Hepatology and Consultant Physician, Queen Elizabeth Hospital, Birmingham, UK.
14.21.7 Drugs and liver damage. 14.21.8 The liver in systemic disease

John Newell-Price Senior Lecturer in Endocrinology, Division of Clinical Sciences, Sheffield University, Northern General Hospital, Sheffield, UK.
12.3 Disorders of the posterior pituitary

A. J. Newman Taylor Consultant Physician and Head, Department of Occupational and Environmental Medicine, Royal Brompton Harefield NHS Trust, Faculty of Medicine, Imperial College London, UK.
17.4.4 Asthma. 17.4.5 Occupational asthma

C. S. Ng Assistant Professor, Department of Radiology, University of Texas M. D. Anderson Cancer Center, Houston, USA.

14.18.2 Computed tomography and magnetic resonance imaging of the liver and pancreas

S. Nightingale Consultant Neurologist and Honorary Senior Clinical Lecturer, Royal Shrewsbury Hospital and Birmingham University, Shrewsbury, UK.
7.10.23 HTLV-I and II and associated diseases

T. Northfield Professor Emeritus, Department of Biochemical Medicine, St George's Hospital, London, UK.
14.3.2 Gastrointestinal bleeding

John Nowakowski Assistant Professor of Medicine, Department of Medicine, Division of Infectious Diseases, Westchester Medical Center, Valhalla, New York, USA.
7.11.29 Lyme borreliosis

Fujio Numano Director, Tokyo Vascular Disease Institute, Tokyo, Japan.
15.14.4 Takayasu arteritis

D. O'Gradaigh Research Registrar, Department of Medicine, Addenbrooke's Hospital, Cambridge, UK.
18.11 Miscellaneous conditions presenting to the rheumatologist . 19.5 Avascular necrosis and related topics

Stephen O'Rahilly Professor of Clinical Biochemistry, University of Cambridge, and Honorary Consultant Physician, UK.
10.5 Obesity

S. C. O'Reilly Consultant Rheumatologist, Rheumatology Department, Derbyshire Royal Infirmary, Derby, UK.
18.9 Crystal-related arthropathies

P. J. Oldershaw Consultant Cardiologist, Royal Brompton Hospital, London, UK.
15.13 Congenital heart disease in adolescents and adults

James G. Olson Head, Department of Virology, U. S. Navy Medical Research Center Detachment, Lima, Peru.
7.10.6.1 Nipah and Hendra viruses . 7.11.39 Bartonelloses, excluding *Bartonella bacilliformis* infections

M. Osame Professor, Third Department of Internal Medicine, Faculty of Medicine, Kagoshima University, Japan.
7.10.23 HTLV-I and II and associated diseases

Jackie Palace Consultant Neurologist, Radcliffe Infirmary, Oxford, UK.
24.17 Diseases of the neuromuscular junction

Thalia Papayannopoulou Professor of Medicine (Hematology), University of Washington, Division of Hematology, Seattle, USA.
22.5.1 Erythropoiesis and the normal red cell

S. Parish Senior Research Fellow, Clinical Trial Service Unit, Nuffield Department of Clinical Medicine, University of Oxford, UK.
2.4.3 Large-scale randomized evidence: trials and overviews

G. R. Park Director of Intensive Care Research, John Farman Intensive Care Unit, Addenbrooke's Hospital, Cambridge, UK.
16.6.1 Sedation and analgesia in the critically ill

David Parkes Professor of Clinical Neurology, King's College Hospital, London, UK.
24.13.4 Narcolepsy

C. Parry University of Oxford-Wellcome Trust Clinical Research Unit, Centre for Tropical Diseases, Ho Chi Minh City, Vietnam.
7.11.8 Typhoid and paratyphoid fevers

Steve W. Parry Consultant Physician and Honorary Senior Lecturer, Freeman Hospital and University of Newcastle upon Tyne, UK.
24.13.5.1 Head-up tilt-table testing in the diagnosis of vasovagal syncope and related disorders

J. Paul Consultant Microbiologist and Director, Brighton Public Health Laboratory, Royal Sussex County Hospital, Brighton, UK.
7.11.42 Newly identified and lesser-known bacteria . 7.17 Non-venomous arthropods

Malik Peiris Professor, Department of Microbiology, University of Hong Kong.
7.10.1 Respiratory tract viruses

Edmund D. Pellegrino Emeritus Professor of Medicine and Medical Ethics, Georgetown University Medical Center, Washington DC, USA.
2.3 Medical ethics

T. H. Pennington Professor of Bacteriology, University of Aberdeen Medical School, UK.
7.3 Biology of pathogenic micro-organisms

M. B. Pepys Professor and Head of Medicine, Department of Medicine, Royal Free Campus, Royal Free and University College Medical School, London, UK.
11.12.1 The acute phase response and C-reactive protein . 11.12.4 Amyloidosis

P. L. Perine Professor of Epidemiology, School of Public and Community Medicine, University of Washington, Seattle, USA.
7.11.32 Non-venereal treponematoses: yaws, endemic syphilis (bejel), and pinta

G. D. Perkin Consultant Neurologist, Department of Neurology, Charing Cross Hospital, London, UK.
24.13.3 Epilepsy in later childhood and adults

P. L. Perrotta Assistant Professor, Pathology, Stony Brook University Hospital, New York, USA.
22.8.1 Blood transfusion

H. Persson Medical Director and Consultant Physician, Swedish Poisons Information Centre, Stockholm, Sweden.
8.3 Poisonous plants and fungi

M. C. Petch Consultant Cardiologist, Papworth Hospital, Cambridge, UK.
15.4.2.6 The impact of coronary heart disease on life and work

L. R. Petersen Deputy Director for Science, Centers for Disease Control, Division of Vector-borne Infectious Diseases, Fort Collins, Colorado, USA.
7.10.11 Alphaviruses. 7.10.13 Flaviviruses

R. Peto Professor of Epidemiology and Medical Statistics, University of Oxford, UK.
2.4.3 Large-scale randomized evidence: trials and overviews. 6.1 Epidemiology of cancer

T. E. A. Peto Consultant Physician in Infectious Diseases, Nuffield Department of Medicine, John Radcliffe Hospital, Oxford, UK.
7.10.21 HIV and AIDS

A. Phillips Senior Lecturer, Institute of Nephrology, University of Wales College of Medicine, Cardiff, UK.
20.1 Structure and function of the kidney

R. J. Playford Professor, Imperial College School of Medicine, Hammersmith Hospital, London, UK.
14.9.7 Effects of massive small bowel resection

J. M. Polak Professor and Director, Tissue Engineering and Regenerative Medicine Centre, Imperial College School of Medicine, London, UK.
14.8 Hormones and the gastrointestinal tract

Eleanor S. Pollak Associate Director, Clinical Coagulation Laboratory, Hospital of the University of Pennsylvania, University of Pennsylvania Medical Center, Philadelphia, USA.
22.6.4 Genetic disorders of coagulation

P. A. Poole-Wilson Professor of Cardiology and Cardiac Medicine, National Heart and Lung Institute, Faculty of Medicine, Imperial College London, UK.
15.1.3.1 Physical considerations: biochemistry and cellular physiology of heart muscle

F. M. Pope Consultant Dermatologist, West Middlesex University Hospital, London, UK.
19.2 Inherited defects of connective tissue: Ehlers-Danlos syndrome, Marfan's syndrome, and pseudoxanthoma elasticum

Françoise Portaels Professor and Head, Mycobacteriology Unit, Institute of Tropical Medicine, Antwerp, Belgium.
7.11.25 Buruli ulcer: *Mycobacterium ulcerans* infection

J. S. Porterfield Formerly Reader in Bacteriology, Sir William Dunn School of Pathology, University of Oxford, UK.
7.10.14 Bunyaviridae

Jerome B. Posner Attending Neurologist, Memorial Sloan-Kettering Cancer Center, New York, USA.
24.18 Paraneoplastic syndromes

William G. Powderly Professor of Medicine, Washington University School of Medicine, St Louis, Missouri, USA.
7.12.2 Cryptococcosis

J. J. Powell Senior Lecturer - Nutrition and Medicine, GI Laboratory, Rayne Institute, St Thomas' Hospital, London, UK.
8.5.8 Podoconiosis

Janet Powell Medical Director, University Hospitals, Coventry and Warwickshire NHS Trust, Coventry, Warwickshire, UK.
15.14.2 Peripheral arterial disease

J. W. Powles University Lecturer in Public Health Medicine, Institute of Public Health, Cambridge, UK.
3.2 Human population size, environment, and health

M. A. Preece Professor of Child Health and Growth, Institute of Child Health, University College London, UK.
12.9.2 Normal growth and its disorders

J. S. Prichard* Professor of Medicine, St James's Hospital, Dublin, Eire.
15.15.2.2 Pulmonary oedema

A. T. Proudfoot Consulting Clinical Toxicologist, National Poisons Information Service, City Hospital, Birmingham, UK.
8.1 Poisoning by drugs and chemicals

Charles Pusey Professor of Renal Medicine, Faculty of Medicine, Imperial College, Hammersmith Hospital, London, UK.
20.7.7 Antiglomerular basement membrane disease

N. P. Quinn Professor of Clinical Neurology, Institute of Neurology and Honorary Consultant Neurologist, The National Hospital for Neurology and Neurosurgery, London, UK.
24.10 Subcortical structures-the cerebellum, thalamus and basal ganglia

Anisur Rahman Senior Lecturer in Rheumatology, Centre for Rheumatology, Department of Medicine, University College London, UK.
18.10.2 Systemic lupus erythematosus and related disorders

Lawrence E. Ramsay Professor of Clinical Pharmacology and Therapeutics, University of Sheffield and Consultant Physician, Royal Hallamshire Hospital, Sheffield, UK.
15.16.2.1 Hypertension-indications for investigation . 15.16.2.2 Renal and renovascular hypertension . 15.16.2.5 Aortic coarctation . 15.16.2.6 Other rare causes of hypertension. 20.10.2 Hypertension and the kidney

M. Ramsay Consultant Epidemiologist, Immunisation Division, PHLS Communicable Disease Surveillance Centre, London, UK.
7.7 Immunization

A. C. Rankin Reader in Cardiology, Glasgow Royal Infirmary, UK.
15.2.3 Syncope and palpitation . 15.6 Cardiac arrhythmias

C. W. G. Redman Professor of Obstetric Medicine, John Radcliffe Hospital, Oxford, UK.
13.4 Hypertension in pregnancy

Laurence John Reed Academic Unit of Psychiatry, St Thomas' Hospital, London, UK.
26.3 Neuropsychiatric disorders

A. J. Rees Regius Professor of Medicine, Institute of Medical Sciences, University of Aberdeen, UK.
20.10.3 Vasculitis and the kidney

Jeremy Rees Clinical Senior Lecturer in Neuro-oncology, National Hospital for Neurology and Neurosurgery, London, UK.
24.13.18.1 Intracranial tumours

D. Rennie Adjunct Professor of Medicine, Institute for Health Policy Studies, University of California, San Francisco, USA.
8.5.4 Diseases of high terrestrial altitudes

J. Richens Clinical Lecturer, Department of Sexually Transmitted Diseases, Royal Free and University College Medical School, London, UK.
7.11.8 Typhoid and paratyphoid fevers. 7.11.9 Intracellular Klebsiella infections

B. K. Rima Professor of Molecular Biology, Medical Biology Centre, Queen's University of Belfast, UK.
7.10.5 Mumps: epidemic parotitis

A. J. Ritchie Consultant Cardiothoracic Surgeon, Papworth NHS Trust, Cambridge, UK.
15.4.2.5 Coronary artery bypass grafting

Eberhard Ritz Professor and Head, Department of Nephrology, University of Heidelberg, Germany.
20.5.2 Bone disease in chronic renal failure

Harold R. Roberts Sarah Graham Kenan Professor of Medicine and Attending Physician, UNC Hospitals, Chapel Hill, North Carolina, USA.
22.6.1 The biology of haemostasis and thrombosis. 22.6.2 Evaluation of the patient with a bleeding diathesis

William G. Robertson Clinical Scientist, Institute of Urology and Nephrology, University College London, UK.
20.13 Urinary stones, nephrocalcinosis, and renal tubular acidosis

T. A. Rockall Senior Lecturer/Honorary Consultant, St Mary's Hospital, London, UK.
14.3.2 Gastrointestinal bleeding

Allan R. Ronald Professor Emeritus, University of Manitoba, Winnipeg, Canada.
7.11.13 *Haemophilus ducreyi* and chancroid

P. Ronco Professor of Renal Medicine, Université Pierre et Marie Curie (Paris 6) and Director, Renal Division and INSERM Unit 489, Tenon Hospital (Assistance Publique-Hôpitaux de Paris), Paris, France.
20.10.5 Renal involvement in plasma cell dyscrasias, immunoglobulin-based amyloidoses, and fibrillary glomerulopathies, lymphomas, and leukaemias

Antony Rosen Professor and Director, Division of Rheumatology, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA.
5.3 Autoimmunity

Mark J. Rosen Chief, Division of Pulmonary and Critical Care Medicine, Beth Israel Medical Center, New York, USA.
17.5.2.3 Pulmonary complications of HIV infection

Raymond C. Rosen Professor of Psychiatry, UMDNJ-Robert Wood Johnson Medical School, Department of Psychiatry, Piscataway, New Jersey, USA.
12.8.4 Sexual dysfunction

R. J. M. Ross Professor of Endocrinology, Northern General Hospital, University of Sheffield, UK.
12.9.3 Puberty

D. J. Rowlands Honorary Consultant Cardiologist, Manchester Heart Centre, Manchester Royal Infirmary, UK.
15.3.2 Electrocardiography. 15.3.4 Nuclear techniques

M. B. Rubens Director of Imaging and Consultant Radiologist, Royal Brompton and Harefield NHS Trust, London, UK.
15.3.1 Chest radiography in heart disease. 15.3.5 Cardiovascular magnetic resonance and computed X-ray tomography

David Rubenstein Consultant Physician, Addenbrooke's Hospital, Cambridge, UK.
7.1 The clinical approach to the patient with suspected infection

P. C. Rubin Professor and Dean of Medicine, University of Nottingham, UK.
13.18 Prescribing in pregnancy

Anthony S. Russell Professor of Medicine, University of Alberta, Edmonton, Canada.
18.2 Clinical presentation and diagnosis of rheumatic disease

T. J. Ryan Emeritus Professor of Dermatology, University of Oxford, UK.
23.1 Diseases of the skin

Sara S. T. O. Saad Professor and Haematologist, Department of Internal Medicine, Hematology-Hemotherapy Division, Medical Science Faculty, State University of Campinas, Brazil.
22.5.10 Disorders of the red cell membrane

N. J. Samani Professor of Cardiology, Division of Cardiology, Department of Medicine, University of Leicester, UK.
15.16.1.2 Genetics of hypertension

Brian P. Saunders Senior Lecturer in Endoscopy, St Mark's Hospital, Northwick Park, Harrow, Middlesex, UK.
14.2.1 Colonoscopy and flexible sigmoidoscopy

S. J. Saunders Emeritus Professor, Liver Clinic, Groote Schuur Hospital and Medical Research Council/University of Cape Town Liver Research Centre, Cape Town, South Africa.
14.21.6 Hepatic granulomas

M. O. Savage Professor of Paediatric Endocrinology, St Bartholomew's and The Royal London School of Medicine and Dentistry, London, UK.
12.9.1 Normal and abnormal sexual differentiation. 12.9.3 Puberty

John Savill Professor of Medicine, Royal Infirmary, Edinburgh, UK.
20.7.1 The glomerulus and glomerular injury

K. P. Schaal Professor and Director, Institute for Medical Microbiology and Immunology, Faculty of Medicine, Rheinische Friedrich-Wilhelms-Universität, Bonn, Germany.
7.11.26 Actinomycosis

Michael Schömig Physician in Charge, Division of Nephrology, Ruperto-Carola-University of Heidelberg, Germany.
20.5.2 Bone disease in chronic renal failure

Ruud B. H. Schutgens Head of Department of Clinical Chemistry, Vrije Universiteit Medical Centre (VUMC), Amsterdam, The Netherlands.
11.9 Peroxisomal diseases

J. Schwebke Associate Professor of Medicine, University of Alabama at Birmingham, USA.
21.3 Vaginal discharge

Neil Scolding Burden Professor of Clinical Neurosciences, University of Bristol Institute of Clinical Neurosciences, Frenchay Hospital, Bristol, UK.
24.15 Metabolic disorders and the nervous system. 24.20 Neurological complications of systemic autoimmune and inflammatory diseases

J. Scott Professor of Medicine, Imperial College Faculty of Medicine, Hammersmith Campus, London, UK.
15.1.2.1 The pathogenesis of atherosclerosis

A. Seaton Professor and Head of Department of Environmental and Occupational Medicine, University of Aberdeen, UK.
17.11.7 Pneumoconioses

G. R. Serjeant Professor Emeritus and Chairman, Sickle Cell Trust, Kingston, Jamaica, West Indies.
20.10.7 Sickle-cell disease and the kidney

N. J. Severs Professor of Cell Biology, National Heart and Lung Institute, Faculty of Medicine, Imperial College London, UK.
15.1.3.1 Physical considerations: biochemistry and cellular physiology of heart muscle

C. A. Seymour Professor of Clinical Biochemistry and Metabolic Medicine and Director for Clinical Advice to The Health Service Ombudsman, St George's Hospital Medical School and Office of Health Service Commissioner, London, UK.
11.7.2 Wilson's disease, Menke's disease: inherited disorders of copper metabolism

K. V. Shah Professor, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, USA.
7.10.17 Papovaviruses

L. M. Shapiro Consultant Cardiologist, Papworth Hospital, Cambridge, UK.
15.4.2.2 Management of stable angina. 15.4.2.5 Coronary artery bypass grafting

Michael Sharpe Reader in Psychological Medicine, University of Edinburgh, Royal Edinburgh Hospital, UK.
7.19 Chronic fatigue syndrome (postviral fatigue syndrome, neurasthenia, and myalgic encephalomyelitis) 26.1 General introduction. 26.5.3 Medically unexplained symptoms in patients attending medical clinics. 26.6.2 Psychological treatment in medical practice

J. M. Shneerson Director, Respiratory Support and Sleep Centre, Papworth Hospital, Cambridge, UK.
17.13 Disorders of the thoracic cage and diaphragm

Tom Siddons Clinical Research Assistant, Pfizer Research and Development (UK), Maidstone, Kent, UK.
15.15.1 The pulmonary circulation and its influence on gas exchange

C. A. Sieff Associate Professor in Pediatrics, Dana Farber Cancer Institute, Boston, Massachusetts, USA.
22.2.1 Stem cells and haemotopoiesis

J. Sieper Head of Rheumatology, Department of Medicine, University Hospital Benjamin Franklin, Berlin, Germany.
18.6 Spondyloarthritides and related arthritides

Leslie Silberstein Professor, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA.
22.5.9 Haemolytic anaemias - congenital and acquired

R. Sinclair Senior Lecturer, Department of Dermatology, University of Melbourne, St Vincent's Hospital, Fitzroy, Victoria, Australia.
23.1 Diseases of the skin

Joseph Sinning Yale School of Medicine, New Haven, Connecticut, USA.
22.4.1 Leucocytes in health and disease

Thira Sirisanthana Professor of Medicine and Director, Research Institute for Health Sciences, Chiang Mai University, Thailand.
7.11.18 Anthrax. 7.12.6 Infection due to Penicillium marneffei

J. G. P. Sissons Professor of Medicine, University of Cambridge and Honorary Consultant Physician, Addenbrooke's Hospital, Cambridge, UK.
7.10.2 Herpesviruses (excluding Epstein-Barr virus)

M. B. Skirrow Honorary Emeritus Consultant Microbiologist, Public Health Laboratory, Gloucester Royal Hospital, UK.
7.11.7 Enterobacteria, campylobacter, and miscellaneous food-poisoning bacteria

Geoffrey L. Smith Professor of Virology and Wellcome Trust Principal Research Fellow, The Wright-Fleming Institute, Faculty of Medicine, Imperial College of Science, Technology and Medicine, St Mary's Campus, London, UK.
7.10.4 Poxviruses

P. H. Smith Department of Urology, St James' University Hospital, Leeds, UK.
20.15 Tumours of the urinary tract

R. Smith Consultant Physician, Nuffield Orthopaedic Centre, Oxford, UK.
19.1 Disorders of the skeleton

E. L. Snyder Professor of Laboratory Medicine, Yale University School of Medicine, New Haven, Connecticut, USA.
22.8.1 Blood transfusion

R. L. Souhami Director of Clinical Research, Cancer Research UK and Emeritus Professor of Medicine, University College London, London, UK.
6.6 Cancer: clinical features and management

C. W. N. Spearman Senior Specialist and Co-Head of Liver Clinic, Groote Schuur Hospital, Cape Town, South Africa.
14.21.6 Hepatic granulomas

C. A. Speed Honorary Consultant Rheumatologist, Addenbrooke's Hospital, Cambridge, UK.
19.5 Avascular necrosis and related topics

G. P. Spickett Consultant Clinical Immunologist, Regional Department of Immunology, Royal Victoria Infirmary, Newcastle upon Tyne, UK.
17.11.8 Pulmonary haemorrhagic disorders. 17.11.9 Eosinophilic pneumonia. 17.11.11 Extrinsic allergic alveolitis. 17.11.19 Drug-induced lung disease

S. G. Spiro Professor of Respiratory Medicine and Medical Director, Medicine, University College London Hospitals NHS Trust, Middlesex Hospital, London, UK.

17.14.1 Lung cancer. 17.14.2 Pulmonary metastases

Jerry L. Spivak Professor of Medicine and Oncology, Johns Hopkins School of Medicine, Baltimore, Maryland, USA.
22.3.9 Idiopathic myelofibrosis

A. Spurgeon Senior Lecturer, Institute of Occupational Health, University of Birmingham, UK.
8.4.1 Occupational and environmental health and safety

Paul D. Stein Director of Research, St Joseph Mercy-Oakland, Pontiac, Michigan, USA.
15.15.3.1 Deep venous thrombosis and pulmonary embolism

Tom Stevens Consultant Psychiatrist, St Thomas' Hospital and Maudsley NHS Trust, London, UK.
26.3 Neuropsychiatric disorders

J. C. Stevenson Reader and Consultant Physician, Endocrinology and Metabolic Medicine, Faculty of Medicine, Imperial College London, UK.
13.20 Benefits and risks of hormone replacement therapy

P. M. Stewart Professor of Medicine, University of Birmingham and Consultant Physician, Queen Elizabeth Hospital, Birmingham, UK.
12.7.1 Disorders of the adrenal cortex

August Stich Consultant in Tropical Medicine, Medical Mission Institute, Unit of Tropical Medicine and Epidemic Control, Wurzburg, Germany.
7.13.10 Human African trypanosomiasis

John H. Stone Associate Professor of Medicine, Johns Hopkins University, Baltimore, Maryland, USA.
18.10.7 Polymyositis and dermatomyositis

J. R. Stradling Consultant Physician and Professor of Respiratory Medicine, Churchill Hospital, Oxford, UK.
17.1.1 The upper respiratory tract. 17.8.1 Upper airways obstruction. 17.8.2 Sleep-related disorders of breathing

Frank J. Strobl Director, Scientific Affairs, Therakos Inc., Exton, Pennsylvania, USA.
22.5.9 Haemolytic anaemias - congenital and acquired

M. A. Stroud Senior Lecturer in Medicine, Southampton University Hospitals Trust, UK.
8.5.1 Environmental extremes - heat. 8.5.2 Environmental extremes - cold

Michael Strupp Associate Professor of Neurology, Department of Neurology, Klinikum Grosshadern, University of Munich, Germany.
24.12.1 Eye movements and balance

P. H. Sugden Professor of Cellular Biochemistry, Imperial College of Science, Technology and Medicine, London, UK.
15.1.3.1 Physical considerations: biochemistry and cellular physiology of heart muscle

Daniel P. Sulmasy Sisters of Charity Chair in Ethics, St Vincent's Manhattan and New York Medical College, New York, USA.
2.3 Medical ethics

J. A. Summerfield Professor of Experimental Medicine, Faculty of Medicine, Imperial College London, UK.
14.19.1 Congenital disorders of the liver, biliary tract, and pancreas . 14.19.2 Diseases of the gallbladder and biliary tree

Pravan Suntharasamai Emeritus Professor of Tropical Medicine, Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand.
7.14.9 Gnathostomiasis

J. Swales* Professor of Medicine, University of Leicester, UK.
15.16.1.3 Essential hypertension

P. Sweny Consultant Nephrologist, Royal Free Hospital, London, UK.
20.6.3 Renal transplantation

D. Swirsky Consultant Haematologist, Leeds General Infirmary, UK.
22.4.4 The spleen and its disorders

I. C. Talbot Professor of Histopathology, St Mark's Hospital for Colorectal Disorders, London, UK.
14.15 Tumours of the gastrointestinal tract

D. Tarin Director, UCSD Cancer Center, University of California at San Diego, La Jolla, USA.
6.4 Tumour metastasis

D. Taylor-Robinson Emeritus Professor of Genitourinary Microbiology and Medicine, Division of Medicine, Imperial College of Science, Technology and Medicine, St Mary's Hospital, London, UK.
7.11.40 Chlamydial infections including lymphogranuloma venerum . 7.11.41 Mycoplasmas

P. J. Teddy Consultant Neurosurgeon/Clinical Director, Department of Neurological Surgery, Radcliffe Infirmary, Oxford, UK.
24.14.3 Intracranial abscess

H. J. Testa Professor and Consultant (retired), Royal Infirmary, Manchester, UK.
15.3.4 Nuclear techniques

R. V. Thakker May Professor of Medicine, Nuffield Department of Medicine, University of Oxford, UK.
12.6 Parathyroid disorders and diseases altering calcium metabolism

David G. T. Thomas Professor of Neurological Surgery, National Hospital for Neurology and Neurosurgery, London, UK.
24.13.18.2 Traumatic injuries of the head

D. L. Thomas Associate Professor of Medicine, Johns Hopkins School of Medicine, Baltimore, Maryland, USA.
7.10.20 Hepatitis C virus

P. K. Thomas Emeritus Professor of Neurology, Royal Free Hospital School of Medicine and Institute of Neurology, London, UK.
24.6.1 Inherited disorders. 24.13.15.00 Disorders of cranial nerves. 24.19 Diseases of the peripheral nerves

D. G. Thompson Professor of Gastroenterology, University of Manchester, UK.

14.1.1.1 Structure and function of the gut. 14.12 Functional bowel disorders and irritable bowel syndrome

R. P. H. Thompson Consultant Physician, St Thomas' Hospital, London, UK.
8.5.8 Podoconiosis. 14.19.3 Jaundice

S. A. Thorne Royal Brompton and Harefield NHS Trust, London, UK.
15.13 Congenital heart disease in adolescents and adults

Ph. Thulliez Head, Laboratoire de la Toxoplasmose, Institut de Puericulture, Paris, France.
7.13.4 Toxoplasmosis

Tran Tin Hien Vice Director, Centre for Tropical Diseases (Cho Quan Hospital), Ho Chi Minh City, Vietnam.
7.11.1 Diphtheria

J. A. Todd Professor of Medical Genetics, University of Cambridge, UK.
12.11.2 The genetics of diabetes

C. Tomson Consultant Nephrologist, Southmead Hospital, Bristol, UK.
20.12 Urinary tract infection

Keith Tones Professor of Health Education (Emeritus), Leeds Metropolitan University, UK.
3.5 Health promotion

P. A. Tookey Lecturer, Centre for Epidemiology and Biostatistics, Institute of Child Health, London, UK.
7.10.12 Rubella

P. P. Toskes Professor of Medicine, Division of Gastroenterology, Hepatology, and Nutrition, Department of Medicine, University of Florida College of Medicine, Gainsville, USA.
14.9.2 Small bowel bacterial overgrowth. 14.18.3.2 Chronic pancreatitis

Thomas A. Traill Professor of Medicine, Johns Hopkins Hospital, Baltimore, Maryland, USA.
15.11.1 Cardiac myxoma. 15.11.2 Other tumours of the heart. 15.12 Cardiac involvement in genetic disease

David F. Treacher Consultant Physician in Intensive Care, St Thomas' Hospital, Guy's and St Thomas' NHS Trust, London, UK.
16.2 The circulation and circulatory support of the critically ill

A. S. Truswell Emeritus Professor of Human Nutrition, University of Sydney, New South Wales, Australia.
10.1 Diseases of overnourished societies and the need for dietary change

D. M. Turnbull Professor of Neurology, The Medical School, University of Newcastle upon Tyne, UK.
24.22.5 Mitochondrial encephalomyopathies

H. E. Turner Consultant Physician, Radcliffe Infirmary, Oxford, UK.
12.12 Hormonal manifestations of non-endocrine disease

A. Neil Turner Professor of Nephrology, Royal Infirmary, Edinburgh, UK.
20.7.8 Infection-associated nephropathies. 20.7.9 Malignancy-associated renal disease

Robert Twycross Emeritus Clinical Reader in Palliative Medicine, Oxford University, Sir Michael Sobell House, Churchill Hospital, Oxford, UK.
31 Palliative care

F. E. Udwadia Emeritus Professor of Medicine, Grant Medical College and J. J. Hospital, Bombay; Consultant Physician and Director-in-charge of ICU, Breach Candy Hospital; Consultant Physician, Parsee General hospital, Bombay, India.
7.11.20 Tetanus

S. Richard Underwood Professor of Cardiac Imaging, Imperial College of Science, Technology and Medicine, National Heart and Lung Institute, and Royal Brompton Hospital, London, UK.
15.3.5 Cardiovascular magnetic resonance and computed X-ray tomography

Robert J. Unwin Professor of Nephrology and Physiology, Centre for Nephrology, The Middlesex Hospital, London, UK.
20.13 Urinary stones, nephrocalcinosis, and renal tubular acidosis

V. Urquidi Assistant Professor, University of California San Diego Cancer Center and Department of Pathology, La Jolla, California, USA.
6.4 Tumour metastasis

J. A. Vale Director, National Poisons Information Service and West Midlands Poisons Unit, City Hospital, Birmingham, UK.
8.1 Poisoning by drugs and chemicals

P. Vallance Professor of Clinical Pharmacology and Therapeutics, Centre for Clinical Pharmacology, University College London, UK.
15.1.1.2 Vascular endothelium, its physiology and pathophysiology

J. van Gijn Professor and Chairman, Department of Neurology, University Medical Centre, Utrecht, The Netherlands.
24.13.7 Stroke: cerebrovascular disease

Sirivan Vanijanonta Emeritus Professor of Tropical Medicine, Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand.
7.16.3 Lung flukes (paragonimiasis)

Patrick J. W. Venables Professor and Honorary Consultant, Kennedy Institute Division, Imperial College London, UK.
18.10.6 Sjogren's syndrome

B. J. Vennervald Senior Research Scientist, Danish Bilharziasis Laboratory, Charlottenlund, Denmark.
7.16.1 Schistosomiasis

C. M. Verity Consultant Paediatric Neurologist and Associate Lecturer, Faculty of Medicine, University of Cambridge, Addenbrooke's Hospital, Cambridge, UK.
24.21 Developmental abnormalities of the nervous system

M. P. Vessey Emeritus Professor of Public Health, Unit of Health Care Epidemiology, Department of Public Health, Oxford University, UK.
13.19 Benefits and risks of oral contraceptives

R. Viner Consultant in Adolescent Medicine and Endocrinology, University College London Hospitals and Great Ormond Street Hospital, UK.
29 Adolescent medicine

Peter D. Wagner Professor of Medicine and Bioengineering, University of California, San Diego, USA.
17.1.2 Structure and function of the airways and alveoli

Ann E. Wakefield* Professor of Paediatric Infectious Diseases, Department of Paediatrics, Institute of Molecular Medicine, University of Oxford, UK.
7.12.5 Pneumocystis carinii

D. H. Walker The Carmage and Martha Walls Distinguished Chair in Tropical Diseases, Professor and Chairman, Department of Pathology, and Director, WHO Collaborating Center for Tropical Diseases, Galveston, Texas, USA.
7.11.36 Rickettsial diseases including ehrlichiosis

J. A. Walker-Smith Emeritus Professor of Paediatric Gastroenterology, Royal Free and University College Medical School, London, UK.
14.14 Congenital abnormalities of the gastrointestinal tract

Mark J. Walport Professor of Medicine and Head, Division of Medicine, Faculty of Medicine, Imperial College London, Hammersmith Hospital, London, UK.
5.4 Complement

Julian R. F. Walters Reader in Gastroenterology, Imperial College of Science, Technology and Medicine, Hammersmith Campus, London, UK.
14.2.4 Investigation of gastrointestinal function. 14.9.1 Differential diagnosis and investigation of malabsorption

Gary S. Wand Professor of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA.
26.7.1 Alcohol and drug dependence

Ronald J. A. Wanders Professor of Inborn Errors and Metabolism and Deputy Head of the Laboratory for Metabolic Diseases, Academic Medical Centre, Amsterdam, The Netherlands.
11.9 Peroxisomal diseases

B. Ward Anaesthetic Registrar, Coventry School of Anaesthetics, UK.
16.6.1 Sedation and analgesia in the critically ill

T. E. Warkentin Professor, Department of Pathology and Molcular Medicine and Department of Medicine, McMaster University, Hamilton, Ontario, Canada.
22.6.5 Acquired coagulation disorders

D. A. Warrell Professor of Tropical Medicine and Infectious Diseases and Head, Nuffield Department of Clinical Medicine, University of Oxford, UK.
7.8 Travel and expedition medicine. 7.10.9 Rhabdoviruses: rabies and rabies-related viruses. 7.10.10 Colorado tick fever and other arthropod-borne reoviruses. 7.11.28 Rat bite fevers. 7.11.30 Other borrelia infections. 7.11.32 Non-venereal treponematoses: yaws, endemic syphilis (bejel), and pinta. 7.13.2 Malaria. 7.13.5 Cryptosporidium and cryptosporidiosis. 7.18 Pentostomiasis (porocephalosis). 8.2 Injuries, envenoming, poisoning, and allergic reactions caused by animals. 24.14.1 Bacterial meningitis. 24.14.2 Viral infections of the central nervous system. 24.22.6 Tropical pyomyositis (tropical myositis). 33 Emergency Medicine

M. J. Warrell Clinical Virologist, Centre for Tropical Medicine, John Radcliffe Hospital, Oxford, UK.
7.10.9 Rhabdoviruses: rabies and rabies-related viruses. 7.10.10 Colorado tick fever and other arthropod-borne reoviruses

Paul Warwicker Consultant Nephrologist, Renal Unit, Lister Hospital, Stevenage, Hertfordshire, UK.
20.10.6 Haemolytic uraemic syndrome

J. A. H. Wass Professor of Endocrinology and Consultant Physician, Radcliffe Infirmary, Oxford, UK.
12.12 Hormonal manifestations of non-endocrine disease

Laurence Watkins Consultant Neurosurgeon and Senior Lecturer, Institute of Neurology, London, UK.
24.13.18.2 Traumatic injuries of the head

George Watt Department of Medicine, AFRIMS, Bangkok, Thailand.
7.11.31 Leptospirosis. 7.11.37 Scrub typhus

Richard W. E. Watts Visiting Professor and Honorary Consultant Physician, Imperial College School of Medicine, Hammersmith Hospital, London, UK.
11.1 The inborn errors of metabolism: general. 11.4 Disorders of purine and pyrimidine metabolism. 11.10 Disorders of oxalate metabolism

D. J. Weatherall Regius Professor of Medicine Emeritus, University of Oxford, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK.
2.2 Scientific medicine and the art of healing. 22.1 Introduction. 22.5.2 Anaemia: pathophysiology, classification, and clinical features. 22.5.3 Anaemia as a world health problem. 22.5.5 Normochromic, normocytic anaemia. 22.5.7 Disorders of the synthesis or function of haemoglobin. 22.7 The blood in systemic disease

D. K. H. Webb Consultant Paediatric Haematologist, Great Ormond Street Hospital for Children, London, UK.
22.4.7 Histiocytoses

Kathryn E. Webert Clinical Scholar, Hematology and Fellow in Transfusion Medicine, Canadian Blood Services, McMaster University, Hamilton, Ontario, Canada.
22.6.3 Disorders of platelet number and function

A. D. B. Webster Consultant Immunologist, Department of Immunology, Royal Free Hospital, London, UK.
5.6 Immunodeficiency

Anthony P. Weetman Professor of Medicine and Dean, University of Sheffield Medical School, UK.
12.4 The thyroid gland and disorders of thyroid function. 12.5 Thyroid cancer

R. A. Weiss Professor, University College London, UK.
7.10.21 HIV and AIDS. 7.10.24 Viruses and cancer

Peter L. Weissberg BHF Professor of Cardiovascular Medicine, University of Cambridge, UK.
15.1.1.1 Introduction. 15.1.1.3 Vascular smooth muscle cells. 15.4.2.1 The pathophysiology of acute coronary syndromes

Peter F. Weller Professor of Medicine, Harvard Medical School; Chief of Allergy and Inflammation and Co-Chief, Infectious Diseases Division, Beth Israel Deaconess Medical Center, Boston, Massachusetts, USA.
22.4.6 Eosinophilia

A. K. Wells Consultant Respiratory Physician, Royal Brompton Hospital, London, UK.
17.11.4 The lungs and rheumatological diseases

Simon Wessely Professor of Epidemiological Psychiatry, Guy's, King's and St Thomas' School of Medicine and Institute of Psychiatry, London, UK.
26.6.2 Psychological treatment in medical practice

Gilbert C. White, II John C. Parker Professor of Medicine and Pharmacology and Director, Center for Thrombosis and Hemostasis, University of North Carolina School of Medicine, Chapel Hill, North Carolina, USA.
22.6.1 The biology of haemostasis and thrombosis. 22.6.2 Evaluation of the patient with a bleeding diathesis

Joseph White SPHTM at TUMC, New Orleans, Louisiana, USA.
3.7.1 The cost of health care in Western countries

H. C. Whittle Visiting Professor, London School of Hygiene and Tropical Medicine and Deputy Director, MRC Laboratories, Banjul, The Gambia.
7.10.6 Measles

D. E. L. Wilcken Professor Emeritus of Medicine and Head, Cardiovascular Research Laboratory, University of New South Wales and Prince of Wales Hospital, Sydney, Australia.
15.1.3.2 Clinical physiology of the normal heart

James S. Wiley Professor and Head of Haematology, Nepean Hospital, Penrith, New South Wales, Australia.
22.5.8 Anaemias resulting from defective red cell maturation

P. J. Wilkinson Consultant Medical Microbiologist, University Hospital, Queen's Medical Centre, Nottingham, UK.
7.11.34 Listeriosis

R. G. Will Professor of Clinical Neurology, Western General Hospital, Edinburgh, UK.
24.13.9 Human prion disease

C. B. Williams Consultant Physician in Endoscopy, St Mark's Hospital for Colorectal Disorders, UK.
14.2.1 Colonoscopy and flexible sigmoidoscopy. 14.15 Tumours of the gastrointestinal tract

D. J. Williams Senior Lecturer/Honorary Consultant in Obstetric Medicine, Division of Paediatrics, Obstetrics and Gynaecology, Imperial College of Science, Technology and Medicine, Chelsea and Westminster Hospital, London, UK.
13.1 Physiological changes of normal pregnancy. 13.2 Nutrition in pregnancy. 13.3 Medical management of normal pregnancy

Gareth Williams Professor of Medicine, Department of Medicine, Clinical Sciences Centre, University Hospital Aintree, Liverpool, UK.
12.11.1 Diabetes

J. D. Williams Professor of Nephrology and Consultant Physician, Institute of Nephrology, University of Wales College of Medicine, Cardiff, UK.
20.1 Structure and function of the kidney

Paul F. Williams Consultant Nephrologist, The Ipswich Hospital NHS Trust, UK.
20.6.2 The treatment of endstage renal disease by peritoneal dialysis

Robert Wilson Consultant Physician and Reader, Royal Brompton Hospital and National Heart and Lung Institute, Imperial College of Science, Technology and Medicine, London, UK.
17.3.3 Microbiological methods in the diagnosis of respiratory infections

C. G. Winearls Consultant Nephrologist, Oxford Kidney Unit, Churchill Hospital, Oxford, UK.
20.5.1 Chronic renal failure

F. Wojnarowska Professor of Dermatology and Consultant Dermatologist, Oxford Radcliffe Hospital, Oxford, UK.
13.13 The skin in pregnancy

R. Wolman Consultant in Rheumatology and Sports Medicine, Royal National Orthopaedic Hospital, Stanmore, Middlesex, UK.
28 Sports and exercise

Kathryn J. Wood Professor of Immunology, Nuffield Department of Surgery, University of Oxford, UK.
5.7 Principles of transplantation immunology

Nicholas Wood Professor of Clinical Neurology, Institute of Neurology, London, UK.
24.6.2 Neurogenetics. 24.13.12 Ataxic disorders

Trevor Woodage Clinical Investigator, Celera Genomics, Rockville, Maryland, USA.
4.1 The genomic basis of medicine

H. F. Woods Professor of Medicine, University of Sheffield, UK.
11.11 Disturbances of acid-base homeostasis

Gary P. Wormser Vice Chairman, Department of Medicine, and Chief, Division of Infectious Diseases, New York Medical College, Valhalla, New York, USA.
7.11.29 Lyme borreliosis

D. J. M. Wright Emeritus Reader in Medical Microbiology, Cell and Molecular Biology Section, Imperial College School of Medicine, London, UK.
7.11.33 Syphilis

V. M. Wright Consultant Paediatric Surgeon, Barts and The London NHS Trust, London, UK.
14.14 Congenital abnormalities of the gastrointestinal tract

F. C. W. Wu Senior Lecturer (Endocrinology), Royal Infirmary and University of Manchester, UK.
12.8.2 Disorders of male reproduction

Andrew H. Wyllie Professor and Head of Department of Pathology, University of Cambridge, UK.
4.6 Apoptosis in health and disease

M. A. S. Yasuda Professor, Department of Infectious and Parasitic Diseases, University of São Paulo Medical School, Brazil.
7.12.4 Paracoccidioidomycosis

Newman M. Yeilding Assistant Professor, University of Pennsylvania, Philadelphia, USA.
4.3 Molecular cell biology

Jenny Yiend Postdoctoral Research Assistant, MRC Cognition and Brain Science Unit, Cambridge, UK.
26.5.1 Grief, stress, and post-traumatic stress disorder

V. Zaman Professor, Department of Microbiology, The Aga Khan University, Karachi, Pakistan.
7.13.7 Sarcocystosis. 7.14.6 Other gut nematodes. 7.14.7 Toxocariasis and visceral larva migrans

* It is with regret that we report the death of Professor John Calam during the preparation of this edition of the textbook.
* It is with regret that we report the death of Professor Alvan R. Feinstein during the preparation of this edition of the textbook.
* It is with regret that we report the death of Professor C. D. Marsden.
* It is with regret that we report the death of Professor J. S. Prichard.
* It is with regret that we report the death of Professor J. Swales during the preparation of this edition of the textbook.
* It is with regret that we report the death of Professor Ann E. Wakefield during the preparation of this edition of the textbook.

Color Plate

Plates for Section 5

Chapter 5.4 Complement

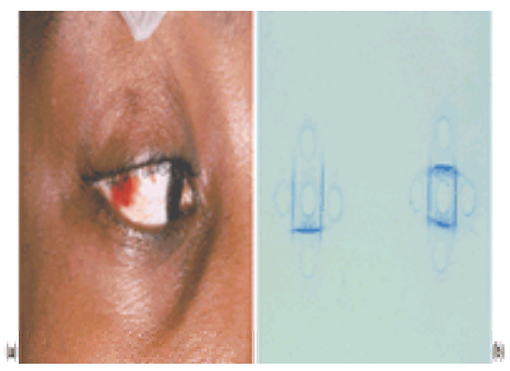

Plate 1 Patient with hereditary deficiency of C6 who presented with meningococcal septicaemia. (a) A subconjunctival haemorrhage. (b) The deficiency of C6. Serum from the patient was placed in the central well of an agarose-coated plate. In each of the outer wells was placed antiserum to, respectively, C5, C6, C7, and C8. The antibody and antigen were allowed to diffuse in the gel and where the antibody encountered its antigen a precipitate formed, which was stained blue. No precipitate formed between the anti-C6 antibody and the patient's serum, indicating the presence of C6 deficiency.

Plates for Section 6

Chapter 6.2 The nature and development of cancer

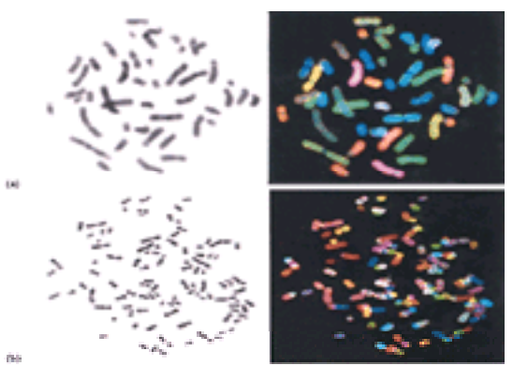

Plate 1 In a spectral karyotype (SKY), each normal chromosome stains homogeneously with a single distinct colour, making translocations evident by the presence of more than one colour in a single chromosome. (a) Forty-five chromosomes are visible in this karyotype (left) from a patient with Turner's syndrome. Despite the loss of the X chromosome, the spectral karyotype (right) clearly shows the homogeneous chromosomal staining pattern typical of normal chromosomes. (b) In contrast, SKY analysis of a metaphase spread prepared from a breast cancer cell line displays both numerical and structural chromosomal aberrations. (By courtesy of Dr Bassem Haddad, Department of Oncology, Georgetown University Medical Center.)

Plates for Section 7

Chapter 7.10.2 Herpesviruses (excluding Epstein-Barr virus)

Plate 1 Primary herpetic gingivostomatitis.

Plate 2 Primary HSV-2 of the buttocks.

Plate 3 (a) Severe chickenpox also involving the lungs. (b) Details of the rash.

Plate 4 Herpes zoster affecting the ophthalmic division of the Vth nerve.

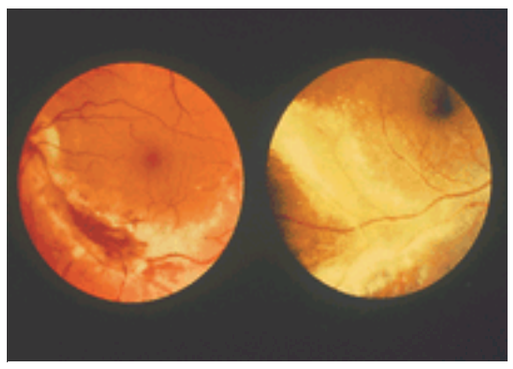

Plate 5 Human cytomegalovirus.

Plate 6 Kaposi's sarcoma affecting the palate and producing symmetrical skin lesions in association with HIV infection.

Chapter 7.10.4 Poxviruses

Plate 1 Ethiopian patient, in 1968, showing classical centrifugal distribution of lesions. (Copyright D.A. Warrell.)

Plate 2 Tanapox lesion on the leg of a Kenyan patient (by courtesy of the late P.E.C. Manson-Bahr).

Chapter 7.10.6 Measles

Plate 1 Measles rash on the legs of an English teenager. (Copyright D.A. Warrell.)

Plate 2 Measles rash (African).

Plate 3 Stomatitis with Herpes simplex ulcers in an African child with severe measles. (Copyright D.A. Warrell.)

Plate 4 Herpes simplex keratoconjunctivitis in an African child with severe measles. (Copyright D.A. Warrell.)

Plate 5 Measles rash (African).

Chapter 7.10.6.1 Nipah and Hendra viruses

Plate 1 Pteropid fruit bat (flying fox), the natural reservoir of Nipah, Hendra, and Menangle paramyxoviruses and Australian bat lyssavirus. (From the painting by John Gould.)

Chapter 7.10.9 Rhabdoviruses

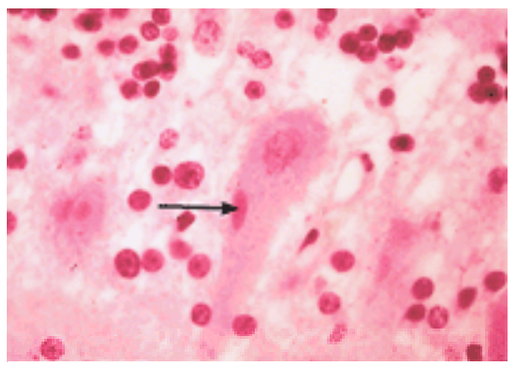

Plate 1 Street rabies virus in human cerebellar Purkinje cells as seen with the light microscope. Several Negri bodies can be seen (one is arrowed). (By courtesy of the Armed Forces Institute of Pathology 73–12330.)

Chapter 7.10.18 Parvovirus B19

Plate 1 'Slapped cheek' rash of erythema infectiosum: note circumoral pallor. (By courtesy of Dr Ken Mutton.)

Chapter 7.11.2 Streptococci and enterococci

Plate 1 Bilateral facial erysipelas. (Copyright S. Eykyn.)

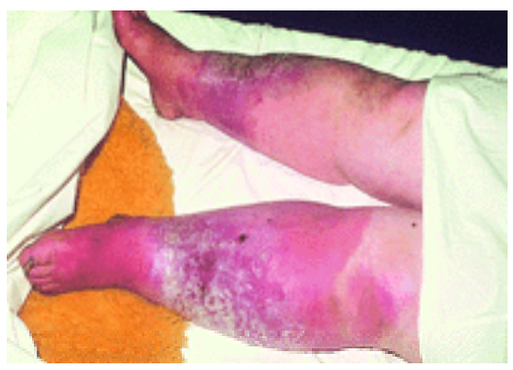

Plate 2 Cellulitis. (Copyright S. Eykyn.)

Plate 3 Streptococcus pyogenes bacteraemia 3 days after a skin graft. (Copyright S. Eykyn.)

Plate 4 Peeling of the skin of the soles of the feet in a patient with *Streptococcus pyogenes* pericarditis. (Copyright S. Eykyn.)

Chapter 7.11.5 Meningococcal infections

Plate 1 Massive skin haemorrhage on the extremities of a 4-year-old girl with fulminant meningococcal septicaemia. The infection was caused by *Neisseria meningitidis* group B. The left leg had to be amputated below the knee. She needed extensive skin transplantation and several fingers had to be amputated.

Plate 2 Macular lesions on the legs, some with a central haemorrhagic spot in a 17-year-old girl with mild meningococcaemia caused by *Neisseria meningitidis* group C. She recovered completely after 5 days treatment with benzylpenicillin.

Plate 3 Macular and haemorrhagic lesions on the legs of a 21-year-old man with mild meningococcaemia caused by *Neisseria meningitidis* group B. He recovered completely after 5 days of penicillin treatment.

Plate 4 The 'glass test' used to differentiate haemorrhagic skin lesions from viral or drug rash in an infant with meningococcal meningitis caused by *Neisseria meningitidis* group B. There was complete recovery after 5 days treatment with benzylpenicillin.

Chapter 7.11.6 *Neisseria gonorrhoeae*

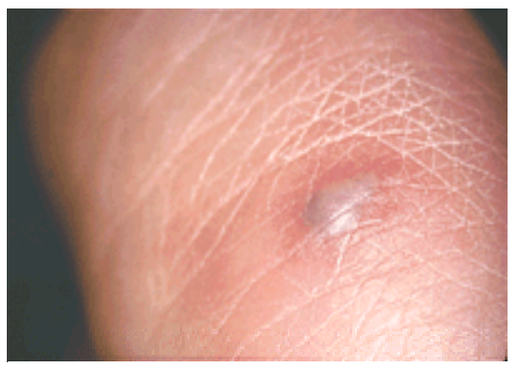

Plate 1 Disseminated gonococcal infection, haemorrhagic vesiculopustule.

Plate 2 Disseminated gonococcal infection: healing lesions with desquamation and deposition of haemosiderin.

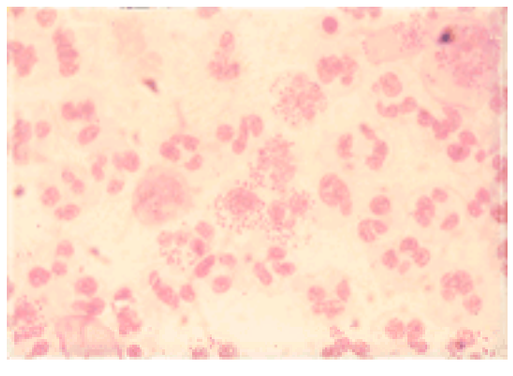

Plate 3 Gram-stained urethral discharge showing Gram-negative intracellular diplococci.

Chapter 7.11.8 Typhoid and paratyphoid fevers

Plate 1 Typhoid rash in a Melanesian child – sparse, purpuric (non-blanching) macules.

Chapter 7.11.17 Yersinia, Pasteurella, and Francisella

Plate 1 Hands in a case of ulcero-(cutano)-glandular tularaemia (by courtesy of A. Berglund, Fallund, Sweden).

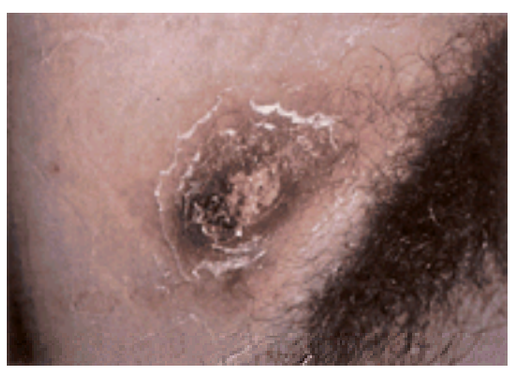

Plate 2 Inguinal lymphadenopathy in ulceroglandular tularaemia (by courtesy of A. Berglund, Fallund, Sweden).

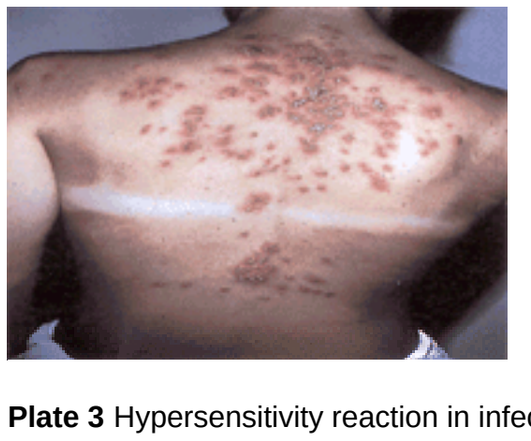

Plate 3 Hypersensitivity reaction in infection with *Francisella tularensis* subsp. *holarctica* (type B) in Scandinavia (by courtesy of A. Berglund, Fallund, Sweden).

Plate 4 Oral tularaemia in a case from northern Sweden (by courtesy of A. Berglund, Fallund, Sweden).

Chapter 7.11.18 Anthrax

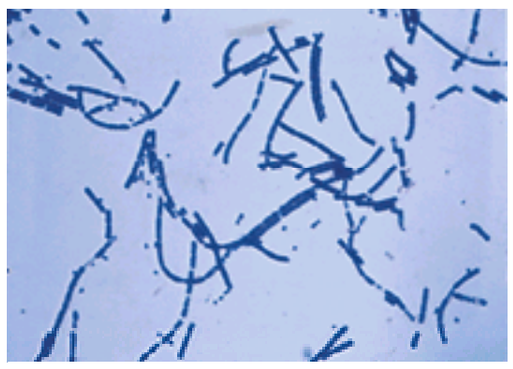

Plate 1 Large Grampositive bacilli in chains are typical of *Bacillus anthracis*. An individual bacillus is 3 to 5 µ m long and 1 to 1.25 µ m wide with a flattened end.

Plate 2 Cutaneous anthrax lesion on the forearm on day 10 showing an ulcer with a depressed black eschar.

Plate 3 Oropharyngeal anthrax on day 9 showing a pseudomembrane covering an ulcer.

Chapter 7.11.20 Tetanus

Plate 1 Facies in tetanus.

Plate 2 Opisthotonos in severe tetanus during seizures.

Plate 3 Brazilian patient with local tetanus confined to muscles innervated by the left VIIth cranial nerve and with trismus, showing the wound causing the infection. (By courtesy of Dr Pedro Pardal, Belém, Brazil.)

Plate 4 Characteristic facies in neonatal tetanus.

Chapter 7.11.24 Leprosy (Hansen's disease)

Plate 1 BT leprosy. This Ethiopian woman has several hypopigmented patches. Testing for anaesthesia will confirm the diagnosis of BT leprosy.

Plate 2 Advanced nodular lepromatous leprosy. This Indian patient presented with ulcerating nodules all over his body.

Plate 3 Reversal (Type 1) reaction. This Ethiopian woman had a postpartum reaction presenting with numerous erythematous raised lesions 8 weeks after delivery.

Plate 4 Severe reversal (Type 1) reaction. This Indian woman has erythematous, oedematous, and desquamating reactional lesions.

Plate 5 Peripheral nerve thickening in leprosy. This young man had marked thickening of his great auricular nerve.

Plate 6 Nerve damage in leprosy. This patient with BT leprosy has damage to the ulnar and median nerves on both sides. This has resulted in hands which are wasted, clawed, and lack finger and thumb opposition.

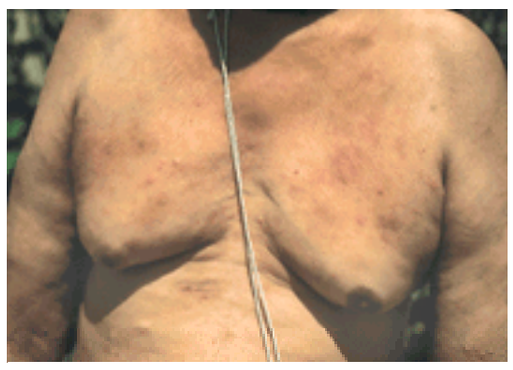

Plate 7 Complications of lepromatous leprosy. Gynaecomastia is visible in this man, secondary to testicular involvement in lepromatous leprosy. Multiple nodules are present, many dark brown, due to clofazimine pigmentation. He also has new erythematous lesions of ENL.

Chapter 7.11.25 Buruli ulcer: *Mycobacterium ulcerans*; infection

Plate 1 Buruli ulcer on the left deltoid area in a 12-year-old Congolese boy who had received a hypodermic injection at this site 3 months previously. Note central necrotic slough in the base of the ulcer, and undermined edges.

Chapter 7.11.29 Lyme borreliosis

Plate 1 Adult female (right) and nymphal (left) – ticks of the *Ixodes scapularis* species.

Plate 2 Erythema migrans rashes from patients who were culture positive for borrelia. (a) A rash with typical central clearing appearance. (b) A rash with more homogenous appearance.

Chapter 7.11.30 Other borrelia infections

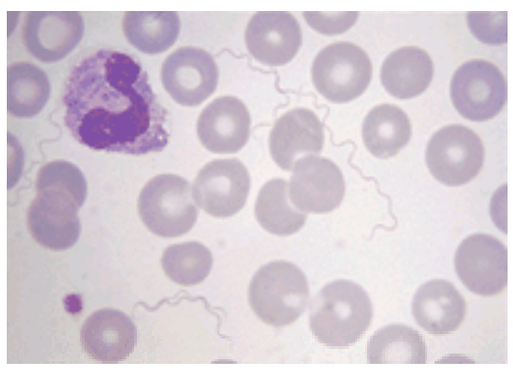

Plate 1 *Borrelia recurrentis* spirochaetes in a Giemsastained thin blood film from a patient with louse-borne relapsing fever. (Copyright D.A. Warrell.)

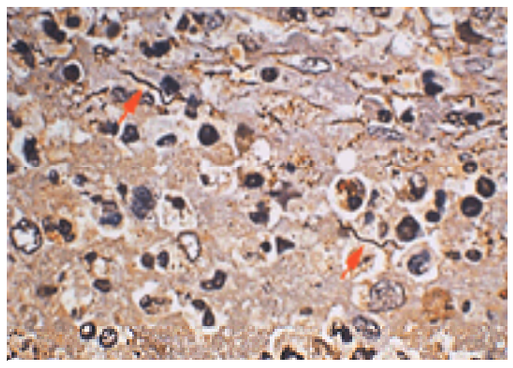

Plate 2 Spleen in louseborne relapsing fever. Warthin Starry stain showing *Borrelia recurrentis* (arrows). (By courtesy of Dr Ken Fleming.)

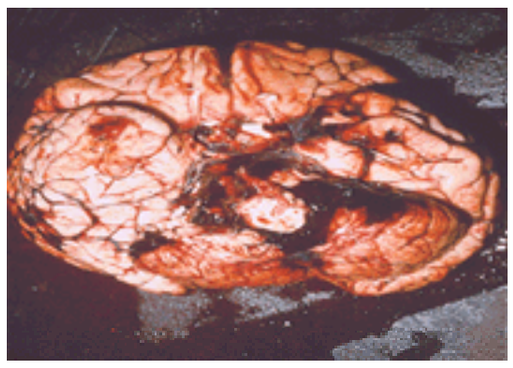

Plate 3 Cerebral haemorrhage in a patient with louse-borne relapsing fever. (Copyright D.A. Warrell.)

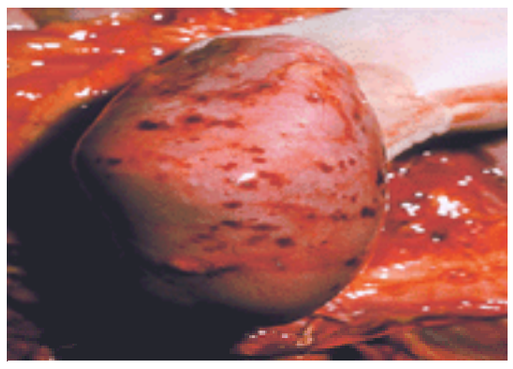

Plate 4 Petechial haemorrhages on the surface of the kidney in a victim of louse-borne relapsing fever. (Copyright D.A. Warrell.)

Plate 5 Ethiopian patient with severe louse-borne relapsing fever. Note emaciation and petechial rash. (Copyright D.A. Warrell.)

Plate 6 Subconjunctival haemorrhages in louse-borne relapsing fever. (Copyright D.A. Warrell.)

Chapter 7.11.31 Leptospirosis

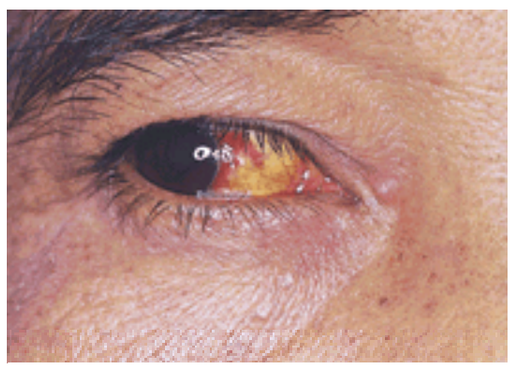

Plate 1 Jaundice, haemorrhage, and conjunctival suffusion in acute leptospirosis.

Chapter 7.11.36 Rickettsial diseases including ehrlichiosis

Plate 1 Boutonneuse fever (South African tick typhus). Eschar with lymphangitic lines spreading towards the femoral lymph nodes in a patient who had visited the Kruger National Park, South Africa, 7 days earlier. (Copyright D.A. Warrell.)

Plates 2 and 3 Boutonneuse fever (South African tick typhus) in a British traveller. (Copyright E. Dunbar.)

Chapter 7.11.37 Scrub typhus

Plate 1 Typical eschars (a, b) and one less typical (c) on the distal foreskin. Lesions in locations such as these can be easily missed during a cursory examination of a febrile patient presenting to a busy outpatient clinic.

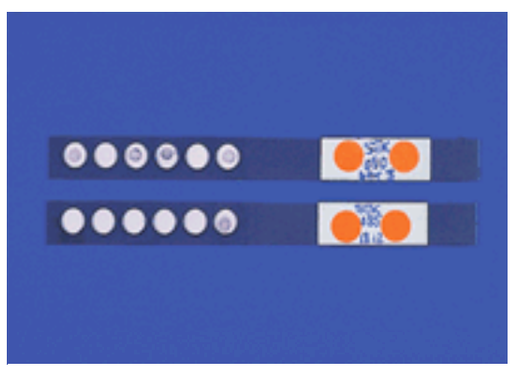

Plate 2 Diagnosis by rapid immunoblot dipstick. The test strip above indicates active scrub typhus, with clearly visible staining within several circles. The test strip below was read as non-reactive, because only the reagent control (last dot on the right) contains staining.

Chapter 7.11.39 Bartonellosis

P><**Plate 1** Miliary haemangioma-like of 'verruga peruana'.

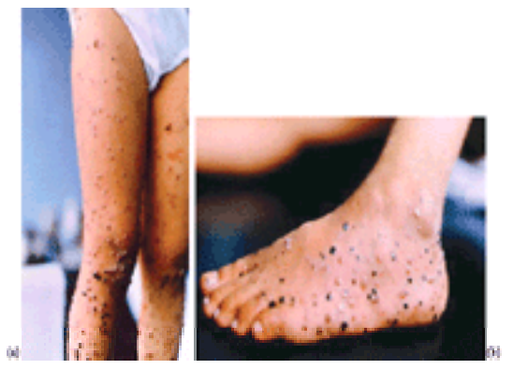

Plate 2 (a, b) Nodular lesions of 'verruga peruana'.

Chapter 7.11.40 Chlamydial infections including lymphogranuloma venerum

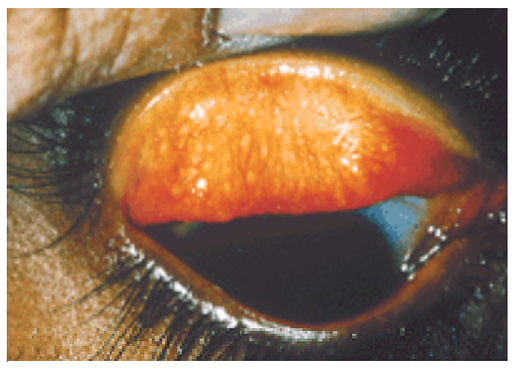

Plate 1 Everted upper eyelid showing follicular trachoma (TF).

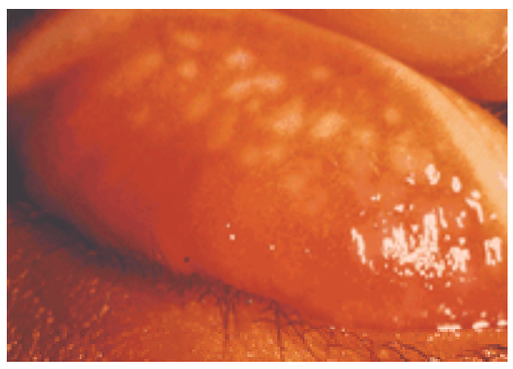

Plate 2 Everted upper eyelid showing intense inflammatory trachoma (TI).

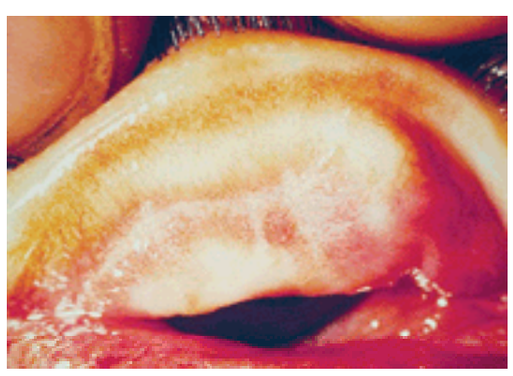

Plate 3 Extensive neovascularization of the cornea (pannus) due to trachoma.

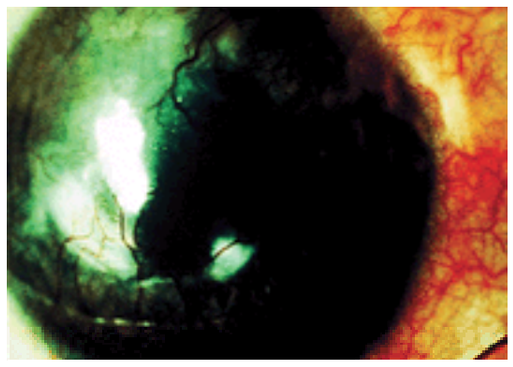

Plate 4 Everted upper eyelid showing trachomatous scarring (TS).

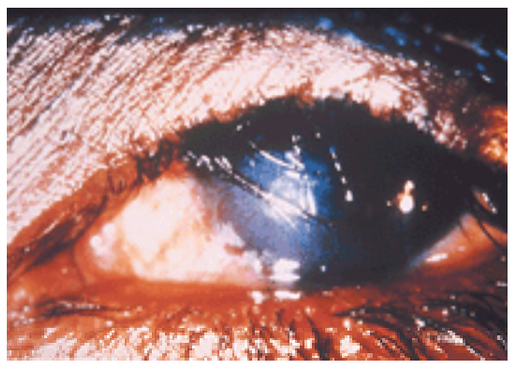

Plate 5 Trachomatous trichiasis (TT).

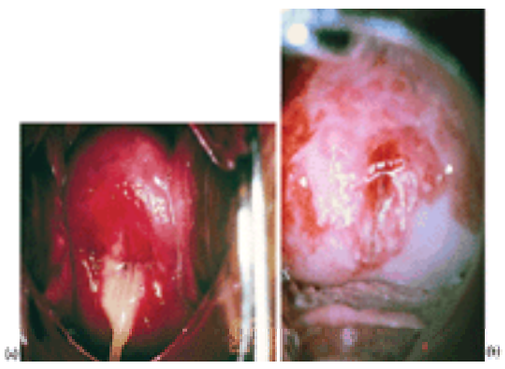

Plate 6 (a) Mucopurulent cervicitis; (b) follicular cervicitis.

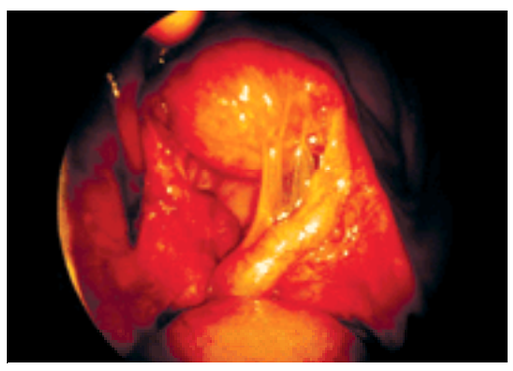

Plate 7 Laparoscopic view of inflamed fallopian tube due to *C. trachomatis*. (By courtesy of P. Greenhouse.)

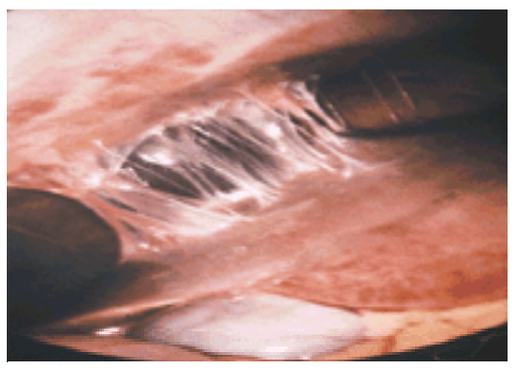

Plate 8 Adhesions in perihepatitis (Curtis Fitz-Hugh syndrome) due to *C. trachomatis*. (By courtesy of P. Greenhouse.)

Plate 9 Mucopurulent neonatal conjunctival discharge due to *C. trachomatis*.

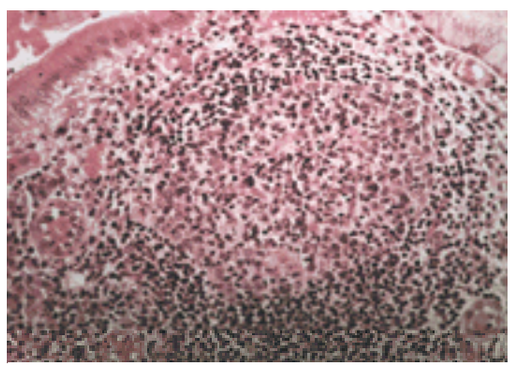

Plate 10 Germinal centre formation in lymphoid follicle of cervicitis due to *C. trachomatis*.

Chapter 7.12.1 Fungal infections

Plate 1 Palmar scaling due to *Trichophyton rubrum*.

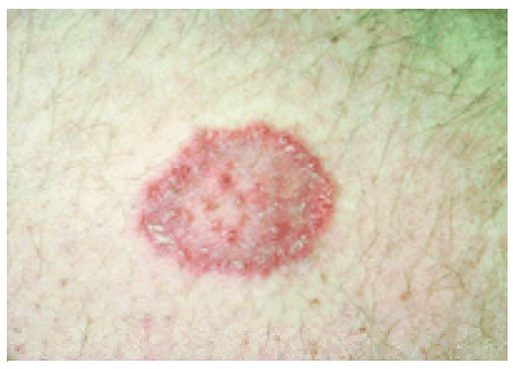

Plate 2 Tinea corporis due to *Microsporum gypseum*.

Plate 3 Oral candidosis in a patient with chronic mucocutaneous candidosis.

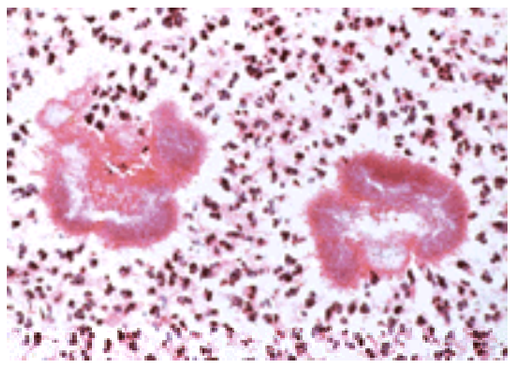

Plate 4 Grains in abscess in actinomycetoma (*Nocardia brasiliensis*) (H & E).

Plate 5 A mycetoma caused by *Madurella grisea*.

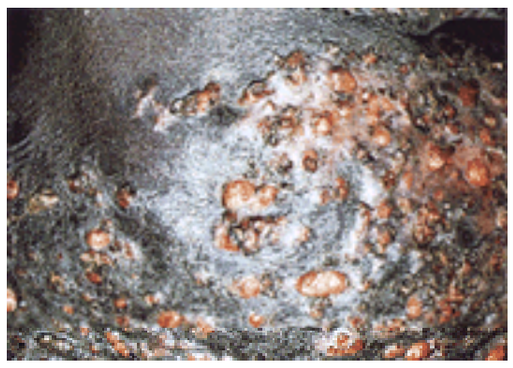

Plate 6 *Nocardia brasiliensis* actinomycetoma draining sinus.

Plate 7 Lobo's disease in a Brazilian man. (Copyright D.A. Warrell.)

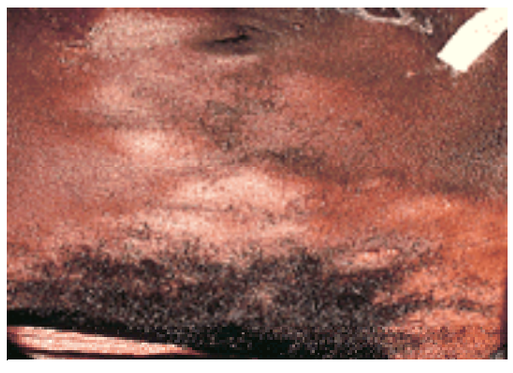

Plate 8 Nodular subcutaneous lesions of African histoplasmosis in a Nigerian man. (Copyright D.A. Warrell.)

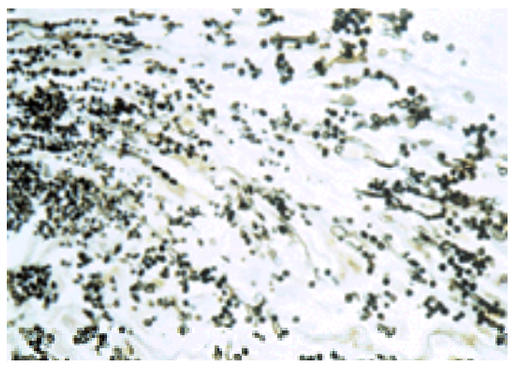

Plate 9 Candidosis disseminated to skin (methenamine silver ×516).

Chapter 7.13.1 Amoebic infections

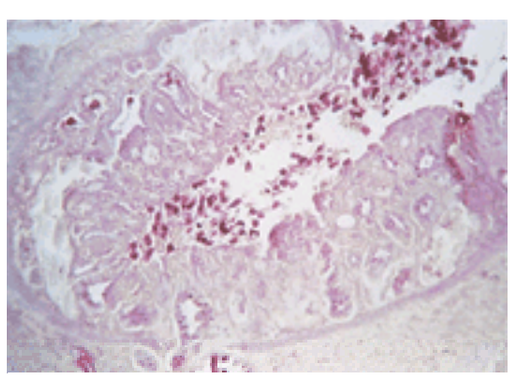

Plate 1 Amoebic colitis. Crypt abscess. PAS stains amoebae red. (Copyright Viqar Zaman.)

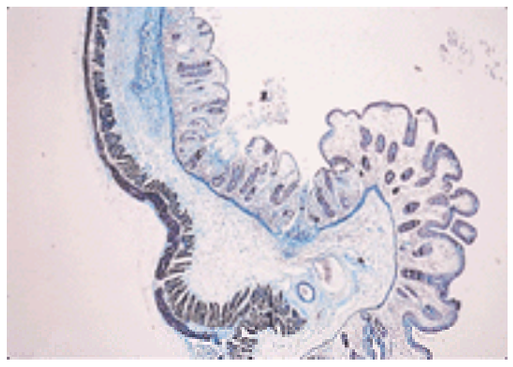

Plate 2 Amoebic colitis. Superficial ulcer breaching the muscularis mucosae. (Copyright Viqar Zaman.)

Plate 3 'Anchovy sauce' pus drained from an amoebic liver abscess. (Copyright Viqar Zaman.)

Plate 4 Sixteen-year-old Peruvian boy with a chronic facial lesion that had been present for 3 years and intracranial space-occupying lesions cuased by *Balamuthia mandrillaris* (a). Perforating lesion of the palate (b). (Copyright D.A. Warrell.)

Chapter 7.13.2 Malaria

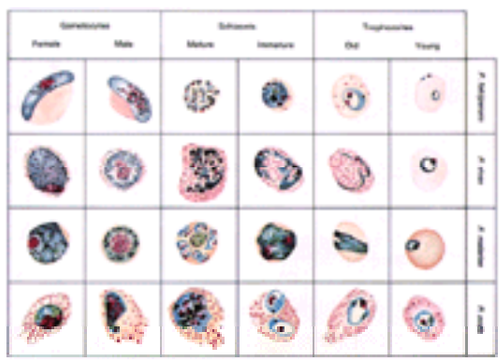

Plate 1 Malaria parasites developing in erythrocytes. (By courtesy of The Wellcome Trust.)

Plate 2 Section of frontal cortex from a Vietnamese patient who died of cerebral malaria, showing sequestration of parasitized red blood corpuscles in blood vessels (N=neurone, V=vessel). (By courtesy of Dr Gareth Turner, Oxford.)

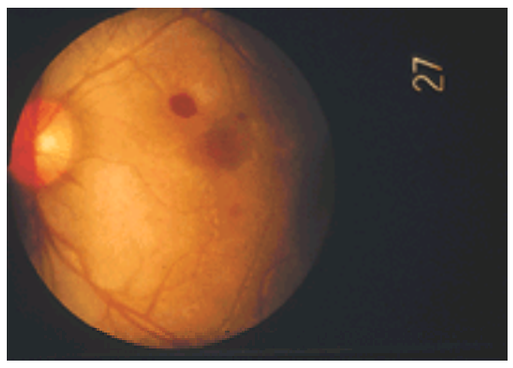

Plate 3 Retinal haemorrhages close to the macula in a Thai patient with cerebral malaria. (Copyright D.A. Warrell.)

Plate 4 Profound anaemia (haemoglobin 1.2 g/dl) in a Kenyan child with *P. falciparum* parasitaemia. (Copyright D.A. Warrell.)

Plate 5 Cerebral malaria. Spontaneous systemic bleeding in a Thai patient with disseminated intravascular coagulation. (Copyright D.A. Warrell.)

Plate 6 Deep jaundice in a Vietnamese man with severe falciparum malaria. (Copyright D.A. Warrell.)

Plate 7 Intravascular haemolysis in a Karen patient with glucose 6-phosphate dehydrogenase deficiency in whom treatment with an oxidant drug resulted in haemoglobinuria and anaemia (normal hand in comparison). (Copyright D.A. Warrell.)

Chapter 7.13.3 Babesia

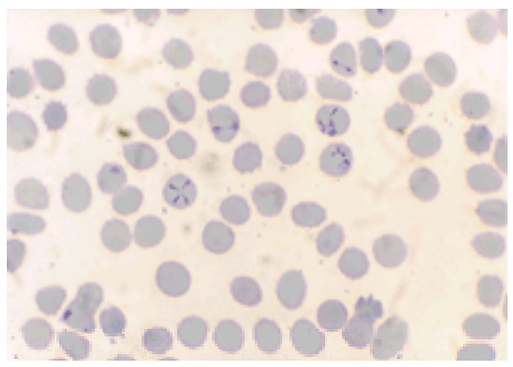

Plate 1 *Babesia divergens* infection in a 29-year-old French man, infected in Normandy. He had been splenectomized 4 months previously for idiopathic thrombocytopenia. Parasitaemia reached 30 per cent. He was successfully treated with exchange transfusion, clindamycin, and quinine. (Copyright P. Brasseur.)

Chapter 7.13.5 Cryptosporidium and cryptosporidiosis

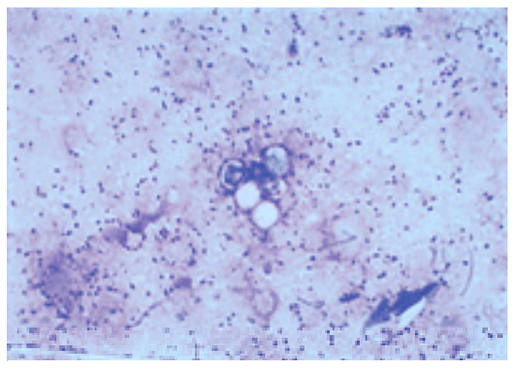

Plate 1 Modified Giemsa-stained faecal smear showing oocysts of *C. parvum*, examined with × 100 oil-immersion objective lens. The uniformity of size (4.5-5 µ m) but variability of staining of oocysts can be seen. The eosinophilic nuclei and basophilic bodies of the sporozoites can be clearly seen within the oocysts that have taken up the stain.

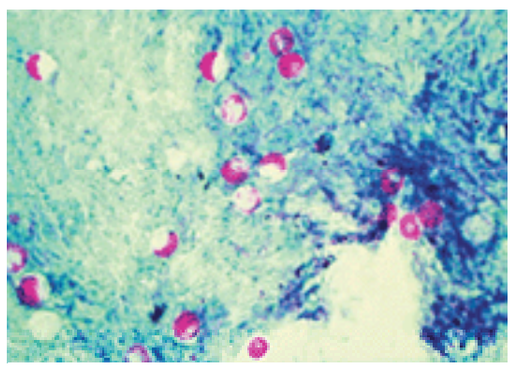

Plate 2 Modified Ziehl-Neelsenstained faecal smear showing oocysts of *C. parvum* examined with × 100 oil-immersion objective lens. The uniformity of size (4.5-5 µ m) but variability of staining of oocysts can be seen.

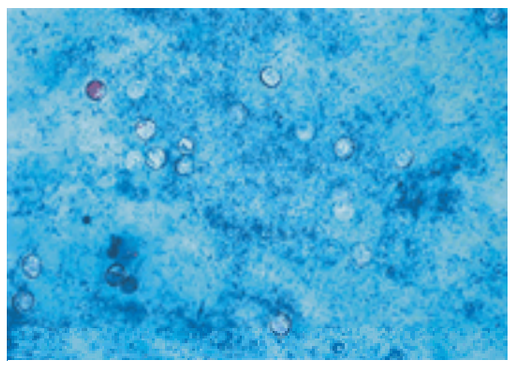

Plate 3 Modified Ziehl-Neelsenstained faecal smear showing oocysts of *C. parvum*. The uniformity of size (4.5-5 µ m) is apparent but the oocysts in this preparation show a definite increase in refractility and marked failure to take up the stain (identity confirmed by immunofluorescence and electron microscopy).

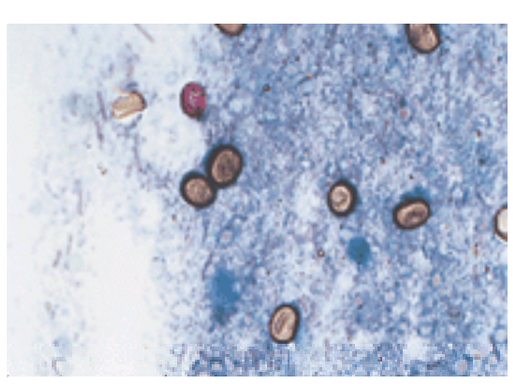

Plate 4 Modified Ziehl-Neelsenstained faecal smear showing oocyst-like bodies (mushroom spores) examined with × 100 oilimmersion objective lens (from specimen submitted to Reference Unit for identification).

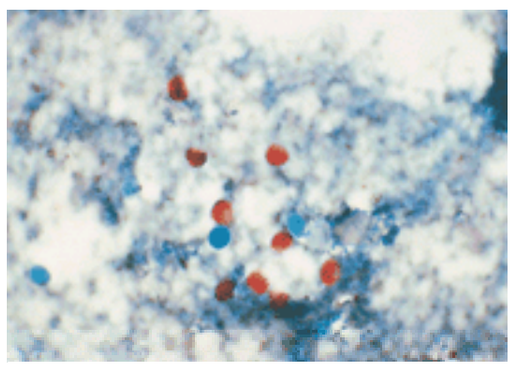

Plate 5 Modified Ziehl-Neelsenstained faecal smear showing oocyst-like bodies (mould spores) examined with × 100 oilimmersion objective lens. The spores are uniform in size but a little smaller (4.0 µ m) than oocysts of *C. parvum*. They are generally more uniform in their acid-fast staining (identity con- firmed by mycological culture and electron microscopy).

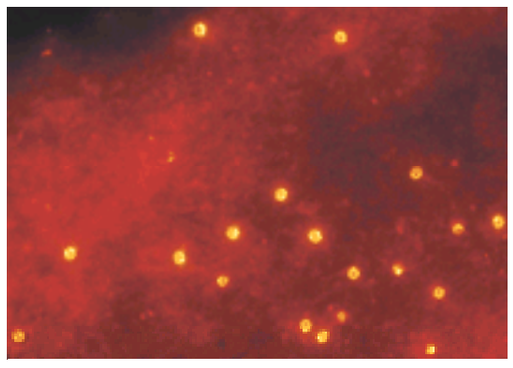

Plate 6 Phenol-auramine/carbol fuchsin-stained faecal smear showing oocysts of *C. parvum*, examined with × 20 dry objective lens (screening magnification) on a fluorescence microscope.

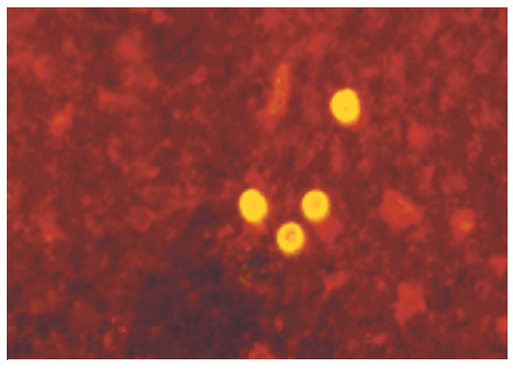

Plate 7 Phenol-auramine/carbol fuchsin-stained faecal smear showing oocysts of *C. parvum*, examined with × 100 oil-immersion objective lens on a fluorescence microscope.

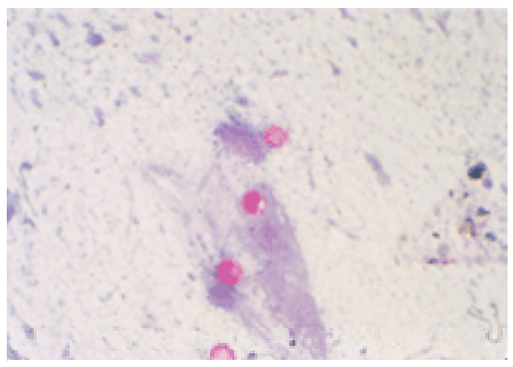

Plate 8 Fluorescent dye-tagged monoclonal antibody-stained faecal smear showing oocysts of *C. parvum*, examined with × 50 oil-immersion objective lens (screening magnification) on a fluorescence microscope. The suture or associated surface cleft or fold, through which the sporozoites are released, can be seen.

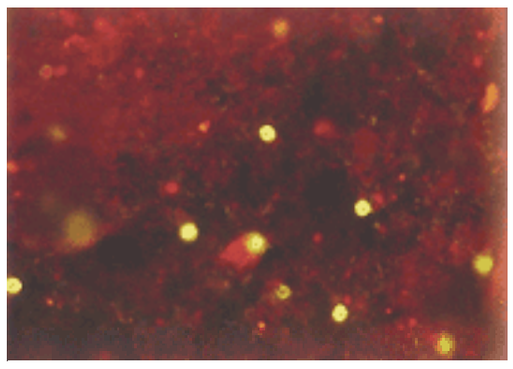

Plate 9 Modified Ziehl-Neelsen-stained sputum smear from an AIDS patient with respiratory involvement (examined with × 100 oil-immersion objective lens). The *C. parvum* bodies present may include endogenous (tissue) stages attached to exfoliated cells. For this reason, oocyst wall-specific indirect immunofluorescence may show a poor reaction. There may also be less uniformity of size and differences in the staining appearance of the internal structures.

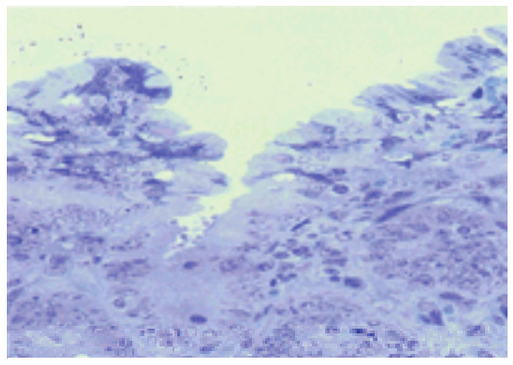

Plate 10 Toluidine blue-stained semithin section of human rectal biopsy tissue of an AIDS patient with cryptosporidiosis. The apparent pseudo-external location of the parasite can be seen, the true location being intracellular but extracytoplasmic. Plates for this Chapter were kindly provided from photographs by A. Curry and D.P. Casemore.

Chapter 7.13.6 Cyclospora

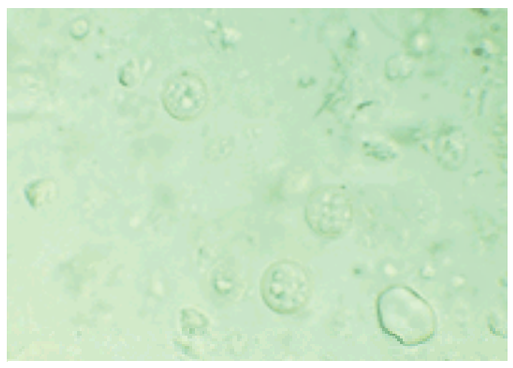

Plate 1 Unstained wet preparation of human faecal material showing oocysts of *Cyclospora* sp., examined with × 100 water-immersion objective lens by phasecontrast microscopy. The uniformity of size (8-10 µ m) and the morular (mulberry) internal structure of the oocysts can be seen.

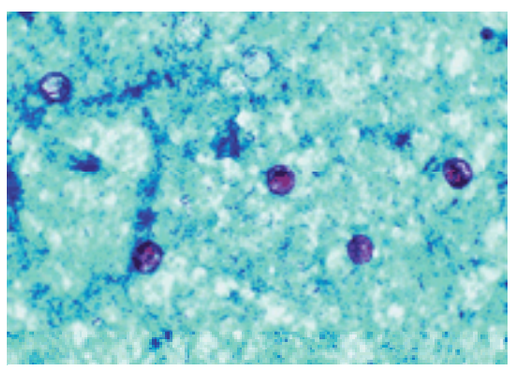

Plate 2 Modified Ziehl-Neelsen-stained faecal smear showing oocysts of *Cyclospora* sp. examined with × 50 oil-immersion objective lens. The uniformity of size (8-10 µm) but variability of staining of the oocysts can be seen. Apart from the greater size, the oocysts can be distinguished from those of *Cryptosporidium parvum* by the different pattern of acid-fast staining. Unstained oocysts within the smear sometimes show the morular structure apparent in wet preparations.

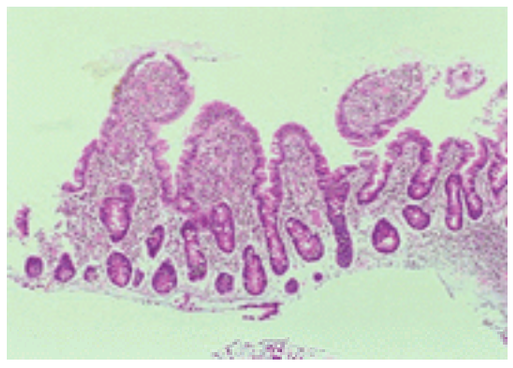

Plate 3 Jejunal biopsy from a patient with cyclosporiasis showing jejunitis with blunting of villi (low power H & E stain). (By courtesy of Dr Sebastian Lucus, London.)

Chapter 7.13.10 Human African trypanosomiasis

Plate 1 Adult tsetse fly (*Glossina morsitans*).

Plate 2 Trypanosomal chancre on the shank of a missionary returning from the Congo.

Plate 3 Patient with late-stage trypanosomiasis.

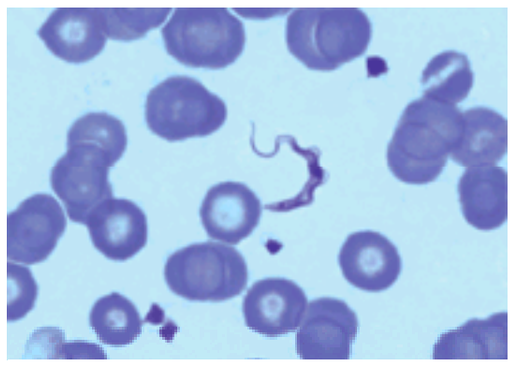

Plate 4 Trypanosomes in thin human blood film (Giemsa stain, × 1000 magnification).

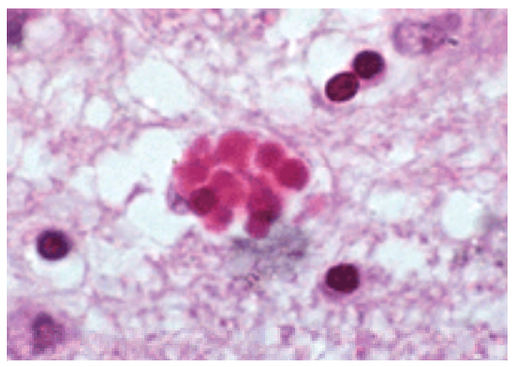

Plate 5 Morular cell of Mott in a histological brain section of a stage II HAT patient (H & E stain, × 1000 magnification).

Chapter 7.13.11 Chagas' disease

Plate 1 Adult female triatomine bug (*Panstrongylus megistus*), with a single egg shown adjacent to the tip of the abdomen. (By courtesy of Dr T.V. Barrett.)

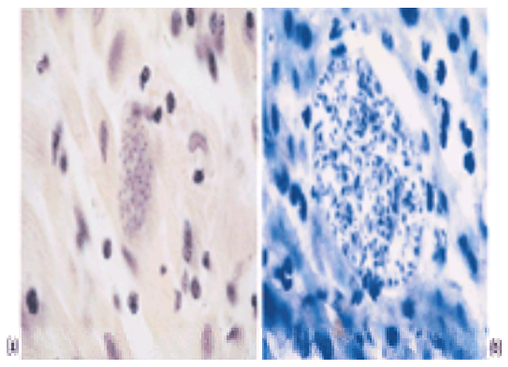

Plate 2 (a) Pseudocyst of *Trypanosoma cruzi* in heart muscle. (By courtesy of J.E. Williams.) (b) Pseudocyst of *Trypanosoma cruzi* in umbilical cord, from a congenital case of Chagas' disease. (By courtesy of Dr Hipolito de Almeida.)

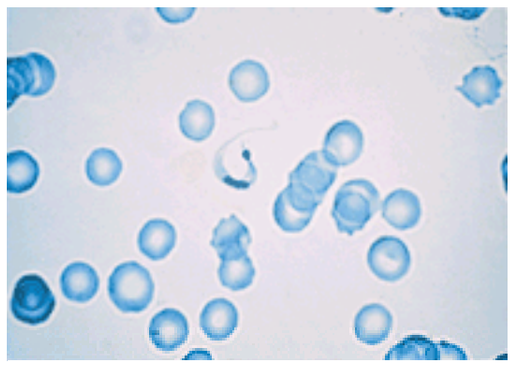

Plate 3 *Trypanosoma cruzi* C-shaped trypomastigote in blood, note large posterior kinetoplast.

Plate 4 Romaña's sign in acute Chagas' disease.

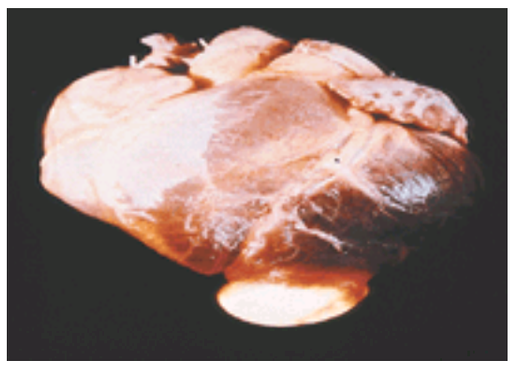

Plate 5 Apical aneurysm of the left ventricle in chronic Chagas' disease. (By courtesy of Dr J.S. de Oliveira.)

Plate 6 Mural thrombus filling the right atrial appendage. (Copyright D.A. Warrell.)

Plate 7 Mega-oesophagus seen by radiography in chronic Chagas' disease. (By courtesy of Dr J.S. de Oliveira.)

Plate 8 Megacolon postmortem in chronic Chagas' disease. (By courtesy of Dr J.S. de Oliveira.)

Chapter 7.13.12 Leishmaniasis

Plate 1 Shallow ulcer with raised edge due to *L. brasiliensis* (copyright A.D.M. Bryceson).

Plate 2 Lupoid or recidivans leishmaniasis in a citizen of Baghdad. (By courtesy of Dr Ahmed.)

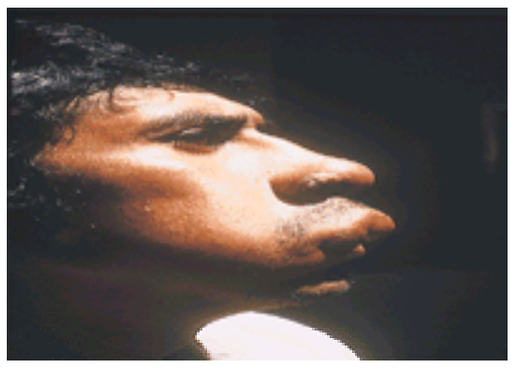

Plate 3 Swollen upper lip and nose due to mucosal leishmaniasis in Peru (copyright A.D.M. Bryceson).

Plate 4 Infiltration of lip and palate due to mucosal leishmaniasis in Peru (copyright A.D.M. Bryceson).

Chapter 7.13.13 Trichomoniasis

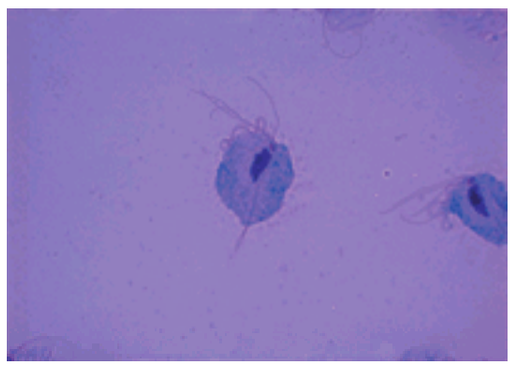

Plate 1 Trichomonads, Giemsa stain, in vaginal secretions. (Copyright J.P. Ackers.)

Chapter 7.14.1 Cutaneous filariasis

Plate 1 A 3-cm subcutaneous nodule.

Plate 2 Excoriated papular lesions of onchocerciasis with hyperpigmentation.

Plate 3 Lichenified skin lesions with atrophy.

Plate 4 Depigmented 'leopard skin'.

Plate 5 Migrating *Loa loa*.

Chapter 7.14.2 Lymphatic filariasis

Plate 1 Microfilaria of *Wuchereria bancrofti* in a blood film from a patient in Samoa. (By courtesy of the Wellcome Museum of Medical Science.)

Chapter 7.14.3 Guinea-worm disease: dracunculiasis

Plate 1 Blister at site of imminent emergence of the female worm. (By courtesy of the late P.E.C. Manson-Bahr.)

Plate 2 Emergent female worm being wound out on a stick. (Copyright D.A. Warrell.)

Plate 3 Guinea worm in the scrotum. (Copyright D.A. Warrell.)

Chapter 7.14.4 Strongyloidiasis, hookworm, and other gut strongyloid nematodes

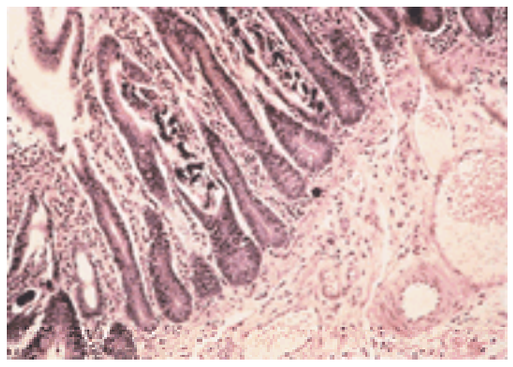

Plate 1 Strongyloides stercoralis in the intestinal mucosa. (Copyright Viqar Zaman.)

Plate 2 Larva currens rash on the back of a Nigerian patient resulting from autoinfection with *Strongyloides stercoralis*. (Copyright D.A. Warrell.)

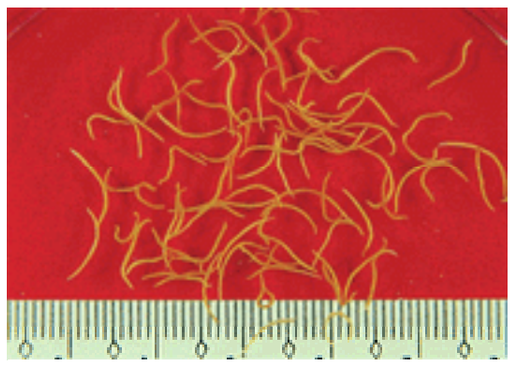

Plate 3 Adult *Ancylostoma duodenale* – scale in millimetres. (Copyright Viqar Zaman.)

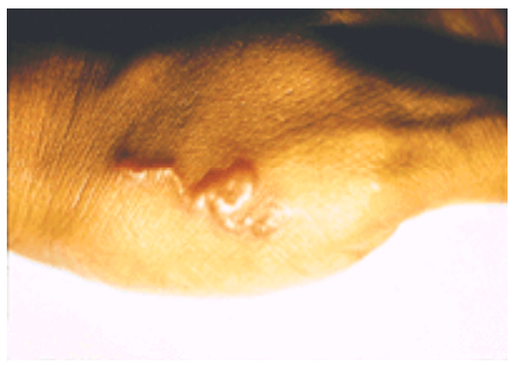

Plate 4 Cutaneous larva migrans of the hand in a Thai patient. (Copyright Sornchai Looareesuwan.)

Chapter 7.14.6 Other gut nematodes

Plate 1 Ascaris – scale in millimetres.

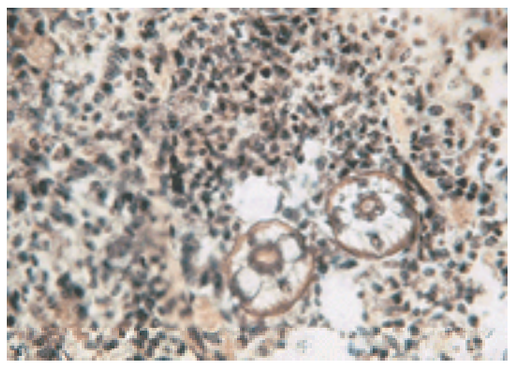

Plate 2 Ascaris in the lungs. (Copyright Viqar Zaman.)

Plate 3 Enterobius – scale in millimetres.

Chapter 7.14.8 Angiostrongyliasis

Plate 1 *Angiostrongylus cantonensis* under the conjunctiva in a Thai girl with a left facial nerve palsy. (Copyright D.A. Warrell.)

Chapter 7.15.1 Cystic hydatid disease (*Echinococcus granulosus*)

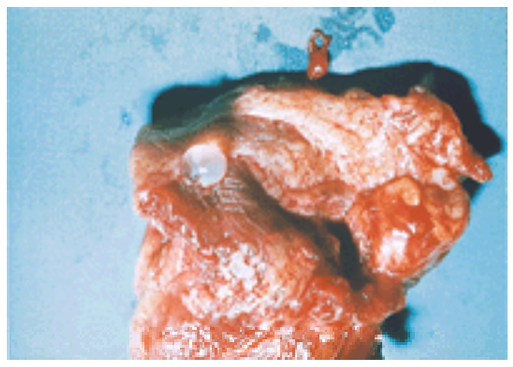

Plate 1 Hydatid cyst in muscles excised from around the femoral head (same case as shown in Fig, 3).

Chapter 7.16.1 Schistosomiasis

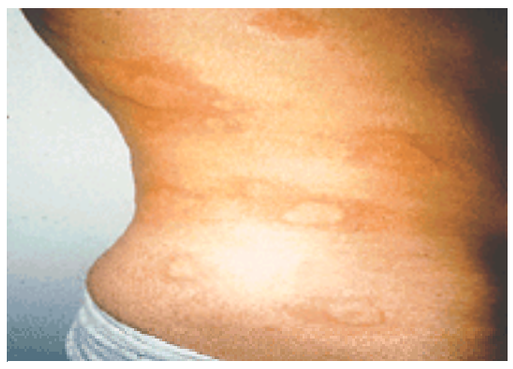

Plate 1 Giant urticarial rash in a patient with Katayama fever (*Schistosoma mansoni* infection). (Copyright R.N. Davidson.)

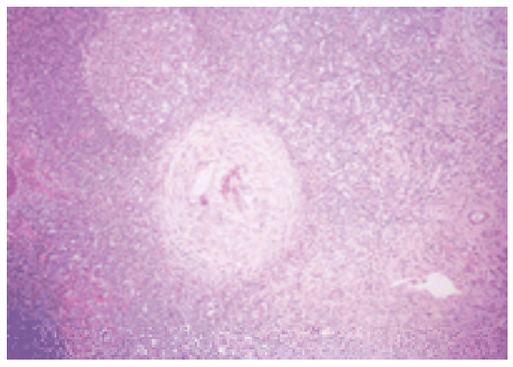

Plate 2 Schistosomal granuloma in the appendix. (Copyright Gareth Turner.)

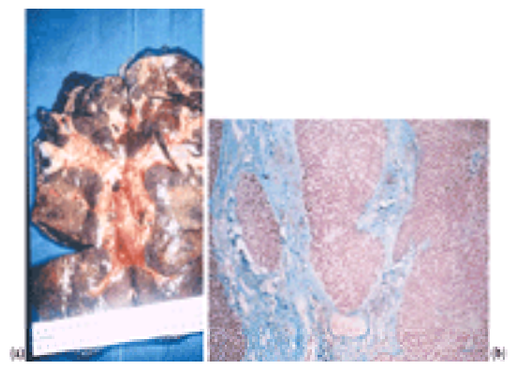

Plate 3 The liver in *Schistosoma mansoni* infection in South Africa. Clay pipestem fibrosis. (Copyright Gareth Turner.) (a) Macrosopic view. (b) Masson trichrome stain.

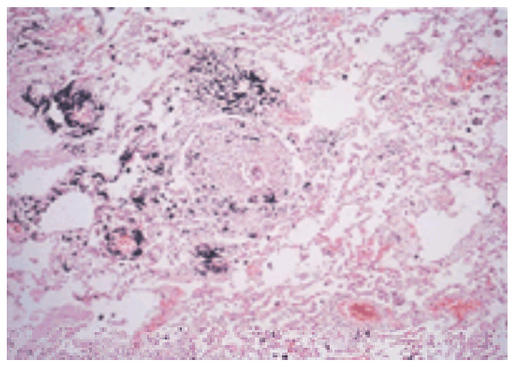

Plate 4 Schistosomal granuloma in the lung. (Copyright Gareth Turner.)

Chapter 7.16.3 Lung flukes (paragonimiasis)

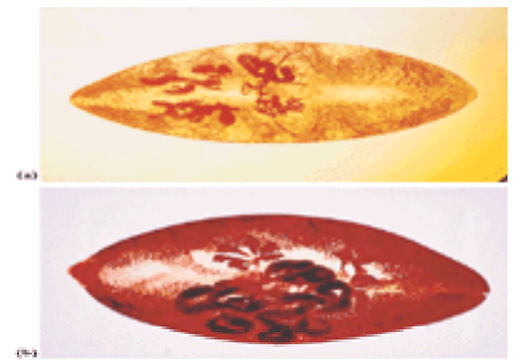

Plate 1 Adult lung fluke. (a) *Paragonimus heterotremus* (1.5 cm). (b) *P. westermani* (1.5 cm). (Copyright Sanan Yaemput.)

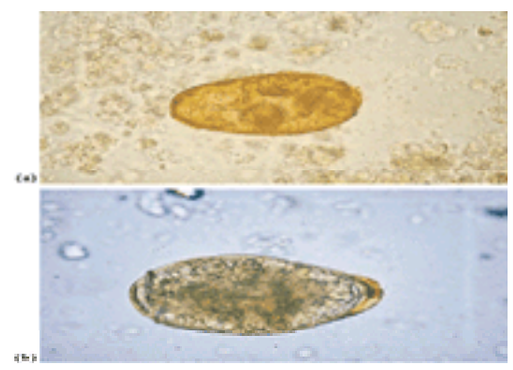

Plate 2 Ova of lung flukes. (a) *Paragonimus heterotremus*. (b) *P. westermani*. (Copyright Sanan Yaemput.)

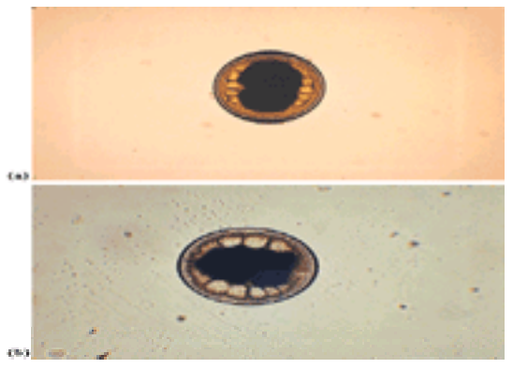

Plate 3 Metacercariae of lung fluke in crabs, the second intermediate host. (a) *Paragonimus heterotremus*. (b) *P. westermani*. (Copyright Sanan Yaemput.)

Plate 4 Freshwater crab *Larnaudia beusekomae* (*Tawaripotamon beusekomae*), the second intermediate host. (Copyright Sanan Yaemput.)

Chapter 7.17 Non-venomous arthropods

Plate 1 Bedbugs, *Cimex lectularius*.

Plate 2 Catflea, *Ctenocephalides felis* : a common cause of flea bites in humans.

Plate 3 Underside of hedgehog tick, *Ixodes hexagonus* to show sucking mouthparts (hypostome).

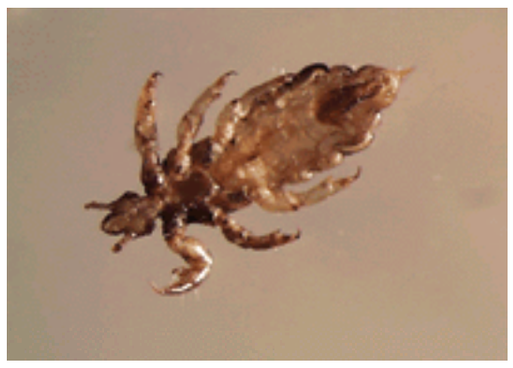

Plate 4 Louse, *Pediculus humanus* : head lice and body lice are morphologically similar.

Plate 5 An Asian carabid beetle, *Sciates sulcatus*, from a patient complaining of vaginal discharge: a rare example of genital cantharíasis.

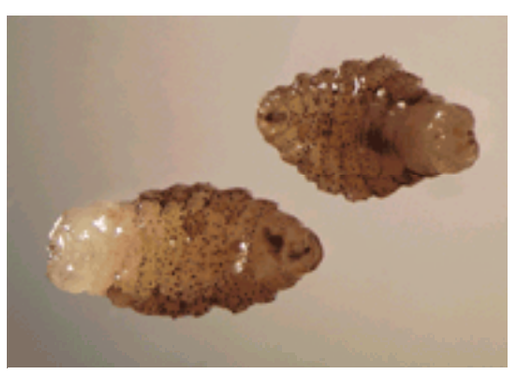

Plate 6 Larvae of African tumbu fly, *Cordylobia anthropophaga* : a common agent of dermal myiasis.

Plates for Section 8

Chapter 8.2 Injuries, envenoming, poisoning, and allergic reactions caused by animals

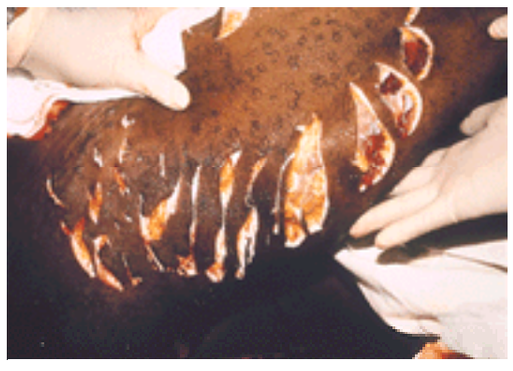

Plate 1 Shark attack: wounds inflicted on the thigh by a tiger shark (*Galeocerdo cuvier*), Madang, Papua New Guinea. (Copyright S. Allen.)

Plate 2 Farmer swallowed by a reticulated python (*Python reticulatus*), Palu, Sulawesi. (Copyright Excel Sawuwu.)

Plate 3 White-lipped pit viper from south-east Asia (*Trimeresurus albolabris*) showing the heat-sensitive pit organ between eye and nostril. (Copyright D.A. Warrell.)

Plate 4 Bleeding from gingival sulci in a victim of the West African saw-scaled or carpet viper (*Echis ocellatus*). (Copyright D.A. Warrell.)

Plate 5 The two species of venomous lizards: left, Mexican beaded lizard (*Heloderma horridum*); right, gila monster (*H. suspectum*). (By courtesy of the Zoological Society of London.)

Plate 6 Poison frog – *Dendrobates histrionicus* (Dendrobatidae) from Bahia Solauo, Colombia. Its skin secretion contains potent nicotinic receptor antagonists, histrionicotoxins. (Copyright D.A. Warrell.)

Plate 7 Poison dart frogs – *Phyllobates terribilis* (Dendrobatidae) from the Chocó region of Colombia, where their skin secretions, containing potent batrachotoxins, are used to coat blow gun darts. (Copyright D.A. Warrell.)

Plate 8 Hooded Pitohui (*Pitohui dichrous*), Vararata National Park, near Port Moresby, Papua New Guinea. (By courtesy of Dr Ian Burrows, Port Moresby.)

Plate 9 Venomous lion fish or butterfly cod (*Brachirus* or *Dendrochirus zebra*), from Madang, Papua New Guinea. (Copyright D.A. Warrell.)

Plate 10 Necrotic and secondarily infected wound at the site of a sting by a freshwater ray (*Potamotrygon hystrix*) in a Brazilian patient. (By courtesy of Dr João Luiz Costa Cardoso, São Paulo, Brazil.)

Plate 11 Extensive weals from contact with the stinging tentacles of the box jellyfish (*Chironex fleckeri*) in an Australian patient stung in Darwin. (By courtesy of Drs B. Currie and P. Nitschke, Darwin.)

Plate 12 Geography coneshell (*Conus geographus*) 10 cm long, responsible for killing a nine-year-old boy at Samarai, Papua New Guinea. (Copyright D.A. Warrell.)

Plate 13 Northern blue-ringed or spotted octopus (*Hapalochlaena lunulatus*) from Madang, Papua New Guinea. (Copyright D.A. Warrell.)

Plate 14 Fourteen-year-old Brazilian boy severely envenomed after more than 1000 stings by Africanized honey bees (*Apis mellifera scutellata*). (Copyright D.A. Warrell.)

Plate 15 Lepidopterism. Lesions caused by urticating abdominal hairs of female moths (*Hylesia* sp.) during an epidemic on the Brazilian coast near São Paulo. (Copyright D.A. Warrell.)

Plate 16 Caterpillar of *Lonomia achelous* whose bristle venom can cause a fatal bleeding diathesis. (By courtesy of Dr Habib Fraiha, Belém, Brazil.)

Plate 17 Beetle (*Paederus crebripunctatus*, Staphylinidae) responsible for causing 'Nairobi eye'. (By courtesy of Dr John Paul, Brighton.)

Plate 18 Scorpion (*Tityus serrulatus*) from Brazil. (Copyright D.A. Warrell.)

Plate 19 Local blistering and necrosis caused by the sting of the scorpion *Hemiscorpius lepturus* (Scorpionidae) found in Iran and Iraq. (By courtesy of Dr M. Radmanesh, Shiraz, Iran.)

Plate 20 Threatening posture of a female Brazilian 'banana spider' (*Phoneutria nigriventer*). Note multiple eyes and large chelicerae. (Copyright D.A. Warrell.)

Plate 21 Female *Loxosceles laeta*. (Copyright D.A. Warrell.)

Plate 22 Australian red back spider (*Latrodectus hasseltii*). (Copyright D.A. Warrell.)

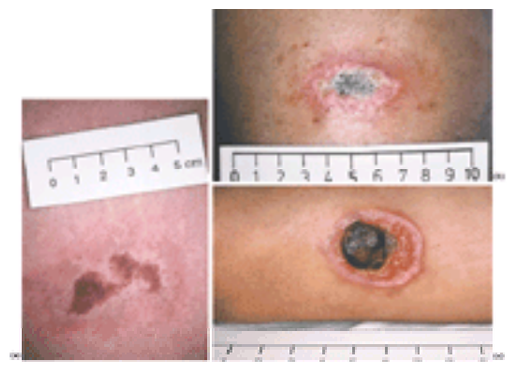

Plate 23 Necrotic araneism. Evolution of the typical lesion following bites by *Loxosceles gaucho* in Brazil. (a) Early ischaemic lesion showing the 'red, white, and blue' sign. (b) 2 weeks later. (c) Necrotic eschar 6 weeks later. (Copyright D.A. Warrell.)

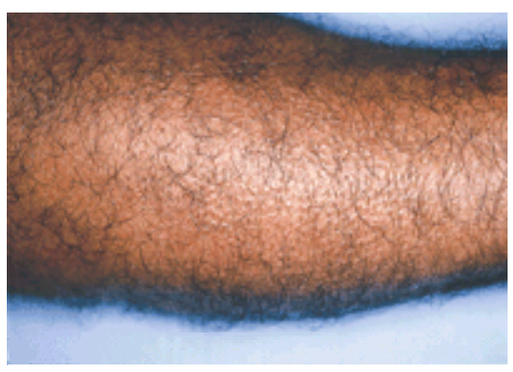

Plate 24 Local sweating and piloerection at the site of a bite by the banana spider *Phoneutria nigriventer*. (Copyright D.A. Warrell.)

Chapter 8.3 Poisonous plants and fungi

Plate 1 Dumb cane, *Dieffenbachia* sp. (GTC).

Plate 2 Laburnum, *Laburnum anagyroides* (GTC).

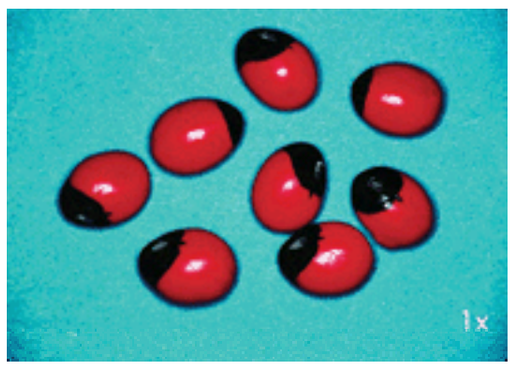

Plate 3 Jequirity beans, *Abrus precatorius* (RBG, Kew).

Plate 4 Castor beans, *Ricinus communis* (GTC).

Plate 5 Woody nightshade, *Solanum dulcamara* (GTC).

Plate 6 Foxglove, *Digitalis purpurea* (GTC).

Plate 7 Oleander, *Nerium oleander* (GTC).

Plate 8 Monkshood, *Aconitum* sp. (GTC).

Plate 9 Yew, *Taxus baccata* (GTC).

Plate 10 Khat, *Catha edulis* (RBG, Kew).

Plate 11 Comfrey, *Symphytum offi- cinale* (GTC).

Plate 12 Poison ivy, *Rhus radicans* (MCC).

Plate 13 Giant hogweed, *Heracleum mantegazzianum* (GTC).

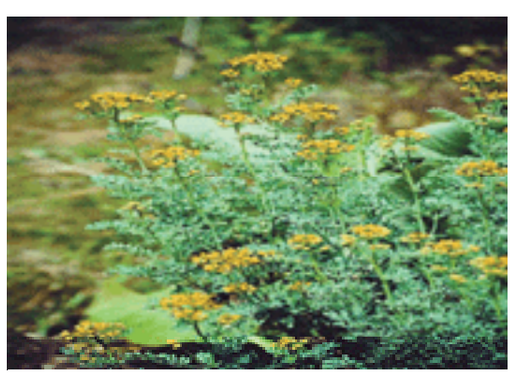

Plate 14 Rue, *Ruta graveolens* (GTC).

Plate 15 Hemlock, *Conium maculatum* (GTC).

Plate 16 Deadly nightshade, *Atropa belladonna* (GTC).

Plate 17 Angel's trumpets, *Brugmansia* sp. (GTC).

Plate 18 Thorn apple, *Datura stramonium* (GTC).

Plate 19 Cycad, *Zamia* sp. (GTC).

Plate 20 Fly agaric, *Amanita muscaria* (GTC).

Plate 21 Death cap, *Amanita phalloides* (GTC).

Plate 22 Roll-rim cap, *Paxillus involutus* (GTC).

Plate 23 Ergot, *Claviceps purpurea* (JW). We thank the following for permission to reproduce their photographs: The Trustees, The Royal Botanic Gardens, Kew (RBG, Kew), G.T. Cooper (GTC), M.C. Cooper (MCC), and Professor J. Webster (JW).

Plates for Section 11

Chapter 11.5 The porphyrias

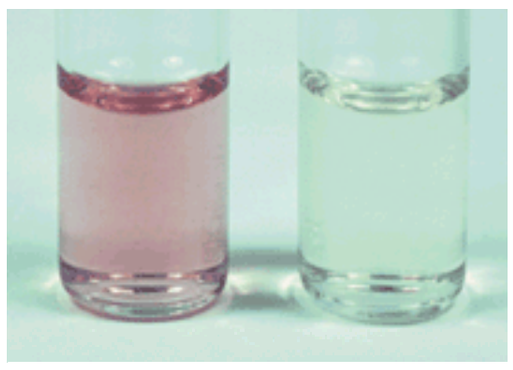

Plate 1 Urine from a patient with acute intermittent porphyria around the time of an acute attack (left); control urine (right). A positive reaction with Ehrlich's diazo reagent is shown in the patient following the addition of 50 µ l of urine to 1 ml of 2 per cent acidic dimethyl benzaldehyde. Subsequent tests showed that the pink diazo adduct was insoluble in chloroform and other organic solvents indicating the presence of excess porphobilinogen. (Urobilinogen in excess may give a positive reaction with the diazo reagent but the product is readily extracted into organic solvents.)

Plate 2 Porphyria cutanea tarda in a 60-year-old heterozygote for the *HFE* C282Y mutation. This man, a taxi driver, had noticed irritation after exposure of his hands to light transmitted through the windscreen. He had noticed fragility and blistering combined with pigmentary changes typical of this disorder. After treatment by controlled phlebotomy his skin complaint has regressed.

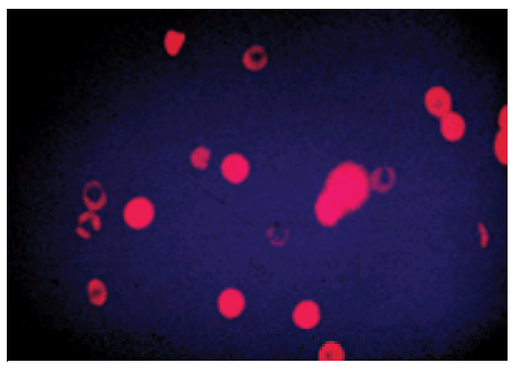

Plate 3 Fluorescent microscopy of an unstained blood film from a patient with erythropoietic protoporphyria. Note the red fluorescence of increased free protoporphyrin within individual young erythrocytes and reticulocytes.

Plate 4 Examination of human plasma under long-wave ultraviolet light. Plasma on the right was obtained from a patient with protoporphyrin hepatopathy and greatly increased photosensitivity and is compared with plasma obtained from a healthy subject on the left. Note the bright red fluorescence due to the presence of high concentrations of free protoporphyrin. Maximum fluorescence was obtained by exposure to visible light in the violet and green–yellow spectral regions corresponding to the absorbance bands of porphyrins.

Chapter 11.6 Lipid and lipoprotein disorders

Plate 1 Achilles tendon xanthoma (heterozygous familial hypercholesterolaemia).

Plate 2 Tendon xanthomata on the dorsum of a hand (heterozygous familial hypercholesterolaemia).

Plate 3 Eruptive and tuberous xanthomata on an arm (type III hyperlipoproteinaemia with marked hypertriglyceridaemia).

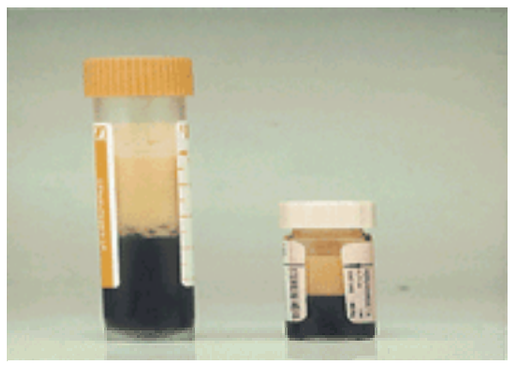

Plate 4 Milky plasma indicating marked hypertriglyceridaemia (blood samples from a patient with acute abdominal pain).

Chapter 11.7.1 Hereditary haemochromatosis

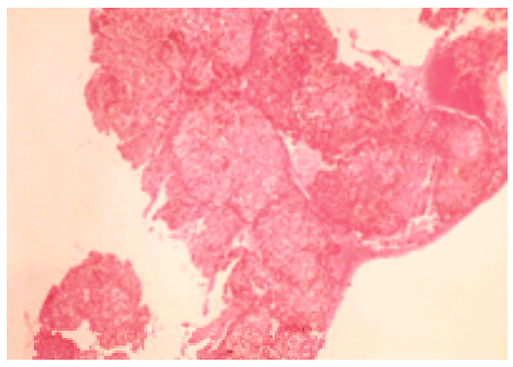

Plate 1 Low-power, needle-biopsy appearance of liver specimen stained with haematoxylin and eosin from a 67-year-old man with adult haemochromatosis due to homozygosity for the *C282Y* mutation. Note the large hyperplastic nodules and fibrosis.

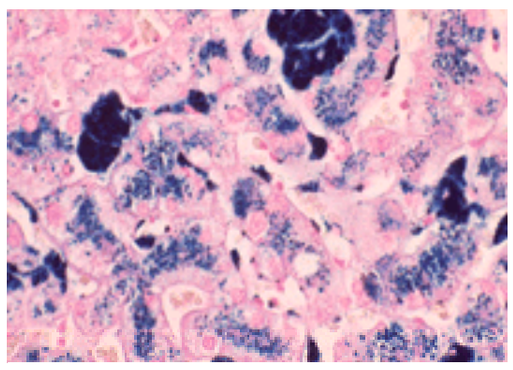

Plate 2 High-power micrograph of the liver biopsy specimen shown in Plate 1 stained with Perls' reagent. Note extensive deposits of ferric iron in all cell types including Kupffer cells, cells lining small biliary radicles, and in a punctate distribution within parenchymal hepatocytes. Liver cells are hyperplastic.

Plate 3 Arthropathy in a man with adult haemochromatosis forced to stop manual work because of painful arthritis especially in the second and third metacarpophalangeal joints; note increased skin pigmentation.

Plate 4 Adult haemochromatosis. Section of liver lobe after surgical resection to remove a primary hepatocellular carcinoma arising in an iron-loaded but, unusually, non-cirrhotic liver in this disorder. The patient, aged 62 years, had been partially treated by venesection but recently noticed increasing lethargy: a raised serum a-fetoprotein concentration led to the diagnosis; moderate histochemical evidence of iron storage was found in the non-malignant tissue excised at surgery.

Chapter 11.7.2 Wilson's disease, Menke's disease: inherited disorders of copper metabolism

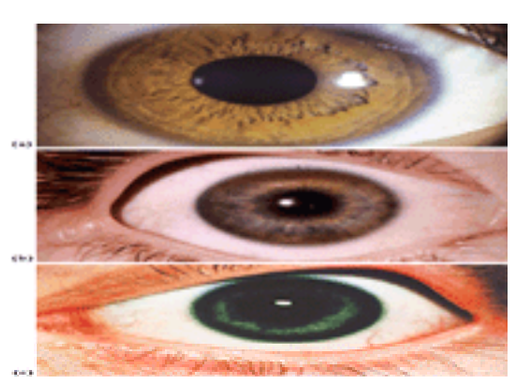

Plate 1 (a–c) Kayser–Fleischer ring in Wilson's disease.

Plate 2 Penicillamine dermatopathy—elastosis perfringens serpiginosa.

Plate 3 Appearance in Menkes' disease.

Chapter 11.8 Lysosomal storage diseases

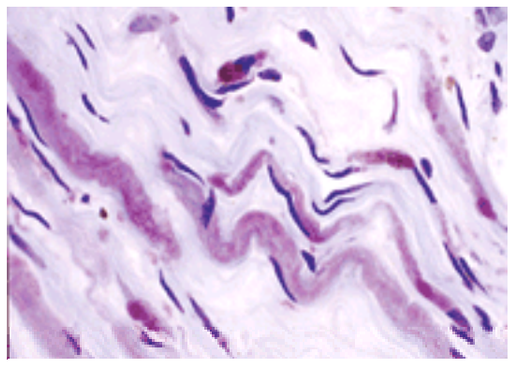

Plate 1 Sural nerve biopsy stained with toluidine blue from the patient shown in Plate 2 with metachromatic leucodystrophy. Note the brown-staining granular material within Schwann and perineurial macrophages typical of this disorder due to the deposition of the glycolipid sulphatide. (By courtesy of Dr J. Xuereb, Addenbrooke's Hospital).

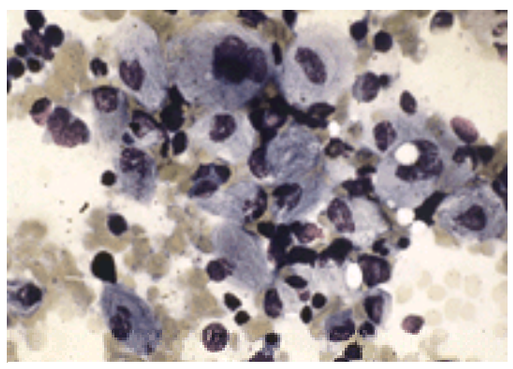

Plate 2 Light micrograph of a Leishmann-stained bone marrow biopsy obtained from a 23-year-old man with type 1 Gaucher's disease. Note that the large, pale-blue staining Gaucher's cells with striated cytoplasm replace the Kupffer cells of the liver, alveolar macrophages of the lung, and of the bone marrow.

Chapter 11.13 a_1-Antitrypsin deficiency and the serpinopathies

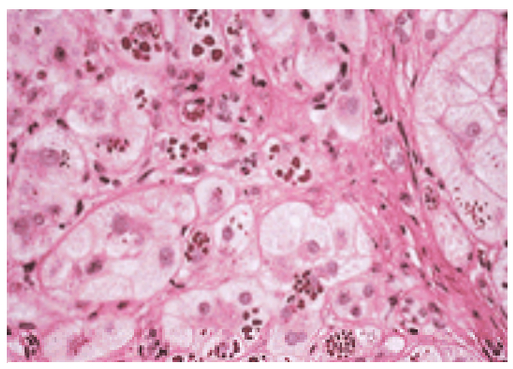

Plate 1 A chain of loop-sheet polymers isolated from a patient with a_1-antitrypsin deficiency. These polymers can form filaments or circlets that tangle within the endoplasmic reticulum of the hepatocyte to form the inclusions which are the hallmark of the disease. These intrahepatic inclusions are characteristically periodic acid–Schiff (**PAS**)-positive and diastase-resistant and stain positive for a_1-antitrypsin on immunohistochemistry.

Plates for Section 12

Chapter 12.4 The thyroid gland and disorders of thyroid function

Plate 1 Thyroid dermopathy (pretibial myxoedema) affecting the lateral aspect of the shin and the dorsum of the foot; the patient also had thyroid acropachy.

Chapter 12.7.1 Diseases of the adrenal cortex

Plate 1 A young woman with Cushing's disease, photographed initially alongside her identical twin sister (a). In this case treatment with bilateral adrenalectomy was undertaken and several years later the patient re-presents with Nelson's syndrome and a right III cranial nerve palsy due to cavernous sinus infiltration from a locally invasive corticotrophinoma.

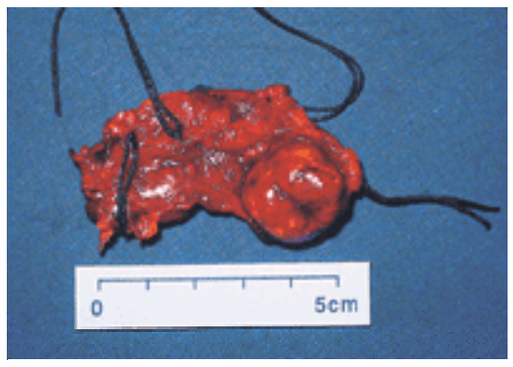

Plate 2 A solitary adrenal adenoma. The characteristic yellow appearance of the cut surface of the excised tumour reflects the high cholesterol content.

Chapter 12.8.1 Approach to the patient with ovarian disorders

Plate 1 Acanthosis nigricans in a young woman with polycystic ovary syndrome.

Chapter 12.10 Non-diabetic pancreatic endocrine disorders and multiple endocrine neoplasia

Plate 1 (a) Necrolytic migratory erythema in a patient with the glucagonoma syndrome. (b) Pigmentation in healed areas.

Chapter 12.11.1 Diabetes mellitus

Plate 1 (a) Diabetic amyotrophy: quadriceps right wasting due to femoral neuropathy (with thanks to Dr Geoff Gill, University Hospital, Aintree, Liverpool). (b) Wasting of small muscles of the hands due to both ulnar and median nerve lesions.

Plate 2 The diabetic foot. (a) Typical punched-out neuropathic ulcer on the lateral aspect of the sole in an ischaemic foot with gangrene of the second, fourth, and fifth toes. (b) Ulceration and digital gangrene, caused by wearing tight shoes on a severely ischaemic foot.

Plate 3 The hands in long-standing diabetes. (a) Limited joint mobility (cheiroarthropathy), showing the 'prayer sign'. (b) Thickening of the skin over the knuckles and proximal interphalangeal joints (Garrod's pads).

Plate 4 Necrobiosis lipoidica diabeticorum (with thanks to Dr Geoff Gill, University Hospital, Aintree, Liverpool.

Plates for Section 13

Chapter 13.13 The skin in pregnancy

Plate 1 Polymorphic eruption of pregnancy: urticated papules and plaques on the thigh.

Plate 2 Pemphigoid gestationis: urticated papules and plaques and blisters (reproduced with permission from Charles-Holmes R, Black MM (1990). Herpes gestationis. In: Wojnarowska F, Briggaman RA, eds. *Management of blistering disease*, pp. 93–104. Chapman and Hall, London).

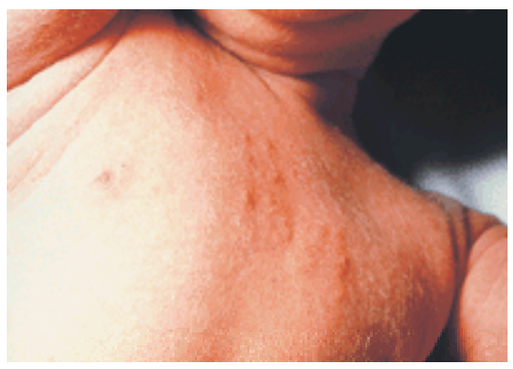

Plate 3 Pemphigoid gestationis: urticated papules in the neonate (reproduced with permission from Charles-Holmes R, Black MM (1990). Herpes gestationis. In: Wojnarowska F, Briggaman RA, eds. *Management of blistering disease*, pp. 93–104. Chapman and Hall, London).

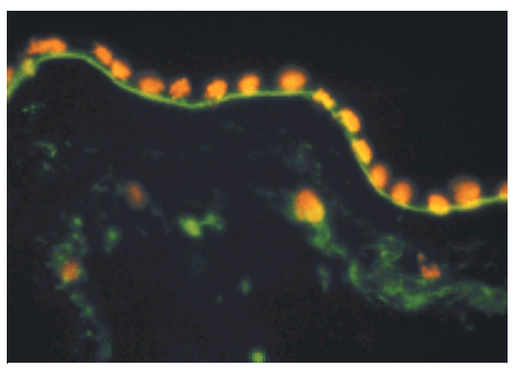

Plate 4 Pemphigoid gestationis: linear deposition of C3 at the amnion basement membrane zone as demonstrated by immunofluorescence. The nuclei are counterstained with propidium iodide. (Provided by B.S. Bhogal and M.M. Black, St John's Institute of Dermatology, St Thomas's Hospital, London.)

Plates for Section 14

Chapter 14.4 Immune disorders of the gastrointestinal tract

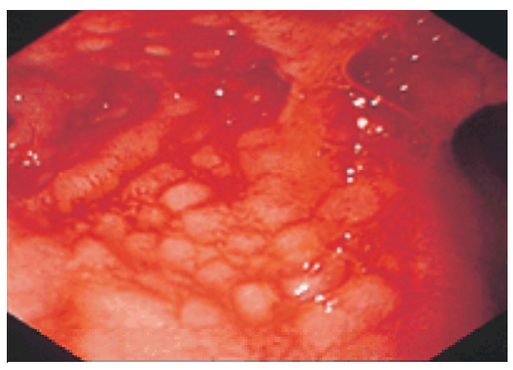

Plate 1 The appearance of nodular lymphoid hyperplasia on upper gastrointestinal endosocpy.

Chapter 14.20.1 Viral hepatitis – clinical aspects

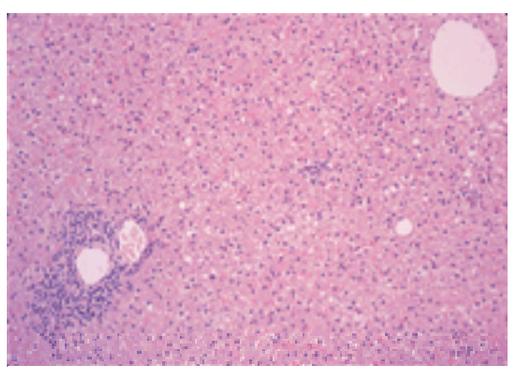

Plate 1 Serological changes during chronic hepatitis C.

Chapter 14.20.2.1 Autoimmune hepatitis

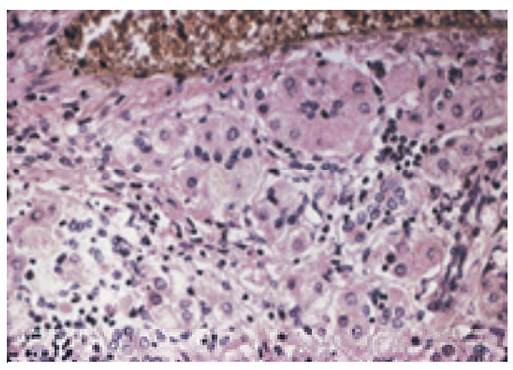

Plate 1 Haematoxylin and eosin stained liver histology showing 'rosettes' of regenerated hepatocytes, surrounded by lymphocytes that have spread into the hepatic parenchyma.

Chapter 14.21.3 Hepatocellular failure

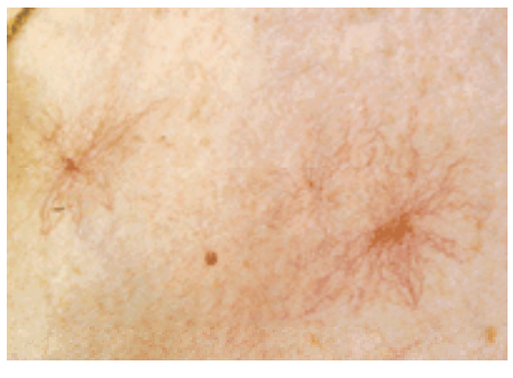

Plate 1 Spider naevi in a patient with cirrhosis.

Plate 2 Palmer erythema in a patient with cirrhosis.

Plate 3 White nails in a patient with cirrhosis.

Plate 4 Finger clubbing in a patient with cirrhosis.

Chapter 14.21.6 Hepatic granulomas

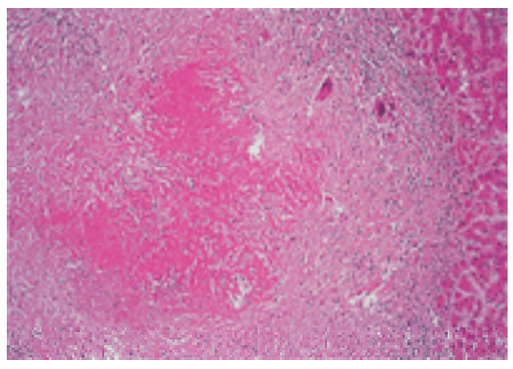

Plate 1 Liver showing a portion of a large caseating granuloma from a patient with miliary mycobacterium tuberculosis. Several Langhans' giant cells are also seen. (Haematoxylin and eosin, total magnification 25.)

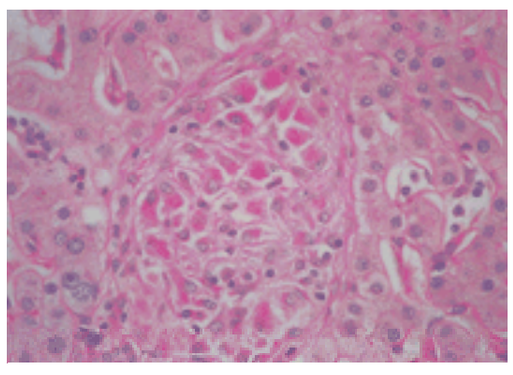

Plate 2 Liver from an HIV/AIDS patient infected with *Mycobacterium avium intracellulare*, showing a granuloma composed of epithelioid cells which contain large numbers of micro-organisms. (Diastase/periodic acid–Schiff stain, total magnification 100.)

Plates for Section 15

Chapter 15.3.3 Echocardiography

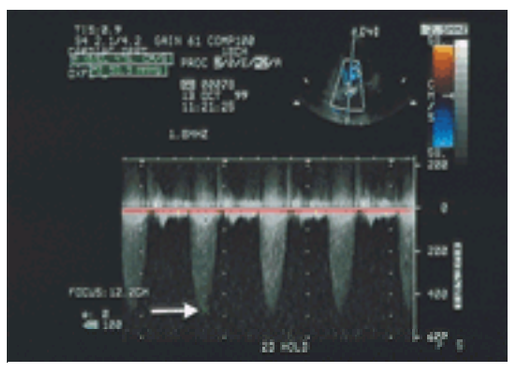

Plate 1 Apical continuous wave Doppler across the aortic valve in a patient with severe aortic stenosis. The peak velocity is greater than 4.5 m/s consistent with a peak instanteneous gradiant across the aortic valve of 90 mmHg.

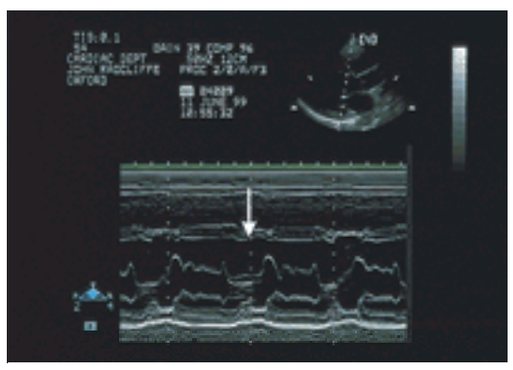

Plate 2 M-mode echocardiogram through the mitral valve in a normal patient. Opening of the leaflets during ventricular diastole and closing during systole (arrow) can be observed.

Chapter 15.8.2 The cardiomyopathies: hypertrophic, dilated, restrictive, and right ventricular

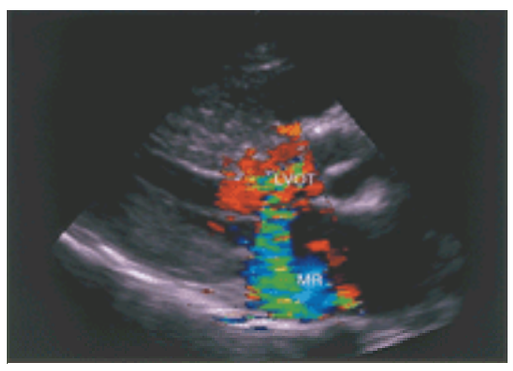

Plate 1 Colour flow Doppler image (parasternal long axis view) of the same patient as shown in Fig. 3 of Chapter 15.8.2, demonstrating left ventricular outflow tract (LVOT) turbulence (shown in red) and mitral regurgitation (MR) with a posteriorly directed jet (shown in blue/green).

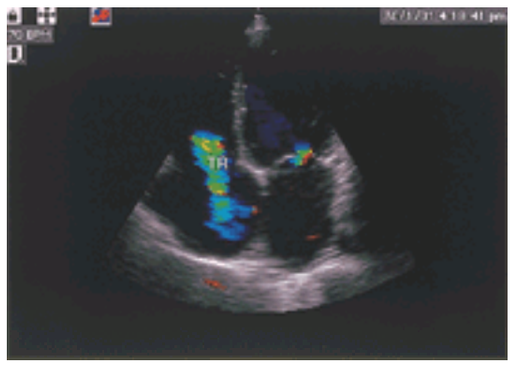

Plate 2 Colour flow Doppler image of the same patient as shown in Fig. 5 of Chapter 15.8.2 showing a regurgitant tricuspid jet (TR, shown in blue).

Chapter 15.10.2 Infective endocarditis

Plate 1 Splinter haemorrhages in a case of infective endocarditis.

Plate 2 Vasculitic rash on lower limb of a patient with infective endocarditis.

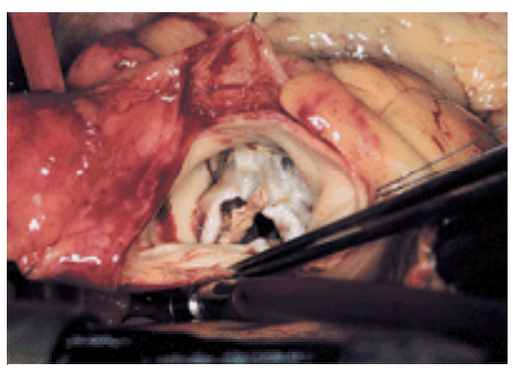

Plate 3 A large vegetation on the aortic valve of a patient with infective endocarditis as seen at the time of surgery.

Chapter 15.14.1 Thoracic aortic dissection

Plate 1 Post-mortem specimen of aortic dissection. The intimal/medial flap is pulled back with a retractor to show the false lumen parallel to the true lumen.

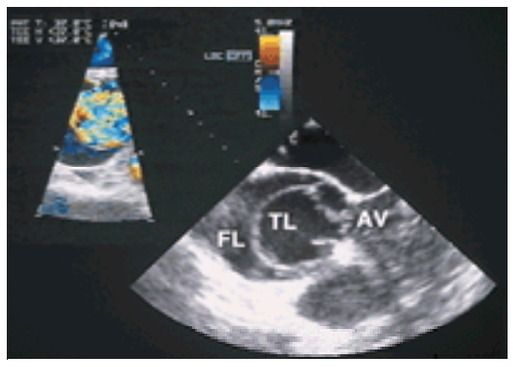

Plate 2 Transoesphageal transverse two-dimensional and colour Doppler echo images of the ascending aorta showing a dissection membrane partitioning the true (TL) and false lumen (FL). Upper left panel shows systolic flow in the true but not the false lumen.

Chapter 15.14.2 Peripheral arterial disease

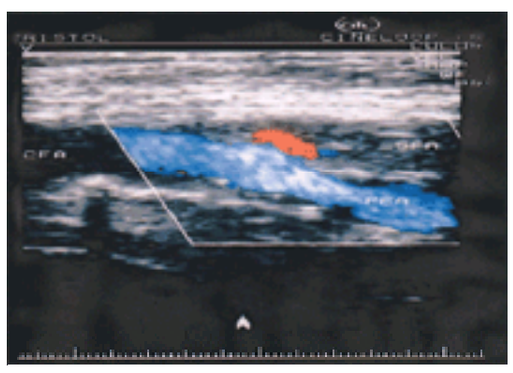

Plate 1 Occlusion of the superficial femoral artery demonstrated by colour-coded duplex ultrasonography. On the left, the common femoral artery (CFA) lies outside the colour box. In the colour box antegrade flow through the profuma femoris artery (PFA) is shown in blue. The red flash represents rebound flow against the occluded origin of the superficial femoral artery (SFA).

Chapter 15.14.3 Cholesterol embolism

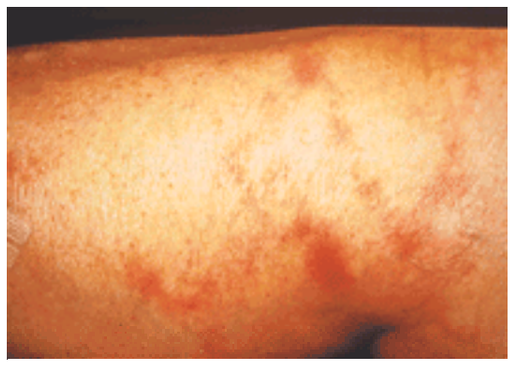

Plate 1 Livedo reticularis and vasculitic-like erythematous nodules on the leg of a patient in whom cholesterolcrystal embolization occurred after coronary angiography.

Plate 2 Purpuric spots and acral cyanosis of the toes from cholesterol embolism after aortic aneurysm repair.

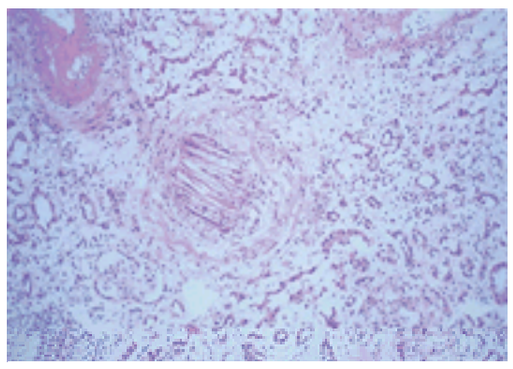

Plate 3 Renal biopsy demonstrating the characteristic needle-shaped cholesterol clefts occluding a medium-sized renal arteriole with surrounding inflammatory cell infiltration, intimal proliferation, thickening, and concentric fibrosis. There is extensive autolysis (postmortem sample).

Chapter 15.14.4 Takayasu arteritis

Plate 1 Typical coronary anastomosis of retinal vessels in Takayasu arteritis.

Chapter 15.15.2.1 Primary pulmonary hypertension

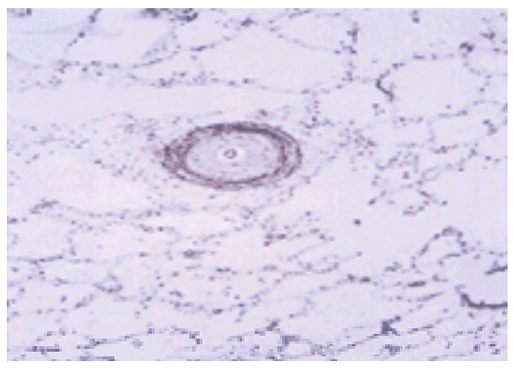

Plate 1 Intimal thickening of a pulmonary artery in pulmonary hypertension (Chazova I *et al.*, 1995. Pulmonary artery adventitial changes and venous involvement in primary pulmonary hypertension. *American Journal of Pathology* **146**, 389–97).

Chapter 15.16.3 Hypertensive emergencies and urgencies

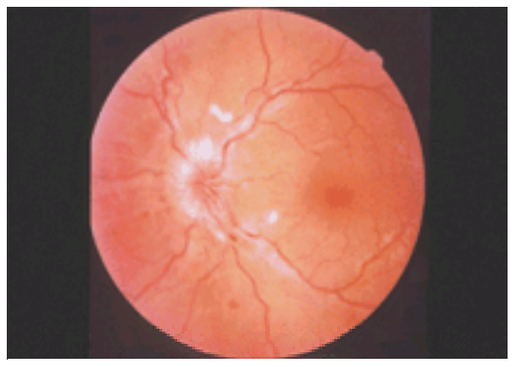

Plate 1 Ocular fundus in hypertension, showing papilloedema, exudates, and a few haemorrhages.

Plates for Section 17

Chapter 17.3.4 Diagnostic bronchoscopy, thoracoscopy, and tissue biopsy

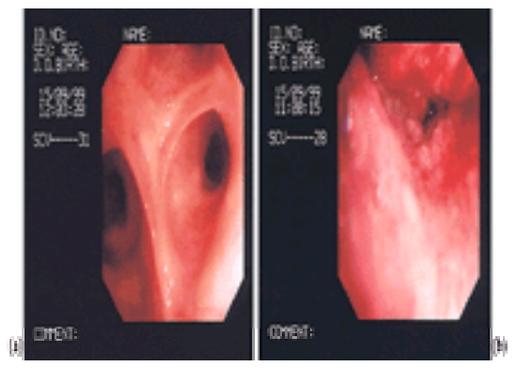

Plate 1 Appearances at bronchoscopy. The normal thin mucosa and sharp interlobar carinae of the normal left side (a) are in contrast to the irregular exophytic appearance of an advanced non-small cell tumour of the right main bronchus (b) in the same 73-year-old patient.

Chapter 17.11.2 Cryptogenic fibrosing alveolitis

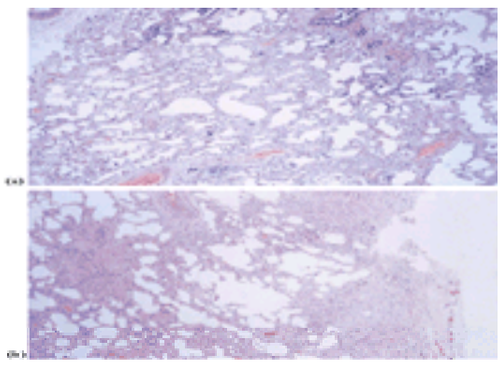

Plate 1 Histopathological appearance of cryptogenic fibrosing alveolitis and the non-specific interstitial pneumonia 'mimic'. (a) Usual interstitial pneumonia, the histopathological pattern seen in cryptogenic fibrosing alveolitis. Note the pale, fibroblast foci that are the hallmark of usual interstitial pneumonia. (b) The nonspecific interstitial pneumonia 'mimic' of cryptogenic fibrosing alveolitis. This is much less common than usual interstitial pneumonia. Note the uniformity of the pathology throughout the section.

Chapter 17.11.3 Bronchiolitis obliterans and organizing pneumonia

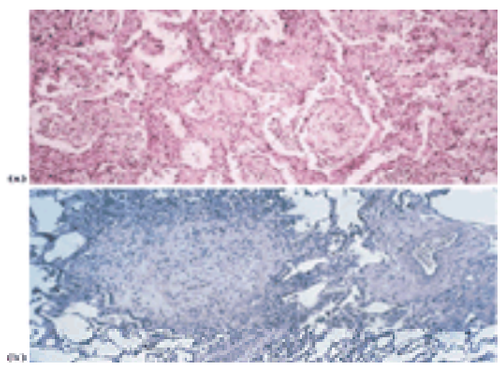

Plate 1 Histopathology. (a) Proliferative bronchiolitis. (b) Constrictive bronchiolitis. Note the loosely packed granulation tissue in (a) in contrast to the more established scarring in (b).

Plates for Section 18

Chapter 18.3 Clinical investigation (rheumatological disorders)

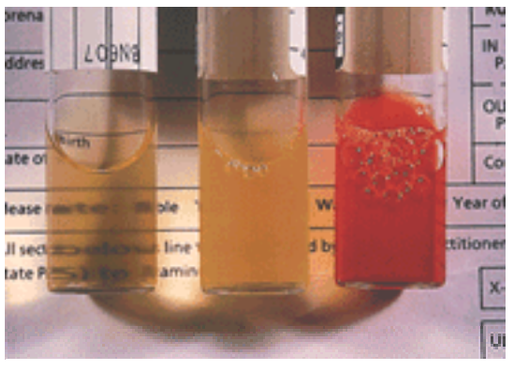

Plate 1 Different macroscopic appearances of synovial fluids: (a) on the left, clear straw-coloured fluid from an osteoarthritic knee (easy to read writing behind it); (b) less viscous, turbid (high cell count) 'inflammatory' fluid from a rheumatoid knee; and (c) uniform bloodstaining (haemarthrosis) due to acute pseudogout.

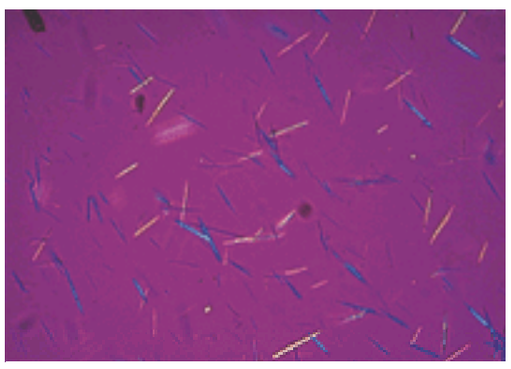

Plate 2 Monosodium urate crystals viewed by compensated polarized light microscopy (×400) showing bright birefringence (negative sign) and needle-shaped morphology.

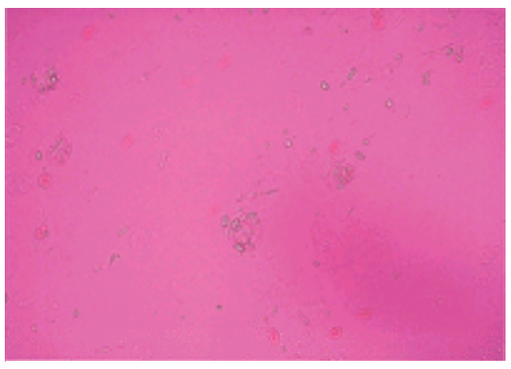

Plate 3 Calcium pyrophosphate crystals viewed by polarized light microscopy (×400) showing weak birefringence (positive sign), scant numbers, and a predominantly

rhomboid morphology. These are clearly more difficult to detect than urate crystals.

Chapter 18.5 Rheumatoid arthritis

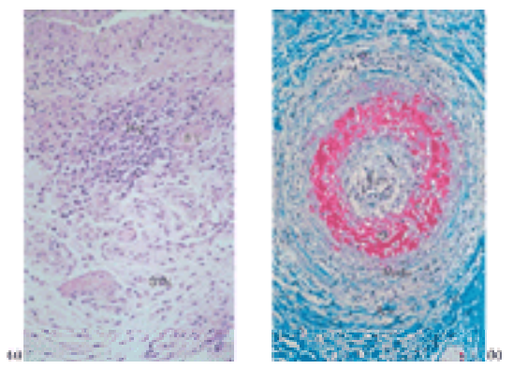

Plate 1 Histology of rheumatoid arthritis. (a) Rheumatoid arthritis synovitis. L.L., lining layer; P.V., perivascular aggregate of lymphocytes and macrophages; B.V., blood vessel; SYN, synoviocytes; (haematoxylin and eosin staining). (b) Small vessel arteritis. Lum., lumen; Int., Intima; P.V., perivascular inflammation; Adv., adventitial tissue. Arterial wall shows a thrombosed vessel with intimal hyperplasia, destruction of internal elastic lamina, and mononuclear cell infiltration of media and perivascular tissue (methylene blue and safranine staining).

Plate 2 The hands of a person suffering from rheumatoid arthritis. Features to note include symmetrical soft tissue swelling of the second and third metacarpophalageal joints, early swan-neck deformity of the left ring finger, ulnar deviation at the metacarpophalageal joints, and wasting of the small muscles of the hand. In addition, several small rheumatoid nodules are present.

Chapter 18.6 Spondyloarthritides and related arthritides

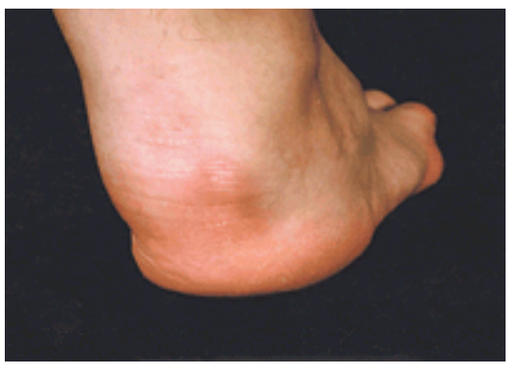

Plate 1 Enthesitis at the insertion of the Achilles tendon in a patient with reactive arthritis.

Plate 2 Dactylitis of the third finger of the right hand in a patient with undifferentiated spondyloarthropathy.

Plate 3 30-year-old man with rapidly progressive ankylosing spondylitis (disease of 5 years duration).

Plate 4 Severe psoriatic arthritis (arthritis mutilans).

Plate 5 Arthritis/hyperostosis of the left sternoclavicular joint in a 52-year-old man with SAPHO syndrome.

Chapter 18.10.2 Systemic lupus erythematosus and related disorders

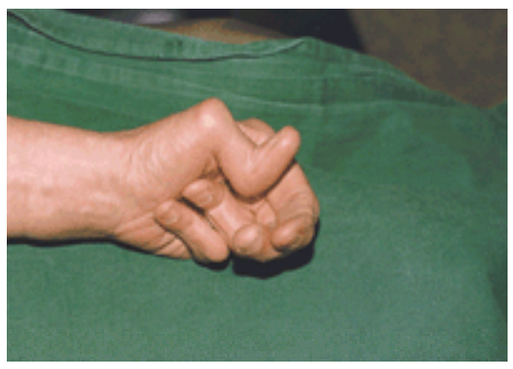

Plate 1 Deforming Jaccoud's arthropathy.

Plate 2 Malar 'butterfly' rash.

Plate 3 Severe scarring alopecia.

Plate 4 Livedo reticularis.

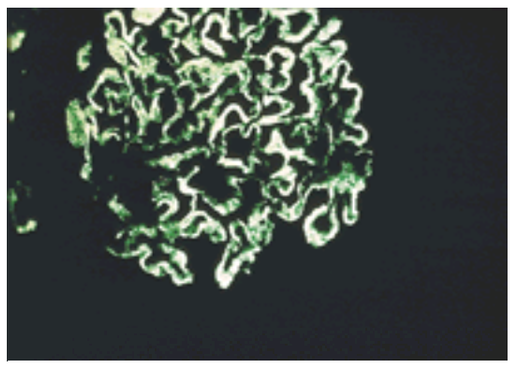

Plate 5 Immuno fluorescence microscopy showing deposition of IgG in the glomerulus of a patient with lupus nephritis.

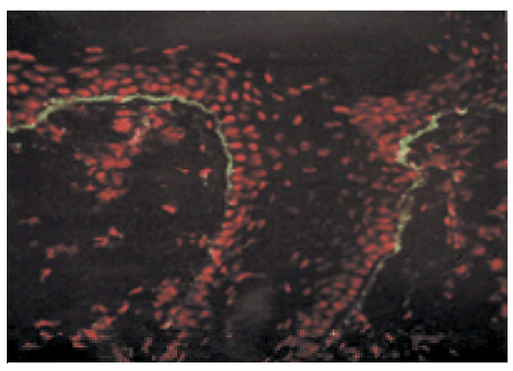

Plate 6 Immunofluorescence microscopy showing deposition of IgG at the dermoepidermal junction in the skin of a patient with systemic lupus erythematosus (sometimes called the lupus band test).

Chapter 18.10.4 Polymyalgia rheumatica and giant cell arteritis

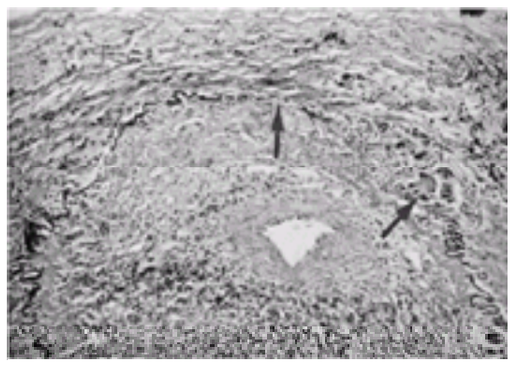

Plate 1 Photomicrograph of a temporal artery biopsy showing giant cells, mononuclear infiltrate, and disruption of the internal elastic lamina.

Chapter 18.10.7 Polymyositis and dermatomyositis

Plate 1 Gottron's sign. Roughened, violaceous papules over the dorsal surfaces of several metacarpophalangeal and proximal interphalangeal joints. Note also the erythema at the bases of the fingernail, caused by capillary loop dilatation.

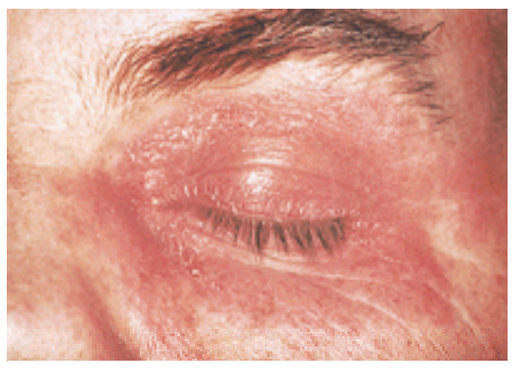

Plate 2 Heliotrope rash. An erythematous (often lilac-coloured) rash over the eyelids in a patient with dermatomyositis (reproduced from Mousari HC, Wigley FM (2000). *Journal of Rheumatology* **27**, 1542-5 with permission).

Chapter 18.10.8 Kawasaki syndrome

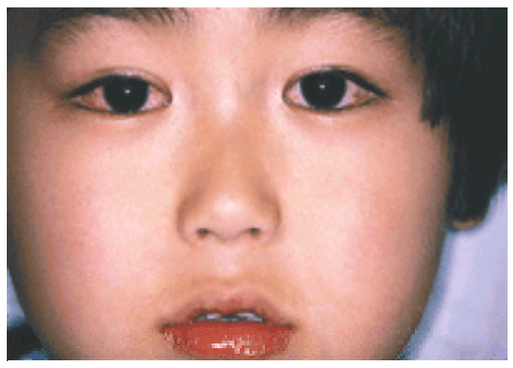

Plate 1 Typical appearance of a patient with Kawasaki disease; note the red eyes and red lips (picture of a 5-year-old boy, taken on the fourth day of illness).

Chapter 18.11 Miscellaneous conditions presenting to the rheumatologist

Plate 1 Pyoderma gangrenosum.

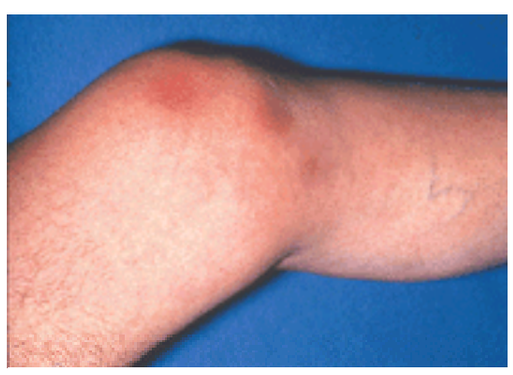

Plate 2 Erythema nodosum.

Plates for Section 19

Chapter 19.2 Inherited defects of connective tissue: Ehlers Danlos syndrome, pseudoxanthoma elasticum, and Marfan syndrome

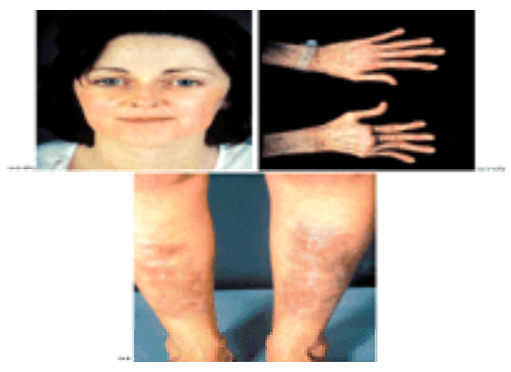

Plate 1 See *caption overleaf*.

EDS type IV (vascular type). (a) Acrogeria–a specific clinical feature of EDS IV. Note the large eyes and thin (b) nose (Madonna facies) with periorial wrinkling. (c) Premature wrinkling of the skin on the dorsum of the hands; note also the joint contractures (d) superficially resembling rheumatoid arthritis. (e) Pretibial bruising and

haemosiderosis.

Plate 2 Skin lesions in pseudoxanthoma elasticum (PXE). (a) Typical flexural skin lesions of PXE of the lateral neck. (b) Widespread cutis laxa in PXE. (c) Mucosal infiltration of the lower lip in PXE. (d) Elastic van Giessen stain of skin section showing mid-dermal elastic fragmentation and degeneration.

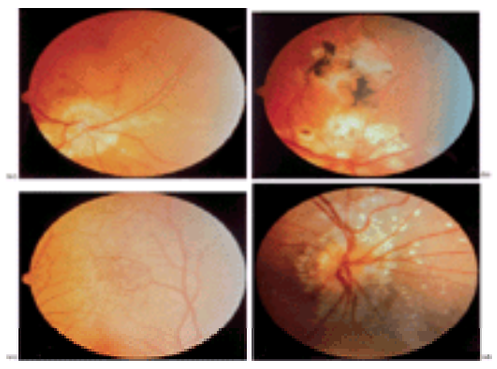

Plate 3 See *caption overrleaf*.

Retinal changes in PXE. (a) Angioid streaks caused by fracture of the retroretinal Bruch's membrane—an early feature. (b) Macular haemorrhage with consequential choroideretinitis. (c) Specked *peau d'orange* mottling. (d) Salmon spotting and drusen.

Plates for Section 20

Chapter 20.3.2 Clinical investigation of renal disease

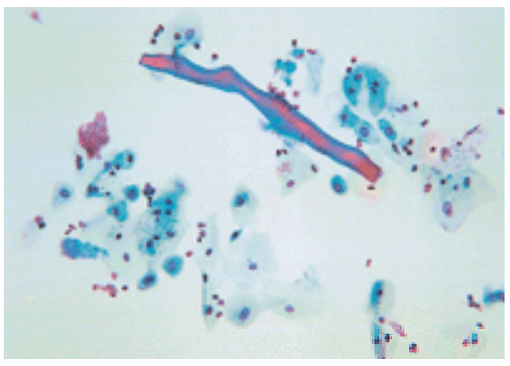

Plate 1 Papanicolaou-stained urine showing a hyaline cast with both normal transitional and squamous cells (blue) and renal tubular cells (pink). (By courtesy of Dr Deery.)

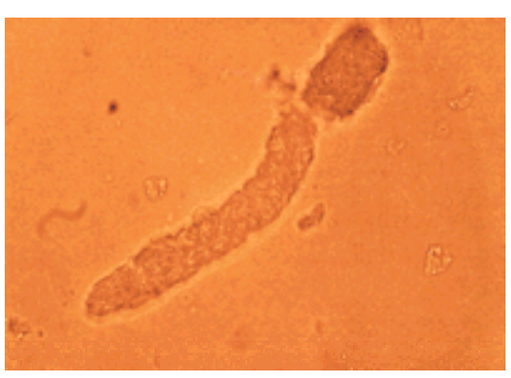

Plate 2 Unstained urine specimen showing a granular cast.

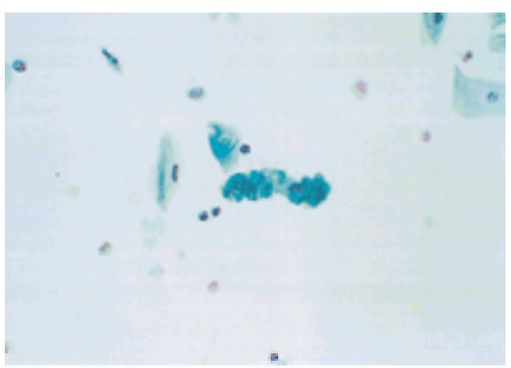

Plate 3 Papanicolaou-stained urine deposit showing a red cell cast.

Chapter 20.7.2 IgA nephropathy and Henoch-Schönlein purpura

Plate 1 Characteristic purpuric rash affecting the lower limbs in Henoch Schönlein purpura.

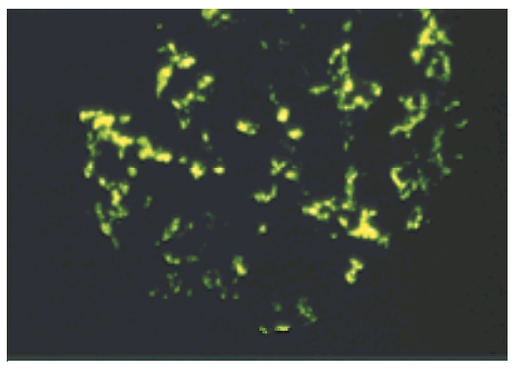

Plate 2 Immunofluorescence of a glomerulus in IgA nephropathy. Bright fluorescent staining is seen within the mesangium with labelled antibodies to IgA. In some cases similar staining is also seen on along capillary walls. A similar distribution of staining for C3 is commonly present (anti-human IgA, × 375).

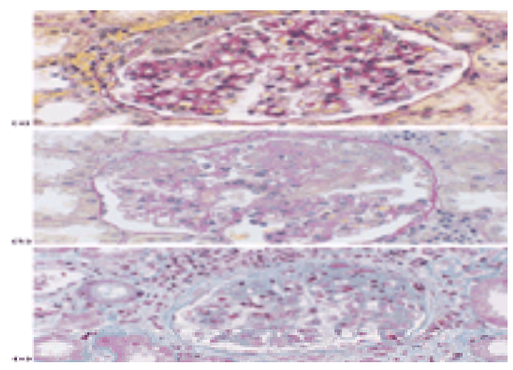

Plate 3 See *caption overleaf*.

Light microscopic appearances of IgA nephropathy. (a) Glomerulus showing global increase in mesangial matrix and cellularity. (Alcian Blue/PAS stain × 375). (b) Glomerulus showing segmental increase in mesangial matrix and hypercellularity with fibrinoid necrosis (solid arrow) and synechia formation (open arrow) between the segmental lesion and parietal epithelium of Bowman's capsule (Alcian Blue/PAS stain, × 375). (c) Glomerulus showing segmental increase in mesangial matrix, segmental sclerosis with synechia formation (open arrows) to overlying Bowman's capsule (Masson Trichrome stain, × 375).

Chapter 20.7.4 Minimal change nephropathy, focal segmental glomerulosclerosis, and membranous nephropathy

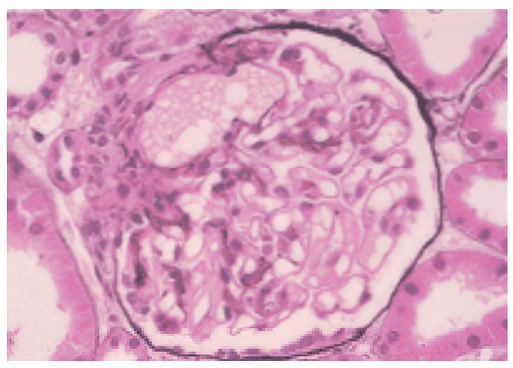

Plate 1 Minimal-change nephropathy. The glomerulus looks normal on light microscopy. Periodic acid-methenamine silver staining (64 ×). (By courtesy of Dr A.J. Howie.)

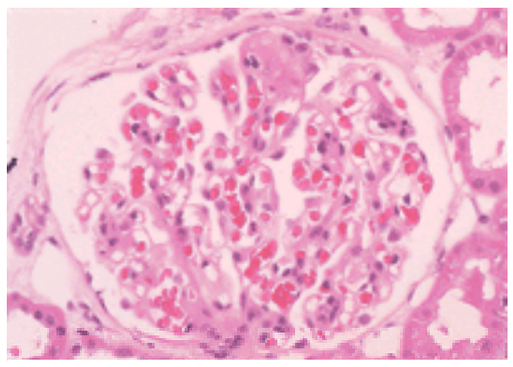

Plate 2 Classical segmental sclerosing glomerulonephritis at an early stage. The glomerulus shows an erratic increase in mesangium with a segmental area of foamy cells and sclerosis opposite the vascular pole, next to the tubular origin. Haematoxylin and eosin staining (50 ×). (By courtesy of Dr A.J. Howie.)

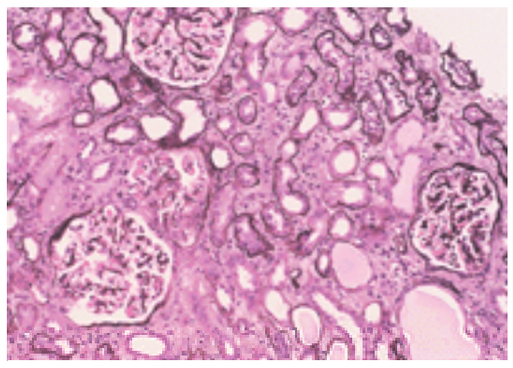

Plate 3 Classical segmental sclerosing glomerulonephritis at a late stage. Four glomeruli show an erratic increase in mesangium and segmental lesions at various sites. Periodic acid-methenamine silver staining (× 64). (By courtesy of Dr A.J. Howie.)

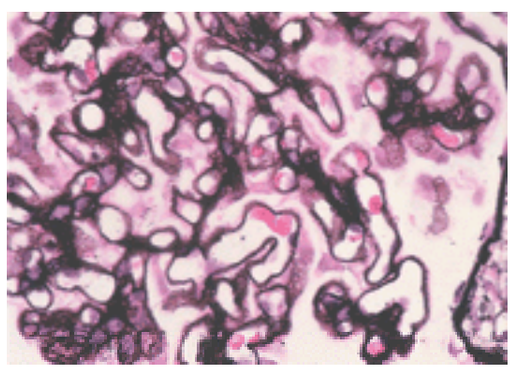

Plate 4 Membranous nephropathy. There are regular short spikes on the outside of glomerular capillary loops. Periodic acid-methenamine silver staining (80 ×).

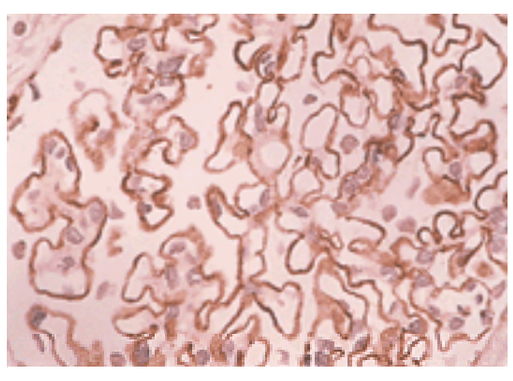

Plate 5 Membranous nephropathy. Immunoperoxidase staining shows uniform granular deposits of IgG on the epithelial side of glomerular basement membranes (80 ×). (By courtesy of Dr A.J. Howie.)

Chapter 20.7.5 Proliferative glomerulonephritis

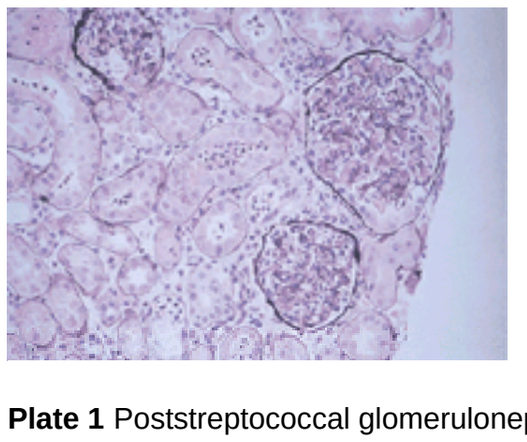

Plate 1 Poststreptococcal glomerulonephritis.

Chapter 20.7.6 Mesangiocapillary glomerulonephritis

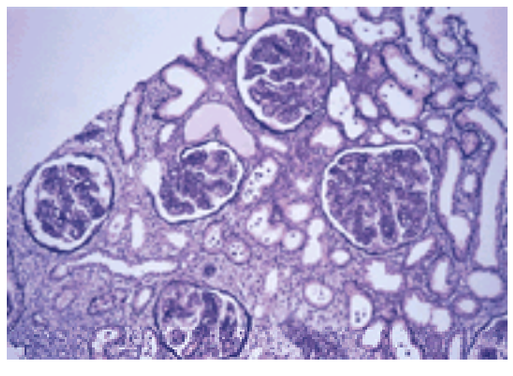

Plate 1 Mesangiocapillary glomerulonephritis. Note characteristic appearance of expanded glomerulus.

Chapter 20.7.7 Antiglomerular basement membrane disease

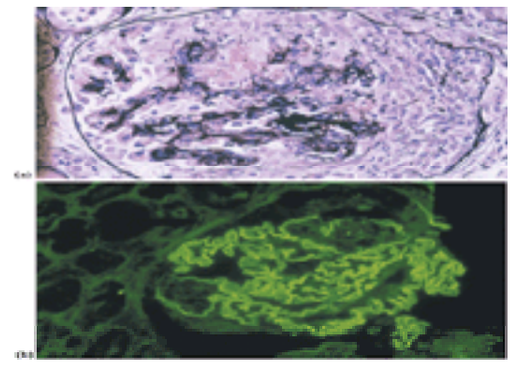

Plate 1 Renal biopsy from a patient with Goodpasture's disease. (a) Light microscopy showing a single glomerulus with cellular crescent and focal necrosis (silver stain). (b) Immunoflourescence of a single glomerulus with linear deposition of IgG along the GBM. (Figure by courtesy of Dr H.T. Cook.)

Chapter 20.7.8 Infection-associated nephropathies

Plate 1 Cutaneous vasculitis in a patient with *Staphylococcus aureus* endocarditis.

Chapter 20.9.1 Acute interstitial nephritis

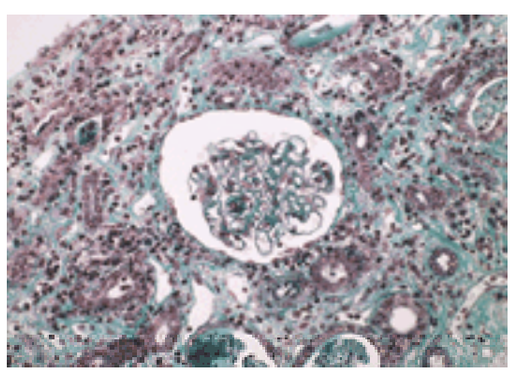

Plate 1 Acute interstitial nephritis. The renal interstitium is invaded by numerous mononuclear cells. The glomerulus is normal. Mason's trichrome 250×.

Chapter 20.10.3 Vasculitis and the kidney

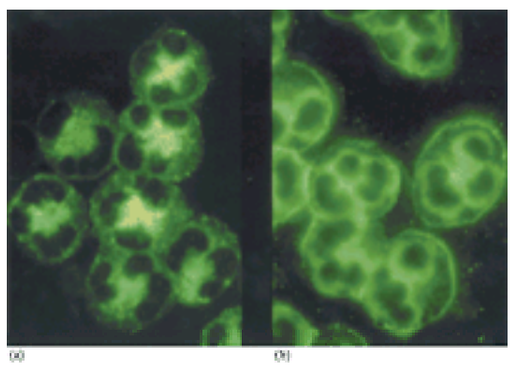

Plate 1 Indirect immunofluorescence assay for ANCA. (a) Typical staining of cytoplasmic ANCA that is usually due to antibodies to proteinase 3. (b) Typical staining pattern of perinuclear ANCA most often due to antimyeloperoxidase antibodies.

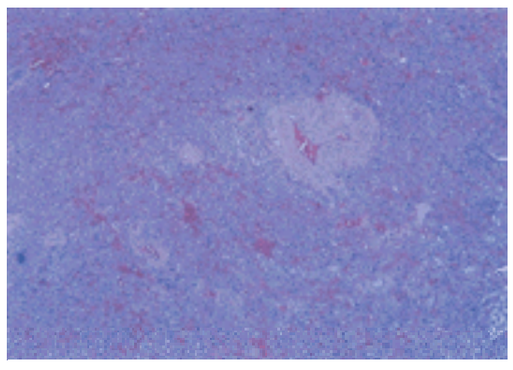

Plate 2 Morphological appearances of pulmonary granulomas in a specimen obtained by video-endoscopic lung biopsy from a patient with Wegener's granulomatosis.

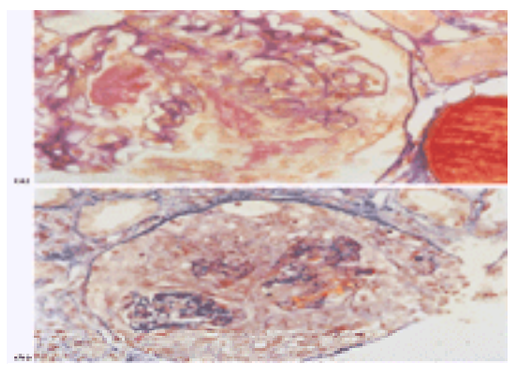

Plate 3 Morphological appearances on a renal biopsy from a patient with pauciimmune focal necrotizing glomerulonephritis. (a) An early lesion with necrosis of one glomerular segment. (b) A much more florid lesion with the whole glomerular tuft surrounded by a crescent.

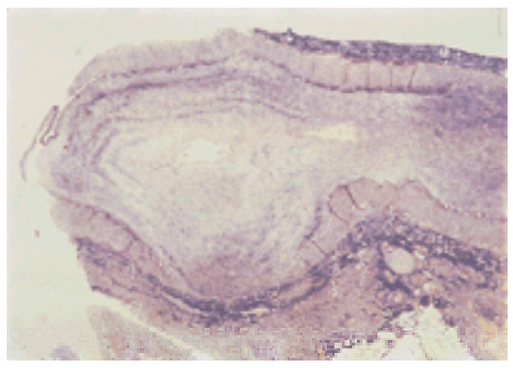

Plate 4 Morphological appearances of a renal artery from a patient with polyarteritis nodosa. The elastic lamina has been destroyed and the artery has become aneurysmal.

Chapter 20.10.4 The kidney in rheumatological disorders

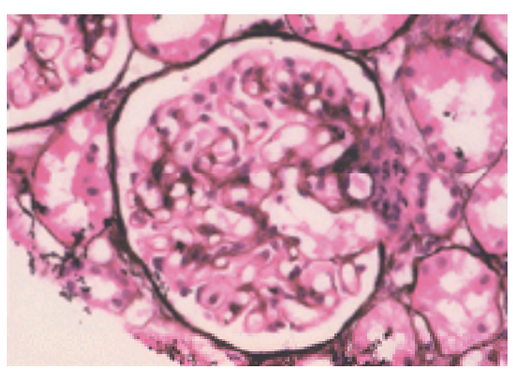

Plate 1 Lupus nephritis. The glomerulus has mild mesangial increase (WHO class II). Periodic acid-methenamine silver staining (×50). (By courtesy of Dr A.J. Howie.)

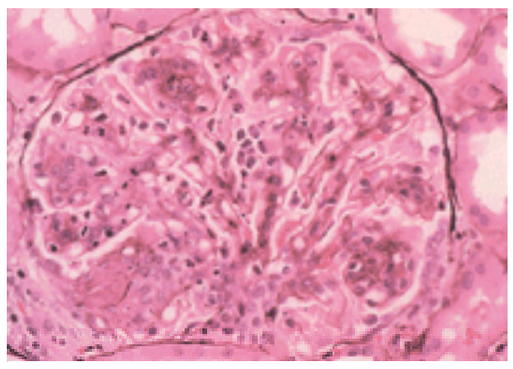

Plate 2 Lupus nephritis. The glomerulus has marked mesangial increase with wire loops, a few doubled basement membranes and segmental lesions (WHO class IV). Periodic acid-methenamine silver staining (×40). (By courtesy of Dr A.J. Howie.)

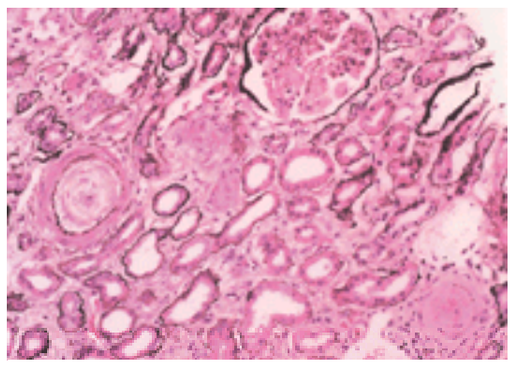

Plate 3 Scleroderma kidney. A small artery has concentric mucoid intimal thickening, an arteriole has thrombosis and fibrinoid necrosis, and tubules and a glomerulus have ischaemic damage. Periodic acid-methenamine silver staining (×25). (By courtesy of Dr A.J. Howie.)

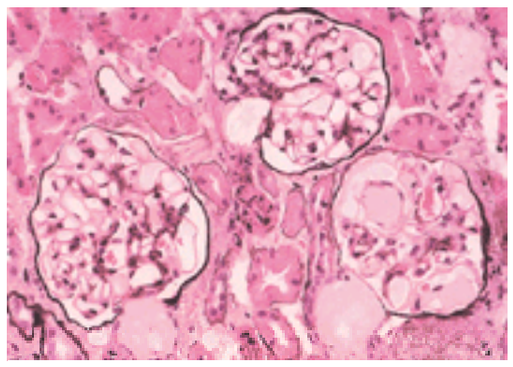

Plate 4 Amyloidosis in rheumatoid arthritis. Arterioles and glomeruli contain acellular masses of amyloid. Periodic acid-methenamine silver staining (×40). (By courtesy of Dr A.J. Howie.)

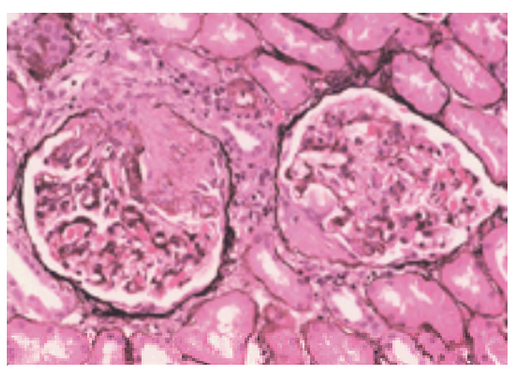

Plate 5 Vasculitic glomerulonephritis in rheumatoid arthritis. Two glomeruli have sharply defined segmental lesions where there has been disruption of the tuft and partial obliteration of Bowman's space. Periodic acid-methenamine silver staining (×32). (By courtesy of Dr A.J. Howie.)

Chapter 20.10.5 Renal involvement in plasma cell dyscrasias, amyloid and fibrillary glomerulopathies, lymphomas, and leukaemias

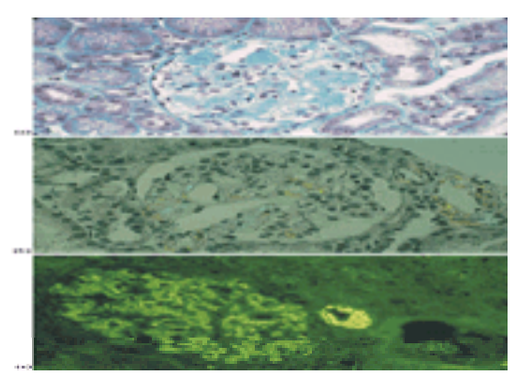

Plate 1 Light-chain amyloidosis. (a) Amyloid deposits in a renal glomerulus (Masson's trichrome stain, ×312). (b) Congo red stain. Apple-green/yellow dichroism under polarized light (×312). (c) Immunofluorescence with anti-lantibody. Note glomerular and arteriolar deposits (×312). (From Béatrice Mougenot's personal collection.)

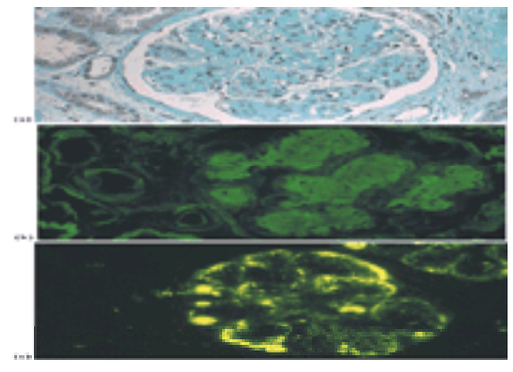

Plate 2 See *caption overleaf*

Cryoglobulinaemic glomerulonephritis. (a) The glomerulus shows a marked endocapillary hypercellularity with massive infiltration of mononuclear leucocytes (Masson's trichrome stain, ×500). (b) Frequent double-contour aspect, and intraluminal thrombi (periodic acid-Schiff stain, ×312). (c) Thrombi and segments of glomerular basement membrane are brightly stained with anti-IgM antibody (immunofluorescence, ×312). (From Béatrice Mougenot's personal collection.)

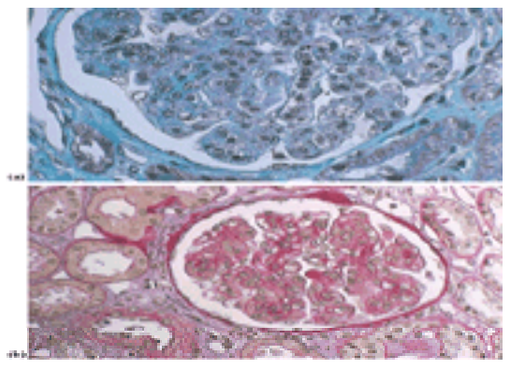

Plate 3 Monoclonal immunoglobulin deposition disease. (a) Typical nodular glomerulosclerosis. Note the membrane-like material in the centre of the nodules and nuclei at the periphery. Some glomerular capillaries show double contours. Note also thickening of the basement membrane of atrophic tubules (Masson's trichrome stain, ×312). (b) Bright staining of tubular basement membranes and mesangial nodules and, to a lesser extent, of glomerular basement membrane with anti-kantibody in a case of klight-chain deposition disease (immunofluorescence, ×312).

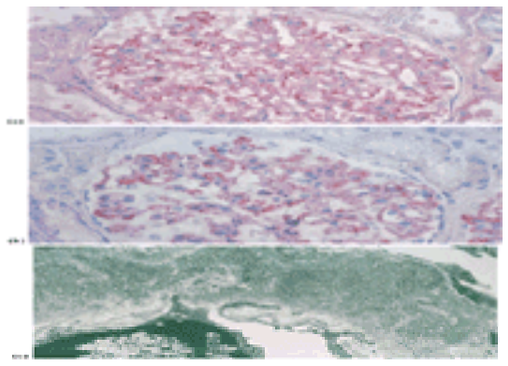

Plate 4 Immunotactoid glomerulopathy in a patient with chronic lymphocytic leukaemia. A typical membranous glomerulonephritis showing exclusive staining of the deposits with anti-g(a) and anti-k(b) antibodies (immunohistochemistry, alkaline phosphatase, × 312). (c) Electron micrograph of glomerular basement membrane, showing the microtubular structure of the subepithelial deposits (uranyl acetate and lead citrate, ×12 000). (From Béatrice Mougenot's personal collection.)

Chapter 20.10.6 Haemolytic uraemic syndrome

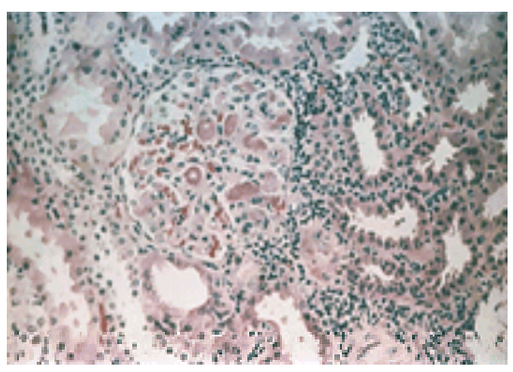

Plate 1 Typical changes of glomerular thrombotic microangiopathy in a patient with HUS (figure kindly provided by Dr Marie O'Donnell).

Plates for Section 21

Chapter 21.5 Infections and other medical problems in homosexual men

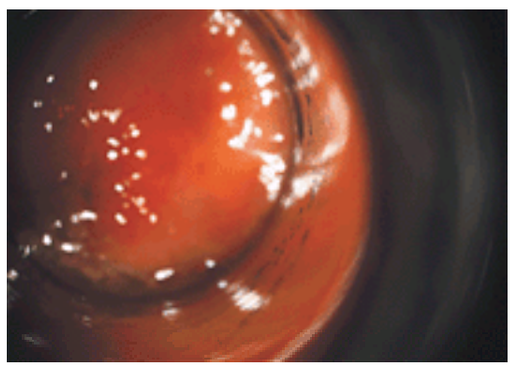

Plate 1 Gonococcal proctitis.

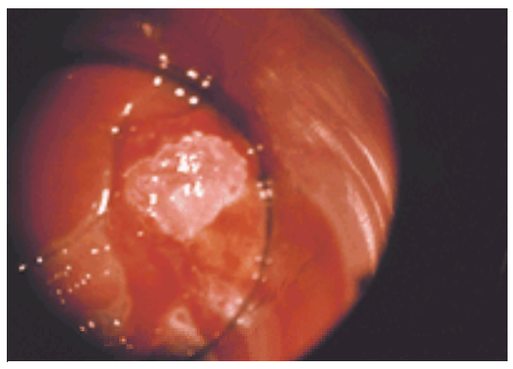

Plate 2 Condylomata acuminata of anal canal.

Chapter 22.3.4 Acute myeloblastic leukaemia

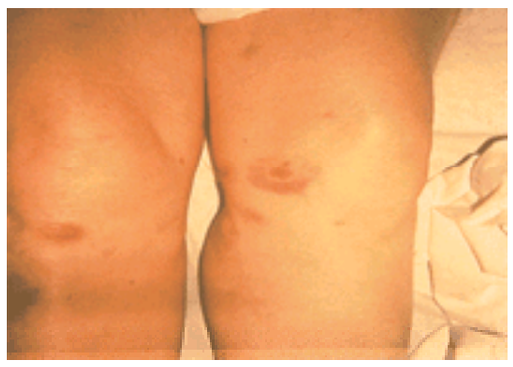

Plate 1 Target purpura. Classic target appearance of purpura formed by infarction of an arteriole by a dividing cluster of leukaemic myeloblasts. Typically, a deep, firm nodule can be felt in the pale centre of the lesion.

Chapter 22.3.5 Chronic lymphocytic leukaemia and other leukaemias of mature B and T cells

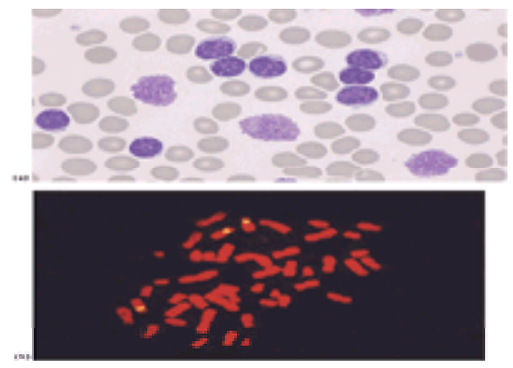

Plate 1 (a) Peripheral blood film from a case of chronic lymphocytic leukaemia showing small lymphocytes and smear cells. (b) Lymphocyte metaphase demonstrating trisomy 12 by *in situ* hybridization with a centromeric probe shown as single fluorescent dots in three chromosomes no. 12.

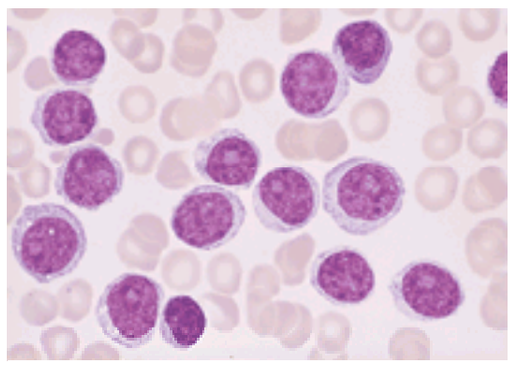

Plate 2 Peripheral blood film from a case of B-prolymphocytic leukaemia with characteristic nucleolated prolymphocytes.

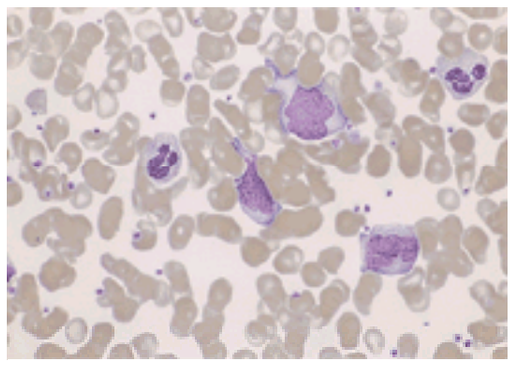

Plate 3 Circulating lymphocytes from a case of mantle-cell lymphoma.

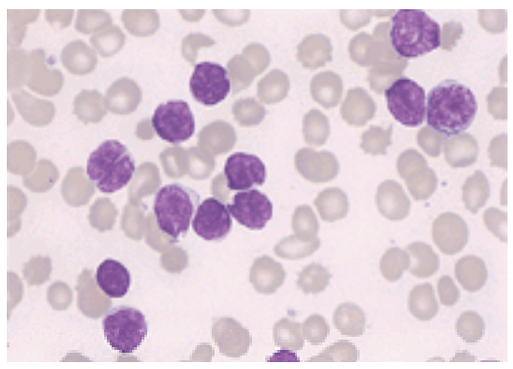

Plate 4 Peripheral blood cells from a case of folicular lymphoma presenting with leukaemia and a high leucocyte count.

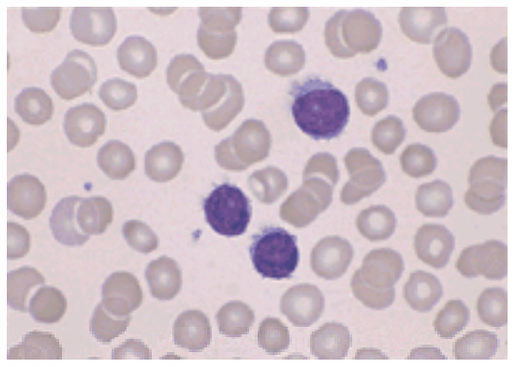

Plate 5 Peripheral blood lymphocytes with short villous projections from a case of splenic lymphoma with villous lymphocytes.

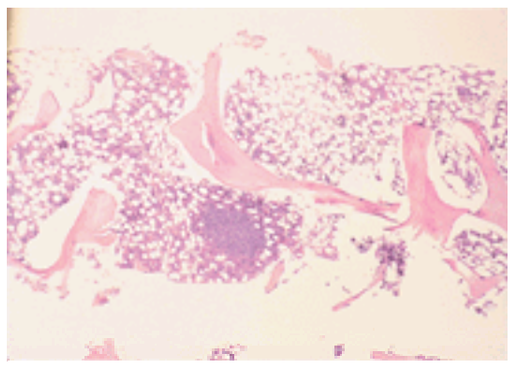

Plate 6 Nodular lymphocytic infiltration pattern in a bone marrow section from a case of mantle-cell lymphoma.

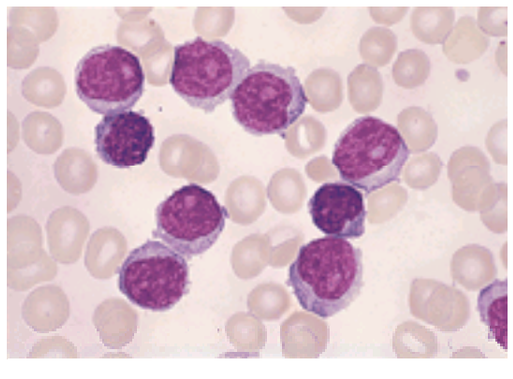

Plate 7 Peripheral blood from a case of T-cell prolymphocytic leukaemia.

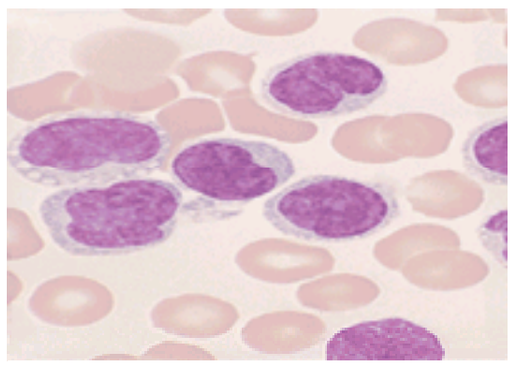

Plate 8 Circulating convoluted T cells from a Caribbean-born patient with adult T-cell leukaemia/lymphoma.

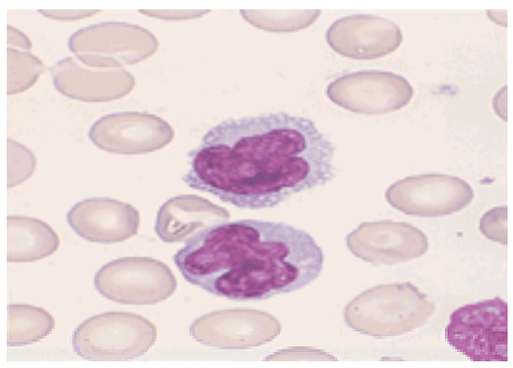

Plate 9 Cerebriform cells from a case of Sezary syndrome evolving with erythroderma and a high lymphocyte count.

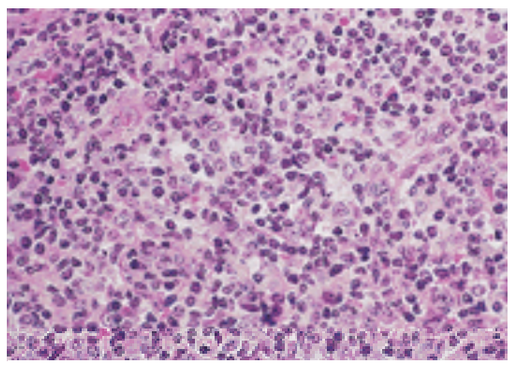

Plate 10 Lymph node section from a case of adult T-cell leukaemia/lymphoma showing diffuse infiltration with pleomorphic small, medium, and large cells.

Chapter 22.3.6 Chronic myeloid leukaemia

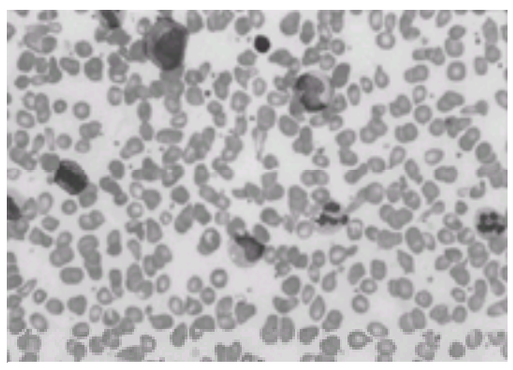

Plate 1 Peripheral blood film from a patient with CML in chronic phase. (Photograph kindly provided by Professor Barbara Bain, Imperial College London.)

Chapter 22.4.1 Leucocytes in health and disease

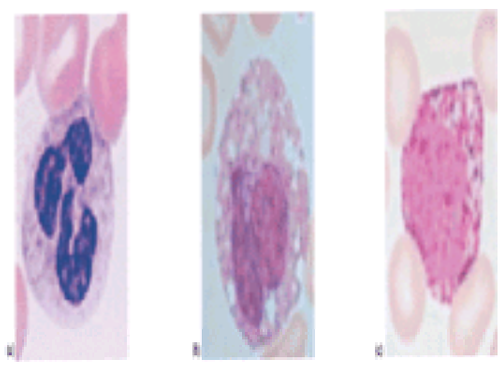

Plate 1 Peripheral blood granulocytes. (a) Polymorphonuclear leucocyte (neutrophil). (b) Eosinophil. (c) Basophil.

Chapter 22.4.7 Histiocytoses

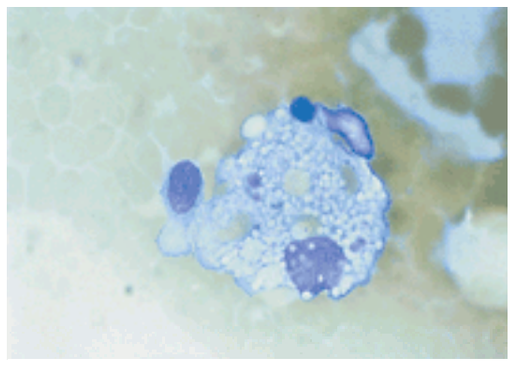

Plate 1 Macrophage exhibiting haemophagocytosis in the bone marrow of a child with haemophagocytic lumphohistiocytosis.

Chapter 22.5.6 Megaloblastic anaemia and miscellaneous deficiency anaemias

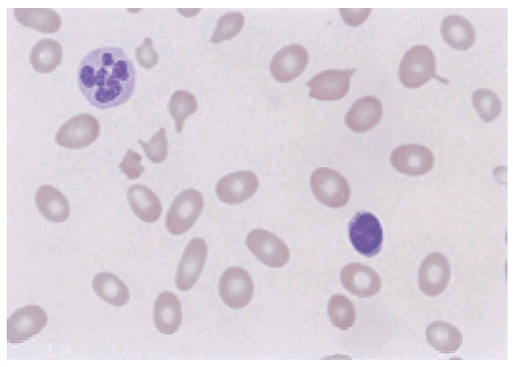

Plate 1 Megaloblastic anaemia. Hb 4.0 g/dl, MCV 120 fl. Hypersegmented neutrophil, oval macrocytes, and a small lymphocyte to show size of macrocytes. The fragmentation of advanced megaloblastosis is present. Thrombocytopenia is marked.

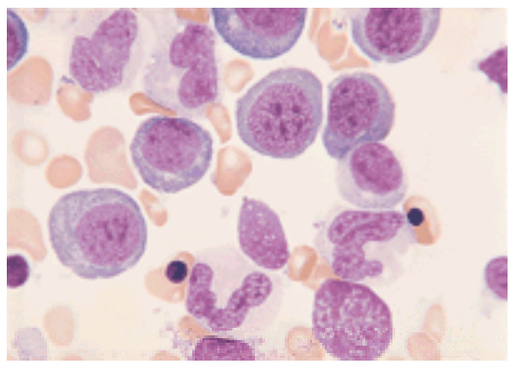

Plate 2 Megaloblastic anaemia. Bone marrow aspirate showing mainly intermediate megaloblasts and four giant metamyelocytes.

Chapter 22.6.2 Evaluation of the patient with a bleeding diathesis

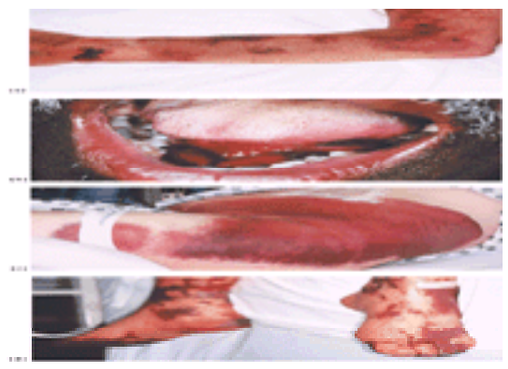

Plate 1 See *caption overleaf*.

Purpura. (a) Confluent ecchymoses of varying size and age on the upper arm in an individual with an acquired factor VIII inhibitor. (b) Spontaneous sublingual haematoma in an individual with severe haemophilia A. (c) Blunt trauma-induced left flank and hip ecchymosis and haemotoma in an individual with severe haemophilia A. (d) Gangrenous ecchymoses in an individual with diffuse intravascular coagulation.

Chapter 22.7 The blood in systemic disease

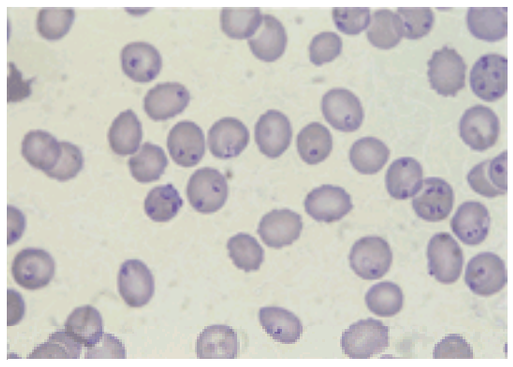

Plate 1 Malaria. Blood film showing fatal *Plasmodium falciparum* infection in a Gambian child.

Plates for Section 23

Chapter 23.1 Diseases of the skin

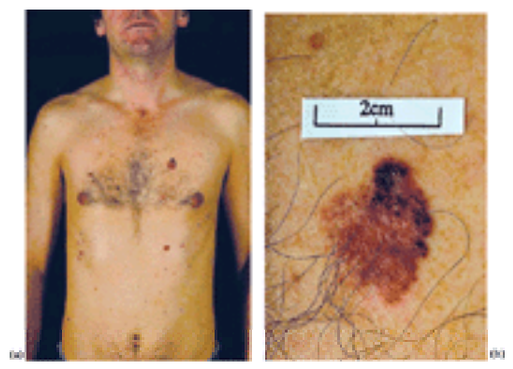

Plate 1 (a) In a patient with multiple atypical naevi one may stand out as different from the others and can be seen to be a melanoma. (b) It has an irregular outline and contains numerous different shades of brown pigmentation.

Plate 2 See *caption next page*.

(a) Most primary melanomas will have some pigmentation, even so-called amelanotic melanoma. (b) Spitz naevi were formerly called juvenile melanoma because of their histological resemblance to melanoma, but their biological behaviour is benign.

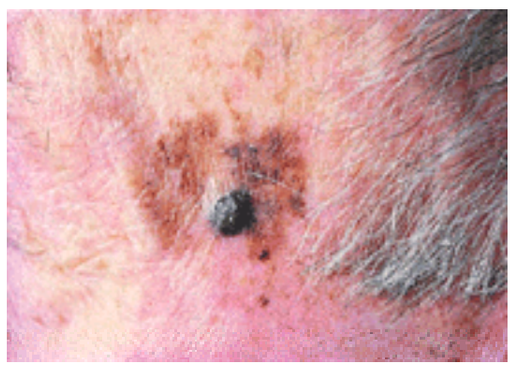

Plate 3 Nodular melanoma arising in a macular lentigo maligna (lentigo maligna melanoma).

Plate 4 Regression in a melanoma making histological assessment of prognosis impossible.

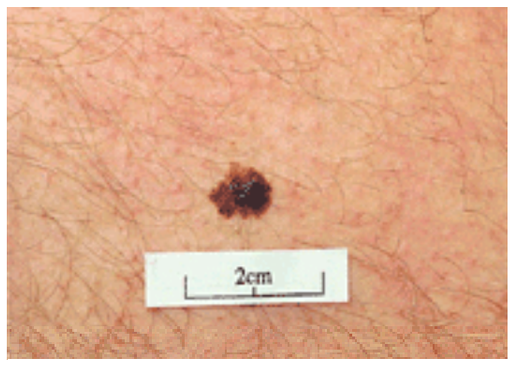

Plate 5 Melanoma most often arises *de novo* on normal skin and grows radially as well as vertically. Early detection requires identification of atypical morphology of smaller lesions.

Plate 6 Acral lentigenous melanoma can be difficult to distinguish from benign junctional naevi on the palms and soles. (a)

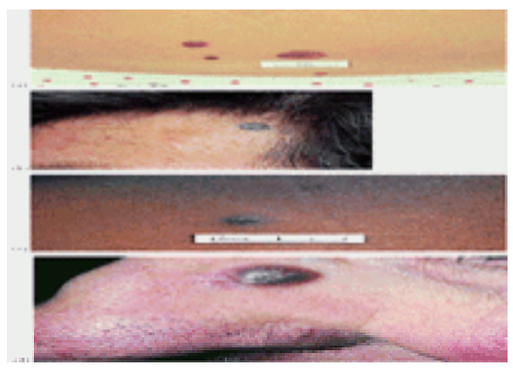

Plate 7 See *caption overleaf*.

Lesions commonly confused with melanoma include (a) naevus *en cocarde*, which are central compound naevi with a surrounding macular junctional component, giving the appearance of a fried egg. Blue naevi (b) are often deeply pigmented, but the pigmentation is uniform and a blue tinge is discernible. Dermatofibromas (c) are sometimes easier to diagnose on palpation as they are hard and tethered to the skin. They may feel like a split pea. Pigmented basal cell epitheliomas (d) often

have a rolled edge; however, sometimes biopsy provides this unexpected diagnosis. (a) (b) (c)

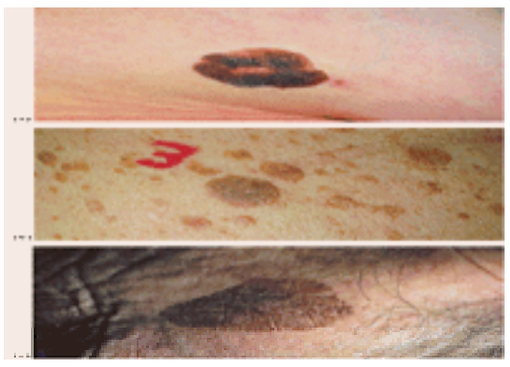

Plate 8 Seborrhoeic warts are often numerous and come in a variety of shapes and sizes. They may be deeply pigmented and elevated (a) or pale (b). They may also be macular (c). Characteristically they have a waxy surface and a 'stuck on' appearance.

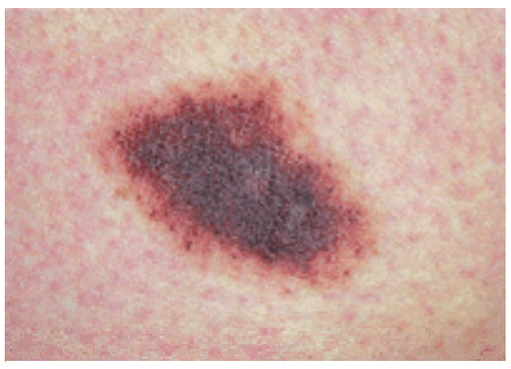

Plate 9 Congenital naevi are often larger than acquired naevi, but are usually evenly pigmented. They have a greater risk of malignant change.

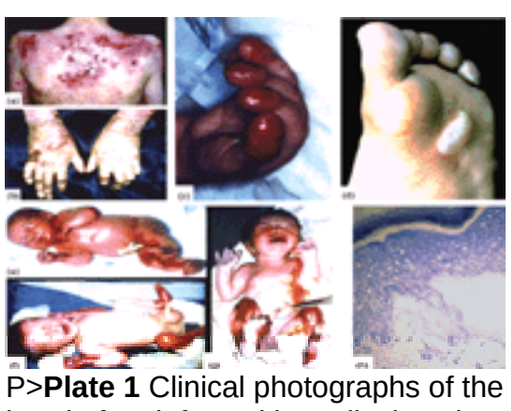
Chapter 23.2 Molecular basis of inherited skin disease



P><**Plate 1** Clinical photographs of the different forms of epidermolysis bullosa. (a) and (b) a patient with Hallopean–Siemans dystrophic epidermolysis bullosa; (c) the hand of an infant with Herlitz junctional epidermolysis bullosa; (d) blister on the foot of a patient with epidermolysis bullosa simplex; (e) baby with epidermolysis bullosa simplex Dowling–Meara; (f) baby with Herlitz junctional epidermolysis bullosa; (g) baby with Hallopean–Siemans dystrophic epidermolysis bullosa; (h) intraepidermal blister from a Weber Cockayne epidermolysis bullosa simplex patient. Skin section stained with Richardson's stain.

Plate 2 Clinical photographs of: (a) bullous ichthyosiform erythroderma (BIE) and three types of keratoderma; (b) focal palmoplantar keratoderma (PPK) associated with a keratin 16 mutation; (c) striate palmoplantar keratoderma associated with a desmoglein 1 mutation; and (d) constriction around the digit from an individual with Vohwinkel's syndrome associated with a C×26 mutation.

Plates for Section 24

Chapter 24.13.3 Epilepsy in later childhood and adults

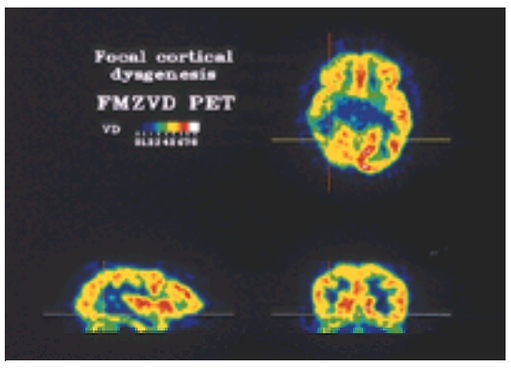


Plate 1 FMZVD PET scan showing a region of probable cortical dysplasia in the right temporal lobe. The 11C-fluamzenil volume of distribution (FMZVD) is an index of GABAa receptor density.

Chapter 24.13.9 Human prion disease

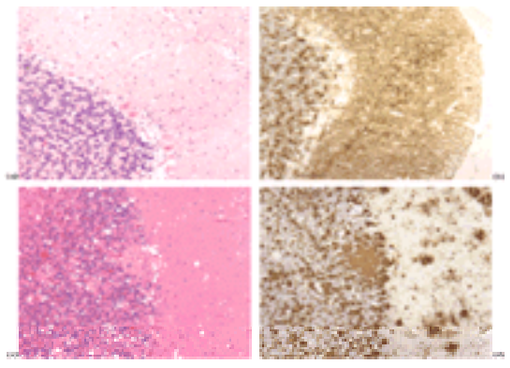

Plate 1 See *caption next page*.

The cerebellum in sporadic CJD shows widespread spongiform change in the molecular layer, with no plaques visible. Haematoxylin and eosin × 250. (b) PrP immunocytochemistry in the cerebellum in sporadic CJD shows a fine granular (synaptic) pattern of deposition in the molecular layer (right) with coarser deposits visible in the granular layer (left). No plaques are visible and the Purkinje cells are unstained. Kg9 monoclonal antibody × 250. (c) The cerebellum in variant CJD shows a group of florid plaques (centre) comprising rounded amyloid deposits surrounded by spongiform change. Spongiform change is also present in the molecular layer (right). Haematoxylin and eosin × 250. (d) Immunocytochemistry for PrP in the cerebellum in variant CJD shows strong staining of the large amyloid plaques (centre) but there is widespread positivity in the form of multiple smaller plaques, with amorphous 'feathery' deposits in the molecular layer (right). Kg9 monoclonal antibody × 250.

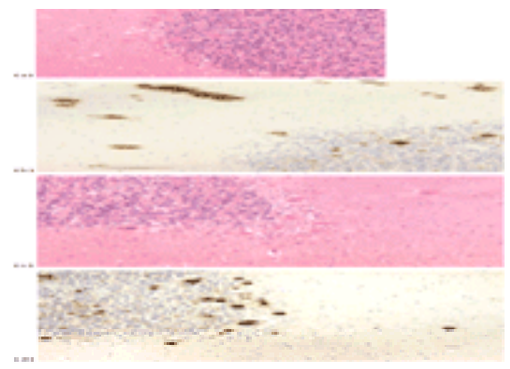

Plate 2 (a) The cerebellum in GSS contains multiple multicentric plaques (centre) which are present both in the molecular layer and in the granular layer. Spongiform change is also present focally in the molecular layer (left). Haematoxylin and eosin ×250. (b) Multicentric plaques in GSS are more easily visualized in the cerebellum using immunocytochemistry for PrP, which shows large deposits of varying size in both the molecular and granular layers. Kg9 monoclonal antibody × 250. (c) The cerebellum in kuru contains typical plaques (the so-called kuru plaques) which are comprised of a rounded structure with a dense centre and a loose fibrillary periphery (centre). Spongiform change is only present to a minimal degree in the molecular layer. Haematoxylin and eosin × 250. (d) Immunocytochemistry for PrP in the cerebellum in kuru shows strong staining of the larger plaques and in addition demonstrates multiple smaller plaques which are not evident on routinely stained preparations. Kg9 monoclonal antibody × 250.

Chapter 24.14.1 Bacterial meningitis

Plate 1 Cutaneous petechiae in a patient with acute meningococcal meningitis. (Copyright D.A. Warrell.)

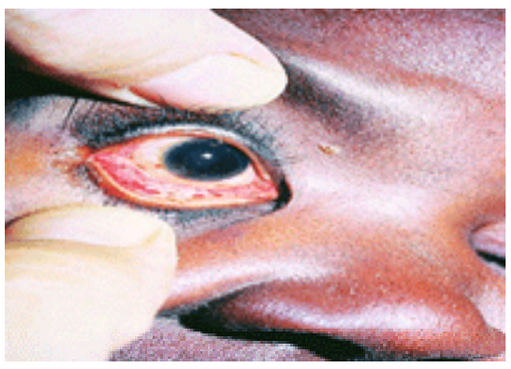

Plate 2 Conjunctival petechiae in a Nigerian boy with meningococcal meningitis. (Copyright D.A. Warrell.)

Plates for Section 25

Chapter 25 The eye in general medicine

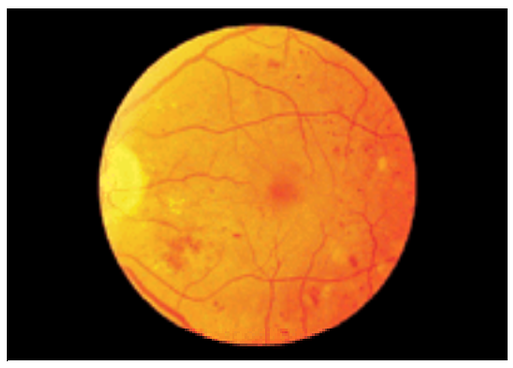

Plate 1 Diabetic, background retinopathy. The hallmarks of background retinal changes are red dots (either microaneurysms or small haemorrhages) and blots (larger haemorrhages) together with glinting hard exudates and. These are no closer than one disc diameter from the central fovea and vision is normal.

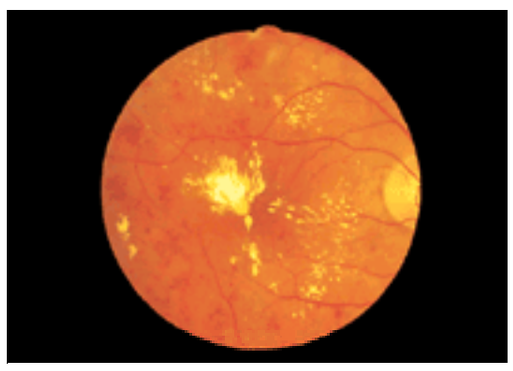

Plate 2 Diabetic, maculopathy. Hard exudate, containing lipid and protein which has leaked from damaged retinal capillaries, has congregated at the fovea. Central vision is irretrievably impaired. Diabetes may present in this way, especially in the elderly.

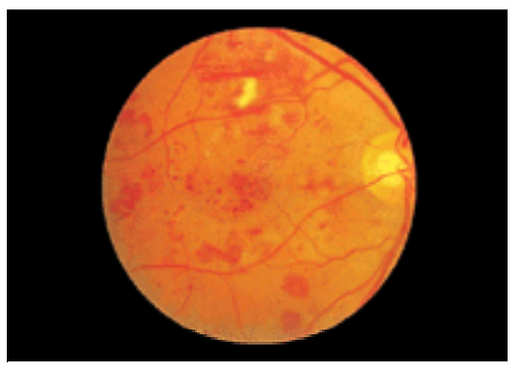

Plate 3 Diabetic, ischaemic retinopathy. Capillary ischaemia creates multiple cotton wool spots—microinfarcts within the nerve fibre layer. Other features are dilatation of retinal veins and multiple blot haemorrhages. Frank proliferation of new vessels is almost inevitable and the retinal changes must be carefully observed.

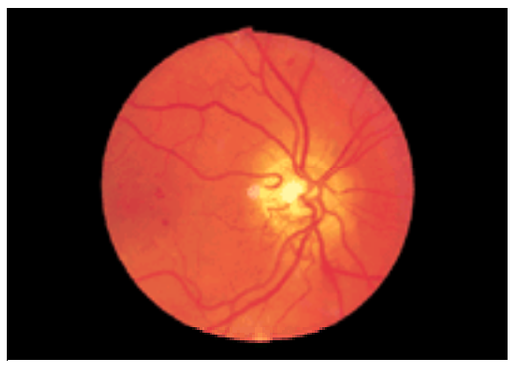

Plate 4 Diabetic, proliferative retinopathy. New vessels have formed on the inferior part of the optic disc. They are fine, looping, and aimless. There may be others in the peripheral retina. If the vessels bleed, vision will become acutely obscured by 'floaters'.

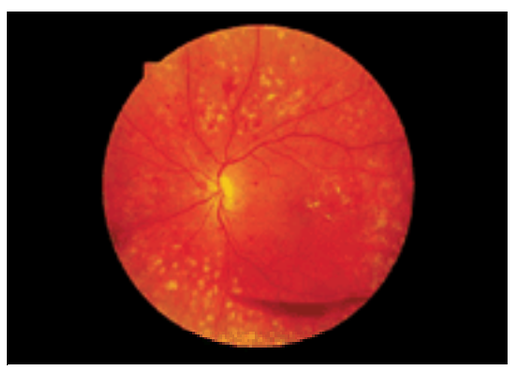

Plate 5 Diabetic, preretinal haemorrhage and laser scars. Neovascular fronds may bleed in front of the retina or into the vitreous, obscuring vision acutely. Here blood

has sedimented into a characteristic 'boat' shape and multiple laser scars have been placed outside the major vascular arcades. There are haemorrhages and hard exudate temporal to the fovea.

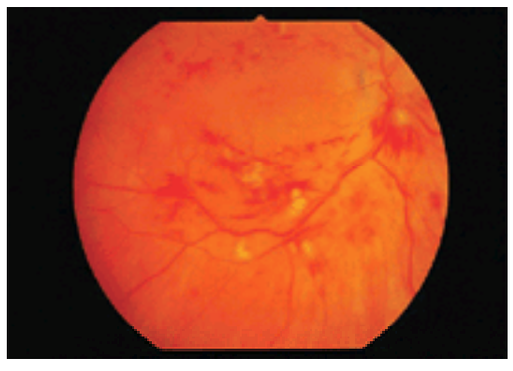

Plate 6 Hypertension, accelerated. Multiple flame shaped haemorrhages, microinfarcts, and swelling of the optic disc margin are characteristic features of accelerated hypertension. Vision may be normal, yet the changes dictate immediate treatment to reduce blood pressure. The diastolic level is usually greater than 110 mmHg and proteinuria is to be expected.

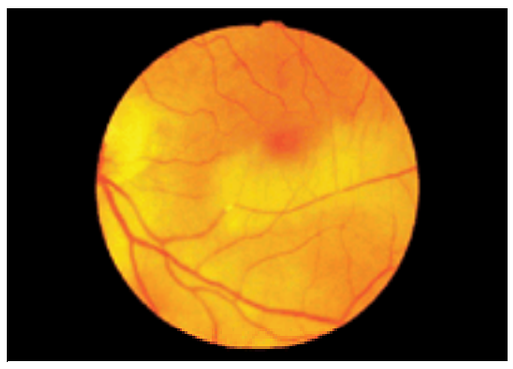

Plate 7 Branch retinal artery occlusion. A small white embolus is lodged at the third bifurcation of the superotemporal branch retinal artery, occluding it. The local retina is oedematous and non-functioning, producing an acute superior scotoma in the left eye. The likely origin is from the ipsilateral carotid or the heart.

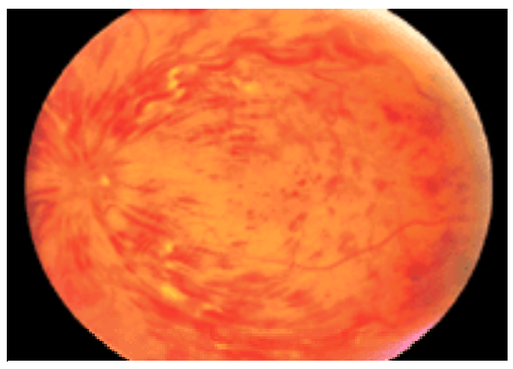

Plate 8 Central retinal vein occlusion. Blockage of the draining central retinal vein results in a 'bloodstorm' appearance with profuse flame haemorrhages forming between the nerve fibres in all quadrants. Cotton wool spots representing microinfarcts are often also present. Vision is acutely blurred as the fovea becomes oedematous.

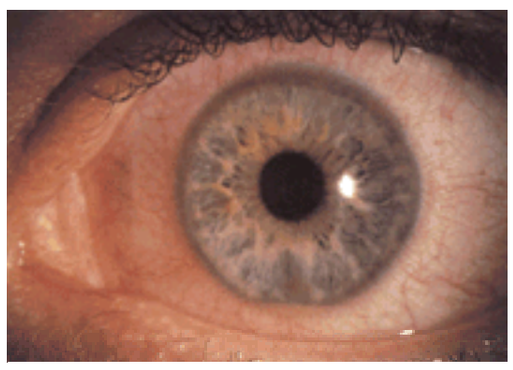

Plate 9 Behçet's hypopyon iritis. The eye is red, painful and photophobic. White cells within the anterior chamber have sedimented into a characteristic hypopyon at the base. If bacterial endophthalmitis is excluded, Behçet's syndrome is a likely cause of this acute, intense, sterile iritis.

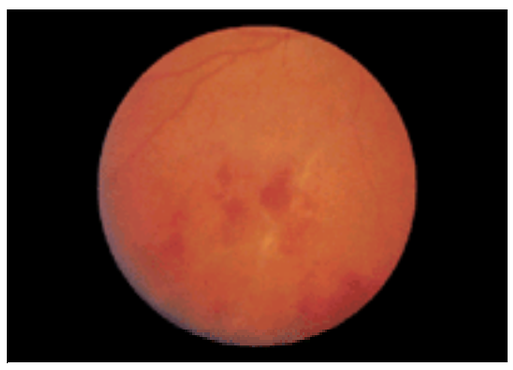

Plate 10 Behçet's retinitis. Occlusion of blood vessels, usually venous, in the peripheral retina produces a wedge of haemorrhage with whitening of the vascular wall. The view is hazy due to inflammatory cells within the vitreous. The retina is ischaemic, function is lost, and neovascularization may occur. Repeated episodes may damage vision irretrievably.

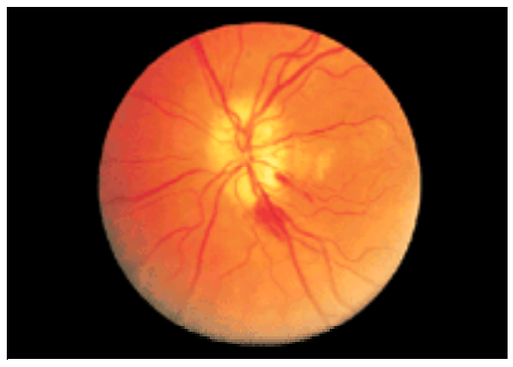

Plate 11 Giant cell arteritis, optic disc infarction. The optic nerve head is infarcted, due to occlusion of multiple ciliary branch arterioles which supply it. The disc is pale and swollen, and juctapapillary haemorrhage has formed. Vision is poor and will not recover. The other eye is at immediate risk unless the systemic inflammatory process is controlled.

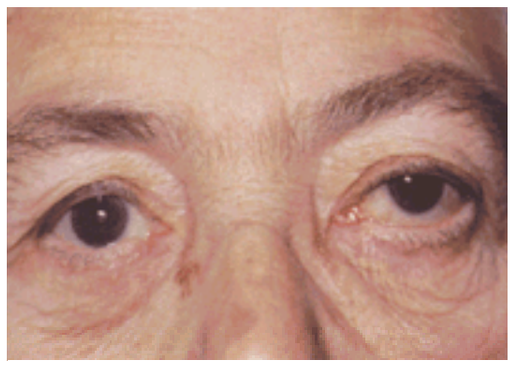

Plate 12 Wegener's granulomatosis of the orbit. An inflammatory mass behind the left eye has displaced it forwards and upwards and the eye moves poorly due to involvement of motor nerves within the orbit. The optic nerve may also be involved. Biopsy confirmed granulomatous vasculitis and ANCA was positive. The adjacent sinuses were involved, with bone loss demonstrated on CT scan.

Plate 13 Scleromalacia in rheumatoid arthritis. Vasculitis results in focal ischaemia, with translucency and thinning of the sclera: the coat of the eye may perforate. The most common associated systemic disorder is rheumatoid arthritis. The eye is usually red, and pain may be intense.

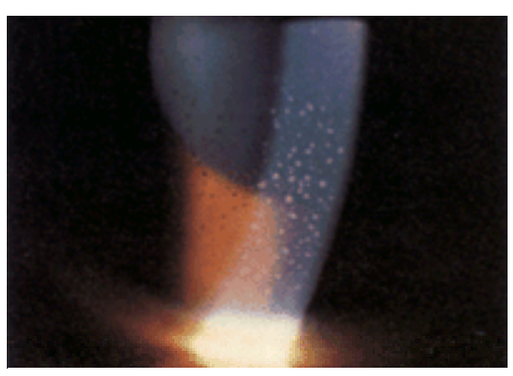

Plate 14 Iritis in ankylosing spondylitis. The slit lamp displays cells within the anterior chamber which have sedimented on to the interior surface of the cornea as white keratic precipitates. These are the hallmarks of iritis (anterior uveitis). The eye is usually red and painful. A frequent association is with ankylosing spondylitis and HLA B27 haplotype.

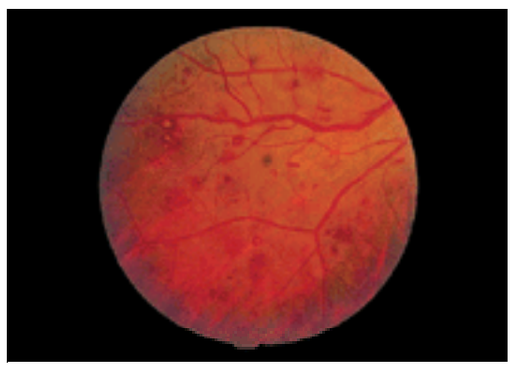

Plate 15 Retinal haemorrhages in leukaemia. Multiple and bilateral retinal haemorrhages suggest a blood dyscrasia, if underlying diabetes and hypertension are excluded. In this case, the peripheral lymphocyte count was considerably raised, consistent with chronic lymphocytic leukaemia. Some haemorrhages have a white centre (Roth spot).

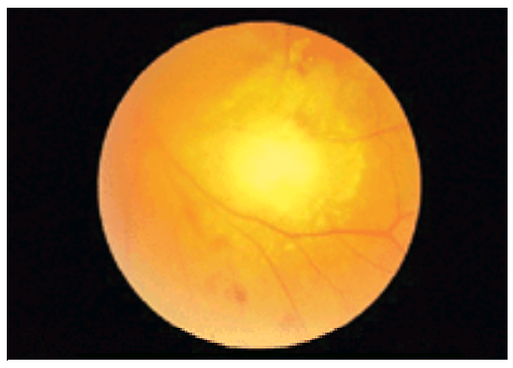

Plate 16 Metastatic staphylococcal endophthalmitis. Blood borne organisms may settle in the eye, forming a focal abscess in the choroid, breaking through the adjacent retina into the vitreous which becomes hazy with inflammatory cells. This patient had poorly-controlled diabetes and a staphylococcal skin infection.

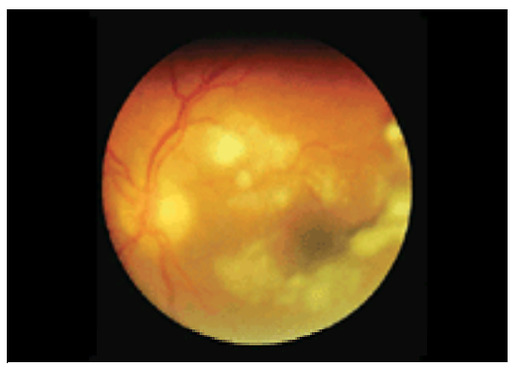

Plate 17 Candida endophthalmitis. Fungal infection of the eye interior forms white 'snowballs' within the vitreous and retina. The organism is usually blood borne and may enter the circulation with intravenously injected agents, including heroin. Infection is indolent, with a relatively white eye and little pain. Vitrectomy and intravitreal antimicrobial treatment may be necessary.

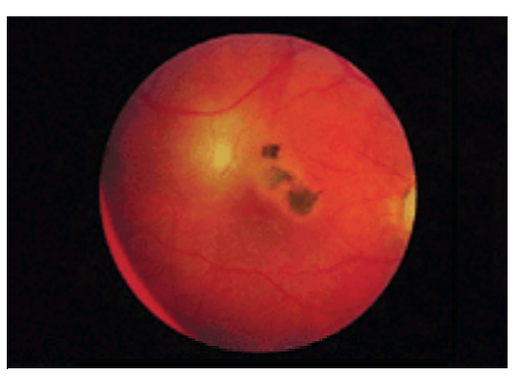

Plate 18 Toxoplasmosis. A fluffy fresh focus of infection within the choroid and retina is found adjacent to an old pigmented scar, typical of toxoplasmosis. The organism encysts within the retina and may reactivate sporadically in this way.

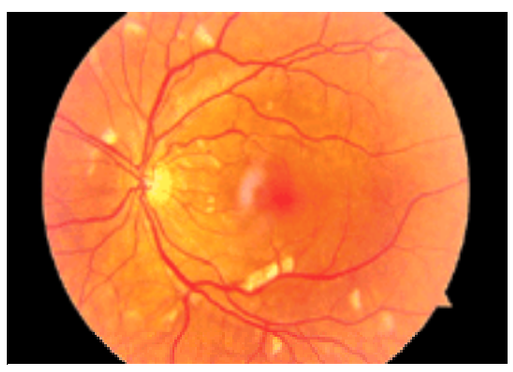

Plate 19 Cotton wool spots. Retinal microinfarcts are due to occlusion of capillaries which supply the nerve fibre layer. These multiple 'cotton wool spots' are found associated with microemboli, as after cardiac surgery employing bypass. In patients with AIDS they may form especially at the time of pulmonary infection, for instance with *Pneumocystis carinii*.

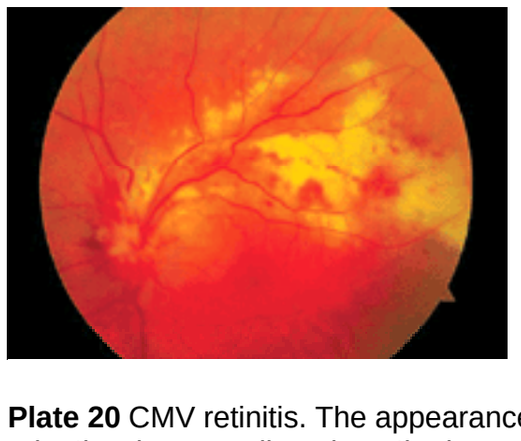

Plate 20 CMV retinitis. The appearance of focal, fluffy, pale retinal necrosis with haemorrhages is characteristic of infection with cytomegalovirus. The area expands relentlessly, spreading along the branch vessels, unless treatment with virustatic agent is instituted or the CD4 lymphocyte count can be improved. The usual underlying disorder is AIDS.

Plate 21 Thyroid eye disease with exophthalmos. Inflammation of orbital tissues— fat and muscles—causes protrustion of the eye—exophthalmos or proptosis. The eyelids also become swollen and the conjunctiva congested. Autoimmune thyroid disease (Graves' disease) is the most common underlying disorder.

Plate 22 Marfan's syndrome. Dislocation of the lens is sometimes easily visible, though lesser degrees may need careful examination using the slit lamp after dilatation of the pupil. The lens may also be unstable, trembling on eye movement. The most common underlying cause is Marfan's syndrome, with deficiency of fibrillin in the suspensory fibres and upward displacement.

Plate 23 Von Hippel Lindau. Angiomas of the retina are an important early feature of this dominantly inherited condition. They begin as small red lesions which expand. Here the angioma is next to the optic disc, a characteristic position which makes management difficult and visual prognosis poor.

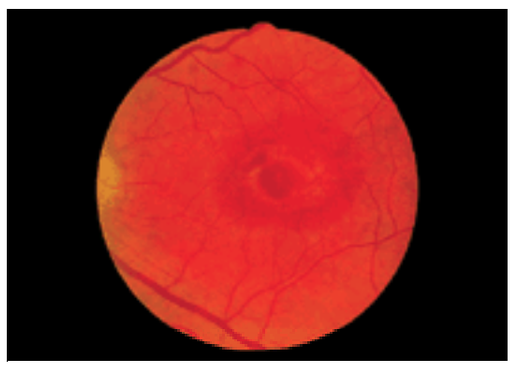

Plate 24 Bull's eye maculopathy. Toxicity at the macula caused by chloroquine results in a concentric target-like pigmentary appearance. The features are reversible in the early, asymptomatic, stages, but once loss of central visual acuity occurs, this may progress despite stopping the drug. Hydroxychloroquine appears to carry a lesser risk.

1 On being a patient

C. M. Clothier

'Patior'—'I am suffering'—one recalls being taught at school. Every student knows that a patient is generally, but not always, one who is suffering, and perhaps not very patiently. Only by derivation has the word become associated with the bearing without complaint, of pain, sorrow, or simple irritation with others. Yet this secondary meaning is important in medicine because it reminds us that the great majority of patients do in fact suffer their illnesses with remarkable fortitude and endurance. Might this be another facet of the urge to survive and to minimize disability in the essentially competitive struggle of life? Is it this instinct, perhaps, which leads the average healthy person who stumbles and falls in the street to declare: 'It's nothing really' or 'I'll be all right in a minute', as they try to rise quickly from the fallen position of the vanquished? For falling to the ground in combat is usually fatal, and voluntary prostration of the body usually signifies submission and defeat.

So when otherwise healthy persons seek help from a doctor, or are admitted to hospital, it may be assumed that they are in some perturbation of mind as well as of body. It is this suffering in the mind that makes every patient different, even when their condition is familiar and well recognized, because the mental element in any illness varies enormously with circumstance and temperament.

Visiting the family doctor is usually less of an ordeal for the patient than admission to hospital. The patient often retains the dignity of an upright position *vis-à-vis* the doctor. However, the element of personal distress may still be there and may mask or distort the objective signs and symptoms for which the doctor is trained to look. The 'dependent well' may only be seeking a listening post for the torments of family dissension, personal tragedy, or just old age. Other patients enjoy being examined, manipulated, or injected because of the personal contact and attention involved, which they otherwise lack. How much time to give to each of the greatly diverse patients of a practice or a hospital is a matter of delicate judgement: most will deserve a sympathetic response, but some will seem to merit a rather positive rejection. Yet one must be careful; for there have been recorded instances of patients who complained of bizarre symptoms, signifying no identifiable illness, who were rejected as malingerers but subsequently were shown to have suffered greatly from insidious disease or poison. Those who are truly ill may be brave, or craven, or something in between, depending upon age, circumstance, or personal quality. However, one thing is certain, each patient will think himself or herself to be reacting normally to the predicament of illness, real or imaginary, and will be expecting the same degree of medical attention. If they do not get it they will be offended and angry: whether that reaction should provoke from the doctor sympathy or dismissal may be as crucial a judgement as writing a prescription.

On the other hand, admission to hospital is a fundamentally different experience both for patients and those caring for them. Here the dominant factors are the concession of defeat and the abandonment of the safe haven of home. To lie down in the presence of others in a strange place, to get undressed in the middle of the day, to give specimens of urine or blood, all on the orders of those who remain upright, are acts of submission. The arrival in hospital is accompanied by feelings of anxious apprehension, fear, isolation, and general mental turmoil which caused Osbert Sitwell to speak of 'First depressions on arrival'. Mingled with these feelings may also be some sense of relief in having finally admitted defeat and agreed to surrender one's body into other hands. When one adds to these varied emotions anxiety about work, about the home, or about the patient's spouse or children, it is a wonder that the admitting doctor gets any sensible or accurate answer out of a patient for the first 24 hours after admission. When histories are taken, these widely variable responses to stress, for the most part concealed, should be in the doctor's mind. Even the lay patient is likely to be aware that blood pressure and heart rate are raised when first they are measured in hospital. Symptoms may be minimized, exaggerated consciously or unconsciously, invented, or simply forgotten. Dates and times of episodes or onsets may be so wide of the mark as to be of little use in diagnosis, if not positively dangerous.

The risk, then, is that the patient in hospital becomes merely an interesting focus of medical attention rather than a person with all those confusions of mind that make him or her an individual. This is a very real danger in modern hospital practice, the more so as we are now equipped with the most sophisticated apparatus for diagnosis, facilities that may be seen by some as reducing the need for any contribution from the patient. The feeling of personal unimportance is a marked cause of unhappiness among patients in hospital and a frequent source of complaint against doctors and nurses. Doctors can and sometimes do speak and look as if the patient was no more than an interesting clinical object and nurses can exacerbate the grievance by discussing their private affairs across the bed of the patient to whom they are attending.

In teaching hospitals, the patient's sense of unimportance may be increased by the ordeal of the professional ward round. It has to be stated that even now, at the start of the twenty-second century, there are consultants who persistently treat patients as the fortunate recipients of their attentions, whose views and feelings are of little relevance in the pursuit of a learned profession. Besides being a technical breach of obligation under the terms of a consultant's National Health Service contract, such conduct is rude. A good doctor, who engages the patients' attention and participation in a discussion of their case, may learn a great deal, besides giving the patient immense satisfaction and inspiring confidence. 'Encourage the patient to talk', said a wise old practitioner, 'and he will eventually tell you what is the matter with him'. It is regrettable that those who practise an excessive clinical detachment are not only the old and authoritarian, but include those who have grown up in a world where medical omniscience is no longer taken for granted. Doctors who cannot naturally feel a surge of sympathy for the body prostrated before them should perhaps consider a career in research.

The patients of today are very different from those of half a century ago. Until the advent of the mass media, the relationship between patient and doctor resembled that between parishioner and pastor, schoolmaster and pupil, or lawyer and client. It was impious to question the wisdom or judgement of the learned professional adviser. The remarkable expression 'sapiential authority' sought to encapsulate this ascendancy of doctor over patient. Such a relationship was often quite a happy one for both parties, and perhaps more conducive to treatment and cure than a less trusting one. However, the mass media, and supremely, television, have changed all that. We have all penetrated behind the camera into the operating theatre and other private places and there seen what doctors and their assistants actually do in the attempt to cure illness or repair damage. However skilful and ingenious, it is obviously not miraculous, and some of it is rather pedestrian. The curtains have been parted and the magic revealed. The magicians themselves have often admitted their humanity and confessed to their failures. When mystery is dispelled, the questions come thick and fast.

It is of no use to resist the tide of doubt and curiosity that now threatens to overwhelm not just medicine but all the learned professions. Family doctors must now expect patients to ask quite penetrating questions about the treatment proposed for them and the drugs it is intended to use. These questions must be answered with some candour if mutual trust is to be maintained. Nothing more disturbs a patient, who may be very intelligent even though not learned in medicine, than hearing their doctor seeking to disguise his own ignorance or doubt by prevarication or deviousness, often easily detected. Besides all of which, it sometimes does professionals in any discipline a great deal of good to be closely questioned about beliefs and practices that they have long held to be unassailably correct; and they should listen to their own explanations and audit them for intelligibility and rationality.

For almost every patient, the general anaesthetic and surgical operation engender particular anxieties which must be recognized and accommodated. It is no small thing to surrender one's consciousness into the hands of others, with all the vulnerability which unconsciousness brings. The intrusion of hands and instruments into the previously intact body equally induces dark fears in many minds. Doctors may not fully appreciate these anxieties, familiar as they are with the procedures used and their general safety and success. Most patients of reasonably resolute temperament face up to these prospects with good enough courage: but having done so, find a postponement of the day especially demoralizing. It is important that surgeons try to arrange lists so that patients do not wait many hours in a state of some tension, only to be told that they must face it all again on another day.

Modern practice and health economics combine nowadays to reduce the patient's stay in hospital to a minimum. Perhaps doctors do not sufficiently realize how much dependence may develop between patients who have been really ill and those who have rescued them from suffering, or even from death, and subsequently cared for them. The cheerful words 'Well, you can go home tomorrow' are not invariably greeted with joy. It is not merely that for some, the attention they receive in hospital is better than anything they get elsewhere: those who have been really ill are often haunted by the prospect of relapse or recurrence and feel a security in hospital, amplified by care and kindness, which they cannot feel at home. Some introductory words of sympathy for the patient's anxiety and reassurance for their ability to survive outside the hospital are often necessary.

An essay entitled 'On being a patient' ought to contain not merely adjurations for doctors but at least some directions for patients. The foremost of these could be to remember the meaning of the newly acquired status and title. Many patients are irritable and demanding, even when those attributes are not produced or justified by some disease process. They are very unattractive qualities in those who have, after all, been obliged to submit themselves to the care and skill of their fellow beings, sometimes through their own fault or neglect. A little humility and gratitude seem called for and no less because the patient is paying for some part of the services rendered, or believes that he has already done so. It is perhaps one of the least likeable of human attitudes to believe that money buys everything and that plenty of it

entitles one to special care and attention. Doctors and nurses do not for the most part do what they do in the expectation of great worldly reward. Patients likewise should recognize and appreciate human kindness when they see it and be grateful for it whether or not they are paying for their treatment.

Finally it is necessary to reflect that, as man is a social animal, the illness of any member of a family affects most of the others. Obviously enough, the spouse of a sick person is liable to be deeply affected by sorrow and by anxiety about the future. Such feelings spring not merely from love and affection but from fear of a future either robbed of economic support or burdened by care for an invalid or disabled person. So a good doctor has more than just the patient to consider and should try to speak to the relatives and to offer them proper and helpful explanations of present treatment and future prospects. It may seem unreasonable to suggest that doctors should treat the relatives of their patients as well as the patients themselves, but human beings are highly interactive and sick people are sensitive to the sorrows and anxieties of their families. If a patient's relatives are much cast down and obviously anxious, this is perceived by the patient and greatly affects morale and the peace of mind that is conducive to recovery.

It is only too tempting to avoid the patient's relatives. Besides being upright and healthy, in contradistinction to the patient, their sorrows and anxieties may make them noisy and demanding. They are apt to ask questions which seem absurd to the doctor and impossible to answer in simple lay terms. However, the effort must be made, not only for humanitarian reasons but because it may rightly be regarded as part of the treatment.

In sum, the patient views those who care for him or her as being in a relationship every bit as confidential and trusting as that which exists within the patient's family, probably more so. The patient has no hesitation in imposing this burdensome connection on one who has hitherto been a total stranger. That is the enormous measure of a doctor's voluntarily assumed responsibilities to the human race.

2.1 Science in medicine: when, how, and what

W. F. Bynum

Introduction

At least since the Hippocratics, medicine has always aspired to be scientific. What has changed is not so much the aspirations but what it has meant to be 'scientific'.

'Science is the father of knowledge, but opinion breeds ignorance', opined the Hippocratic treatise *The Canon*, and Hippocratic practitioners developed an approach to health, disease, and its treatment based on systematic observation and cumulative experience. Even the word physic, the root of physician as well as physicist, derives from the Greek for 'nature'. Further, Hippocratic medicine was experimental, that word stemming from the same classical roots which gave us 'experience'.

Words, however, can be slippery, as philosophers as divergent as Francis Bacon and Ludwig Wittgenstein have stressed. The science and experiment of the Hippocratics can still inspire, but they are not our science and experiment. During the past two or three centuries, an armoury of sciences and technologies has come to underpin medical practice. This essay attempts briefly to describe these, within the context of distinctive and perennial features of medical practice, that is, suffering individuals whose problems and diseases demand attention.

A typology of historical medicine

The late Erwin Ackerknecht always taught that the history of Western medicine revealed five kinds of medicine: bedside, library, hospital, social, and laboratory. Bedside medicine he equated with Hippocratic, with its emphasis on the individual patient, its tendency towards holism, and a concern with the patient within his or her environment. These are some of the reasons why the Hippocratics are still claimed by both orthodox and alternative practitioners. For Ackerknecht, 'library' medicine dominated in the Middle Ages, when learned medicine retreated into the universities and scholars sometimes assumed that everything worth discovering had been discovered by the ancients, and everything worth being revealed could be found in the Bible. The millennium between the sacking of Rome and the discovery of the New World is often dismissed as a sterile period scientifically, but the physicians of the period, linguistically erudite and philosophically inclined, would have been surprised to be described as unscientific. They simply believed that the road to knowledge was through the book.

They also sometimes engaged with nature, although it is undeniable that nature rather than words became an increasing source of truth and knowledge during the Scientific Revolution, a period stretching roughly from just before Andreas Vesalius (1514–1564) to Isaac Newton (1642–1727). Around 1600, it was becoming apparent to many that the Greeks had not left behind a complete and accurate account of the nature of the world, and that scientific knowledge was cumulative. This 'Battle of the Books', the debate over whether the ancients or the moderns knew more, was decided in favour of the moderns. Many of the outstanding scientific achievements of the era were in astronomy and physics, but medicine, both in its theory and its practice, was also affected. Theory has always been easier to change than practice, of course, and it was famously remarked that William Harvey's discovery of the circulation of the blood had no impact on therapeutics. Harvey (1578–1657) also notoriously lamented that his practice actually fell off following the discovery, his patients fearing that he was 'crack-brained'. The fear that too close an identification with science was detrimental to patient confidence recurs in medical history, and is still part of the delicate negotiations between the profession and its public.

Within the discipline of medicine itself there have always been individuals, some of them, like Thomas Sydenham (1624–1689), eminently successful, who believed that experimental science had little to offer to patient care. But these 'artists' of medicine could still invoke the authority of Hippocrates, with its older connotations of knowledge and experience, and during the early modern period, the whole spectrum of the sciences—mathematics, physics, chemistry, the life sciences (not yet called biology)—made their ways into formulations of health and disease. Iatrophysics, iatromathematics, and iatrochemistry all had their advocates in the seventeenth and eighteenth centuries.

That these systems tended to encourage speculation to run ahead of evidence was recognized at the time, and this was part of the reason why 'hospital medicine' had little recourse to those disciplines we now call 'basic medical sciences'. The founders of French hospital medicine, Xavier Bichat (1771–1802), J. N. Corvisart (1755–1821), and R. T. H. Laennec (1781–1826), often referred to chemistry, physiology, and the like as sciences 'accessory' to medicine. The medicine that developed in the Paris hospitals, after the reopening in 1794 of the medical schools closed by the Revolution a couple of years earlier, emphasized above all the study of disease in the sick patient. In a sense, this was Hippocratic medicine writ large, but with some significant differences. First, the hospital offered the curious doctor a vast arena for observing disease. The equivalent of a lifetime's experience of a lone practitioner in the community could be experienced in a few months of hospital work. Hospitals offered the possibility of defining disease based on hundreds of cases. Second, Hippocratic humoralism gradually disappeared as the dominant explanatory framework of health and disease, replaced by the primacy of the lesion, located in the solids—the organs, tissues and, by mid-century, cells. In this new orientation, disease was literally palpable, its lesions to be discovered in life by the systematic use of physical examination—Corvisart rediscovered percussion, Laennec invented the stethoscope—and these findings to be correlated after death by routine autopsy. French high priests of hospital medicine brought diagnosis to a new stage and replaced the older symptom-based nosologies with a more objective, demonstrable one of lesions. The third feature of hospital medicine was what Pierre Louis called the numerical method, the use of numbers to guide both disease classification and therapeutic evaluation.

The philosophy underlying early nineteenth-century French medicine was most systematically expounded by one of the many American students who studied in Paris, Elisha Bartlett, in his *Philosophy of medical science* (1844). The medical science whose philosophy he chronicled was one of facts. All systems of medicine, past and present, were speculative, vague, and useless. Cullen, Brown, Broussais, and Hahnemann were all consigned to the historical dustbin. The new medicine was one of systematic observation and collection of facts, which, properly compared and organized, could provide an objective understanding of disease and a rational basis for its treatment. Bartlett's philosophy was essentially undiluted Baconian inductivism applied to medicine. Unsurprisingly, he counted Hippocrates as well as Pierre Louis among his heroes.

One consequence of the lesion-based medicine was the recognition that not much of what doctors did actually altered the natural history of disease. Therapeutic scepticism, or even nihilism, flourished among doctors whose lives were spent, as Laennec put it, 'among the dead and dying'. It was less likely to be expressed among doctors concerned with earning a living treating private patients, but the concern with medicine's therapeutic impotency also fuelled the movement to prevent disease. Ackerknecht's fourth kind of medicine, social, also flourished in the nineteenth century. Just as hospitals existed long before 'hospital medicine', so epidemics and preventive measures were not invented by the public health movement of the 1830s. Nevertheless, the preventive infrastructures developed partly in response to the cholera pandemics still exist, *mutatis mutandis*. The chief architect of the British public health movement, Edwin Chadwick (1800–1890), was a lawyer who thought that, on the whole, doctors were overrated. (He was neither the first nor the last lawyer to hold that opinion.) He held that epidemic diseases were caused by filth and spread via the foul smells (miasma) of rotting organic matter. His solutions were engineering ones, clean water and efficient waste disposal, which he argued would leave the world an altogether more pleasant and healthier place. His ideas were formed during the 1830s and early 1840s, and they remained more or less fixed for the rest of his long life, which extended well into the bacteriological age. Nevertheless, Chadwick also invoked science in his public health reform programme, above all the science of statistical investigation. His use of statistics can easily be shown to have been naïve, but it was ardent. In his own sphere of enquiry, Chadwick was as much in awe of the unadorned 'fact' as was his contemporary Bartlett. A later generation of Medical Officers of Health and others concerned with disease prevention (or containment) would develop new investigative techniques, more sophisticated statistics, and especially, new theories of disease causation and transmission. But the early public health movement was firmly based on the science of its time.

The final locus of medicine, the laboratory, was also largely a product of the nineteenth century, though of course laboratories (a place where one worked, especially to mutate gold from lead) had existed for much longer. A leading exponent of the laboratory, and one of its most thoughtful philosophers, had experienced Paris hospital medicine as a medical student. Claude Bernard's *Introduction to the study of experimental medicine* (1865) is both an intriguing account of his own brilliant career and a sophisticated analysis of the philosophy of experimentation within the life sciences. Hospitals, he argued, are merely the gateways to medical knowledge, and bedside clinicians can be no more than natural historians of disease. To understand the causes and mechanisms of disease, it is necessary to go into

the sanctuary of the laboratory, where experimental conditions can be better controlled. There are in nature no uncaused causes: determinism is the iron law of the universe, extending equally to living systems and inorganic ones. However, organisms present special experimental problems, and it is only through isolating particular features, and holding other parameters as constant as possible, that reliability and reproducibility can be achieved.

Bernard identified three primary branches of experimental medicine: physiology, pathology, and therapeutics. His own research programme touched all three pillars: his research on the roles of the liver and pancreas in sugar metabolism contributed to understanding normal physiology as well as diseases such as diabetes; his investigations of the sites of action of agents such as curare and carbon monoxide foreshadowed structural pharmacology and drug receptor theory; his work on the functions of the sympathetic nerves buttressed his own more general notion of the constancy of *milieu interieur* as the precondition to vital action (and freedom), a precursor of Walter Cannon's concept of homeostasis. Bernard stands supreme as the quintessential advocate of the laboratory.

Who was the first modern medical experimentalist?

When Bernard wrote, experimental medical science was still a fledgling activity, best developed in the universities of the German States and Principalities. The German university ideal of medical education was to be extolled by the American educational reformer Abraham Flexner in the early twentieth century. It was in the reformed and newly created German universities that the forms of modern scientific research were established. Research careers were created; copublication in specialist journals became common; scientific societies flourished. The microscope became the symbol of the medical scientist even as the stethoscope was becoming the hallmark of the forward-looking clinician. In the hands of scientists like Schwann, Virchow, and Weismann, the modern cell theory was developed and applied to medicine and biology more generally. These researchers established the drive to push units of analysis further and further. Eduard Buchner's identification of cell-free ferments in 1897 firmly established the importance of subcellular functions. Pasteur, Koch, Ehrlich, von Behring, and others advanced new notions of the causes of disease, the body's response to infection, and the possibilities of new drugs to combat disease. Any of these scientists might arguably be the answer to the parlour-game question: who was the first modern medical scientist?

The German-speaking lands perfected the modern forms of scientific research, but a good case can be made for a Frenchman to be crowned the first thoroughly modern experimentalist within medicine. François Magendie (1783–1855) (Fig. 1) was a child of the Enlightenment and product of the French Revolution. One of several eminent individuals (Thomas Malthus was another) raised according to the anarchic principles espoused by Jean Jacques Rousseau, Magendie did not learn to read or write till he was 10. His subsequent precocity was such that he was ready for medical studies by the age of 16, learned anatomy and surgery as an apprentice, and made his way through the Paris hospital system. Although he never lost interest in practical medical issues, his reputation was established primarily within the laboratory. His monographs on physiology and pharmacology marked new beginnings, and his life manifests three emblematic qualities which make him one of us.

Fig. 1 François Magendie. Lithograph by N.E. Maurin. (From Burgess R. Portraits of doctors and scientists in the Wellcome Institute, London, 1973, no.1870.2, by courtesy of the Wellcome Library, London.)

First, he valued facts above theories, evidence above rhetoric. But he went beyond Bartlett and the high priests of hospital medicine in insisting that in experiment, and not simply observation, lay the real future of medical knowledge. Like his pupil Claude Bernard, Magendie was a deft experimentalist. He used animals (and occasionally patients) to probe into a whole range of problems in physiology, pathology, and pharmacology: the functions of the spinal nerves; the physiology of vomiting; important facets of absorption, digestion, circulation, and nutrition; and the actions of drugs and poisons. He described anaphylaxis a century before it was named. He was as philosophically naïve as Bernard was sophisticated: of course he had theories, but his image of himself as a ragpicker with a spiked stick, gathering isolated experimental facts where he found them, is a telling one.

Second, he was modern in sometimes backing the wrong horses. He judged cholera and yellow fever to be non-contagious, was suspicious of anaesthesia, and sometimes claimed more than we might for his newly introduced therapeutic substances, such as strychnine and veratrine.

Finally, Magendie was the scientist who first expunged the double-faced Janus from the medical mentality. William Harvey worshipped Aristotle, Albrecht von Haller was steeped in history, and Isaac Newton popularized the pious conceit of pygmies standing on the shoulders of giants. Magendie looked only in one direction: the future. He had no sense of history and no use for it. He meant what he said when he insisted that most physiological 'facts' had to be verified by new experiments, and he undertook to provide a beginning. He made the laboratory the bedrock of medicine.

What happened next?

Like everyone, Magendie was of his time. Nevertheless, his values were symptomatic of important themes within nineteenth-century medicine and medical science. By the beginning of the First World War, most of the structures and the fundamental concepts of 'our' medicine were in place. Of course, both medical science and medical practice have been utterly transformed since. But the impulse of experimentation and its variable translation into practice were there. We have gone far beyond the cell in our analytical procedures, and our medical, surgical, and therapeutic armamentaria are vastly more sophisticated and powerful.

Our medicine is fundamentally different in one important respect, even if the trend was already evident in the nineteenth century: the fusion of science and technology. Science and technology have become so intertwined that the older distinctions between them are blurred. Technology made a real but minimal impact on nineteenth-century medicine. Some instruments, such as Helmholtz's ophthalmoscope, came into clinical medicine through the laboratory; and German experimental scientists were eager to exploit the latest equipment such as kymographs, sphygmographs, and the profusion of artefacts (Petri dishes, autoclaves, etc.) that Koch and his colleagues devised for the bacteriological laboratory.

Most important of all was probably the X-ray, discovered by Roentgen in late 1895. It made an immediate impact on medical diagnosis, and the associated science of radioactivity soon was felt within therapeutics. Significantly, perhaps, the pioneers of the radioactive phenomena—Roentgen, Becquerel, the Curies—received their Nobel Prizes in physics or chemistry. Hounsfield and Cormack gained theirs for computer-assisted tomography in medicine or physiology. More recently, Kary Mullis's Nobel Prize was for a technological development within molecular biology.

Both medical science and medical practice are now inseparably rooted in technology. So is modern life, another reflection of a perennial historical truth: medical knowledge and medical practice are products of wider social forces with unique historical individualities.

When Henry Dale, the distinguished British physiologist and pharmacologist, arrived at St Bartholomew's Hospital as a medical student in 1900 he was told by his first clinical teacher, Samuel Gee, that, as medicine was not a science but merely an empirical art, he must forget all the physiology that he had learnt at Cambridge. This advice reflects a deep-rooted tension between the art and science of clinical practice, which still permeates the medical profession.

Patient care, from its earliest beginnings to the present day, has always been a mixture of sympathy and kindness backed up with a well-meaning but often empirical effort to alter the natural course of events. In this sense it has been, and still is, an art, practised against a background of incomplete scientific knowledge about the nature of disease processes. Human beings, like all living things, are immensely complex biological systems. Even today, with all our knowledge of their chemistry and physiology, we have a very limited understanding of the mechanisms that underlie most of the diseases that we encounter in day-to-day practice. Caring for sick people involves making considered judgements based on limited evidence and information. At best, we are slowly reaching the stage at which we are aware of how little we know.

In view of the remarkable progress in the biological sciences over the last few hundred years, today's doctors must try to establish the extent to which the balance of medical practice has shifted from 'craft' to 'science'. How far do the contents of a modern textbook of medicine reflect genuine scientific knowledge as compared with received wisdom and experience? And, of particular relevance to current medical practice and its future development, to what extent have advances in patient care in the twentieth century depended on progress in the basic sciences rather than improvements in our environment and lifestyles? In short, how much of our day-to-day clinical practice depends on a scientifically based understanding of the diseases that we encounter? It is important that we address these questions at a time when there is growing public and governmental disillusion with high-technology scientific medicine, and when many believe that the medical profession has lost its way and become more interested in diseases than in those who suffer from them. Before we tackle these difficult questions it may be helpful to define what we mean by 'scientific medicine' and to outline the way in which it has developed over the years.

Philosophers and historians of science and medicine always seem unhappy when it comes to deciding what is meant by 'scientific medicine'; this is dangerous country for the unwary! Here we shall take a pragmatic (if circular) approach, and use the term simply to describe the prevention and management of illness using methods that have been subjected to the same kinds of rigorous experimental, statistical, and observational scrutiny that are applied in other branches of science.

The earliest documentary evidence to survive from the ancient civilizations of Babylonia, Egypt, China, and India suggests, not surprisingly, that longevity, disease, and death are among our oldest preoccupations. From ancient times to the Renaissance, knowledge of the living world changed very little and the distinction between animate and inanimate objects was blurred. The Babylonians and Egyptions believed that water, air, and earth were the primary constituents of the world; a fourth, fire, was added later. This notion of the all-pervading influence of the four elements was extended to form a theory about how the human body is constituted. In short, it was thought to consist of four humours, blood, phlegm, yellow bile, and black bile. The notion that disease results from an imbalance of the humours permeated Graeco-Roman medicine and persisted until the seventeenth century. Health was viewed as a harmonious balance of the humours, while disease was thought to reflect an imbalance, or dyscrasia, leading to an abnormal mixture of the humours. This view of pathology, which provided an explanation for both mental and physical illness, formed the basis for what, at the time, was a rational approach to treatment by bleeding, purging, and dietary modification.

The extraordinary developments in natural philosophy in the seventeenth century created an environment that led to the birth of scientific medicine as we now understand it. Modern physics was founded by Isaac Newton, and the work of Boyle and Hooke finally disposed of the Aristotlean elements of earth, fire, and water. The shape of medical and biological thinking was moulded by the French mathematician, philosopher, and biologist René Descartes, who held that material things, whether animals, plants, or inorganic objects, are ruled by the same mechanical laws. All living things, he held, can be looked on as machines. A sick man is like an ill-made clock; a healthy man a well-made clock. And it was during this time that William Harvey published an almost complete description of the circulation of the blood, work that involved many years of animal experimentation and the application of simple statistical methods to determine the output of blood from the heart, and which, in effect, formed the foundation for modern investigative physiology and, later, medicine.

During the eighteenth and nineteenth centuries, the sciences that underpin medicine were further developed. In particular, the concept of the cell became the centrepiece of biology. As perceived by the French Nobel laureate, Francois Jacob, 'with the cell biology discovered its atom'. In 1858 Rudolph Virchow published his celebrated *Die Cellular Pathologie*, in which cell theory was applied to the study of pathology. All diseases, he held, are diseases of cells. This was the dawning of modern cellular pathology and the study of disease at the microscopic, and later submicroscopic, levels. The nineteenth century also saw the gradual decline of vague theories about life forces and a growing belief, helped by the emergence of organic chemistry, that living processes can be understood in terms of chemistry and physics working through complex interactions between the many different types of cells that constitute all living things, a movement that was to culminate in the extraordinary achievements in biochemistry and molecular biology in the twentieth century.

This was also the time when a start was made at assessing the value of therapeutic practices that had gone on largely unchanged for centuries. For despite these rapid advances in the biological sciences, very little could be done for the majority of the disorders that doctors faced in everyday practice. Blood letting and the administration of a variety of useless and potentially harmful treatments were still rife, and although a few drugs of genuine value had been found, foxglove extract and quinine for example, much of the doctors' armamentarium was of unproven value. In the mid-nineteenth century a French clinician, Pierre Charles Alexandre Louis, pioneered the application of statistical analysis to medical practice. One of his earliest ventures was to compile sufficient data to prove that blood letting, which had been practised for centuries, was not only useless but positively harmful in the management of many diseases. During the latter half of the nineteenth century the focus of medical science moved from France to Germany. It was here that, during the late nineteenth and early twentieth centuries, laboratories were set up where men and women could devote their time to research in the blossoming basic sciences, anatomy, physiology, and, later, biochemistry. In this atmosphere a new generation of clinical scientists evolved who became interested in physiological medicine, that is in understanding the fundamental mechanisms of disease.

These developments led to the establishment of university medical schools in the United States and parts of Europe, based on the German tradition. In 1910 the American educationalist Abraham Flexner, after visiting several German medical schools, wrote a withering critique of medical education and science in North America. This attack stimulated the development of specialist clinical departments in many American and European medical schools. Flexner's revolutionary study advocated that medical education should begin with a strong foundation in the basic sciences followed by the study of clinical medicine in an atmosphere of critical thinking and with adequate time and facilities for research. His philosophy was widely accepted, not only in North America but in many European medical schools.

The development of university clinical academic departments in the period between the two world wars, and particularly after the second, led to the emergence of 'clinical science', experimentation on patients or laboratory animals on problems that stemmed directly from observations made at the bedside. Ultimately, this led to a remarkable improvement in our understanding of disease mechanisms. Together with the expanding pharmaceutical industry, it set the scene for the development of modern, high-technology medical practice. Not surprisingly, it also had a profound effect on medical education. Indeed, those who criticize modern methods of teaching doctors, in particular the Cartesian approach to the study of human biology and disease, believe that the organization of university clinical academic departments along Flexner's lines may have done much to concentrate the minds of doctors on diseases rather than those who suffer from them.

The twentieth century has seen a revolution in the basic sciences, which started in physics, spread to chemistry, and, ultimately, completely changed the face of biology. Remarkable developments in physics at the end of the nineteenth century paved the way to an understanding of how atoms are joined together to form molecules and for the development of a new kind of chemistry, which would start to explain the structure of the molecules that make up living things. The amalgamation of physics and chemistry spawned a new discipline, molecular biology, which was to unravel the way in which genetic information is passed from generation to generation and how individual cells function, both as self-contained units and as part of the complex communication network which is the basis of life itself. In the last 20 years there has been a slow shift of emphasis in medical research from the study of disease at the level of patients or their diseased organs to their cells and molecules. Although major scientific achievements do not always have practical benefits for many years, it is already apparent that molecular and cell biology have enormous potential for the future of medical research and practice.

There is no doubt that a combination of improvements in the environment combined with the fruits of scientific medicine have greatly improved the health of Western

industrialized societies. In England a century ago, four out of ten babies did not survive to adult life, the life expectancy at birth was only 44 years for boys and 47 for girls, and even as recently as the 1930s 2500 women died each year during pregnancy or childbirth. Today, life expectancy at birth is about 73 years for boys and 78 years for girls. The major triumph for scientific medicine and public health has undoubtedly been the control of many infectious diseases. Consequently, the proportion of deaths due to infection and respiratory diseases has declined dramatically and the major causes of mortality in the West are now vascular disease and cancer. Although relatively little progress has been made towards their prevention, their management has been transformed by the ingenuity of the pharmaceutical industry combined with development of high-technology medical practice based on a better understanding of disease mechanisms.

Modern scientific medicine is not without its detractors however. Early this century George Bernard Shaw, in his brilliant Preface to *The doctor's dilemma*, derided medical research of his time. His cry 'stimulate the phagocytes' came straight from the laboratory of Almroth Wright at St Mary's Hospital Medical School. But this work was written with style and humour and was concerned mainly with debunking the pomposity of the medical profession. This was not the case in the book, *Medical nemesis*, written by the philosopher and theologian Ivan Illich, which first appeared in 1975. Using a mass of statistics, Illich set out to show that modern medical practice in general, and scientific medicine in particular, has had no effect whatever on the health of society. His thesis holds that common infections such as tuberculosis and poliomyelitis were disappearing long before the advent of antibiotics and vaccines, and, even worse, that modern medicine is a threat to society as well as to individual patients. It is, he believes, more harmful than good because it generates demands for its services and encourages aspects of behaviour that lead to more ill health and reduce our ability to cope with illness and to face suffering and death. Illich concludes that the medical profession, at least in its present form, should be disbanded.

A series of much more thoughtful critiques of modern medicine were published in the late 1970s by Thomas McKeown and others. McKeown extended Illich's thesis that the advent of vaccination, immunization, and antibiotics has had little effect on the control of infectious disease. He argued that the dominance of the mechanistic approach to the problems of disease, which started in the seventeenth century, had caused doctors to overlook important messages that the patterns of disease origins in the past had left for them, and that it had led them to underestimate their potential value for the organization of health care in the future. McKeown believed that the vast majority of diseases are environmental in origin and that if we had been thinking of disease origins rather than mechanisms it would not have taken us so long to suspect the importance of environmental agents or lifestyles in the genesis of our current killers, smoking or lack of exercise as the cause of heart disease for example. In short, writers like Illich and McKeown believe that, because practically all disease stems from the environment, modern scientific medicine, with its accent on disease mechanisms rather than origins, has had little effect on the health of society. While flawed in many ways, particularly with respect to their lack of appreciation of the relative roles of nature and nurture in the genesis of disease, arguments of this kind have had an important influence on current perceptions of the role of science in medicine.

These criticisms of modern scientific medicine have been mirrored by increasing disenchantment with modern medical practice on the part of the public, media, politicians, and even some doctors themselves. Paradoxically, the origins of this mood of disillusionment can be traced to some of the extraordinary successes of scientific medicine earlier this century. In the period after the Second World War, which saw the emergence of vaccines and antibiotics and the control of many infectious diseases, it appeared that medical science was capable of almost anything. The virtual disappearance overnight of scourges like smallpox, diphtheria, and poliomyelitis led to the expectation that similar successes would soon follow. In effect, society came to expect a state of constant rude health as its right. But this did not happen. The diseases that replaced infection, heart attacks, strokes, cancer, rheumatism, and psychiatric disorders, turned out to be much more intractable. Granted there were some remarkable advances in their symptomatic control, but these new killers could not be prevented or cured. As this became clear there was a move on the part of society to alternative medicine; if medical science could not cope with chronic backache or lung cancer why not turn for help to those who claimed they had the answers? Dietary manipulation, food allergy, herbal remedies, and a variety of other approaches to chronic illness were taken up with enthusiasm.

Yet coincident with this disillusionment with modern medicine and the search for better alternatives, it became apparent that the revolution in the biological sciences, stemming from applications of molecular and cell biology, promised to change completely the face of health care in the future. Today, hardly a week goes by without a new breakthrough being splashed all over our television screens and newspapers; another human gene has been isolated and the cause of a disease of which we have never heard is announced. New cures for heart disease or cancer appear to be just round the corner. Whenever these new remarkable discoveries are announced, excited scientists or journalists tell us that they will have a major impact on health care 'within the near future'. Yet time goes by and this doesn't seem to happen. There is a growing feeling that much which goes on in modern science is motivated more by scientists' wish for self-glorification rather than by any practical goals. Furthermore, many believe that modern science, whether it involves the manipulation of human genes or enquires into the origins of the universe, is a debasing activity that is damaging our environment and moving into areas of knowledge that are best left alone. There is a growing fear about the increasing reductionist approach to medical research. This, combined with concerns about the dehumanizing effect of modern hospitals and the feeling that doctors must return to a more holistic approach to their patients, that is to treat them as individuals rather than diseases, is causing increasing concern to our medical educationalists.

Clearly, younger readers of this book are learning their trade at a time when the whole ethos of scientific medicine is being questioned, and when thoughts are turning more to preventive medicine by modification of our environment and lifestyles, with less emphasis on understanding the basic mechanisms of disease. What are they to make of this confusing scene?

In effect, the doctors of today find themselves in a similar position to their predecessors at the beginning of this century. It was already apparent that many of the infectious diseases that were killing their patients could be partly controlled by better housing, hygiene, and other improvements in the environment; a few could be prevented by vaccination. Yet it was far from clear how far measures of this kind would be successful in controlling these diseases. In the meantime there was little that they could do for their patients with tuberculosis, meningitis, poliomyelitis, or puerperal sepsis, except improve their general well-being and manage their symptoms. They knew that there were some exciting developments in the basic biological sciences, microbiology, and, in particular, immunology, which promised to provide the solution to their problems. Yet these fields had been on the move for over half a century and still appeared to be of limited practical value. Hopes for the development of a cure for tuberculosis, following Koch's discovery of the tubercle bacillus in the 1880s, had still come to nothing. In the event it was to be another 60 years before the discovery of streptomycin provided a definitive cure for tuberculosis.

The situation is more or less the same today. We know that we can reduce the frequency of heart disease and cancer by changes in our environment and lifestyles, stopping cigarette smoking for example. But we have no idea of the extent to which we can control our major killers. For this reason it is essential that we continue to support the basic sciences and to provide the doctors of the future with sufficient understanding of them so that, as practical applications come along, as they certainly will, they are in a position to take advantage of them. If the story of the development of scientific medicine from the seventeenth century onwards has anything to tell us, it is simply this. The bulk of our major advances in health care have stemmed from advances in both public health and scientific research, the latter quite often stemming from fields that were driven by curiosity rather than any practical end in view. Harvey's discovery of the circulation of the blood had no practical value for patients with heart disease at the time; it was to be several hundred years before advances stemming from the disparate sciences of physiology, anatomy, pharmacology, and biochemistry, together with the discovery of anaesthesia and remarkable developments in surgical technology, laid the ground for modern cardiological practice. We must not neglect the role of the basic sciences in medical education and practice simply because they do not appear to have any immediate benefits.

As scientifically trained clinicians we try and analyse our patients' illnesses as far as we can with the tools of modern medical science, but frequently we find ourselves in a situation in which knowledge is incomplete and some form of therapy, even if it is of unproven value, has to be tried. The further scientific knowledge increases, the more difficult it is for caring clinicians to dissociate their scientific training from the practical necessity of doing something to relieve suffering, even though they are aware that they are rarely sure about what they are doing. Medicine has remained an art, but one that has become increasingly difficult to practise as knowledge of the scientific ignorance that underlies it has increased. The central problem for those who educate doctors of today is, on the one hand, how to encourage a lifelong attitude of critical, scientific thinking to the management of illness, yet, at the same time, recognize that moment when the scientific approach, because of ignorance, has reached its limits and must be replaced by sympathetic empiricism. Doctors have to learn to live with uncertainty. For many, this can be one of the most difficult and disturbing aspects of their work.

Textbook descriptions of disease are, of necessity, misleading. Even in the case of the most straightforward of illnesses, for which we know the cause down to the last building-block of DNA, the presentation, course, and management is never the same in any two patients. Not only are they modified by the protean physiological adaptations that occur in response to disease, but also by an individual's reaction to illness, depending on their personality, degree of family support, and many other factors that we do not understand. If, as is frequently done in our better teaching hospitals, we attempt to analyse all the features of a patient's illness and explain them in terms of current scientific knowledge, we always fail. And because we know so little about the mechanisms that underlie most of the illnesses that we encounter, a great deal of what we do must still remain empirical. It is the sheer complexity of the manifestations of illness that is responsible for the notion that medicine is still an art. And if this is the case for the relatively well-defined diseases that we see in hospital, the situation is even more complex in the community. The bulk of a family doctor's work involves non-specific complaints that seem totally foreign to anything that they learnt in the laboratory or lecture theatre as a student, often reflecting an individual patient's reactions to stresses of work, family, and environment rather than clearly defined organic disease.

Thus, apart from pastoral qualities, good doctoring requires an ability to cut through many of the unexplained manifestations of disease, to appreciate what is important and what can be disregarded, and hence to get to the core of the problem, knowing when scientific explanation has failed and empiricism must take over. This is the real art of clinical practice. It comes naturally to some doctors, but for others the difficult transition from theory to practice, from the relative certainty of the preclinical sciences to complexities of sick people, is never quite accomplished. This may be the reason for the notion that good medical practice depends more on the acquisition of experience based on long years of practice, rather than on methods of prevention, diagnosis, and treatment based on sound scientific principles. Unfortunately, this view, which may partly reflect doctors' defence mechanisms against continued ignorance, has been responsible for a great deal of poor practice, often based on fashion and anecdote rather than anything more substantive. An overexaggerated perception of the importance of medicine as a craft may also have been responsible for the dogmatism, unhealthy respect for received wisdom of the past, and extreme pomposity that has characterized many aspects of medical practice over the years. Like most human endeavours, the art of medicine has both its good and bad aspects.

In 1941 Sir Arthur Hall wrote:

> Medicine—however much it develops—must always remain an 'applied science' and one differing from all the rest in its applications to man himself. Were there no sick persons there would be no need for Medicine, either the Science or the Art. So long as there are both, both will be necessary. The application of its Science, to be of value, must be made in such a way that it will produce the maximum relief to the sick man. This calls for certain qualities in the practising physician which differ entirely from anything required in the practice of the other applied sciences. Herein lies the Art of Medicine. The need for it is as great today as it ever was, or ever will be, so long as human sickness continues.

As we have seen, our greatest difficulty is to recognize that moment in caring for a sick patient when the scientific approach, because of ignorance, has reached its limits and has to be replaced by sympathetic empiricism. It is the ability to choose that moment, partly by instinct and partly by experience gained by caring for sick people, that is the main characteristic of a good doctor. Undoubtedly, modern medical science, with its increasingly reductionist approach to the study of disease, has tended to focus our attention more on disease mechanisms than on those who are suffering from the diseases that fascinate us so much. We must redress this balance, and return to a more holistic approach to medical care, without, at the same time, allowing ourselves to develop those uncritical attitudes and reliance on received wisdom which permeated the medical profession for so many centuries. For genuine advances in medicine have stemmed from science, as defined at the beginning of this chapter, regardless of whether it involved cells and molecules, or people and populations.

2.3 Medical ethics

Edmund D. Pellegrino and Daniel P. Sulmasy

Introduction

Clinical ethics, like all ethics, is a practical discipline. Whatever theory it employs, its ultimate aim is a morally defensible decision that is in the patient's best interests. This was the central moral precept of the Hippocratic oath:

> I will follow that system of regimen which, according to my ability and judgement, I consider for the benefit of my patient and I will refrain from whatever is deleterious and mischievous.

Today, this is known as the principle of beneficence, which derives its moral force from the special nature of the relationships between sick persons and health professionals. When patients seek help they are anxious, often in pain, fearful, dependent, and therefore vulnerable and exploitable. In that state, physicians ask then, 'How can I help you?' By that act physicians invite the patient's confidence and trust that they are competent and will use that competence primarily in the patient's interests.

The relationship is therefore not a contract but a covenant of trust, to which physicians must be faithful even if it means some suppression of their own self-interest. The good of the patient is thus a moral compass with four directional guide marks for the physician: medical good (competence), the patient's good expressed in his own preferences (respect for autonomy), the patient's inherent good as a human being (respect for dignity), and the patient's ultimate good (respect for spirituality). To act for the patient's good requires integration of these four elements on behalf of this person who presents as my patient now.

This chapter concentrates on the questions that must be asked, and the conditions that must prevail at the bedside to assure that each of the four levels of the patient's good is attained. Two moral algorithms are provided: one to assess the moral validity of the decision-maker, and the second, to provide a clinical framework or 'work-up' by which to analyse the ethical issues.

Who decides?

Since the good of the patient is far broader than the patient's biomedical good, clinical ethics requires the patient's participation in decision-making. Figure 1 presents an algorithm for determining the morally valid decision-maker. If the patient has sufficient decision-making capacity, the patient is the ultimate decision-maker. If the patient's decision-making capacity is variable, the physician should be guided by the last decision made when the patient was capable. If the patient has never had decision-making capacity (for example an infant or patient with mental retardation), the physician must turn to a morally valid surrogate. If the patient has lost decision-making capacity in a reversible manner (for example through depression) and it can be restored through medical treatment in a timely manner, the decision should be postponed until the patient is treated and capacity restored. If the loss of capacity is irreversible or the decision too urgent, the physician turns to any anticipatory declarations by the patient such as a living will, or the designation of a surrogate decision-maker through a legal document such as a durable power of attorney for health care. Lacking these expressions of the patient's prior wishes, the physician must engage a morally valid surrogate, that is, someone who can responsibly and knowledgeably represent the patient's wishes, and who has intact decision-making capacity and is free of significant conflicts of interest.

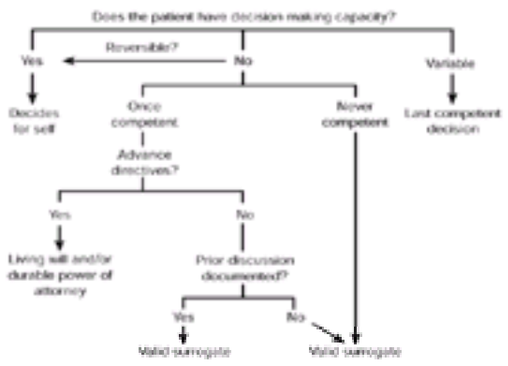

Fig. 1 Who decides?

Decision-making capacity

Accurate determination of a patient's decision-making capacity is an essential clinical skill. In North American jurisprudence, the term 'incompetence' refers to a judge's decision that an individual has lost all capacity to make decisions. The physician, however, is concerned with a narrower question: is this patient capable of making a decision about *this* clinical option in these particular clinical circumstances? The threshold of capacity will vary according to the gravity of the decision. For example, a patient suffering from suicidal depression might be allowed to refuse venepuncture, but not be allowed to sign out of the hospital against medical advice. Psychiatric consultation is often important, but the determination of decision-making capacity is generally the responsibility of the attending physician. The criteria for decision-making capacity are as follows.

1. What is the patient's neurological status? If the patient is profoundly delirious, demented, obtunded, or aphasic, the patient will not have the capacity to participate in medical decision-making.
2. Does the patient have intact judgement? That is, is the patient free of impulsiveness, able correctly to assess the seriousness of situations, to plan, and to appreciate the connections between acts and consequences?
3. Does the patient understand the nature of the procedure, its risks, benefits, and the consequences of deciding either to accept or to forgo the procedure?
4. Can the patient explain the reasons for a decision in a way that is logical and also consistent with his or her life history and previously held values?
5. Does the patient's decision remain relatively stable over time? Patients must certainly be free to change their minds, but a patient whose decision vacillates minute to minute or who refuses to make any decision may not have intact decision-making capacity.

Informed consent

Every physician must be able to obtain a morally adequate informed consent. This is not synonymous with obtaining a signature on a piece of paper. Informed consent is a process. It is one of the fundamental ways in which the physician shows respect for the good of patients as whole persons.

There are four basic elements in informed consent. The first is that the patient must have decision-making capacity. The rudiments of how to assess decision-making capacity were described above.

Second, the decision by the patient must represent an autonomous authorization, that is, it must be free from coercion, or even subtle manipulation by the physician or by others. Information must be presented in a fair and balanced fashion. This does not imply absolute neutrality nor does it imply that the physician cannot make a recommendation or even try to persuade a patient if the physician thinks the patient is making a mistake. But a physician ought not, for instance, purposefully distort the facts or threaten to sever the physician–patient relationship if the patient does not follow the physician's advice.

Third, all relevant information must be disclosed to the patient. The content to be disclosed should generally include the indications and the nature of the procedure, its potential benefits and risks, and the alternatives, including not having any procedure.

The final element of informed consent, but certainly not the least, is comprehension. The patient must not merely have been told; the patient must understand. The common clinical practice of asking, 'Do you have any questions?' is probably inadequate. If one is seriously interested in being sure that the patient has understood, it is better to ask the patient to explain back in his own words the information just disclosed.

Limits to autonomy

While the good of patients as autonomous agents must be respected, patient autonomy is not absolute. Autonomy is limited, for instance, when there is a probable threat of serious injury to an identifiable third party or parties. An example would be a demand for confidentiality by a patient testing positive for HIV who refuses to tell a sexual partner. Autonomy is further limited by the intellectual integrity of medicine as a practice. For instance, a patient cannot demand a treatment that has been proved ineffective, such as laetrile for cancer. Autonomy can also be limited to protect public health, such as in mandatory vaccination in an epidemic of a lethal infection. Finally, autonomy is limited when it violates the moral integrity of health care professionals as individual moral agents whose freedom of conscience must not be violated; for instance, a physician opposed to euthanasia ought not be forced to comply with a patient request even in settings where this is legal.

The ethics work-up

Once the appropriate decision-maker has been identified, and the conditions for autonomy assured, the physician must turn to analysis of the ethical dilemma and its substantive resolution. Ethics committees and consultations sometimes help, but ultimately clinicians are accountable for what they do or agree to. Every clinician is obliged to master the 'work-up' of the ethical problems just as surely as that of a clinical problem like coma, jaundice, or oedema.

The analytical approach we use consists of the following seven steps.

1. Secure the facts

Good ethics begins with reliable clinical and social data, with as accurate an assessment as possible of factors such as diagnosis, prognosis, effectiveness, benefits, burdens of treatments, brain function, patient preferences, and life situations. Each and all may be ethically relevant.

2. Define the ethical issue

The specifically ethical issue must be identified among the communication, interpersonal, and interprofessional problems, which usually intermingle, especially when conflicts arise. The first step in resolving conflict is clarity in the statement of the issues.

3. Frame the issue

By applying generally accepted ethical principles, one can better understand the important moral dimensions of the issue. These principles are: (i) preservation of the good of the patient as a whole person (the principle of beneficence), and (ii) respecting the good and interests of others (the principle of justice). Beneficence for persons, as noted above, demands an examination of all four aspects of the patient's good—the biomedical good, the good of the patient's autonomous choices, the patient's good as a person, and the patient's own beliefs about the ultimate good. So, for example, a severely anaemic Jehovah's Witness might refuse blood transfusion. Transfusion would serve the biomedical good of the patient, but it would violate the patient's autonomy and idea of the higher or ultimate spiritual good. Or a patient's family might demand continued treatment in the intensive care unit when such care was futile or unnecessary. This might impede other patients' access to intensive care and thus violate the principle of justice.

4. Situate the issue

It is helpful to place the case in relation to one's personal experience and that of the profession. This method of moral analysis is called 'casuistry' and asks whether the case at hand is analogous to any paradigmatic case for which a broad moral consensus has been reached. If so, one could reason by analogy to that case. For example, consider a novel case, such as whether one ought to allow a prisoner who has donated one kidney to his daughter to donate his remaining kidney to her after she has rejected the first kidney. It is useful to ask how this case compares with a more familiar case in which there is a broad moral consensus. For example, this case might be likened to the case of a man who jumps in front of a car to save his daughter's life. Such a man would be considered a hero. Casuistic analysis would ask how analogous these cases really are. What is the same about these two cases? What is different? What is the moral relevance of any similarities or differences?

5. Identify the options

In almost every case, a variety of clinical options are possible. Ethics involves selection of the morally correct choice. It is therefore necessary that all the available clinical options be identified and considered from a clinical as well as a moral point of view. This is where the technically correct and the morally good should intersect for the patient's good.

6. Reason

It is important is to weigh all the facts of the case critically and rigorously in light of one's ethical framework and clinical experience. One must interrelate the facts, the relevant principles, and any paradigm cases. Physicians should also play 'devil's advocate' and examine possible objections to their own positions. They should seek colleagues' input if time permits. An ethics committee or an ethics consultation service may be useful at this juncture. Once resolved, a retrospective critique of the reasoning employed in the case is helpful in preparing for the next time such a situation arises.

7. Decide

In clinical ethics, as in all other aspects of medicine, a decision must be made. Taking all of the aforesaid into account, a choice must be made even in the throes of uncertainty. There is no formula that guarantees the right choices. The answer will require a judicious combination of clinical judgement, practical wisdom, and common sense. In the final analysis, the decision rests with the physician's character and commitment to the good of the patient.

The ethics of end-of-life care

The most common ethical issues faced by clinicians arise at the end of life. Here the good of the patient might include decisions to withhold and withdraw life-sustaining treatments, decisions not to resuscitate, and the use of potent opioid analgesics that may hasten death.

The moral propriety of withholding or withdrawing life-sustaining treatment may be analysed systematically by examining the proposed treatment for its effectiveness, benefit, and burdens. Effective treatments are those that alter the natural history of an illness or alleviate an important symptom. Hippocrates counselled that physicians should 'refuse to treat those who are overmastered by their diseases, recognizing that in such cases medicine is powerless'. When, to a reasonable degree of medical certainty, it can be determined that a treatment will not be effective in securing the goals of treatment mutually determined by the medical team and the patient or the patient's surrogates, that treatment can be called clinically ineffective or 'futile'. In general, there is no moral obligation to provide futile treatment, although allowances must often be made for the psychological unpreparedness of the patient or family to accept the idea of futility.

If it is determined that a medical treatment is biomedically effective, the next question is whether it is beneficial. Beneficial treatments are those that bring some good to the patient beyond the biomedical good. Beneficial treatments serve not only the body, but the good as the patient chooses it, the good of the patient as a human person, or the patient's ultimate sense of the spiritual good. For instance, antibiotic treatment of pneumonia in a patient dying of malignancy might be effective, but it might not be beneficial if it merely postpones dying when the patient sees no benefit in it.

Both the effectiveness and benefits of a treatment must be weighed against their burdens—physical, financial, or emotional. When the burdens are disproportionate to effectiveness and benefits, treatment can be withheld or withdrawn. Planned re-examination of the three variables at previously agreed time intervals will avoid much of the confusion that surrounds do-not-resuscitate orders. Cardiopulmonary resuscitation is a treatment which is ineffective, burdensome, and without benefit in many terminally ill patients. When this is the case, a do-not-resuscitate order is morally licit.

It is incontrovertible that there is a moral mandate to treat pain. None the less, some physicians might hesitate to do so adequately because there is a risk that this might unintentionally hasten the death of the patient. The centuries old Rule of Double Effect may be invoked in such cases. According to this rule, a physician completely opposed to euthanasia can act with clear conscience in administering a drug like morphine to a dying patient if several conditions are met. First, the physician must sincerely intend pain relief, not the death of the patient. Second, the dose must be consistent with a plan to relieve pain through the analgesic effects of morphine, not through causing respiratory arrest and death as the means of relieving pain. Finally, the need for pain relief must be great compared with the risk of respiratory arrest and death in that patient. For example, if a patient is dying of metastatic breast cancer and is in severe pain, the potential benefit of intravenous morphine would seem overwhelming compared with the small risk that morphine might contribute to hastening an already imminent death. If these conditions are fulfilled, a physician should be able to control pain with a clear conscience, even knowing that death may unintentionally be hastened as a side-effect.

At present, these is significant controversy about whether physicians should be authorized to hasten the death of the patient intentionally through euthanasia or assisted suicide, actions not permitted by Western medicine since the Hippocratic ethic became dominant many centuries ago. Legal bans on these practices are being challenged through legislative initiatives and civil suits. Almost all professional organizations remain opposed.

Conclusion

This chapter has focused on the heart of clinical ethics, that is, acting for the good of the patient. This is the physician's central moral obligation, from which he cannot be relieved since he is bound in a covenant of trust to respond to the sick person who is in need of his medical knowledge.

We have illustrated this moral theme by analysing the four levels of the good of the patient at the bedside in several ways: first, through defining the appropriate decision-maker, the assessment of capacity, and the elements of informed consent; second, through the explication of an ethical work-up for specific cases; and third, by analysing several important ethical decisions in caring for patients at the end of life.

We acknowledge the great importance of many emerging ethical issues such as those raised by genetics, preventive medicine, and information technology. We also recognize that many ethical issues now arise in the context of team care, cost containment, managed care, and in organizational settings in which the physician is simultaneously an employee, a manager, and perhaps even an investor. These issues are too important for superficial treatment. We would only point out that in these instances too the physician's primary responsibility is the good of the sick person. If physicians default on this commitment, the last moral safeguard of the sick will have been compromised to the peril of us all.

2.4.1 Bringing the best evidence to the point of care

P. Glasziou

> 'You must always be students, learning and unlearning till your life's end'.
>
> Joseph Lister

Imagine you, rather than your patient, have just been diagnosed with a serious cancer outside your field of specialty. Wouldn't you prefer that your oncologist colleague had ready access to all the relevant clinical evidence, such as the results of the relevant randomized trials? But we know this is difficult. Our textbooks are often out of date, and the relevant trials scattered across the vast ocean of medical literature. This inaccessibility of the best research data at the point of clinical decision-making has consequences for patient care, and has given rise to the discipline of evidence-based medicine.

Definition

> 'Evidence-based medicine is the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients. This practice means integrating individual clinical experience with the best external clinical evidence from systematic research'.
>
> DL Sackett, *et al*. 1996.

History

With basic research continually developing new diagnostic and treatment modalities, we would like to know: what options have been demonstrated to be effective and which is best? These are not new questions. Ambroise Paré faced them in 1536 as surgeon to French soldiers on campaign in Italy. He followed the advice of the most authoritative texts and treated their battle wounds with cautery using 'the oyle the hottest that was possible into the wounds'. However, he eventually ran short of oil and was 'constrained insteed to apply a digestive'. After a troubled night, he awoke to find those he had cauterized in great pain, whereas those he had not were doing well. This accidental experiment changed Paré's and French treatment. In 1747, James Lind more deliberately set out to examine alternative treatments for scurvy: he 'took 12 cases of scurvy on board the Salisbury at sea. The cases were as similar as I could have them'. Housing and diet were standardized. Of the six pairs of sailors, the two assigned oranges and lemons recovered within 3 weeks. Unlike Paré's results, Lind's took several decades to be implemented.

The methods for conducting, and the criteria for assessing, research have been considerably strengthened in the twentieth century. Bradford Hill introduced the randomized trial to medicine: the Medical Research Council trial of streptomycin for pulmonary tuberculosis in 1948. Since then more than a quarter of a million such trials have been conducted. Almost simultaneously, Yerushalmy introduced greater rigour into the evaluation of diagnostic tests by quantifying the accuracy—the sensitivity and specificity—of chest radiograph screening for pulmonary tuberculosis.

Interest in improving clinical evaluation has grown, giving rise to disciplines such as clinical epidemiology and evidence-based medicine, and a flood of clinical research. This is welcome, but has also hampered the dissemination of research results. Medline started in 1966 and currently adds to its 9 million references over 1000 new articles per day (www.nlm.nih.gov/pubs/factsheets/medline.html). Though these are culled from about 4300 journals in 30 languages and 70 countries, it is only a modest portion of the estimated 13 000 to 14 000 biomedical journals currently being published. No clinician's reading time is sufficient to keep up with this flow directly.

Keeping up to date: two strategies

So how can we cope with our information overload? Fortunately, most of the published information is not sufficient to alter clinical practice: much is 'scientist-to-scientist' communication directed at unravelling mechanisms; and many of the clinically relevant studies are not of adequate quality. Thus filtering for quality and clinical relevance reduces the flow to a manageable trickle as illustrated in Fig. 1.

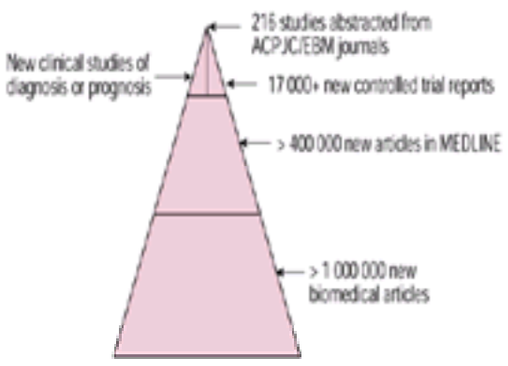

Fig. 1 The yearly flow of new biomedical publications.

There are two complementary ways of obtaining this filtered information. First we need to keep abreast of major new studies that should alter our clinical practice. However, rather than trying to scan hundreds of journals ourselves, it is wiser to enlist a group of our peers to do this. For example, journals such as the *ACP Journal Club*, *Evidence-Based Medicine*, and *Evidence Based Mental Health* review over 100 journals and appraise the articles for the quality of the research methods (less than 1 in 20 pass), relevance, and interest in order to identify new studies that could change the way we practise. The best systematic reviews and studies are reabstracted and an expert commentary helps place the new data in their current context.

The second, and more radical, process is to formulate and answer clinical questions as they arise with our patients. This is a 'just-in-time' approach: instead of trying to keep up to date with all areas of clinical practice, hoping that we have read and remembered the correct articles when we need to apply them, we shift focus to answering questions as they arise. This implies being able to say 'I don't know' and adding 'but I will find out!' When a problem appears, we formulate an answerable question, devise an information-gathering strategy, appraise the information achieved, and take it into account when deciding treatment with our patient. Learning

becomes an active, integral, and daily part of clinical practice.

Asking clinical questions

Answering patient-stimulated questions is unlikely to be done unless we can do it rapidly: finding the information in about 30 s and assimilating it within a couple of minutes. This sounds formidable, but has been shown to be feasible. In many ways it is similar to looking up drug doses: the information must be available in our consulting room, it must be well indexed, and the presentation must be readily usable. Currently none of the continually updated evidence-based resources is as comprehensive and rapid as a pharmacopoeia, and we need some skills to navigate those available.

The steps in answering clinical questions are: (i) formulating an answerable question; (ii) formulating an information-gathering strategy; (iii) assessing the quality and relevance of the information retrieved; and (iv) applying the results to our patient. To illustrate these steps consider the following patient:

Case 1. A 74-year-old man presents with his second episode of trigeminal neuralgia. As with the previous episode, he is is managing to control the pain with carbamazepine, but is requiring such large doses that he is drowsy throughout the day. He presents asking about alternatives.

In answering questions, it is helpful to classify questions into the types presented in Table 1: differential diagnosis, diagnostic accuracy, prediction/prognosis, and therapeutic effectiveness. For case 1, the issue is therapy, and a useful breakdown of such questions is: the patient, the intervention, the comparison, and the outcome. So with our patient this might be: 'In patients with trigeminal neuralgia is there a single or combined therapy which is as effective as carbamazepine at controlling pain but with less drowsiness?'

Finding answers

For treatment, we would generally first seek the results of randomized controlled trials; if there were several then we should seek existing systematic reviews. If we had answered this question previously, then the stored result would provide the fastest answer. However, since we hadn't, the first try might be *Best Evidence*: the electronic accumulation of the abstracted articles in the *ACP Journal Club* (since 1991) and *Evidence-Based Medicine* (since 1995), with over 1300 studies reviewed. Searching on the term 'trigeminal' within Therapeutics and Prevention yields one abstract (within 20 s). This was a systematic review of anticonvulsants, including carbamazepine: three placebo controlled trials showed that at 5 to 14 days follow-up 56 per cent of patients had improved with carbamazepine compared with 18 per cent with placebo ($p < 0.001$). The absolute response difference is 38 per cent, and hence for every three patients we treat there will be one additional responder (the number-needed-to-treat). This confirms carbamazepine's efficacy, but does not give us an alternative.

The next possibility is the Cochrane Library which contains Cochrane systematic reviews (the Cochrane Database Systematic Reviews, CDSR), other systematic reviews (the Database of Abstracts of Reviews of Effectiveness, DARE), and a compendium of randomized trials (the Cochrane Controlled Trials Register, CCTR) identified in Medline, EMBASE, and the handsearching by contributors to the Cochrane Collaboration. Starting the Cochrane Library CD and searching on 'trigeminal neuralgia' identifies (within 50 s) one Cochrane review (an update of the McQuay article we found in Best Evidence), and 54 controlled trials. Among these are several trials studying alternatives to carbamazepine. First, a 1988 double-blind crossover study showed baclofen significantly decreased pain in 7 of 10 patients, and in an open label study was useful in combination with carbamazepine. Second, a tantalizing but single-arm study suggested that topical capsaicin was quite effective (a Zhang's systematic review of randomized trials demonstrated clear efficacy in diabetic neuropathy and postherpetic neuralgia). Having discussed these options the patient chose to add baclofen and decrease his carbamazepine. This controlled his symptoms without drowsiness, but he later switched to the topical capsaicin which, applied to two trigger points, appeared effective.

The application of results in Case 1 was straightforward, but this is not always so. The process varies depending on the type of question (Table 1) but there are some overall similarities across these. First, is the study's illness group sufficiently similar (it need not be identical) to our patient to justify a judgement that the biological behaviour of the test or treatment would not be importantly different? Second, can we implement the test, measure, or treatment in a sufficiently similar manner? If these are fulfilled, then we need to consider how the individual features of our patient might influence the results. The next two sections look at the application of studies of diagnostic tests and of treatments.

Using the results of diagnostic test studies

Most clinical information is imperfect. This includes the history, signs, and laboratory tests. The simplest demonstration of this problem is the extensive data on the lack of agreement among experienced clinicians about the presence or absence of a clinical sign, and even between histopathologists looking at the same image. The sources of this variation and error may be in the patients, in the instruments, or in the observers. For example, true blood pressure varies considerably, but the measured blood pressure varies even more because of ifferent calibration of instruments, cuff sizes, and clinical skill. While it is important to find ways to reduce this variation by standardization and training, some residual error is inevitable.

With experience we learn, implicitly or explicitly, some simple rules to minimize the problems of error. For example, we learn to repeat unexpected abnormal test results: the majority will have disappeared on a second reading, saving us and our patients much anxiety. Experience also teaches us that test results must be interpreted in the light of the clinical picture, or equivalently that we must combine our estimate of the chance a patient has a disease (the pretest probability) with imperfect information from the test. A test's imperfection can be quantified by two measures: (i) the sensitivity, the probability of a positive test result in someone with the target disease, and (ii) the specificity, the probability of a negative test result in someone without the target disease.

Case 2. A 70-year-old man being investigated for fatigue is found to have an iron-deficiency anaemia. As part of the physical examination you do a HemeSelect (a faecal occult blood test) which is negative. Does this obviate the need for a colonoscopy?

Colorectal cancer is clearly high in the differential diagnosis; investigations of consecutive cases of iron-deficiency anaemia suggest a frequency of between 10 and 20 per cent. Let us say our estimate is 16 per cent for our case. To interpret the HemeSelect result we need to know its accuracy, that is, its sensitivity and specificity. A check of the *Best Evidence* CD provides the necessary information (in less than 30 s)—Allison *et al*. followed over 8000 consecutive people screened with three different faecal occult blood tests, with the gold standard being screen-detected cancers or cancers within 2 years of follow-up (which was 96 per cent complete). This study, which is acceptable according to the criteria in Table 1, tells us that the sensitivity is 69 per cent, that is 69 per cent of patients with cancer will have a positive HemeSelect, and the specificity is 94 per cent, that is 94 per cent of patients without cancer will have a negative HemeSelect.

To apply this to our patient with iron deficiency we need to work backwards from his chance of cancer before the test—see Fig. 2.

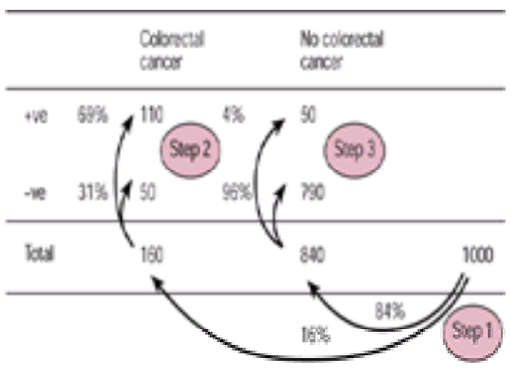

Fig. 2 Breakdown of HemeSelect results for a hypothetical 1000 patients.

Using a hypothetical 1000 patients similar to our Case 2, Fig. 2 works through this probability in three steps.

1. Of the 1000 similar patients, we would expect 160 to have a colorectal cancer and 840 not (bottom row of Table 1.)
2. Of the 160 with cancer 69 per cent (the sensitivity) will have a positive result, that is, 0.69 × 160 = 110 and the remaining 50 will have a negative result (column 1),
3. Of the 840 without cancer 94 per cent (the specificity) will have a negative result, that is, 0.94 × 840 = 790 and the remaining 50 will have a positive result (column 2).

Thus our patient with the negative HemeSelect is among the 50 (false) + 790 (true) negatives, that is, his chance of cancer is 50/(840) = 6 per cent (the post-test probability after a negative test).

We clearly cannot repeat such calculations with every patient, but methods have been developed to simplify the process (see Sackett). However, the important principle illustrated here is the need to use both the clinical picture—quantified as the pretest probability—and the test accuracy. Harold Sox has expressed this succinctly: 'What you believe after the test depends on what you believed before the test'. In particular, it is important not to be misled by false positives when screening; nor to be misled by false negatives when attempting to confirm the most likely diagnosis. Figure 3(a) illustrates this geometrically for our case 2, where even after a negative HemeSelect there is still substantial chance of colorectal cancer, whereas in the screening situation of (b) the positive HemeSelect is more likely to be a false than a true positive.

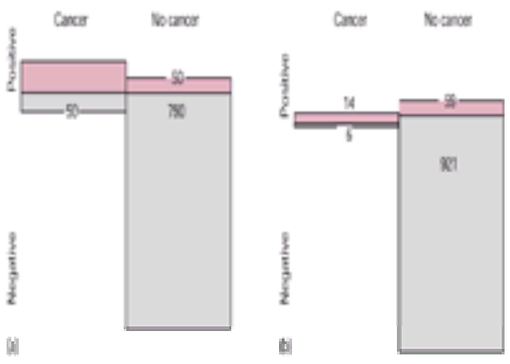

Fig. 3 Interpreting faecal occult blood results in different groups: 2 × 2 tables for (a) patient with iron-deficiency anaemia (16 per cent chance of cancer), and (b) an asymptomatic 70-year-old patient being screened (2 per cent chance of cancer).

Using the results of treatment studies

The overall results of treatment trials apply to the 'average' patient and need to be individualized. If our patient is at a higher or lower risk, then we need to adjust our estimate of the effects of treatment for this. Consider the following case.

Case 3. During a routine check of his blood pressure, a 58-year-old male with stable angina and a history of hypertension was noted to have atrial fibrillation. A check of his chart showed this had been noted several months earlier. Routine investigations revealed no cause, and because of the duration, cardioversion was not warranted. But should he be taking aspirin or warfarin?

The Cochrane Library contains both Cochrane and other systematic reviews of the five relevant randomized trials: warfarin is extremely effective therapy, with a 68 per cent reduction in the risks of ischaemic stroke. However, we must also be concerned about the dangers of antico-agulation— specifically the risks of bleeding, and most crucially the risks of intracranial haemorrhage. Should he be treated? Guidelines seem unhelpful here: a recent review by Thomson showed that the proportion of patients with atrial fibrillation recommended for anticoagulation by the 20 different guidelines ranged from 13 up to 100 per cent!

So how do we apply the systematic review results? The following four questions have been suggested.

1. Is my patient so different from those in the study that the results cannot be applied?

The inclusion and exclusion criteria of clinical trials tell us about the broad category of patients tested in the trials, but are not necessarily a good guide to the applicability of the trials to individuals. A better approach is, first, to think about the potential modifiers of the therapeutic effect, and second, the benefits and harms in the individuals.

The biological effect of an intervention may be modified by several factors: patient characteristics, comorbidities, compliance, or cointerventions. To predict these may require pathophysiological knowledge and empirical data. For example, would a patient with Parkinson's disease having problems with dental hygiene be helped by an electric toothbrush? The randomized trials suggest that certain types of electric brush are clearly better than manual brushing, but did not include patients with Parkinson's disease. However, our knowledge of Parkinson's disease does not suggest there would be any reduction in benefit, and it may be even greater given the effect of bradykinesia on manual brushing.

Treatment decisions must usually balance positive and negative effects of the intervention. For our patient on warfarin the 68 per cent relative reduction in the ischaemic stroke risk must be weighed against the inconvenience of therapeutic monitoring, and more seriously, the risks of major bleeding, particularly the risks of intracranial haemorrhage: an excess of about 1 per cent per year.

2. Is the treatment feasible in my setting?

Barriers to usage include local organization of services, costs, and skills. Patients in remote settings may have difficulty with regular monitoring; service costs and hence access will vary across countries and settings; many new therapies or procedures may require skills or technology that are unavailable, for instance cognitive behavioural therapy is helpful in many conditions but access to a skilled practitioner is often limited. These issues may make the treatment infeasible or threaten the balance of benefits and harms.

3. What are my patient's likely benefits and harms from the treatment?

Low-risk patients usually gain less absolute benefit and high-risk patients more than the 'average' patient in the trials. Hence we need to predict, based on the individual's clinical characteristics, their expected risk. By applying the relative risk reduction seen across the trials, this individualized prognosis can then be used to predict the gains of therapy. Figure 4 summarizes this process. The horizontal axis is the stroke rate per year; the vertical axis is the stroke equivalents prevented by anticoagulation using warfarin. This represents the 68 per cent relative reduction seen across the trials.

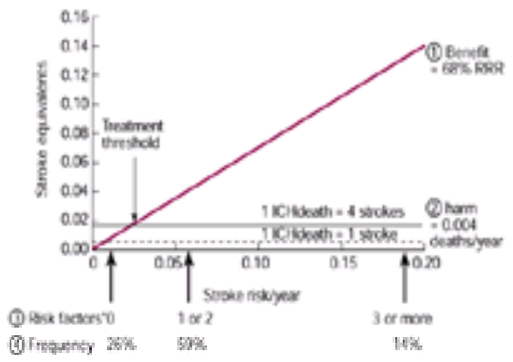

Fig. 4 Warfarin for atrial fibrillation plotting how benefits and harms vary with stroke risk (horizontal axis): (1) Expected benefit from a 68 per cent relative reduction in risk of ischaemic stroke. (2) Expected harms from intracranial haemorrhage: deaths (dashed line) or if one death is considered equal to four strokes (solid line). (3) Predicted risk based on three clinical and two echocardiographic risk factors. (4) The frequency of these risk categories in the Stroke Prevention in Atrial Fibrillation trial.

Where does our patient lie in this spectrum? On the bottom and top axis are marked the clinical risk factors. Our 58-year-old male patient had a normal echocardiogram but ischaemic heart disease and a history of hypertension, and so fitted into the one to two risk-factor category.

4. How will my patient's values influence the decision?

The essence of making wise clinical management is to follow the aphorism of Hippocrates 'Firstly do no (net) harm'. We should now compare the absolute benefits and the absolute harms of therapy, then use the strength of the individual's preferences to weigh these. In large cohort studies of the use of warfarin in the community, the rates of excess intracranial haemorrhage deaths have been about 4 per 1000 per year. This rate is shown as the bottom line in Fig. 4. This line, however, would assume that one death was equivalent to one ischaemic stroke; the line above this values one death equivalent to four ischaemic strokes. The relative value is an individual judgement, but measurements of quality of life in patients after stroke show an average quality of life of roughly 0.75 (on a scale of 0 for death to 1 for normal well health). Where the lines of benefit and harm cross one another, the expected benefit and harms are equal. It is only above this line that we begin to avoid our Hippocratic net harm, and hence the treatment that could be considered worthwhile to the patient, as with case 3.

Conclusions

If we are to advance the use of the best clinical research evidence in patient decision-making then at least two things are required. First, the compilation of the necessary information so that it is quickly accessible by practitioners in the clinic and at the bedside. Answers are needed in minutes not months. The Cochrane Collaboration has gone a long way to achieve this for questions of therapeutic interventions, but similar efforts will be needed for prognosis, diagnosis, and other types of clinical questions. Second, more serious efforts are needed in looking at the applicability and presentation of the results of studies and systematic reviews of studies to allow rapid interpretation and individual application of the results.

2.4.2Evidence-based medicine

*Alvan R. Feinstein**

Evidence-based medicine can be viewed as a novel form of clinical practice, as a special compendium of approved information, or as a revolutionary change in medical education. After all three views are discussed, the rest of this chapter will describe the advantages and disadvantages of the new approach.

Basic views

Each of the three cited views of evidence-based medicine has been often discussed.

'Novel' form of practice

Despite the apparent novelty of the phrase itself, many practising clinicians believe that evidence-based medicine is 'nothing new'. Almost all thoughtful practitioners have regularly assembled evidence when they reviewed their own experience, developed clinical judgement, read medical literature, attended medical meetings, and talked with one another. This activity seems entirely compatible with statements by evidence-based medicine advocates that the information used to practice evidence-based medicine contains 'clinically relevant research, often from the basic sciences of medicine', including studies of diagnostic tests, prognostic markers, and 'the efficacy and safety of therapeutic, rehabilitative, and preventive regimens'. The traditional mode of clinical practice easily seems to fit not only the foregoing description, but also another statement that the practice of evidence-based medicine consists of 'integrating individual clinical expertise with the best available external clinical evidence from systematic research'.

For these reasons, clinicians may not regard the practice of evidence-based medicine as a novelty, and may wonder why it has received so much exhortation and attention. The source of novelty becomes more apparent, however, in the phrase that evidence-based medicine contains 'the best... evidence from systematic research'. Regardless of what might be offered as criteria for what is best or even good evidence, the evidence-based medicine advocates have a clear, unambiguous requirement. The 'gold standard' is 'the randomized trial, and especially the systematic review of several randomized trials'. This constraint on the acceptable 'best evidence' produces the special compendium of information that is the distinctively novel feature of evidence-based medicine.

Special compendium of information

The new journals and books devoted to evidence-based medicine concentrate on data from randomized trials and their meta-analyses (which are sometimes called 'overviews' or 'systematic reviews'). The volume of work and the scope of topics have been prolific. The first pertinent textbook, in 1996, was followed by a series of additional books, all titled as evidence-based topics in clinical practice, general practice, primary care, health care, family medicine, nursing, cardiology, and consultations. The 'evidence-based' prefix has also been applied in titles for individual articles addressing medical education, prescription guidelines, humanitarian relief intervention, organ allocation, budgeting, and health-care reform.

The intellectual centre of evidence-based medicine is the Cochrane Collaboration, based at Oxford and named after the late Archie Cochrane, a pioneering epidemiologist in urging careful evaluation of health-care interventions. The Collaboration, which co-ordinates the activities of acquiring and maintaining the special compendium, comprises an international consortium of research workers who construct an ever-enlarging data base by contributing results of their own randomized trials, by adding discoveries of previously unpublished trials, and by performing the summary aggregations that constitute the meta-analyses. The collected information, which extends through all branches of medicine, becomes the 'best evidence'. It can be published as reports in conventional literary formats or accessed via electronic media, such as the Internet. Coming mainly from activities in clinical epidemiology, the information has sometimes been called 'epi-dense' evidence.

Revolutionary change in learning

A revolutionary change in medical education is produced by the evidence-based medicine demand that clinical decisions be derived from, or sanctioned by, the contents of the new compendium. The new approach drastically alters the traditional pedagogic system in which medicine was learned from presumably knowledgeable personal authorities. They would express their knowledge either in publications or in the direct supervisory instruction given in the distant past to apprentices, and in modern medicine to students, house officers, and fellows. In the education proposed by evidence-based medicine, however, the wisdom and appraisals of a personal expert are no longer encouraged. They are replaced by the meta-analyses and printouts of the evidence-based medicine computer.

A movement that overthrows academic authorities is not a surprising modern development. The urge to purge leaders of the educational 'establishment' began in universities about 30 years ago, provoked by various national and international political discontents, often arising from the war in Viet Nam. Initiated at a time when many current leaders of evidence-based medicine were undergraduates, this drive was later enhanced by four types of new medical events.

One event, at many academic medical institutions, was the exchanging of part-time teaching faculty, who were clinical practitioners in the neighbouring community, for the increasing numbers of full-time faculty, who were clinical investigators. A second event was the reduced clinical expertise of the clinical investigators. Having been chosen mainly for achievements in laboratory research, the new pedagogic leaders were often more knowledgeable about pathophysiology than therapy and patient care. Both of these events tended to remove expert clinical authorities from being readily available in teaching activities.

A third event was the increasing development and use of randomized trials, which were usually applied to demonstrate the efficacy of new therapeutic agents. When older regimens were occasionally tested, however, the trials sometimes produced dramatic contradictions, showing that firmly-held establishment beliefs were either wrong or harmful. Perhaps the most memorable of these refutations occurred in the randomized trial of high concentration oxygen therapy for newborn premature babies. This treatment had been vigorously endorsed by renowned professors of paediatrics, and it was used for more than a decade, particularly at academic medical centres in the United States, for the goal of preventing respiratory distress. About 10 000 infants were permanently blinded with retrolental fibroplasia before the randomized trial ended the 'academic epidemic' by demonstrating that the oxygen, while avoiding respiratory distress, often produced blindness. The results greatly elevated the reputation of randomized trials for resolving controversies about therapy, but sharply diminished respect for academic authorities as sources of wise clinical advice.

A fourth problem was produced by the enormous expansion of technological tests and treatments. A generalist who could formerly keep track of almost all important changes in the field could no longer do so, and became supplanted by an array of specialists in different organ–system domains, such as cardiology. As new information continued to proliferate, the scope of the specialists also became limited. They often could no longer encompass an entire organ system, and became subspecialized in such subdomains as coronary, congenital, rheumatic, or hypertensive heart disease. The expansion and diffusion of domains of expertise would require a large array of individual authorities, not just a few; and all of them would not be readily available for personal consultation at each teaching institution.

In an atmosphere in which personal authorities were often generally viewed with suspicion, sometimes specifically impugned, and seldom always available, the time was ripe for an entirely new system to replace what was derisively called 'eminence-based' medicine. In the new system, the evidence-based medicine compendium

would be the source of 'established wisdom'; and the new authorities would be persons with evidence-based medicine credentials. In medicine, as often in politics, the leaders of the new order would be those who had fomented the overthrow of the old.

Advantages and disadvantages of the new approach

To produce the revolution that would alter long-entrenched patterns of education, the proponents often used extreme vigour and sometimes evangelical fervour in advocating evidence-based medicine and responding to adverse criticism. The zeal itself could evoke either additional admiration or further denunciation. In commenting on complaints, one of the prominent leaders said that 'most of the criticisms have to do with our hubris, style, and conviction'. The value of evidence-based medicine should be judged, however, not by the behaviour of its advocates, but by what it actually does and does not do.

Perhaps the most obvious positive accomplishment of the evidence-based medicine movement is the emphasis on citing explicit data and reasons for clinical decisions. Although this approach had previously been urged for several decades, the renewed demand for citing 'evidence' has helped end the old tradition in which decisions were justified only by non-specific explanations such as 'intuition' or 'judgement'.

A second positive accomplishment has been the demonstration that active clinicians, in an era of extensive and rapid technologic changes, can no longer rely on their previous medical education to provide a permanent basis for clinical practice. Conventional lectures and courses in 'continuing medical education', however, have not offered a satisfactory method to 'keep up' with what is happening. The evidence-based medicine movement has demonstrated a way for clinicians to 'stay alive' by doing computerized searches of accruing literature.

Several other claims of achievement have always been part of good clinical practice, and are not unique to the evidence-based medicine style. Among such claims are the contentions that evidence-based medicine integrates medical education with clinical practice, and that it helps clinicians resist unwarranted pressures.

In the original proposal for evidence-based medicine, a clinical analysis was divided into four main steps. Each step, as discussed in the next four sections, has its own distinctive advantages and disadvantages when conducted with the current evidence-based medicine compendium.

Formulating a question to be answered

The obvious first step in any process of clinical reasoning is to choose a 'prime topic' as the question to be answered. This topic is the doctor's counterpart of the patient's chief complaint. Nevertheless, just as the chief complaint may not always indicate what a patient really wants and expects, the prime topic may not always represent, and may sometimes misrepresent, what is needed for the care of the patient. To be answerable, the chosen question may have to be altered to suit the available data. Thus, the desire to learn about post-therapeutic outcomes, such as relief of symptoms and quality of life, may be diverted to an answer that indicates outcomes such as survival duration and changes in laboratory tests.

A greater, but less apparent, problem is the occasional or frequent mismatch between the available evidence and the nuances of the individual clinical situation. Most published reports of treatment, whether observational studies or randomized trials, will contain results for a stipulated therapy given to patients with a stipulated baseline clinical condition. The stipulations, however, may not include important details—such as concomitant therapy, comorbidity, severity of illness, and functional status—that distinguish the particular patient for whom the question is being asked. The general answer, reflecting results for the larger total group of patients who were treated for the condition, may not be pertinent for the patient's individual distinctions.

This problem is heightened when the evidence comes solely from randomized trials. Designed to answer questions of general efficacy rather than to guide individual treatment, the trials often contain a highly selected group of patients, treated with a relatively rigid therapeutic protocol. Furthermore, with the currently popular intention-to-treat analytic principle, the results of the trials are appraised without regard to whether or how well the patients actually maintained (or even received) the randomly assigned treatment. The results of each trial thus indicate what happens to an 'average' patient assigned to the treatment; and the meta-analyses produce an average of the averages. The average results may be satisfactory for the decisions made by economists, health-plan managers, regulatory agencies, and pharmaceutical companies; but averages are often grossly unsatisfactory for individual decisions about specific patients.

Searching the literature

An important past role of medical textbooks and published 'review articles' was to produce an authoritative summary of pertinent comments and evaluations for each prime topic. The summary may sometimes have been out-of-date, and the authority incorrect, but the search was relatively easy to do and the authority was clearly identified.

With this traditional approach rejected, clinicians are now urged to do their own computerized search of 'the literature'. For only a single topic, among the many others that may be cogent, the computer will regularly produce a large display of multiple reports that can take considerable time to obtain and read. This time can be greatly shortened, however, if clinicians forgo their own full search, and use the approved but highly truncated selection contained in the evidence-based medicine compendium. The clinician thus relies on the evidence-based medicine authorities, who may be relatively anonymous or cited in a multitude of names, instead of the individually identified expert who wrote the section in a chosen textbook or review article.

Relying on the evidence-based medicine compendium, however, can be a frustrating activity in two types of situations. One of them occurs in the 'grey zones of clinical practice' for which gold-standard randomized-trial evidence is available, but inconclusive. In the other situation, the selected prime topic has not been included in the evidence-based medicine collection. Because most randomized trials and their concomitant meta-analyses have been devoted to specific individual therapeutic regimens, very few or no trials have been done for most of the common topics of clinical practice. They include decisions about 'risk factors' and aetiological agents (such as cigarette smoking), pathophysiological challenges (such as restoring electrolyte balance), appraising the relative merits of diagnostic tests, choosing prognostic indicators, or evaluating the 'polypharmacy effects' that occur when several different treatments are used concomitantly. The published literature contains many reports on these topics, but the results come from non-randomized observational studies rather than trials.

Randomized trials (as well as observational studies) are also sparse or non-existent for many interpersonal clinical decisions, such as how to communicate with difficult patients, and how to offer useful reassurance. All of these topics will be omitted from the evidence-based medicine compendium.

Evaluating the literature

The third step in the process is to evaluate what has been found in the literature. The evaluation is relatively quick and easy for topics supplied in the evidence-based medicine compendium, since they have already been assessed and deemed worthwhile. Nevertheless, thoughtful readers may have both qualitative and quantitative difficulties in using the results. Qualitatively, as noted earlier, the evidence-based medicine information may not be suitably pertinent for the individual patient who inspired the search. Quantitatively, the actual magnitude of the cited effects may be difficult to discern and understand when reported in the statistical jargon of proportionate increments, odds ratios, relative risks, and attributable risks.

For example suppose the mortality rates are 24 per cent with treatment A and 18 per cent with the control treatment. This contrast may accurately, but alternatively, be reported as favouring the treatment by a proportional increment of 33 per cent, an odds ratio of 1.44, a relative risk of 1.33, or an attributable risk of 6 per cent.

Aware of the difficulties in interpreting these numbers, the proponents of evidence-based medicine have begun to urge that results be expressed as the inverse of the attributable risk. It is called NNT—the number of patients needed to be treated to produce one extra effect. Its calculation in this example would be 1/0.06 = 16.7, thus indicating that about 17 patients must be treated to save one more life than would occur with treatment in the 'control' group.

For the same set of data, the realization that 17 patients must be treated to get a single extra 'success' is much easier for clinicians and patients to understand than the possibly misleading improvement proportion of 33 per cent, or the often incomprehensible odds ratio of 1.44. The simple, desirable NNT expressions have not yet become ubiquitous in the evidence-based medicine compendium, however, and many results are still summarized, for statistical convenience, as odds ratios or (even worse) as logarithms of odds ratios.

A separate problem is produced when the quantitative magnitude of the difference is obscured by an evidence-based medicine headline such as 'Treatment A is

better than Treatment B for Condition C'. As long as the results have acquired the probabilistic accolade of 'statistical significance', a difference of 0.4 per cent between two treatments may be impressively hailed as 'better', even though 250 patients must receive the 'better' treatment for one to be benefited.

In an era of excessive attention to 'statistical significance', the problem of discerning and interpreting quantitative magnitudes occurs for any type of report, and is not unique to evidence-based medicine. The problem is accentuated, however, when an evidence-based medicine claim of 'better' is accepted uncritically, and particularly when the claim is used to construct guidelines for clinical practice, or criteria for policy recommendations and fiscal reimbursements.

A different type of problem occurs if the desired evidence is not contained in the evidence-based medicine compendium. The clinician must then appraise other sources of information, ranging from published literature to direct discussion with respected colleagues. The evidence-based medicine proponents have offered a hierarchy of rankings for the appraisal of published literature. Randomized trials rank at the top, followed by analyses of non-randomized observational studies, such as the groups appraised in cohort and case–control research. The lowest rank is given to uncontrolled case series, case reports, or the 'anecdotal recommendations' offered by an individual expert.

Although a reasonable generalization, this hierarchy can resemble a ranking of methods for achieving sterile precautions before entering a surgical operating room. Regardless of what is done and how well the precautions are carried out, the most important events occur during the operation, not beforehand. A well conducted observational study that answers the right question can often be more helpful than a randomized trial that is inadequately aimed; and a single case report or small series of cases can sometimes be extraordinarily enlightening. Unfortunately, a concentration on learning the methods of randomized trials and meta-analyses offers no guidance for evaluating non-randomized research, and may lead to underdeveloped critical skills with which 'young physicians who are educated only in evidence-based medicine become completely lost when they have to think about instances in which randomization is impossible'. Evaluating observational research requires special scientific principles for identifying subtle sources of bias that do not occur in randomized trials, but the principles are seldom carefully considered or discussed during an emphasis on randomized trials and meta-analyses.

A separate challenge is to appraise the quality of 'gold' in the 'gold-standard' evidence itself. Diverse 'check-lists' have been proposed for this purpose, but the lists often contain different components; and higher counts of positive components may not always indicate better quality. A major flaw in a crucial single component can invalidate the main results, despite positive counts for all other components.

Implement useful findings

The last step in the recommended process calls for the clinician to implement useful findings. Before beginning the implementation, however, the clinician must first be confident that the findings are indeed useful.

In the old 'eminence-based' system, the authoritative opinions may sometimes have been contradictory, out-of-date, or wrong, but the same phenomena can occur in the evidence-based medicine system. Randomized trials of the same topic have sometimes produced opposing results; different meta-analyses have reached different conclusions for the same set of data; meta-analyses in the evidence-based medicine compendium will often become out-of-date if not promptly revised whenever each pertinent new randomized trial appears; and a later large randomized trial may sometimes contradict results of an existing meta-analysis for smaller previous trials.

A separate problem in usefulness, as discussed earlier, is that the necessary information for an individual patient may be incomplete, inadequate, or wholly absent in the evidence-based medicine compendium. By emphasizing and averaging the 'hard data' of randomized trials, the evidence-based medicine movement can augment the 'statistical reductionism' that tends to dehumanize modern medicine, particularly when evidence-based medicine advocates refer to the care of patients as 'disease management'.

Yet another difficulty in appraising usefulness can arise from the pedagogic revolution that rejects not only the writings of individual authorities, but also their supervisory role in rounds and other teaching activities. When the probing questions of an instructor are replaced by 'evidence carts' or other electronic devices for acquiring evidence-based medicine information, students and house staff are deprived of stimuli that can lead to contemplative thought, and to the learning that comes from justifying decisions and recognizing errors. Without this type of supervisory probing to develop mental agility, young physicians may learn to seek, receive, and excrete the 'best evidence' without simultaneously being challenged to digest, absorb, and evaluate it.

Conclusions

The foregoing comments are not intended to detract from the remarkable accomplishments of the evidence-based medicine movement. Like the Internet itself, evidence-based medicine has had extraordinary growth—developing with unparalleled speed and spreading rapidly throughout the world. The movement has brought a valuable emphasis on the need for using explicit evidence to justify clinical decisions and for maintaining a constant awareness of new and changing evidence. The special evidence-based medicine compendium may contain flaws analogous to those of the old system, but the compendium itself is also a remarkable achievement. It has demonstrated a method to summarize and synthesize a vast plethora of information. The process and the results may be imperfect, but they can serve as a useful basis for future improvements.

The compendium itself, however, can never become fully satisfactory if it continues to rely solely on a 'best evidence' that may sometimes be neither good nor complete, and if the vast bulk of medical evidence, which does not come from randomized trials, continues to be excluded. The methods needed to improve the quality of non-randomized evidence, however, will be delayed or diverted, if talented young clinical investigators, who might construct those methods, are preoccupied with doing meta-analyses for contributions to the evidence-based medicine compendium.

The evidence-based medicine movement can be admired and applauded for its obvious success at inaugurating an exciting new approach to clinical reasoning. The ultimate success of the movement will depend on its ability to escape from self-imposed constraints, and to incorporate all of the contributions, in mind and data, that constitute 'medicine-based evidence'.

2.4.3 Large-scale randomized evidence

R. Collins, R. Peto, R. Gray, and S. Parish

Introduction and summary

This chapter is intended principally for practising clinicians who need to use the results of clinical trials in their routine practice, and who want to know why some types of evidence are much more reliable than others. It is concerned with treatments that might improve survival (or some other major aspect of long-term disease outcome), and its chief point is that, as long as doctors start with a healthy scepticism about the many apparently striking claims that appear in the medical literature, trials do make sense. The main enemy of common sense is over-optimism: there are a few striking exceptions where treatments for serious disease really do turn out to work extremely well, but in general most of the claims of vast improvements from new therapies turn out to be evanescent. Hence, clinical trials need to be able to detect or to refute more moderate differences in long-term outcome. Once this common-sense idea is explicitly recognized the rest follows naturally, and it becomes obvious what types of evidence can and cannot be trusted. Although the chapter may also be of some interest or encouragement to doctors who are considering participating in (or even planning) large trials, its main intended readers are practising clinicians. For, even the most definite results from large-scale randomized evidence cannot save lives unless such practitioners accept and apply them. This chapter does not include large amounts of statistical detail: instead, it tries to communicate the spirit that underlies the increasing emphasis on large-scale randomized evidence that has developed since the 1980s.

Unrealistic hopes about the chances of discovering large treatment effects can be a serious obstacle not only to appropriate patient care but also to good clinical research. For, such hopes may misleadingly suggest to some research workers or funding agencies that small or even non-randomized studies may suffice. In contrast, realistically moderate expectations of what a treatment might achieve (or, if one treatment is to be compared with another, realistically moderate expectations of how large any difference between these treatments is likely to be) should tend to foster the design of studies that aim to discriminate reliably between: (1) differences in outcome that are realistically moderate but still worthwhile; and (2) differences in outcome that are too small to be of any material importance. Studies having this particular aim must guarantee strict control of bias (which, in general, requires proper randomization and appropriate statistical analysis, with no unduly 'data-dependent' emphasis on specific parts of the overall evidence) and strict control of the play of chance (which, in general, requires large numbers rather than much detail). The conclusion is obvious: moderate biases and moderate random errors must both be avoided if moderate benefits are to be assessed or refuted reliably. This leads to the need for large numbers of properly randomized patients, which in turn leads to both large but simple randomized trials (or 'mega-trials') and large systematic overviews (or 'meta-analyses') of related randomized trials.

Non-randomized evidence, unduly small randomized trials, or unduly small overviews of trials are all much inferior as sources of evidence about current patient management or as foundations for future research strategies. They cannot discriminate reliably between moderate (but worthwhile) differences and negligible differences in outcome, and the mistaken clinical conclusions that they engender could well result in the undertreatment, overtreatment, or other mismanagement of millions of future patients worldwide. In contrast, hundreds of thousands of premature deaths each year could be avoided by seeking appropriately large-scale randomized evidence about various widely practicable treatments for the common causes of death, and by disseminating such evidence appropriately. Likewise, appropriately large-scale randomized evidence could substantially improve the management of many important, but non-fatal, medical problems.

The value of large-scale randomized evidence is illustrated in this chapter by the trials of fibrinolytic therapy for acute myocardial infarction, antiplatelet therapy for a wide range of vascular conditions, hormonal therapy for early breast cancer, and drug therapy for lowering blood pressure. In these examples proof of benefit, that could not have been achieved by either small-scale randomized evidence or non-randomized evidence, has led to widespread changes in practice that are now preventing tens of thousands of premature deaths each year.

Moderate (but worthwhile) effects on major outcomes are generally more plausible than large effects

Some treatments have large, and hence obvious, effects on survival: for example, it is clear without randomized trials that prompt treatment of diabetic coma or cardiac arrest saves lives (and, indeed, a plaque at the entrance to our own hospital records the first clinical use of penicillin). However, perhaps in part because of these striking successes, for the past few decades the hopes of large treatment effects on mortality and major morbidity in other serious diseases have been unrealistically high. Of course, treatments do quite commonly have large effects on various less fundamental measures: drugs readily reduce blood pressure, blood lipids, or blood glucose; many tumours or leukaemias can be controlled temporarily by radiotherapy or chemotherapy; in acute myocardial infarction, lidocaine (lignocaine) can prevent many arrhythmias and streptokinase can dissolve most coronary thrombi; in early HIV infection, antiretroviral drugs substantially reduce viraemia. However, although all these effects are large, any effects on mortality are much more modest; indeed, there is still dispute as to whether any net improvement in survival is provided by the routine use of radiotherapy for common cancers, lidocaine for acute myocardial infarction, or antiretroviral agents for early HIV infection.

In general, if substantial uncertainty remains about the efficacy of a practicable treatment, its effects on major endpoints are probably either negligibly small, or only moderate, rather than large. Indirect support for this rather pessimistic conclusion comes from many sources, including: the previous few decades of disappointingly slow progress in the curative treatment of the common chronic diseases of middle age; the heterogeneity of each single disease, as evidenced by the unpredictability of survival duration even when apparently similar patients are compared with each other; the variety of different mechanisms in certain diseases that can lead to death, only one of which may be appreciably influenced by any one particular therapy; the modest effects often suggested by systematic overviews (see later) of various therapies; and, in certain special cases, observational epidemiological studies of the strength of the relationship between some disease and the factor that the treatment will modify (for example, blood pressure, blood cholesterol, or blood glucose: see later).

Having accepted that only moderate reductions in mortality are likely with many currently available interventions, how worthwhile might such effects be if they could be detected reliably? To some clinicians, reducing the risk of early death in patients with myocardial infarction from 10 per 100 patients down to 9 or 8 per 100 patients treated may not seem particularly worthwhile, and if such a reduction was only transient, or involved an extremely expensive or toxic treatment, this might well be an appropriate view. Worldwide, however, several million patients a year suffer an acute myocardial infarction, and if just one million were to be given a simple, non-toxic, and widely practicable treatment that reduced the risk of early death from 10 per cent down to 9 or 8 per cent (that is, a proportional reduction of 10 or 20 per cent), this would avoid 10 000 to 20 000 deaths. (For example, about half a million patients a year now receive fibrinolytic therapy for acute myocardial infarction, avoiding about 10 000 early deaths, and large trials have shown that this difference in early mortality persists for several years afterwards.) Such absolute gains are substantial, and might considerably exceed the numbers of lives that could be saved by a much more effective treatment of a much less common disease.

Reliable detection or refutation of moderate differences requires avoidance of both moderate biases and moderate random errors

If realistically moderate differences in outcome are to be reliably detected or reliably refuted, then errors in comparative assessments of the effects of treatment need to be much smaller than the difference between a moderate, but worthwhile, effect and an effect that is too small to be of any material importance. This in turn implies that moderate biases and moderate random errors cannot be tolerated. The only way to guarantee very small random errors is to study really large numbers, and this can be achieved in two main ways: make individual studies large, and combine information from as many relevant studies as possible in systematic overviews (Table 1). However, it is not much use to have very small random errors if there may well be moderate biases, so even the large sizes of some non-randomized analyses of

computerized hospital records cannot guarantee medically reliable comparisons between the effects of different treatments.

Avoiding moderate biases

Proper randomization avoids systematic differences between the types of patient in different treatment groups.

The fundamental reason for randomization is to avoid moderate bias, by ensuring that each type of patient can be expected to have been allocated in similar proportions to the different treatment strategies that are to be compared, so that only random differences should affect the final comparisons of outcome. Non-randomized methods, in contrast, cannot generally guarantee that the types of patient given the study treatment do not differ systematically in any important ways from the types of patient given any other treatment(s) with which the study treatment is to be compared. For example, moderate biases might arise if the study treatment was novel and doctors were afraid to use it for the most seriously ill patients, or, conversely, if they were more ready to use it for those who were desperately ill. There may also be other ways in which the severity of the condition differentially affects the likelihood of being assigned to different treatments by the doctor's choice (or by any other non-random procedure).

It might appear at first sight that by collecting enough information about various prognostic features it would be possible to make some mathematical adjustments to correct for any such differences between the types of patients who, in a non-randomized study, receive the different treatments that are to be compared. The hope is that such methods (which are sometimes called 'outcomes analyses') might achieve comparability between those entering the different treatment groups, but they cannot be guaranteed to do so. For, some important prognostic factors may be unrecorded, while others may be difficult to assess exactly and hence difficult to adjust for. There are two reasons for this difficulty. First, it is often not realized that even if there are no systematic differences between one treatment group and another in the accuracy with which prognostic factors are recorded, purely random errors in assessing prognostic factors can introduce systematic biases into the statistically adjusted comparison between treatments in a non-randomized study. Second, in a non-randomized comparison the care with which prognostic factors are recorded may differ between one treatment group and another. Doctors studying a novel treatment may investigate their patients particularly carefully, and, perhaps surprisingly, this extra accuracy can introduce a moderate bias. For example, an unusually careful search of the axilla among women with early breast cancer will sometimes result in the discovery of tiny deposits of cancer cells that would normally have been overlooked, and hence some women who would have been classified as stage I will be reclassified as stage II. The prognosis of these 'down-staged' women is worse than that of those who remain as stage I, but better than that of those already classified as stage II by less intensive investigation. Paradoxically, therefore, such down-staging improves not only the average prognosis of stage I breast cancer but also the average prognosis of stage II breast cancer, biasing any non-randomized comparison with other average women with stage I or stage II disease for whom the staging was less careful.

The machinery of a properly randomized trial: no foreknowledge of treatment allocation, no bias in patient management, unbiased outcome assessment, and no postrandomization exclusions

No foreknowledge of what the next treatment will be

In a properly randomized trial, the decision to enter a patient is made irreversibly and in ignorance of which of the trial treatments he or she will be allocated. The treatment allocation is made after trial entry has been decided upon. (The purpose of this sequence is to ensure that foreknowledge of what the next treatment is going to be cannot affect the decision to enter the patient; if it did, those allocated one treatment might differ systematically from those allocated another.) Ideally, any major prognostic features should also be irreversibly recorded before the treatment is revealed, particularly if these are to be used in any treatment analyses. For, if the recorded value of some prognostic factor might be affected by knowledge of the trial treatment allocation, then treatment comparisons within subgroups defined by that factor might be moderately biased. In particular, treatment comparisons just among 'responders' or just among 'non-responders' can be extremely misleading unless the response is assessed before treatment allocation.

No bias in patient management or in outcome assessment

An additional difficulty, in both randomized and non-randomized comparisons of various treatments, is that there might be systematic differences in the use of other treatments (including general supportive care) or in the assessment of major outcomes. A non-randomized comparison may well suffer from moderate biases due to such systematic differences in ancillary care or assessment, particularly if it merely involves the retrospective review of medical records. In the context of a randomized comparison, however, it is generally possible to devise ways to keep any such biases small. For example, placebo tablets may be given to control-allocated patients and certain subjective assessments may be 'blinded' (although this is less important in studies assessing mortality).

'Intention-to-treat' analyses with no postrandomization exclusions

Even in a properly randomized trial, unnecessary biases may be introduced by inappropriate statistical analysis. One of the most important sources of bias in the analysis is undue concentration on just one part of the evidence, that is to say on 'data-derived subgroup analyses' (see below). Another easily avoided bias is caused by the postrandomization exclusion of patients, particularly if the type (and prognosis) of those excluded from one treatment group differs from that of those excluded from another. Therefore the fundamental statistical analysis of a trial should compare all those originally allocated one treatment (even though some of them may not have actually received it) with all those allocated the other treatment (in other words it should be an 'intention-to-treat' analysis). Additional analyses can also be reported: for example, in describing the frequency of some very specific side-effect it may be preferable to record its incidence only among those who actually received the treatment. (This is because strictly randomized comparisons may not be needed to assess extreme relative risks.) However, in assessing the overall outcome, such 'on-treatment' analyses can be misleading, and 'intention-to-treat' analyses are generally a more trustworthy guide as to whether there is any real difference between the trial treatments in their effects on long-term outcome.

Problems produced by data-dependent emphasis on particular results

Treatment that is appropriate for one patient may be inappropriate for another. Ideally, therefore, what is wanted is not only an answer to the question 'Is this treatment helpful on average for a wide range of patients?', but also an answer to the question 'For which recognizable categories of patient is this treatment helpful?'. However, this ideal is difficult to attain directly because the direct use of clinical trial results in particular subgroups of patients is surprisingly unreliable. Even if the real sizes of the effects of treatment in specific subgroups are importantly different, standard subgroup analyses are so statistically insensitive that they may well fail to demonstrate these differences. Conversely, even if there is a highly significant 'interaction' (that is to say, an apparent difference between the sizes of the therapeutic effects in different subgroups) and the results seem to suggest that the treatment works in some subgroups but not in others (thereby giving the appearance of a 'qualitative interaction'), this may still not be good evidence for subgroup-specific treatment preferences.

Questions about such interactions between patient characteristics and the effects of treatment are easy to ask, but are surprisingly difficult to answer reliably. Apparent interactions can often be produced by the play of chance and, in particular subgroups, can mimic or obscure some of the moderate treatment effects that might realistically be expected. To demonstrate this, a subgroup analysis was performed based on the astrological birth signs of patients randomized in the very large Second International Study of Infarct Survival (**ISIS-2**) trial of the treatment of acute myocardial infarction. Overall in this trial, the 1-month survival advantage produced by aspirin was particularly clearly demonstrated (804 vascular deaths among 8587 patients allocated aspirin, versus 1016 among 8600 allocated as controls; 23 per cent reduction, two-sided *p* value <0.000001). However, when these analyses were subdivided by the patients' astrological birth signs, to illustrate the unreliability of subgroup analyses, aspirin appeared totally ineffective for those born under Libra or Gemini (Table 2). It would obviously be unwise to conclude from such a result that patients born under the sign of Libra or Gemini should not be given this particular treatment. However, similar conclusions based on 'exploratory' data-derived subgroup analyses, which, from a purely statistical viewpoint, are no more reliable than these, are often reported and believed, with inappropriate effects on practice.

There are three main remedies for this unavoidable conflict between the reliable subgroup-specific conclusions that doctors want and the unreliable findings that direct subgroup analyses can usually offer. However, the extent to which these remedies are helpful in particular instances is one on which informed judgements differ.

First, where there are good *a priori* reasons for anticipating that the effects of treatment might be different in different circumstances then a limited number of subgroup analyses may be **pre**specified in the study protocol, along with a prediction of the direction of such proposed interactions. (For example, it was expected that the benefits of fibrinolytic therapy for acute myocardial infarction would be greater the earlier patients were treated, and so some studies prespecified analyses subdivided by the time from the onset of symptoms to treatment: see later.) These prespecified subgroup-specific analyses are then to be taken much more seriously than other

subgroup analyses.

The second approach is to emphasize chiefly the overall results of a trial (or, better still, of all such trials) for particular outcomes, as a guide to—or at least a context for speculation about—the qualitative results in various specific subgroups of patients, and to give less weight to the actual results in each separate subgroup. This is clearly the right way to interpret the findings in Table 2, but it is also likely in many other circumstances to provide the best assessment of whether one treatment is better than another in particular subgroups. Of course, the extrapolation needs to be performed in a sensible way. For example, if one treatment has substantial side-effects, it may be inappropriate for low-risk patients. (In this case, the side-effects in a particular subgroup and the proportional benefit in that subgroup should be estimated separately, but the estimation for both might be more reliable if based on an appropriate extrapolation from the overall results rather than on the results in that one subgroup alone.)

The third approach is to be influenced, in discussing the likely effects on mortality in specific subgroups, not only by the mortality analyses in these subgroups but also by the analyses of recurrence-free survival or some other major 'surrogate' outcome. For, if the overall results are similar but much more highly significant for recurrence-free survival than for mortality, subgroup analyses with respect to the former may be more stable and may provide a better guide as to whether there are any major differences between subgroups in the effects of treatment (particularly if such subgroup analyses were specified before results were available).

Avoiding moderate random errors

The need for large-scale randomization

To distinguish reliably between the two alternatives that there is no worthwhile difference in survival or that treatment confers a moderate, but worthwhile, benefit (for example, 10 or 20 per cent fewer deaths), not only must systematic errors be guaranteed to be small (see above) compared with such a moderate risk reduction, but so too must any of the purely random errors that are produced just by chance. Random errors can be reliably avoided only by studying large enough numbers of patients. However, it is not sufficiently widely appreciated just how large clinical trials need to be in order to detect moderate differences reliably. This can be illustrated by a hypothetical trial that is actually quite inadequate—even though by previous standards it is moderately large—in which a 20 per cent reduction in mortality (from 10 to 8 per cent) is supposed to be detected among 2000 heart attack patients (1000 treated and 1000 controls). In this case, one might predict about 100 deaths (10 per cent) in the control group and 80 deaths (8 per cent) in the treated group. However, even if this difference were observed it would not be conventionally significant ($p = 0.1$); indicating that even if there is no real difference between the effects of the trial treatments, it would still be relatively easy for a result at least as extreme as this to arise by chance alone. Although the play of chance might well increase the difference enough to make it conventionally significant (for example, 110 deaths versus 70 deaths, $2p < 0.001$), it might equally well dilute, obliterate (for example, 90 deaths versus 90 deaths), or even reverse it. The situation in real life is often even worse, as the average trial size may be only a few hundred patients rather than the several thousand that would ideally be needed.

Mega-trials: how to randomize large numbers

One of the chief techniques for obtaining appropriately large-scale randomized evidence is to make trials extremely simple, and then to invite hundreds of hospitals to collaborate. The first of these large simple trials (or mega-trials) were the ISIS and GISSI studies of heart attack treatment, and a few other mega-trials have now been undertaken. However, in terms of medically significant findings, what has been achieved so far is only a fraction of what could quite readily be achieved by the assiduous pursuit of such research strategies. Any obstacle to simplicity is an obstacle to large size, and so it is worth making enormous efforts at the design stage to simplify and streamline the process of entering, treating, and assessing patients. Many trials would be of much greater scientific value if they collected 10 times less data, both at entry and during follow-up, on 10 times more patients. It is particularly important to simplify the entry of patients, otherwise rapid recruitment may be difficult. The current fashions for unduly complicated eligibility criteria, overly detailed 'informed' consent, excessive 'quality-of-life' assessments, extensive auditing of data, and measurements of the economic costs of treatment are often inappropriate.

Inappropriate inclusion of cost and of 'quality-of-life' indices

Eventually, the cost-effectiveness of various treatments needs to be assessed. However, this does not necessarily imply that costs should be assessed in the same studies in which effectiveness is to be assessed. This is particularly so if attempts to assess costs seriously damage attempts to assess the effects on mortality and major morbidity reliably. Moreover, what really matters is the cost of a treatment in routine practice, not its cost when given in the particular circumstances of a randomized trial.

Likewise, of course, any important ways in which treatments affect the quality of life need to be understood; but again this does not necessarily imply that quality-of-life indices should be assessed in the same trials that assess the main effects of treatment. For, although 20 000 patients may be required for reliable assessment of the effects of treatment on mortality and major morbidity, only a few hundred are likely to be needed for sufficiently reliable assessment of the effects of treatment on various proposed quality-of-life measures (or on costs of treatment). It may be possible to incorporate such assessments within a large mortality study as small sub-studies. But, this may be difficult in practice, and there are many instances where what should be a large simple trial of clinical efficacy should not be jeopardized by the measurement of such factors. Moreover, the effects of a treatment on quality of life in a trial, when both the doctors and the patients are uncertain about any clinical benefits of the treatment, may differ substantially from its effects on quality of life after the treatment has been shown to improve survival. Hence, it may be better to assess these other outcome measures only after having determined whether the treatment has any worthwhile effects on mortality and major morbidity, and if (as is often the case) it does not then any costs and adverse effects on quality of life may be largely irrelevant.

Simplification of entry procedures for trials: the 'uncertainty principle'

For ethical reasons, patients cannot have their treatment chosen at random if either they or their doctor are already reasonably certain what treatment is preferred. Hence, randomization can be offered only if both doctor and patient feel substantially uncertain as to which of the trial treatments is best. The question then arises: 'Which categories of patients about whose treatment there is such uncertainty should be offered randomization?' The obvious answer is all of them, welcoming the heterogeneity that this will produce. (For example, either the treatment of choice will turn out to be the same for men and women, in which case the trial might as well include both, or it will be different, in which case it is particularly important to study both sexes.) In large trials, patient homogeneity is generally a defect, while heterogeneity is generally a strength. Consider, for example, the trials of fibrinolytic therapy for acute myocardial infarction. Some had restrictive entry criteria that allowed inclusion of only those patients who presented between 0 and 6 h after the onset of pain, and so those trials contributed almost nothing to the key question of how late such treatment can still be useful. In contrast, trials with wider and more heterogeneous entry criteria that included some patients with longer delays between pain onset and randomization assessed this question prospectively, and were able to show that fibrinolytic therapy can have definite protective effects when given not only 0 to 6 but also 7 to 12 h after the onset of pain (see later).

This approach of randomizing a wide range of patients in whom there is substantial uncertainty as to which treatment option is best, was used in the Medical Research Council's European Carotid Surgery Trial (**ECST**). This trial compared a policy of immediate carotid endarterectomy with a policy of 'watchful waiting' in patients with partial carotid artery stenosis and a recent minor stroke in that part of the brain supplied by the carotid artery. If a patient was prepared at least to consider surgery, then the neurologist and surgeon responsible for that individual's care considered in their own way whatever medical, personal, or other factors seemed to them to be relevant (Fig. 1), including, of course, the patient's own preferences and values.

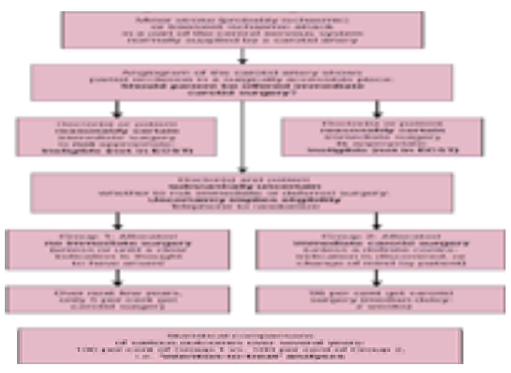

Fig. 1 Example of the 'uncertainty principle' for trial entry: the chief eligibility criterion for the European Carotid Surgery Trial (ECST) was that the doctors and patients

should be substantially uncertain whether to risk immediate or deferred surgery. (Partly because this criterion was appropriately flexible, ECST became the largest ever trial of vascular surgery.)

1. If they were then reasonably certain, for any reason, that they **did wish** to recommend immediate surgery for that particular patient, the patient was ineligible for entry into the ECST.
2. Conversely, if they were reasonably certain, for any reason, that they **did not wish** to recommend immediate surgery, the patient was likewise ineligible.
3. If, but only if, they were **substantially uncertain** what to recommend, the patient was automatically eligible for randomization between immediate versus no immediate surgery (with all patients receiving whatever their doctors judged to be the best available medical care, which generally included advice to stop smoking, treatment of hypertension, and the use of aspirin as an antithrombotic drug).

There were substantial differences between individual doctors in the types of patients about whom they were uncertain (in terms of the severity of carotid stenosis, as well as various other characteristics). This guaranteed that no category—mild, moderate, or severe stenosis—would be wholly excluded, and hence that the trial would yield at least some direct evidence in each case. As a result of the wide and simple entry criteria adopted by the ECST, 3000 patients were randomized, and therefore the study was able to provide some clear answers about who needed carotid endarterectomy. For patients with only mild carotid artery stenosis (0–29 per cent) on their prerandomization angiogram there was little risk of ipsilateral ischaemic stroke, even in the absence of surgery, so that any benefits of surgery over the next few years were small and outweighed by its early risks. Conversely, for patients with severe stenosis (70–99 per cent), the risks of surgery were significantly outweighed by its later benefits over the next few years. The trial stopped early for both categories. However, for the intermediate category of patients with moderate stenosis (30–69 per cent) the balance of surgical risk and eventual benefit remained uncertain, and so recruitment into the study continued with entry still governed by the 'uncertainty principle' as before.

The 'uncertainty principle' simultaneously meets the requirements of ethicality, heterogeneity, simplicity, and maximal trial size. It states that the fundamental eligibility criterion is that both patient and doctor should be substantially uncertain about the appropriateness of each of the trial treatments for the particular patient. With such uncertainty as the fundamental principle of eligibility, informed consent can also be simplified. For, the degree of 'informed consent' that is appropriate in a randomized comparison of different treatments governed by the 'uncertainty principle' should probably not differ greatly from that which is applied in routine practice outside trials when treatment is being chosen haphazardly—or, to put it another way, 'double standards' between trial and non-trial situations are inappropriate. The haphazard nature of many non-randomized treatment choices is reflected in the wide variations in practice between and within countries. Even when a practice is similar it may be similarly wrong: for example, before the ISIS-2 results became available (see later), almost no doctors used fibrinolytic therapy for acute myocardial infarction. Provided that trials are governed by the 'uncertainty principle', there is an approximate parallel between good science and good ethics. Indeed, in such circumstances excessively detailed consent procedures (which can be distressing and inhumane, and so would not be considered appropriate in routine practice) would neither be scientifically nor ethically appropriate.

This 'uncertainty principle' is just one of many ways of simplifying trials and thereby helping them to avoid becoming enmeshed in a mass of wholly unnecessary traditional complexity. If randomized trials can be substantially simplified, as has already been achieved for a few major diseases, and hence made very much larger, then they will play an appropriately central role in the development of rational criteria for the planning of healthcare throughout the world.

Minimizing both bias and random error: systematic overviews (meta-analyses) of randomized trials

Cochrane was one of the first people to emphasize the need to bring together, by specialty, the results from all relevant randomized trials, and the Cochrane Collaboration is now attempting to do this systematically. When several trials have all addressed much the same therapeutic question, the traditional procedure of choosing only a few of them as the basis for practice may be a source of serious bias, since chance fluctuations for or against treatment may affect which trials are chosen. To avoid this, it is appropriate to base inference chiefly on a systematic overview (or meta-analysis) of all the results from all the trials that have addressed a particular type of question (or on an unbiased subset of such trials), and not on some potentially biased subset of the trials. Such overviews will also minimize random errors in the assessment of treatment since, in general, far more patients are involved in an overview than in any contributory individual trial.

The separate trials may well be heterogeneous in their entry criteria, their treatment schedules, their follow-up procedures, their methods of treating relapse, etc. In view of this heterogeneity, at one extreme each trial might be considered in virtual isolation from all others, while at the opposite extreme all might be considered together. Both these extreme views have some merit, and the pursuit of each by different people may prove more illuminating than too definite an insistence on any one particular approach. However, the heterogeneity of the different trials merely argues for careful interpretation of any overviews of different trial results, rather than arguing against any such overviews. For, whatever the difficulties in interpreting overviews may be, without them moderate biases and random errors, which may obscure any moderate treatment effects (or, conversely, may imply effects where none exists), cannot reliably be avoided.

Which overviews are trustworthy?

Since the 1970s, a large (and rapidly increasing) number of meta-analyses of the results of randomized trials have been reported, not all of which are trustworthy. The two fundamental questions are how carefully the overview has been performed and how large it is. The simplest approach is merely to have collected and tabulated the published data from whatever randomized trial reports are easily accessible in the literature, and sometimes this may suffice. At the opposite extreme, extensive efforts may have been made by those organizing the overview to locate every potentially relevant randomized trial, to collaborate closely with the trialists to seek individual data on each patient ever randomized into those trials, and then (after extensive checks and corrections of such data) to produce, in collaboration with those trialists, agreed analyses and publications. The results of some of the largest such collaborations will be described later: the Antiplatelet Trialists' (**APT**) Collaborative Group, the Fibrinolytic Therapy Trialists' (**FTT**) Collaborative Group, and the Early Breast Cancer Trialists' Collaborative Group (**EBCTCG**). Collaboration of the original trialists in the overview process, with collection of individual patient data, can help to avoid or minimize the biases that could be produced by missing trials (for example, owing to the greater likelihood of extremely good, or extremely bad, results being particularly widely known and published), by inappropriate postrandomization withdrawals, or by the failure to allocate treatment properly at random. If randomization was performed properly in the first place, then postrandomization withdrawals can often be followed up and restored to the study for an appropriate 'intention-to-treat' analysis. Knowledge of the exact methods of treatment allocation (backed up by checks on whether the main prognostic factors recorded are non-randomly distributed between the treatment groups in a particular trial) may help to identify trials that were not properly randomized and hence should be excluded from an overview of randomized trials. Overviews based on individual patient data may also provide more information about treatment effects than the more usual overviews of grouped data, for they allow more detailed analyses—indeed, if they are really large then they may actually yield statistically reliable subgroup analyses of the effects of treatment in particular types of patient.

Conversely, even a perfectly conducted overview may not be large enough to be reliable. An overview that brings together complete data from every trial of a certain treatment but which still (because the trials were all small) includes a total of only 100 deaths will have random errors that are no smaller than those for a single trial with 100 deaths among such patients. Small-scale evidence, whether from an overview or from one trial, is often unreliable and will often be found in retrospect to have yielded wrong answers. What is needed is large-scale randomized evidence; it does not matter much whether that evidence comes from a properly conducted overview or a properly conducted trial. The practical medical value of such evidence will now be illustrated by a few recent examples.

Some examples of important results in the treatment of vascular and neoplastic disease that could have been reliably established only by large-scale randomized evidence

Definite result from a single very large trial: benefit from medium-dose aspirin for patients with suspected acute myocardial infarction (and benefits among other groups of patients indicated by overviews of trials)

In the ISIS-2 trial, half of 17 000 patients with suspected acute myocardial infarction were allocated aspirin tablets (162 mg/day for 1 month, which virtually completely inhibits cyclo-oxygenase-dependent platelet activation) and half were allocated placebo tablets. Before 1988, when the ISIS-2 results were published, aspirin was not routinely used in the treatment of acute myocardial infarction, and no other major trial had (or has subsequently) assessed the use of aspirin in cases of suspected acute myocardial infarction. However, the effects of 1 month of aspirin were so definite in ISIS-2 (804/8587 vascular deaths among those who were allocated aspirin versus 1016/8600 among those who were not) that even the lower 99 per cent confidence limit would have represented a worthwhile benefit from such a simple and inexpensive treatment (Fig. 2).

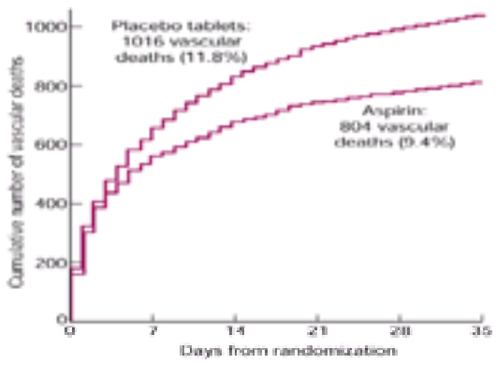

Fig. 2 Effect of administration of aspirin for 1 month on 35-day mortality in the 1988 ISIS-2 trial among over 17 000 patients with acute myocardial infarction. (Absolute survival advantage: 24 SD5 lives saved per 1000 patients allocated aspirin, 2 *p* <0.00001.)

As a result, worldwide treatment patterns changed sharply when the ISIS-2 results emerged, and aspirin is now routinely used in many different countries for the majority of emergency hospital admissions with suspected acute myocardial infarction. In the United Kingdom, for example, two British Heart Foundation surveys found cardiologists reporting that routine aspirin use in acute coronary care had increased from under 10 per cent in 1987 to over 90 per cent in 1989. Worldwide, the annual number of patients with suspected myocardial infarction who would nowadays be given such treatment must be well over a million a year, suggesting that in this clinical context alone aspirin is already preventing tens of thousands of premature deaths each year. However, if the ISIS-2 trial had been a factor of 10 smaller (that is, 1700 instead of 17 000 patients), then exactly the same proportional reduction in mortality as shown in Fig. 2 would not have been conventionally significant and therefore would have been much less likely to influence medical practice—indeed, the result might by chance have appeared exactly flat, greatly damaging future research on aspirin in this context. Likewise, if the ISIS-2 trial had been non-randomized, then it might well have produced the wrong answer (since in a non-randomized study doctors might tend to give active treatment to patients who are particularly ill, or who are rather different in various other ways from those not given active treatment). In addition, even if a non-randomized study did happen to produce an unbiasedly correct answer, it would be impossible to be sure that it had actually done so, and hence again a non-randomized study might have had much less influence on medical practice than did ISIS-2.

In the ISIS-2 trial aspirin significantly reduced the 1-month mortality figure, but it also significantly reduced the number of non-fatal strokes and non-fatal reinfarctions that were recorded in hospital. Combining all these three outcomes into 'vascular events' (stroke, death, or reinfarction), 13 per cent of those who were allocated aspirin versus 17 per cent of the controls were known to have suffered a vascular event in the month after randomization (Table 3)—an absolute difference of 40 events per 1000 treated (or, perhaps more relevantly, of 40 000 per million). The randomized trials of aspirin, or of other antiplatelet regimens, in other types of high-risk patients (for example, a few years of aspirin for those who have survived a myocardial infarction or stroke) have not been as large as ISIS-2, and so, taken separately, most have yielded false-negative results. However, when the results from many such trials are combined, statistically definite reductions in 'vascular events' are seen (Table 3). Since such treatments do not appear to increase non-vascular mortality, all-cause mortality is also significantly reduced.

In principle, these findings could, if appropriately widely exploited, prevent about 100 000 premature vascular deaths a year in developed countries alone, and there are probably at least as many vascular deaths in less-developed as in developed countries. Hence, with realistically achievable levels of the use of 'medium dose' aspirin (75–325 mg/day) for the secondary prevention of vascular disease, it might well be possible in practice to ensure that aspirin is used in enough high-risk patients to prevent, or substantially delay, at least 100 000 vascular deaths per year worldwide, and such use of aspirin would, in addition, prevent a comparable number of non-fatal strokes or heart attacks. (Medium-dose aspirin was the least expensive and most widely tested antiplatelet regimen: it is of proven efficacy, and on review of all the antiplatelet trials no other antiplatelet regimen has been shown to be of greater efficacy in preventing vascular events; see notes to Table 3.) This large-scale randomized evidence regarding medium-dose aspirin is now changing worldwide clinical practice in ways that will, at low cost, prevent much death and disability in high-risk patients. However, small trials, small overviews, or non-randomized studies (however large) could not possibly have provided appropriately reliable evidence about such moderate risk reductions.

Definite result from a very large overview of trials: benefit from 'adjuvant' therapy with tamoxifen for patients with 'early' breast cancer (and possible benefit suggested with ovarian ablation in younger women)

By definition, in 'early' breast cancer all detectable deposits of disease are limited to the breast and the locoregional lymph nodes, and can be removed surgically. However, experience shows that undetectably small deposits may remain elsewhere that eventually cause clinical recurrence at a distant site, perhaps after a delay of several years, which is then usually followed by death from the disease. These micrometastatic deposits may have been stimulated by the body's own hormones during the years before recurrence became detectable. herefore, among women who have had the detectable deposits of breast cancer removed by surgery (or by surgery and radiotherapy), there have been many trials of 'adjuvant' treatments that either reduce the production of endogenous oestrogens (for example, various forms of ovarian ablation) or block the access of those oestrogens to the tumour cells (for example, tamoxifen, which blocks the oestrogen receptor protein in some breast cancer cells).

Taken separately, most of these adjuvant trials have been too small to provide reliable evidence about long-term survival. However, if the results of all of them are combined, some very definite differences in 10-year survival rates emerge (Fig. 3). Among women with stage II disease who are less than 50-years old (and therefore generally pre- or perimenopausal), ovarian ablation appears to produce about a 10 per cent absolute difference in the 10-year survival figure (for example, 50 per cent versus 40 per cent). This finding is based on the analysis of only a few hundred deaths so it is still not as reliable as might ideally be wished and, because substantial uncertainty remains, much larger trials are now in progress. Among older women with stage II disease, ovarian ablation is unlikely to be of much relevance (since most of the endogenous oestrogen at older ages comes from sources other than the ovaries), but, in aggregate, the randomized trials among such women have shown very definitely that a few years of tamoxifen therapy also produces about a 10 per cent absolute difference in the 10-year survival rate. A smaller, but still highly significant, reduction in mortality by tamoxifen is also seen among the 10 000 randomized women with stage I disease. Taken separately, however, 37 of the 42 tamoxifen trials were too small to have yielded statistically reliable evidence on their own (2 *p* >0.01), and the five other trials were significant only because, by chance, they had results that were too good to be true.

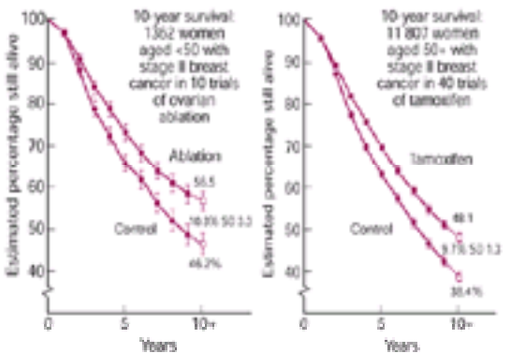

Fig. 3 Effects of hormonal adjuvant treatments for early breast cancer on the 10-year survival rate in a worldwide overview of randomized trials. (Early Breast Cancer Trialists' Collaborative Group, 1992.)

These tamoxifen overview results have already changed clinical practice substantially, and have redirected research towards large randomized trials of the effects of different durations of tamoxifen treatment: should tamoxifen in asymptomatic women be continued for 2 years, for 5 years, or indefinitely? Large randomized studies of tamoxifen in the primary prevention of breast cancer among high-risk women are only just beginning. However, they have been encouraged by the results from the tamoxifen trials' overview in 30 000 patients with established cancer (stage II or stage I) in one breast, among whom there has been a highly significant reduction of

one-third in the likelihood of developing contralateral breast cancer (but a small absolute increase in endometrial cancer). Again, this degree of trustworthy detail would not have been attainable without large-scale randomized evidence.

Promising overview of small trials confirmed by a large trial: benefit from fibrinolytic therapy as emergency treatment for a wide range of patients with acute myocardial infarction

Fibrinolytic drugs that dissolve a thrombus which may be blocking a coronary artery, thereby causing an acute myocardial infarction, were introduced into clinical research in the late 1950s. However, the trials of fibrinolytic drugs in the 1960s and 1970s were too small to be statistically reliable (none involved even 1000 patients). So, by the early 1980s the haemorrhagic side-effects were obvious, the benefits had not been convincingly demonstrated, and these agents were generally considered to be dangerous, ineffective, and hence inappropriate for routine coronary care. Although overviews published in the mid-1980s of the previous small trials (involving a total of only about 6000 patients in 24 trials) indicated a statistically definite benefit, they were not really believed by cardiologists and so such treatments were still not widely used. The situation has been saved by two large randomized trials, ISIS-2 and GISSI-1, both of which involved more than 10 000 patients (and by their aggregation with the seven other randomized trials that involved more than 1000 patients; see below). In ISIS-2, not only were patients randomly allocated to receive aspirin or placebo tablets as described earlier (Fig. 2), but they were also separately allocated to receive intravenous streptokinase (1.5 million units infused over about 60 min) or a placebo infusion. In this 'factorial' design (which allows the separate assessment of more than one treatment without any material loss in the statistical reliability of each comparison), one-quarter of the patients were allocated aspirin alone, one-quarter were allocated streptokinase alone, one-quarter were allocated both streptokinase and aspirin, and one-quarter were allocated neither (that is, they were given placebo tablets and placebo infusion). Streptokinase, like aspirin, produced a highly significant reduction in mortality, and the combination of treptokinase and aspirin was highly significantly better than either aspirin or streptokinase alone (Fig. 4).

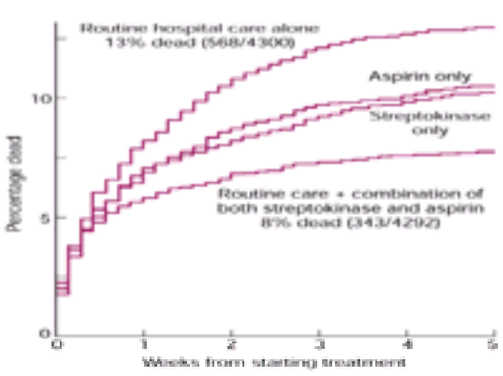

Fig. 4 Effects of a 1-hour streptokinase infusion (and of aspirin for 1 month) on 35-day mortality in ISIS-2 (1988) among 17 187 patients with acute myocardial infarction who would not normally have received streptokinase or aspirin, divided at random into four similar groups to receive aspirin only, streptokinase only, both, or neither. (Any doctor who believed that a particular patient should be given either treatment gave it, but did not include that patient in ISIS-2.)

The results shown in Fig. 4 might suggest that there was no need to collect any more randomized evidence about fibrinolytic therapy, but this ignores the potential hazards of such treatment and the heterogeneity of patients. Taken separately, even ISIS-2, the largest of these trials, was not large enough for statistically reliable subgroup analyses, but when the nine largest trials were all taken together they included a total of about 60 000 patients, half of whom were randomly allocated fibrinolytic therapy. Those entering a coronary care unit with a diagnosis of suspected or definite acute myocardial infarction range from patients who are already in cardiogenic shock with low blood pressure and a fast pulse (half of whom will die rapidly) to those who have merely had a history of chest pain and no very definite changes on their ECG (of whom 'only' a small percentage will die before discharge). Fibrinolytic therapy often causes a frightening blood pressure drop: should it be used in patients who are already dangerously hypotensive? It occasionally causes serious strokes: should it be used in patients who are elderly or hypertensive, and therefore already have an above-average risk of stroke (or who have only slight changes on their ECG, and therefore have only a low risk of cardiac death)? Finally, if the coronary artery has been occluded for long enough, the heart muscle that it supplies will have been irreversibly destroyed: how long after the heart attack starts is fibrinolytic treatment still worth risking—3 h? 6 h? 12 h? 24 h?

These questions needed to be answered reliably before appropriate and generally accepted indications for and against such an immediately hazardous, but potentially effective, therapy could be devised. To address them, all fibrinolytic therapy trialists collaborated in a systematic overview of the randomized evidence. On review of the 60 000 patients randomized between fibrinolytic therapy and control in trials of more than 1000 patients, some of the therapeutic questions were relatively easy to answer satisfactorily. For example, it appears that most of those whose ECG is still normal (or shows a pattern that indicates only a low risk of death) can be left untreated, leaving open the option of starting fibrinolytic treatment urgently if their ECG changes suddenly for the worse in the following few hours. Conversely, among those who already had 'high risk' ECG changes when they were randomized, the absolute benefit of immediate fibrinolytic therapy was, if anything, slightly greater than is indicated by Fig. 4. Age, sex, blood pressure, heart rate, diabetes, and a previous history of myocardial infarction could not identify reliably any group that would not, on average, have their chances of survival appreciably increased by treatment.

The longer that fibrinolytic treatment for such patients was delayed, the less benefit it seemed to produce. Among those whose ECG showed a definite ST-segment elevation or bundle-branch block, the benefit was greatest (about 30 lives saved per 1000) among those randomized between 0 and 6 h after the onset of pain (Fig. 5). However, the mortality reduction was still substantial and significant (about 20 per 1000, 2 p <0.003) when such patients were randomized 7 to 12 h after the onset of pain. Indeed, if they were randomized between 13 and 18 h after the onset of pain there still appeared to be some net reduction in mortality (about 10 per 1000, but not statistically definite). The regression line in Fig. 5 reinforces these separate subgroup analyses in a more reliable way. Yet, before these large trials it was forcefully, but mistakenly, argued that such treatments could not possibly be of any worthwhile benefit if given more than a few hours after the onset of symptoms.

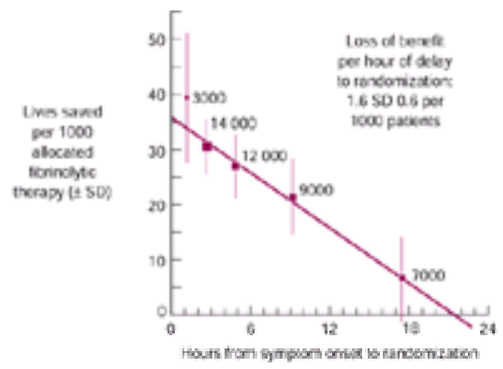

Fig. 5 Benefit versus delay (0–1, 2–3, 4–6, 7–12, or 13–24 h) in the nine largest randomized trials of fibrinolytic therapy versus control in patients with acute myocardial infarction. One-month mortality results for 45 000 patients with ST elevation or bundle-branch block when randomized, showing the definite net benefit even for the 9000 randomized 7–12 h after the onset of pain. (Fibrinolytic Therapy Trialists' Collaboration, 1994.)

Such detailed inferences are difficult enough with large-scale properly randomized evidence, and would be impossible without it; because of their unknowable biases (see above), non-randomized database analyses are simply not a viable alternative to large-scale randomized evidence. Nor would randomization of 'only' several thousand patients have been sufficient. Indeed, in several important respects what is still needed is more, rather than less, randomized evidence about the effects of fibrinolytic therapy in various particular types of patient. First, it is still unclear whether patients who have definite ECG changes such as ST elevation or bundle-branch block, but who present between 12 and 18 h, or even 18 to 24 h, after the onset of pain should be treated; more randomized evidence is still needed (Fig. 5). Second, for one particular poor-prognosis ECG category (ST depression) the 1-month mortality rates still appear unpromising even when all currently available trials are combined (15 per cent dead among those allocated fibrinolytic therapy versus 14 per cent dead among controls, but based on only 4000 patients).

Analogy with the results in other high-risk categories suggests that this result for patients with ST depression may well be a false-negative. Perhaps it has arisen from an unduly data-dependent emphasis on what may, in retrospect, prove to have been a random irregularity in the results in this particular subgroup of only a few thousand individuals. Again, more randomized evidence is needed. Nevertheless, substantial progress has been made in the past decade of mega-trials of fibrinolytic agents. Worldwide, in the mid-1990s, about half a million patients per year were given fibrinolytic therapy, avoiding about 10 000 early deaths each year.

Small trials refuted by a mega-trial: lack of significant benefit from magnesium infusion in suspected acute myocardial infarction

It had been suggested that an infusion of a magnesium salt might reduce early mortality in patients with suspected acute myocardial infarction. Several small trials, involving between them a total of only about 1500 patients, had addressed this question, and their aggregated results indicated a statistically significant, but implausibly large, benefit (42/754 deaths among those allocated magnesium versus 86/740 among the controls, 2 p <0.001). Some argued that such results constituted proof beyond reasonable doubt that magnesium was of sufficient value to justify its widespread usage without seeking further randomized evidence, but others remained sceptical, arguing that the apparent results were far too good to be true.

Therefore two trials, one (LIMIT-2) involving 2000 patients and one (ISIS-4) involving 58 000 patients, were set up to test the possible effects of magnesium more reliably. The former yielded a moderately promising result (Table 4), indicating avoidance of about one-quarter of the early deaths. However, because of its small size this result was statistically compatible with a true benefit that ranged from no effect to about a halving of early mortality. The much larger ISIS-4 trial yielded a completely unpromising result, and so the overall evidence, based on about 60 000 randomized patients, is now non-significantly adverse.

In view of the striking disparity between the apparent effects of magnesium before and after ISIS-4 had provided large-scale randomized evidence, it is of interest to recall some of the expert views that were expressed while ISIS-4 was in progress. Some felt so strongly that magnesium was already of proven benefit (and hence that further randomization was unethical) that the data-monitoring committee of ISIS-4 was lobbied to try to have the study stopped early and all future patients given magnesium. In contrast, the ISIS-4 steering committee was sufficiently sceptical to want large-scale randomized evidence. They believed that the available evidence was consistent with a negligible benefit, or even a small net hazard, although they all thought it more likely that at least some net benefit would be seen. Even after the LIMIT-2 result was available they continued to hold these opinions, and thought that if there was any real benefit then this was likely to be less than LIMIT-2 had suggested (and hence very much less than the other small trials had suggested).

Those who had trusted the implausibly extreme results from the previous small trials may well have been disappointed by the results of the ISIS-4 mega-trial, which now provide strong evidence that the routine use of magnesium has little or no effect on mortality in acute myocardial infarction. However, in a world where moderate benefits are much more plausible than large benefits, striking results in small-scale trials, in small-scale overviews, or in small subgroups will frequently prove evanescent. The medical assumption that both a moderate mortality difference and a zero mortality difference may be plausible, but that an extreme mortality difference is much less so, has surprisingly strong consequences for the interpretation of randomized evidence. In particular, it implies that even quite highly significant (for example, 2p = 0.001) mortality differences that are based on only relatively small numbers of deaths may provide untrustworthy evidence of the existence of any real difference.

Trials in their epidemiological context: effects of lower, and of lowering, blood pressure on the risk of stroke and coronary heart disease

Quantitative epidemiological evidence about the effects of long-term differences in risk factors (such as blood pressure or blood cholesterol level) can help in interpreting the results from trials of the effects of reducing these risk factors for only a few years. This may help not only in interpreting previous trials but also in planning the size and duration of any future risk-factor modification trials. For, epidemiological evidence provides approximate upper limits to the risk reductions that could plausibly be expected in the trials, and may also help to identify populations that are particularly likely to benefit from risk-factor modification.

For example, appropriate analyses of prospective, observational epidemiological studies of diastolic blood pressure and disease indicate that, throughout the range of usual diastolic blood pressure in the populations studied (that is, about 70–110 mmHg), a lower value was associated with a lower risk of suffering a first stroke or episode of coronary heart disease (that is, there seemed to be neither a 'threshold' value nor a 'J-shape' relationship, Fig. 6). The steepness of this continuous relationship suggests that the eventual risk reductions produced by practicable blood pressure lowering measures (for example, with antihypertensive treatment) may well be worthwhile. Not only may this be the case for certain 'hypertensive' individuals, but also for certain individuals who, although considered 'normotensive', are at high risk for some other reason (for example, as a result of a previous stroke or myocardial infarction).

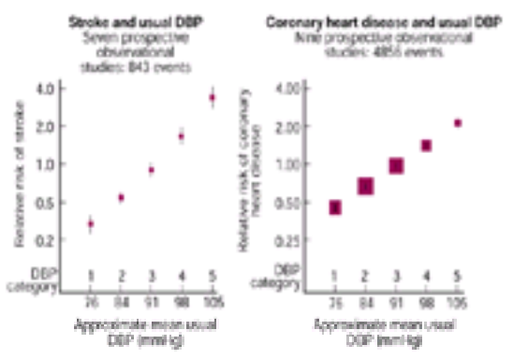

Fig. 6 Relative risks of stroke and coronary heart disease for five categories of diastolic blood pressure from the combined results of prospective observational studies. Solid squares represent the relative risks of disease in each category relative to the risk in the whole study population, and 95 per cent confidence intervals are denoted by vertical lines (MacMahon, 1994).

After making due allowance for the substantial and systematic extent to which the true relationship is diluted by purely random fluctuations in the baseline measurements of blood pressure (that is, the 'regression dilution' bias), the prospective studies suggest that a **prolonged** difference of only 5 mmHg in usual diastolic blood pressure is associated with avoidance of at least one-third of the risk of stroke and at least one-fifth of the risk of coronary heart disease in late middle age. However, although non-randomized, prospective observational studies may be more relevant to the eventual effects of prolonged differences in blood pressure, despite the possibility of confounding by other factors, randomized trials of blood pressure reductions that last for only a few years may be more relevant to assessing the speed with which the epidemiologically expected reductions in stroke or coronary heart disease risk are produced by reducing blood pressure. By comparing the results of a systematic overview of all randomized trials of antihypertensive therapy with the observational epidemiological evidence, it may be possible to estimate the extent to which the eventual effects of a lower blood pressure on disease incidence rates can be achieved within just a few years of treatment in middle or old age. (Ideally, these age ranges should be considered separately, as the fractional avoidance of risk may well be substantially different in middle and in old age.)

Over the past few decades, numerous trials of the treatment of hypertension have been conducted to determine whether blood pressure reduction in middle age reduces the risk of stroke and coronary heart disease. However, although it was fairly rapidly accepted that the treatment of severe hypertension could at least prevent stroke, until recently there has been controversy as to whether the treatment of even severe hypotension could also prevent coronary heart disease. Moreover, questions have also persisted about the effects of the treatment of mild to moderate hypertension on stroke. This continuing uncertainty about the benefits of lowering blood pressure may chiefly have reflected the inability of individual trials (even those with several hundred coronary heart disease events) to detect moderate coronary heart disease reductions reliably, rather than from any important heterogeneity of the real effects of treatment. The mean difference in diastolic blood pressure between treatment and control groups in the trials was only about 5 to 6 mmHg, and the epidemiological evidence suggests that a long-term difference of this magnitude is associated with only about 20 to 25 per cent less coronary heart disease (and about 35–40 per cent less stroke). Even if such trial treatments would eventually produce between 20 and 25 per cent less coronary heart disease after many years, the effects seen within the 2 or 3 years that are available on average between randomization and death in a 5-year trial might well be somewhat smaller (for example, 15 per cent). Considered separately, however, none of the trials recorded enough coronary heart disease events (or enough vascular deaths) for a statistically reliable assessment of 15 per cent risk reductions.

For stroke, the overview of randomized trials provides direct and highly significant evidence that most, or all, of the stroke avoidance associated with a prolonged difference in usual diastolic blood pressure appears soon after the blood pressure is lowered (Fig. 7). In contrast, the significant reduction in coronary heart disease

seen in the trials (16 per cent, SD 4; 95 per cent confidence interval of 8–23 per cent; 2 *p* = 0.0001) falls somewhat short of the difference of about 20 to 25 per cent suggested by the observational epidemiological evidence for a prolonged 5- to 6-mmHg difference in usual diastolic blood pressure. However, this coronary heart disease reduction is substantial and real (2 *p* = 0.0001). Therefore it is reasonable to hope that trials of antihypertensive regimens that can reduce blood pressure to a greater extent than the 5 to 6-mmHg diastolic blood pressure reduction seen in these trials will demonstrate even greater reductions in stroke and coronary heart disease.

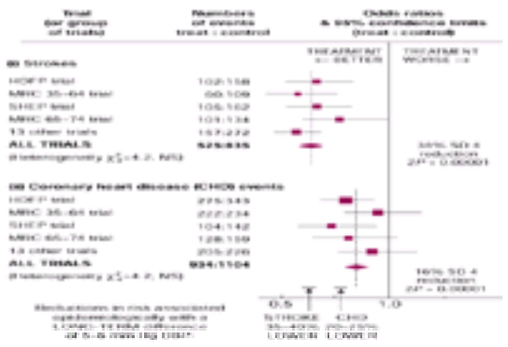

Fig. 7 Reduction in the odds of stroke and coronary heart disease in all unconfounded randomized trials of antihypertensive drug treatment (mean diastolic blood pressure differences of 5–6 mmHg for 5 years). Solid squares represent the odds ratios (treatment:control) for the four larger trials and the properly stratified odds ratio for the combination of the 13 smaller trials. 95 per cent confidence intervals are denoted by horizontal lines (for individual large trials or the combined small trials) and by diamonds (for overviews of all trials) (Collins and Peto, 1994).

The proportional reduction in vascular disease risk observed in the trials appeared to be similar in high- and low-risk individuals, so that the absolute size of the reduction that is produced by treatment may be largely dependent upon the absolute risk. Therefore, for high-risk individuals, the absolute risk reduction produced by antihypertensive treatment might be substantial even among those who are only moderately 'hypertensive'. Indeed, in view of the epidemiological evidence that, for stroke and coronary heart disease risk, there is no 'threshold' level of diastolic blood pressure within the normal range, large randomized trials might even show that blood pressure reduction is of substantial value among many 'normotensive' individuals at high risk of stroke (such as those with a history of cerebral vascular disease) or of coronary heart disease (such as patients with a history of myocardial infarction, angina, peripheral vascular disease, diabetes, or chronic renal failure).

Results from large anonymous trials are relevant to real clinical practice

A clinician is used to dealing with individual patients, and may feel that the results of large trials somehow deny their individuality. This is almost the opposite of the truth, for one of the main reasons why trials have to be large is just because patients are so different from one another. Two apparently similar patients may run entirely different clinical courses, one remaining stable and the other progressing rapidly to severe disability or early death. Consequently, it is only when really large groups of patients are compared that the proportion of patients with a truly good and bad prognosis in each can be relied on to be reasonably similar. One commonly hears statements such as: 'If a treatment effect isn't obvious in a couple of hundred patients then it isn't worth knowing about'. As the previous examples demonstrate, such statements may reveal not clinical wisdom but statistical naïvety.

It is also said that what is really wanted is not a blanket recommendation for everybody, but rather some means of identifying those few individuals who really stand to benefit from therapy. If any criteria (for example, a short-term response to a non-placebo-controlled course of some disease-modifying agent) can be proposed that are likely to discriminate between people who will and will not benefit, then these can be recorded prospectively at entry and the eventual trial results subdivided with respect to them. However, there is a danger in too detailed an analysis of the apparent response of small subgroups chosen for separate emphasis, because of the apparently remarkable effects of treatment in these subgroups. Even if an agent brought no benefit, it would have to be acutely poisonous for it not to appear beneficial in one or two such subgroups! Conversely, if an intervention really avoids an approximately similar proportion of the risk in each category of patient, it will, by chance alone, appear not to do so in some category. The surprising extent to which this happens is evident from the example in Table 2. A large anonymous trial will at least still help to answer the practical question of whether, on average, a policy of widespread treatment (except where clearly contraindicated) is preferable to a general policy of no immediate use of the treatment (except where clearly indicated). Moreover, without a few really large trials it is difficult to see how else many such questions could be resolved over the next few years. For example, digitalis has already been in use for over two centuries, and there is still no reliable consensus as to its net long-term effects on mortality. Trials are at least a practical way of making some solid progress, and it would be unfortunate if desire for the perfect (that is, knowledge of exactly who will benefit from treatment) were to become the enemy of the possible (that is to say, knowledge of the direction and approximate size of the effects of the treatment of many large categories of patient).

2.5 Complementary and alternative medicine

*E. Ernst**

Definition

Most doctors feel they know intuitively what is meant by complementary and alternative medicine (**CAM**). Yet an adequate definition is hard to find. Often CAM is described by characteristics that exclude it from mainstream medicine, for example:

- not taught in medical school
- not scientifically proven
- not based on a scientific rationale
- not used in routine health care

CAM can be positively defined as 'diagnosis, treatment, and/or prevention which complements mainstream medicine by contributing to a common whole, by satisfying a demand not met by orthodoxy or by diversifying the conceptual frameworks of medicine'.

CAM encompasses a large variety of techniques which have little in common except that they are excluded from mainstream medicine, claim to offer help for every condition, and pride themselves on a holistic approach to patient care (Table 1). Some relate to therapeutic modalities (e.g. herbalism), some to diagnostic techniques (e.g. iridology), and some include both diagnostic and therapeutic modalities (e.g. acupuncture).

There are considerable local differences in what is regarded as CAM or mainstream medicine. In Germany, massage therapy and herbalism are orthodox whereas in English-speaking countries they are usually regarded as CAM. Acupuncture is CAM in the West, while in China it is a widespread, traditional, and accepted form of treatment.

Since most CAM therapies are used as adjuncts to conventional treatments, 'complementary' is a more appropriate term than 'alternative'. When used as a true alternative to mainstream medicine, CAM almost invariably becomes a hazard to patients.

Prevalence

In the United States the prevalence of CAM increased from 33 to 42 per cent in the general population between 1990 and 1997, involving an annual expenditure exceeding US$20 billion. In the United Kingdom, the figures are 20 per cent and £1.6 billion, respectively.

In industrialized countries, typical users of CAM are:

- middle aged
- female
- well educated
- high socio-economic class

Indications for CAM range from chronic benign conditions where mainstream medicine is unable to offer a cure (e.g. back pain) to life-threatening diseases like cancer and AIDS. Most patients try CAM in parallel with conventional treatment, yet 30 to 50 per cent do not tell their doctor. A comprehensive medical history should therefore include questions about CAM.

Reasons for CAM's popularity

The following motivations may be important:

- to leave no option untried
- to take control over one's own health
- to accord one's health care with one's (slightly alternative) world views
- to be given time, understanding, and empathy by a practitioner
- to avoid adverse effects of conventional treatments

Disenchantment with orthodox medicine is a reason for trying CAM that should be taken seriously.

Examples of CAM methods

Acupuncture

Description

The Chinese believed that the life energy flowing in particular channels (meridians) govern the human body; the energy is a balance of opposite characteristics: yin and yang. Illness was understood as an expression of an imbalance between yin and yang. One way of re-establishing the proper equilibrium would be to insert needles in acupuncture points located along the meridians. Instead of needles one can also use pressure (acupressure), laser light (laser acupuncture), electrical currents (electroacupuncture), or heat (moxibustion). Neither the meridians nor the acupuncture points have a morphological basis and the philosophy of yin and yang is unscientific.

Mode of action

Nevertheless, modern neurophysiological research has created a (hypothetical) rationale for acupuncture: activation of brainstem nuclei and the release of neural transmitters and endorphins in the brain and descending inhibitory control systems.

There are considerable differences between traditional Chinese and Western acupuncture. With the former, no conventional diagnoses are sought, treatment is highly individualized according to each patient's particular yin/yang imbalance and is considered as a 'cure all'. Western acupuncturists tailor the treatment to the conventional diagnosis established beforehand and normally strive to identify those diagnoses for which acupuncture is helpful.

Efficacy

Rigorous trials are possible but fraught with methodological problems, for example:

- What is an adequate sham procedure?
- How can the patient be blinded?
- How can the therapist be blinded?

Several systematic reviews and meta-analyses of clinical trials of acupuncture for defined conditions have been published suggesting that acupuncture is effective for the following conditions:

- back pain
- nausea and vomiting
- dental pain
- migraine

In the following conditions, results are inconclusive:

- addictions (other than nicotine)
- asthma
- headache
- inflammatory rheumatic conditions
- neck pain
- osteoarthritis
- stroke

Acupuncture is no more effective than sham acupuncture or other control interventions for smoking cessation and weight reduction.

Safety

Serious complications include:

- trauma (e.g. cardiac tamponade, pneumothorax)
- infections (e.g. viral hepatitis)

Phytotherapy

Description

Medical herbalism (phytotherapy) is treatment with whole plants, parts of plants, or plant extracts. The term does not cover treatment with single active constituents such as acetylsalicylic acid, originally from willow bark.

Since all plants contain a multitude of chemicals, phytotherapy involves treatment with a mixture of potentially active compounds. In many cases there is uncertainty about the active ingredients and their pharmacological actions. Herbalists claim that the whole plant (extract) will yield more beneficial effects than any single isolated ingredient.

Most medical cultures have their version of traditional herbalism. Traditional Chinese medicine has a long history of employing mixtures of herbs to prevent and treat disease. This tradition was modified by the Japanese and resulted in Kampo medicine. The Indian tradition has generated Ayurvedic medicine, which relies heavily on plant-based remedies. Likewise, European herbalism has a tradition which is as old as European medicine itself. The scientific investigation of medicinal herbs is, however, a relatively recent innovation.

Mode of action

There are few differences in principle between pharmacotherapy and phytotherapy except that herbal remedies are multicomponent systems which render them pharmacologically more complex. There is no reason why the rules of pharmacokinetics and pharmacodynamics do not apply. For every plant-based medicine discernible modes of action exist. In some cases these have been elucidated; in many other cases they are still hypothetical.

Efficacy

Based on authoritative systematic reviews and meta-analysis, good evidence exists for the efficacy of the following herbal remedies:

- garlic for hypercholesterolaemia
- ginger for nausea and vomiting
- *Ginkgo biloba* for intermittent claudication
- *Ginkgo biloba* to delay the clinical deterioration in dementias
- horse chestnut seed extract for primary venous insufficiency
- kava as an anxiolytic drug
- peppermint oil for irritable bowel syndrome
- saw palmetto for benign prostatic hyperplasia
- St John's Wort for mild to moderate depression

For many other popular medicinal herbs, too few clinical trials have been carried out, or the studies are methodologically flawed, or their results are contradictory. The efficacy of such popular herbal remedies as valerian, aloe vera, and ginseng is undetermined.

Safety

Many medicinal herbs have serious adverse effects, for example:

- aconite (cardiotoxic)
- aristolochia (nephrotoxic)
- broom (cardiotoxic)
- chaparal (nephrotoxic)
- comfrey (hepatotoxic)
- liquorice root (hypokalaemia)
- pennyroyal (hepatotoxic)
- skullcap (hepatotoxic)

Herbal remedies can also interact with synthetic drugs (Table 2), and Asian herbal medicines have been shown repeatedly to be adulterated with synthetic drugs or heavy metals. In many countries (e.g. the United Kingdom and the United States) herbal medicines are marketed as food supplements with no stringent quality

control.

Homoeopathy

Description

Samuel Hahnemann, a German physician, believed in two major principles which formed the basis of an entirely new school of medicine, homoeopathy. The first is known as the 'like cures like' principle. Put simply, it postulates that if a given drug induces symptoms (e.g. a headache) in healthy individuals, this very drug can be employed to treat headaches in patients who suffer from this symptom. The second is that 'potentizing' (i.e. shaking and stepwise diluting) drugs makes them more potent for the treatment of illness. Homoeopathic dilutions prepared thus are believed to be clinically more effective than placebo even if not a single molecule of the original medicine is contained in the potentized remedy. Scientists have for 200 years pointed out that homoeopathy cannot possibly work beyond a placebo effect, but homoeopaths insist that homoeopathic remedies work via 'energy' transfer from the original substance to the diluent (the theory of a 'memory of water').

Homoeopaths do not treat diseases but claim to treat the whole individual. A homoeopath would take a detailed history at each patient's first visit. The aim is to match the totality of the symptoms and characteristics of that patient with a 'drug picture' according to the 'like cures like' principle. This homoeopathic remedy given in the correct potency should then be the optimal treatment for that patient. Clinical improvement may, however, take weeks or months, and in about 20 per cent of all cases symptoms may deteriorate before they become better, a phenomenon termed 'homoeopathic aggravation'.

Homoeopathy has to be seen in its historical context. At the time of Hahnemann it was an important discovery—there were very few effective treatments and many that were overtly harmful. At the very least homoeopathic remedies had virtually no adverse effects. And, if nothing else, Hahnemann can be credited with clinically exploiting the placebo effect to the best benefit of his patients. It is therefore hardly surprising that homoeopathy conquered many countries (e.g. France, the United States, India, and South America) by storm. The advent of more effective and less harmful synthetic drugs eventually led to the decline of homoeopathy. The recent boom of CAM has been associated with a strong revival in homoeopathy.

Mode of action

Even though several hypotheses have been developed to explain the transfer of 'energy' from the mother tincture to the diluent, none have so far withstood the scrutiny of independent assessment. Neither has the 'energy' ever been defined in physical terms, nor are there rational explanations as to how this 'energy' (if it exists) might induce a healing process in a diseased body or organ. Homoeopathy is, therefore, among the least plausible forms of CAM.

Efficacy

A meta-analysis of all 89 randomized or placebo-controlled clinical trials published by 1995 calculated an overall odds ratio of 2.45 in favour of homoeopathy. When only the 26 most rigorous studies were meta-analysed the odds ratio fell to 1.66 but remained statistically significant. However, this publication was criticized for pooling data for all medical conditions and all homoeopathic remedies and for including trials that were not randomized nor placebo-controlled and studies of material (low dilution) remedies where efficacy is not disputed.

The results of further systematic reviews are as follows.

1. The most frequently tested homoeopathic remedy (arnica) has not been conclusively shown to be efficacious beyond a placebo effect by two independent research groups.
2. The clinical condition which has been tested more than any other (delayed-onset muscle soreness) does not respond to homoeopathic remedies better than it responds to placebo; neither do clinical conditions that are common in everyday homoeopathic practice (e.g. migraine or headaches).

Safety

Highly diluted homoeopathic remedies are probably safe. Whether 'homoeopathic aggravations' represent a safety issue is unclear at present. One 'indirect' safety problem deserves to be mentioned: homoeopaths who are not medically qualified tend to advise their clients against immunization. If this happens on a large scale, we are in danger of losing herd immunity against important infectious diseases.

Other forms of CAM

CAM is a highly diverse field comprising more than 150 different forms of therapeutic and diagnostic methods (Table 1).

*The constructive comments of Ted Kaptchuk, Harvard School of Medicine, Boston, United States and Adrian White, University of Exeter, United Kingdom are thankfully appreciated.

3.1 The global burden of disease study

*C. J. L Murray and A. D. Lopez**

Introduction

Reliable, up-to-date epidemiological information is required so that health authorities can assess priorities and evaluate their health systems. National and subnational mortality and morbidity statistics have been published by many countries for several decades. However, before the Global Burden of Disease (**GBD**) Study began in 1992, there had been no attempt to estimate and project the burden of disease and injury globally and regionally, using the same methods and expressing results in a common unit of measurement.

One goal of the GBD Study was to include measures of morbidity in debates about international health policy, which had largely drawn on the available mortality data, much of it referring to children. There was a need to separate epidemiological assessment from advocacy so that estimates of the mortality or disability from a condition were developed as objectively as possible. There was also a need to quantitate the burden of disease using a measure suitable for cost-effectiveness analysis of intervention packages. The GBD method quantifies the impact of premature death and disability on a population, combining these measures into a single unit of measurement of the overall burden of disease in that population. The Study presented the first global and regional estimates of disease and injury burden attributable to 10 important risk factors such as tobacco, alcohol, poor water and sanitation, and unsafe sex. Quantifiable estimates and projections of disease and injury burden from various exposures, measured in a similar fashion, are a key input into priority setting and for policy debates.

In the original GBD Study, 1990 was chosen as the base year for estimating disease burden. A revised Study is now underway to estimate the Global Burden of Disease in 2000, using more extensive and recent data sources, and improved methods, with a broader range of diseases and risk factors. Results of the GBD 2000 Study will be published in 2003; preliminary findings are given in this chapter.

Measuring disease burden

To combine the burden of premature mortality and disability into one summary measure requires a common unit of measurement. Since the late 1940s, it has been generally agreed that time is an appropriate measure: time (in years) lost through premature death, and time (in years) lived with a disability. A range of these time-based measures has been used in different countries, many of them variants of the so-called Quality-Adjusted Life Year or **QALY**. For the GBD, an internationally standardized form of the QALY was developed, called the Disability-Adjusted Life Year (**DALY**). This expresses years of life lost to premature death and years lived with a disability of specified severity. One DALY is one lost year of healthy life. Premature death is defined as occurring before the age to which a person could have expected to survive if he or she were a member of a model population whose life expectancy at birth was approximately equal to that of the world's longest-surviving population, the Japanese.

To calculate total DALYs for a given condition in a population, years of life lost (**YLLs**) and years lived with disability (**YLDs**) for that condition are estimated, and added together. For example, to calculate DALYs incurred through road traffic accidents in India in 1990, the total years of life lost in fatal road accidents must be added to the total years of life lived with disabilities by survivors of such accidents, weighted by the severity of the disability.

To assess premature mortality, the Study used standard life tables for all populations, with life expectancies at birth fixed at 82.5 years for women and 80 years for men. A standard life expectancy allows deaths at the same age to contribute equally to the burden of disease, irrespective of where the death occurs. Other methods, such as using different life expectancies for different populations that more closely match their actual life expectancies, violate this egalitarian principle. As life expectancy is rarely equal for men and women, the GBD assigned men a lower reference life expectancy than women, the magnitude of the difference (2.5 years) being an estimate of the biological advantage of females.

If people are forced to choose between saving a year of life for a 2-year-old and a 22-year-old, most prefer to save the 22 year-old. A range of studies confirm this broad social preference to value a year lived by a young adult more than one lived by a very young child or an older adult. Adults are widely perceived to play a critical role in the family, community, and society. This is why the GBD Study incorporated age-weighting into the DALY. It was assumed that the relative value of a year of life rises rapidly from birth to a peak in the early twenties, after which it steadily declines.

People commonly discount future benefits in the same way that they may discount future against current wealth. Whether a year of healthy life, like money, is also preferred now rather than later, is a matter of debate among economists, medical ethicists, and public health planners, since discounting future health affects both measurements of disease burden and estimates of the cost-effectiveness of an intervention. There are arguments for and against discounting. In the GBD Study, future life years were discounted by 3 per cent per year. This means that a year of healthy life bought for 10 years in the future is worth around 24 per cent less than one bought for now, as discounting is represented as an exponential decay function. Since the impact of discounting is significant, the findings of the GBD Study were published based on DALYs with and without discounting. Discounting future health reduces the relative impact of a child death compared to an adult death. It also reduces the value of interventions that provide benefits largely in the future, such as vaccinating against hepatitis B, which may prevent liver cancer, but some decades later.

In order to measure time lived with a non-fatal disease and assess disabilities in a way that will help to guide health policy, disability must be defined, measured, and valued in a clear framework that inevitably involves simplifying reality. There is surprisingly wide agreement between cultures about what constitutes a severe or a mild disability. For example, a year lived with blindness appears to most people to be a more severe disability than a year lived with watery diarrhoea, while quadriplegia is regarded as more severe than blindness. These judgements must be made formal and explicit if they are to be incorporated into measurements of disease burden.

To formalize social preferences for different states of health, the GBD Study developed a protocol based on the person trade-off method. In a formal exercise involving health workers from all regions of the world, the severity of a set of 22 indicator disabling conditions—such as blindness, depression, and conditions that cause pain—was weighted between 0 (perfect health) and 1 (equivalent to death). These weights were then grouped into seven classes, where class I has a weight between 0.00 and 0.02 and class VII a weight between 0.7 and 1. Subsequent valuations carried out in various cultures have closely matched the results of the original GBD exercise. For the GBD 2000 Study, disability weights are being determined from an extensive household survey programme to obtain valuations based on a visual analogue scale, with required valuations to be determined on the basis of a more intensive valuation exercise among health professionals to correct for

interval-scale biases among respondents.

Sensitivity analyses

To gauge the impact of changing these social choices on the final measures of disease burden, the GBD assessments were recalculated with alternative age-weighting and discount rates, and with alternative methods for weighting the severity of disabilities. Overall, the rankings of diseases and the distribution of burden by broad cause group are largely unaffected by age-weighting, and only slightly affected by changing the method for weighting disability. Changes in the discount rate, by contrast, may have a more significant effect on the overall results. A higher discount rate results in an increased burden in older age groups, while a lower discount rate results in an increased burden in younger age groups. Changes which affect the age distribution of burden, in turn, affect the distribution by cause, as communicable and perinatal conditions are most common in children while non-communicable diseases are most common in adults. The most significant effect of changing the discount and age weights is a reduction in the importance of several psychiatric conditions.

Ultimately, however, the accuracy of the underlying basic epidemiological data from which disease burden is calculated will influence the final results much more than the discount rate, the age weight, or the disability weighting method. If, for example, estimates of the incidence of blindness are incorrect by a factor of two, the results, whatever the social values used in the unit of measurement, will be substantially incorrect. We conclude that much more effort needs to be invested in improving the basic epidemiological data than in analysing the effects of what are ultimately minor adjustments to the particular summary measure of population health employed.

Estimating mortality and disability

Classification

As most developing countries still have only limited information about the distribution of causes of death in their populations, a primary objective of the GBD has been to develop comprehensive, internally consistent, mortality estimates worldwide for each major cause in 1990. Deaths were classified using a tree structure, in which the first level of disaggregation comprises three broad cause groups:

- *group I*—communicable, maternal, perinatal, and nutritional conditions (ICD-10 codes A00–B99, G00, N70–N73, J00–J06, J10–J18, J20–J22, H65–H66, O00–O99, P00–P96, E00–E02, E40–E46, E50, D50);
- *group II*—non-communicable diseases (ICD-10 codes C00–C97, D00–D48, D51–D89, E03–E07, E10–E16, E20–E34, E51–E89, F00–F99, G03–G99, H00–H61, H68–H95, I00–I99, J30–J99, K00–K92, N00–N64, N75–N99, L00–L99, M00–M99, Q00–Q99); and
- *group III*—injuries (ICD-10 codes V01–Y89).

Each group was then subdivided into categories: for example, cardiovascular diseases and malignant neoplasm are two subcategories of group II. Beyond this level, there are two further disaggregation levels such that 107 individual causes from the International Classification of Diseases (ICD) can be listed separately.

Consistent with the goal of providing disaggregated estimates of disease burden to help set priorities in the health sector, estimates for 1990 were prepared by age and sex and for eight broad geographical regions of the world (Fig. 1)

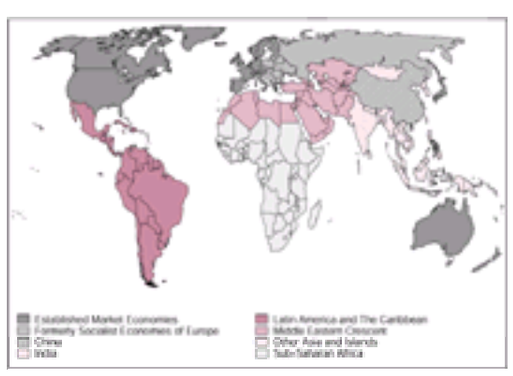

Fig. 1 Regions used for the GBD Study, 1990. EME, Established Market Economies; FSE, Former Socialist Economies of Europe; CHN, China; IND, India; LAC, Latin America and the Caribbean; MEC, Middle Eastern Crescent; OAI, other Asia [countries] and Islands; SSA, Sub-Saharan Africa.

For the GBD 2000 Study, the regional composition has been adapted to the six WHO regions. However, since these groups can be epidemiologically heterogeneous (for instance, the region of the Americas includes the United States, Canada, as well as Peru, Bolivia, and Haiti), each region has been subdivided into five categories of countries (labelled A, B, C, D, E) depending on the relationship between child and adult mortality in each country (Fig. 2).

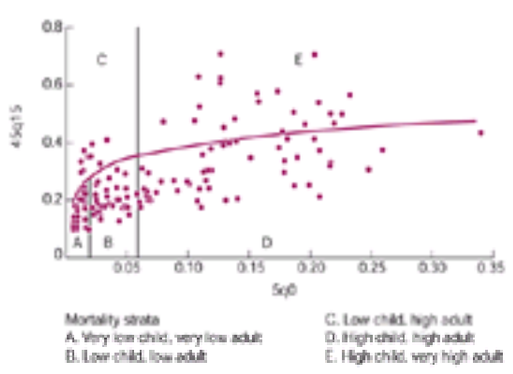

Fig. 2 Child and adult mortality, 1990.

Estimating regional mortality patterns

The Study derived cause-related mortality estimates by using the following four types of data:

1. *Vital registration systems*. Cause-of-death data certified by a physician have been assembled through vital registration systems for over 100 years in some European countries. Data for some 70 countries were available for the 1990s.
2. *Sample death registration systems.* In China, a set of 145 disease surveillance points, representative of both urban and rural areas, and covering about 10 000 000 people, provides useful mortality data. In India, Maharashtra state provides full medical certification for at least 80 per cent of urban deaths, while a rural surveillance system including more than 1300 primary healthcare centres nationwide was used to assess broad rural patterns of mortality. Reliable estimates of age-specific mortality rates in India can be derived, with appropriate adjustment, from the Sample Registration System covering a population of about 6 million but which is representative of all India.
3. *Epidemiological assessments*. Epidemiological estimates exist for specific causes in different regions. These estimates combine information from surveys on the incidence or prevalence of the disease with data on case-fatality rates for both treated and untreated cases.

4. *Cause-of-death models*. These are based on the fact that the broad cause structure of mortality is closely related to the level of mortality in a population. Such models estimate the distribution of deaths by cause in a population from historical studies of mortality patterns in countries with vital registration. The models developed for the initial GBD Study drew on a dataset of 103 observations from 67 countries between 1950 and 1991, and were used primarily to provide plausibility bounds on estimates derived from epidemiological assessments. For the GBD 2000 study, cause-of-death models have been used to ensure that the relative importance of groups I, II, and III as causes of death are consistent with historical observations about the cause structure of mortality, overall mortality, and economic development.

Vital registration data, corrected where necessary for under-registration, were used to construct cause-specific mortality patterns for those regions where registration was complete or virtually complete. For other regions, sex-age-specific mortality rates were estimated from survey and census data on child mortality. Adult mortality levels were inferred from the new WHO model life tables.

Assessing disability

A disease or injury may have multiple disabling effects, or sequelae. To estimate the total burden of disability, the Study measured the amount of time lived with each of the various disabling sequelae of diseases and injuries, in both treated and untreated states, and weighted for their severity, in each population. In all, 483 disabling sequelae of disease and injuries were analysed for the Study, for all regions and age groups, and for both sexes.

Calculating the number of years lived with a disabling condition requires information about its incidence, the average age of onset, the average duration of the disability, and the severity weighting of the condition. Epidemiological experts were asked to estimate each variable for each condition based on a thorough review of published and unpublished studies. For each sequela; prevalence, case fatality, remission, and mortality were estimated. This information allowed correction of the preliminary estimates for internal consistency, ensuring that estimated prevalence and estimated incidence were consistent with one another. Consistency was validated using DisMod software specifically developed for the Study (Fig. 3). When inconsistencies were detected, epidemiological experts were asked to revise their initial estimates. The final disability estimates were the result of several rounds of revision over nearly 5 years.

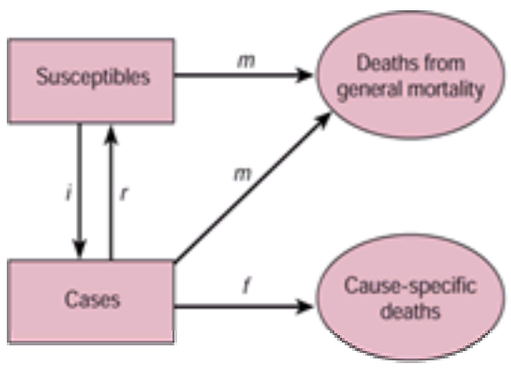

Fig. 3 Basic relationships between susceptibles, cases, and deaths used in developing DisMod.

The number of years that each person had lived with a particular disability was calculated from the incidence of the disability, with the 'stream' of disability arising from it measured from the age of onset, the estimated duration of the disability, multiplied by the condition's severity weight. To calculate the YLDs due to a condition in any given population, the number of YLDs lost per incident case must be multiplied by the number of incident cases. A case of asthma, for example, carries a disability weight of 0.1 if untreated and 0.06 if treated. If the annual incidence of asthma in males aged between 15 and 44 years is 1 million cases, the untreated proportion is 35 per cent, and the average duration is 7 years, then this sequela alone is estimated to cause 664 000 YLDs for that demographic group. Unlike the estimates of years of life lost, not all sequelae of all conditions could be explicitly assessed for YLDs. Estimates for conditions not explicitly considered were made on the basis of information about the ratio of total premature mortality to disability (YLDs) for each broad cause group.

The global burden of disease in 1990 and 2000: main findings

The results demonstrate clearly that disability plays a central role in determining the overall health status of a population. Yet that role has until now been almost invisible to public health. The leading causes of disability are shown to be substantially different from the leading causes of death, which has considerable implications for the practice of judging a population's health from its mortality statistics alone.

A key aim of the GBD was to measure the burden of fatal and non-fatal health outcomes in a single measure, the disability-adjusted life year (DALY). This section presents the main results of the assessments of overall burden for each region. To calculate DALYs due to each disease or injury in a given year and population, the years of life lost through all deaths in that year were added to the years of life expected to be lived with a disability for all new cases of disease or injury occurring in that year, weighted for the severity of the condition.

Regional imbalances in the burden of disease

Sub-Saharan Africa and India together accounted for more than 40 per cent of the total global burden of disease in 1990, although they make up only 26 per cent of the world's population. By contrast, the Established Market Economies and the Formerly Socialist Economies of Europe, with about one-fifth of the world's population between them, together bore less than 12 per cent of the total disease burden. China emerged as substantially the most 'healthy' of the developing regions, with 15 per cent of the global disease burden and one-fifth of the world's population. This means that about 579 years of healthy life were lost for every 1000 people living in Sub-Saharan Africa, compared with just 124 for every 1000 people in the Established Market Economies (Fig. 4).

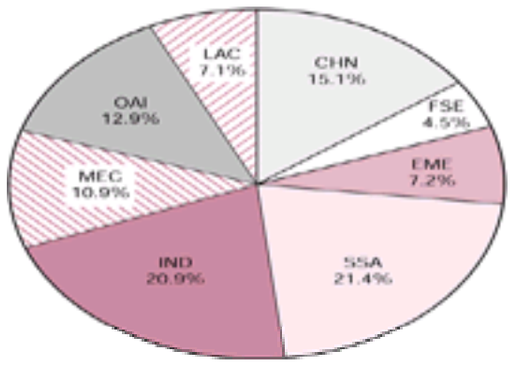

Fig. 4 Distribution of DALYs by region, 1990.

The Study found a sevenfold higher risk of a child dying (that is, a newborn dying before the age of 15) in Sub-Saharan Africa compared to a newborn in the Established Market Economies (Fig. 5). This extraordinary excess mortality in many developing regions must remain a priority for global health programmes. Somewhat surprisingly, the risk of adult death in the FSE region, at least for males, was higher than any other region of the world, except Africa (see Fig. 5). This reflects the rapid increase in adult male death rates in the Russian Federation and neighbouring countries since 1987. In 1990, mortality at these ages (15–59 years) was still rising rapidly in Russia, reaching a peak in 1994. Since then, the probability of death between the ages of 15 and 59 has declined as rapidly as it rose,

although evidence for 1999 suggests that death rates may be rising again; the trends for females are qualitatively similar, though less extreme.

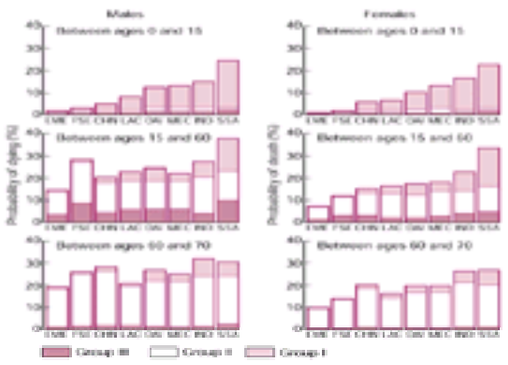

Fig. 5 Regional probabilities of death for males and females by age and group, 1990.

The leading causes of death for 2000 were similar to those estimated for 1990, with two notable exceptions. HIV/AIDS, which killed an estimated 300 000 people in 1990, claimed 10 times that number in 2000 and the annual mortality toll continues to rise. Conversely, interventions to control measles and diarrhoea have had a marked impact on mortality from the two conditions, with measles deaths falling from 2 million in 1990 to less than 800 000 in 2000. Diarrhoeal deaths had fallen to 2.1 million in 2000, 1.3 million of them in children under 5-years-old.

The GBD Study has provided support for the theory that people in high-income, low-mortality populations not only live longer, but also remain healthier for longer. In recent years, opinion has been divided between the view that ill health is compressed into the last few years of life in these populations, and the view that longer life merely exposes people to a longer period of poor health. The results suggest that older people in the developed world are healthier than their counterparts in developing countries. It was also found that babies born in Sub-Saharan Africa could expect to spend about 15 per cent of their lifespan disabled, compared to 8 per cent for babies born in the Established Market Economies. The 60-year-olds in Sub-Saharan Africa can expect to spend about half their remaining years with a disability, whereas 60-year-olds in the Established Market Economies are likely to spend one-fifth of those years disabled. The results suggest that the proportion of the lifespan lived with a disability falls as life expectancy rises.

Major causes of disease burden

The leading causes of disease burden in 1990, were lower respiratory infections, diarrhoeal diseases, perinatal causes, and, perhaps unexpectedly, depression (Table 1). The Study showed that the burden of psychiatric disease had been heavily underestimated. Of the ten leading causes of disability worldwide (in YLDs) in 1990, five were psychiatric conditions: unipolar depression, alcohol abuse, bipolar affective disorder, schizophrenia, and obsessive–compulsive disorder. Unipolar depression alone was responsible for more than 1 in every 10 years of life lived with a disability worldwide. Together, psychiatric and neurological conditions accounted for 28 per cent of all YLDs, compared with 1.4 per cent of all deaths and 1.1 per cent of years of life lost. The predominance of these conditions is not restricted to wealthy countries, although their burden is highest there. They were the most important contributors to YLDs in all regions except Sub-Saharan Africa, where they still accounted for 16 per cent of the total.

Alcohol abuse was the leading cause of male disability, and the tenth largest in women, in developed regions and, perhaps surprisingly, the fourth largest cause in men in developing regions. Other important causes of YLDs were anaemia, falls, road traffic accidents, chronic obstructive pulmonary diseases, and osteoarthritis.

Traditional disease burdens in developing societies—communicable, maternal, perinatal conditions, and nutritional deficiencies—remained of major importance in the 1990s. Even though these group I conditions accounted for only 7 per cent of the burden in the Established Market Economies and less than 9 per cent in the Former Socialist Economies, they accounted for more than 40 per cent of the total global burden of disease in 1990, and for 49 per cent in developing regions. In Sub-Saharan Africa, 2 out of every 3 years of healthy life were lost because of group I conditions. Even in China, where the epidemiological transition is far advanced, a quarter of years of healthy life lost were due to this group. Worldwide, five out of ten leading causes of disease burden (as measured by DALYs) are group I conditions: lower respiratory infections (pneumonia); diarrhoeal disease; perinatal conditions; tuberculosis; and measles.

The burden of injury in 1990 was highest (19%) in the FSE region. China had the second largest injury burden, followed by Latin America and the Caribbean. Even in the Established Market Economies the burden of injuries—dominated by road traffic accidents—was almost 12 per cent of the total. In most regions, unintentional injuries were a greater source of ill health in 1990 than intentional injuries such as interpersonal violence and war. The only exception was the Middle Eastern Crescent, where unintentional and intentional injuries took an approximately equal toll because of a particularly high burden of war in the region at the time.

Preliminary estimates of GBD for 2000 suggest that the leading causes are similar to those in 1990, exception for HIV. In 2000, HIV is estimated to have killed 2.95 million people (2.4 million in Africa). HIV/AIDS is the third leading cause of disease burden, accounting for 6.1 per cent of all DALYs lost in 2000, only marginally behind lower respiratory infections (6.4 per cent) and perinatal conditions (6.2 per cent) (Table 1).

Global burden of disease: risk factors

Exposure to particular hazards, such as tobacco, alcohol, unsafe sex, or poor sanitation, can significantly increase people's risks of developing disease. Health policy makers need accurate information on their impact in order to devise effective prevention strategies. The GBD Study assessed, for the first time, the mortality and loss of healthy life that can be attributed to each of 10 major risk factors in each region: malnutrition; poor water supply, sanitation and personal/domestic hygiene; unsafe sex; tobacco abuse; alcohol abuse; occupation; hypertension; physical inactivity; illicit drug use; and air pollution.

The contributions of risk factors to global burden

Malnutrition, poor water, sanitation, and hygiene, unsafe sex, alcohol, tobacco, and occupation proved the most important, accounting together for more than one-third of the total disease burden worldwide in 1990 (see Table 2). Malnutrition and poor sanitation were the dominant hazards, responsible together for almost a quarter of the global burden. Unsafe sex and alcohol each contributed approximately 3.5 per cent, tobacco and occupation hazards just under 3 per cent each. These are similar to the disease burden due to tuberculosis or measles. Major inequalities exist between regions and between men and women in the burdens of most risk factors. The consequences of unsafe sex, including infections and complications of unwanted pregnancy, are borne disproportionately by women in all regions. In young adult women in Sub-Saharan Africa, unsafe sex accounts for almost one-third of the total disease burden. Tobacco, due to longer exposure, and alcohol caused their heaviest burdens in men in the developed regions, where they accounted together for more than one-fifth of the total burden in 1990. In Asia and other developing regions, the rapid increase in tobacco use over the past few decades is expected to kill many more people in the coming decades than have so far died of this cause in the developed regions.

For the GBD 2000 Study, more than 20 risk factors are being analysed, using a more comparable framework for assessing risk factors. Preliminary results for 2000 suggest little change in the importance of these various risk factors, except for tobacco and unsafe sex, for which disease burdens are rising rapidly, particularly in the developing world. More refined methods have suggested that the blood pressure burden is about twice what was estimated for 1990, although this increase is largely a methodological artefact. Elevated cholesterol is also a major cause of disease burden, about two-thirds that of blood pressure.

Projections of the global burden of disease

To plan health services effectively, policy makers need to know how health needs might change in the future. To meet this need, projections of mortality and disability have been developed for each 5-year period from 1990 to 2020.

Projection methods

Rather than attempt to model the effects of the many different determinants of disease from the limited data available, mortality change has been modelled as a function of a few socioeconomic variables: (1) income per capita; (2) the average number of years of schooling in adults, termed 'human capital'; and (3) time, a proxy measure for the secular improvement in health this century that results in part from accumulating knowledge and technological development. Historically, these variables have been related to mortality rates: for example, income growth was closely related to the improvement in life expectancy that many countries achieved in the twentieth century. Because of their relationships to death rates, these variables may be regarded as indirect, or distal, determinants of health. A fourth variable, tobacco use, was included, because of its overwhelming impact on the occurrence of chronic diseases, using information from more than four decades of research on the time lag between persistent tobacco use (measured as 'smoking intensity') and its effects on health.

Death rates for all major causes based on historical data for 47 countries from 1950 to 1991 were related to these four variables to generate the projections. A separate model was used for HIV, with modifications for the interaction between HIV and tuberculosis.

Mortality projections

In all regions, life expectancy at birth is expected to increase for women. By 2020, infant girls born in the Established Market Economies may expect to survive to almost 88 years. For men, life expectancy will grow much more slowly, mainly because of the impact of the tobacco epidemic. Nevertheless, by 2020, males born in Sub-Saharan Africa, whose life expectancy at birth was below 50 in 1990, may expect to reach 58 years. Males born in Latin America and the Caribbean, who in 1990 could have expected to live to 65, may expect to reach 71 years. However, for men in the Formerly Socialist Economies of Europe, life expectancy is not expected to increase at all between 1990 and 2020. This is partly due to the fact that life expectancy was falling in 1990, so that any positive change is likely to be merely recovering to the 1990 position.

In young children and adolescents under the age of 15, the risk of death is projected to decline dramatically in all regions, falling by about two-thirds in Sub-Saharan Africa and India. In adult women, too, the risk of death is expected to fall in all regions. Men in the Formerly Socialist Economies of Europe and China, because of the tobacco epidemic, may expect a higher risk of dying between the ages of 15 and 60 than they do today. In other regions, the risk of death for men in this age group is expected to fall, but more modestly than in women. Remarkably, by 2020, men of this age group in the Formerly Socialist Economies of Europe could face a higher risk of death even than men in Sub-Saharan Africa.

Deaths from communicable, maternal and perinatal conditions, and nutritional deficiencies (group I) are expected to fall from 17.3 million in 1990 to 10.3 million in 2020. As a percentage of the total burden, group I conditions are expected to drop by more than half, from 34 per cent to 15 per cent. This projected reduction overall, despite increased burdens due to HIV and possibly tuberculosis, runs counter to the now widely accepted belief that infectious diseases are making a comeback worldwide. It reflects, in part, the relative contraction of the world's 'young' population: the under-15 age group is expected to grow by only 22 per cent between 1990 and 2020, whereas the cohort of adults aged between 15 and 60 is expected to grow by more than 55 per cent. In addition, the projection reflects the observed overall decline in group I conditions over the past four decades, due to increased income, education, and technological progress in the development of antimicrobials and vaccines. Even under the pessimistic scenario, in which both income growth and technological progress are expected to be minimal, deaths from these conditions are still expected to fall slightly to 16.9 million.

It should not be taken for granted that the progress against infectious diseases during the past four decades will be maintained. Antibiotic development and other control technologies may not keep pace with the emergence of drug-resistant strains of important microbes such as *Mycobacterium tuberculosis*. If such a scenario were to prove correct, and if, in addition, case-fatality rates were to rise because of such drug-resistant strains, the gains of the twentieth century could be halted or even reversed. None the less, the evidence to date, suggests that, as long as current efforts are maintained, group I causes are likely to continue to decline.

While overall, group I conditions are expected to decline, deaths from non-communicable diseases are expected to climb from 28.1 million deaths in 1990 to 49.7 million in 2020, an increase of 77 per cent in absolute numbers. In proportionate terms, group II deaths are expected to increase their share of the total from 55 per cent in 1990 to 73 per cent in 2020. These global figures do not reveal the extreme nature of the change that is projected in some developing regions because they incorporate the projections for the rich nations, which show little change. In India, deaths from non-communicable diseases are projected almost to double, from about 4 million to about 8 million a year, while group I deaths are expected to fall from almost 5 million to below 3 million a year. In the developing world as a whole, deaths from non-communicable diseases are expected to rise from 47 per cent of the total to almost 70 per cent.

The steep projected increase in the burden of non-communicable diseases worldwide is largely driven by population ageing, augmented by the large numbers of people in developing regions who are now exposed to tobacco. Ageing will result in a rise in the absolute numbers of cases of non-communicable diseases and in their increased share of the total disease burden for the population as a whole, but not in any change in the rates of those diseases in any given age group. As studies in the Established Market Economics show, the age-specific rates of some important non-communicable diseases, such as ischaemic heart disease and stroke, have been falling steadily for at least two decades. Whether these rates are also falling in other regions is much less clear. However, any age-specific decrease in the rates of these diseases that may also emerge in low-income countries is likely to be outweighed by the large and demographically driven increase in the absolute numbers of adults at risk from these diseases, augmented by the tobacco epidemic. As with non-communicable diseases, deaths from injury are also expected to rise for mainly demographic reasons. Young adults are generally exposed to greater risks of injury.

Recent health trends in the 1990s: implications for the GBD projections

The original GBD projections were based on data and information about health conditions worldwide during the late 1980s/early 1990s. At that time, two major epidemics were affecting the health of large population groups: the HIV epidemic, particularly in Africa, which killed an estimated 300 000 people worldwide in 1990 but had, by that time, infected millions more; and the explosive increase in the adult mortality rates in Russia and neighbouring countries, particularly from cardiovascular diseases and injuries, and particularly among men. Making projections at a time of such dramatic epidemiological trends is extremely hazardous.

The 1990 GBD Study's HIV/AIDS projections have severely underestimated the spread of the epidemic in Sub-Saharan Africa, particularly in Southern Africa. By 2000, HIV/AIDS was estimated to have killed 2.4 million Africans, several times more than projected on the basis of what was known in 1990. Whether the disease burden will continue to rise, and how far, is uncertain and new projection methods are being developed to forecast the epidemic better, particularly in Africa.

The other large uncertainty in the projections, namely adult mortality in the FSE region, has confounded epidemiologists with the dramatic change in mortality risks during the 1990s. Death rates had been falling markedly in most large countries in this region, and, if they were to continue to do so, the 1990 forecasts will prove to be unduly pessimistic. It is too early to decide whether the recent declines in mortality are the beginning of a long-term secular trend in mortality. Recent evidence for 1999 and 2000 indicates that death rates, particularly in males, have begun to rise again.

Progress in refining the GBD approach

Measuring and evaluating health

An innovation of the GBD Study was the attempt to measure and evaluate states of ill health in a similar way in different societies. This presupposes a common conceptual framework and measurement strategy. In particular, what are the key domains of health that need to be assessed and what is the minimum number of items and response categories needed to measure them? Self-report instruments currently in use lack cross-cultural comparability, with the result that the measurement of health in various populations cannot be compared. The development and implementation of a conceptual framework to measure and describe health in a way that improves comparability across populations is a key challenge for research on burden of disease.

In the GBD Study, comorbid conditions were evaluated separately, and the time spent with these combined states was measured as the sum of the two. This additive model may not be appropriate. More data are required on the prevalence of major comorbidities to avoid multiple attribution in valuing health states.

Conclusions

The GBD Study has provided a picture of current and projected health needs. It has shown that non-communicable diseases are rapidly becoming the dominant causes of ill health in all developing regions except Sub-Saharan Africa; that mental health problems have been underestimated worldwide; and that injuries are important problems in all regions. The findings pose new and immediate challenges to policy makers.

3.2Human population size, environment, and health

A. J. McMichael and J. W. Powles

Introduction

Homo sapiens originated approximately two hundred thousand years ago. Since then it has undergone three population growth surges: (i) an estimated 50-fold increase as hunter–gatherer humans drifted out of north-eastern Africa and dispersed around the world; (ii) a further 100-fold increase following the advent of agriculture, beginning ten thousand years ago; and then (iii) from just before the industrial revolution, another 10-fold increase from half a billion to six billion.

This third, incomplete, increase has occurred much faster than the two previous increases. Absolute additions to human numbers have been biggest in the past quarter-century, capping an almost-fourfold increase from 1.6 to 6 billion during the twentieth century. However, the annual increase expressed in percentage terms has slowed in the last couple of decades. Demographers expect that by the time the demographic transition is completed worldwide, and birth rates equilibrate with death rates (at historically low levels), world population will have reached between 8 and 11 billion. The medium variant projection for 2050 is approximately 9 billion.

Relationship between environment and population

The relationship between the environment and population size is multifaceted. The main components of that relationships are these: (i) the environment sets limits on the size of the supportable population; (ii) human societies find ways of extending that limit; and (iii) that extension process in turn often leads to the depletion and deterioration of the natural environment.

Carrying capacity

In the natural world, the composition and assets of a species' environment determine the maximum number of individuals of the species that can be supported. For that species, this number is the 'carrying capacity' of its local habitat. There are fluctuations of population size around that number as conditions vary over time. Populations of the human species, uniquely, are not fully constrained by given environmental conditions. Through culture and technology, humans can increase the carrying capacity of their local environments—at least temporarily.

The early domestication of plant species increased food yields and hence population carrying capacity. The subsequent domestication of wild animal species further increased carrying capacity. The advent of agriculture led to a substantial increase in fertility—from an average of 4 to 5 births per completed reproductive lifetime (as reported for traditional hunter–gatherers and, coincidentally, for great apes) to 5 to 7 births per reproductive lifetime in agrarian populations. This greater fecundity meant that the approximate equivalence of birth and death rates in slowly enlarging agrarian populations was attained at very high levels of both. This is well illustrated by India a century ago, when fertility was high (7 to 8 births per woman) and life expectancy was 20 to 25 years (reflecting especially the high death rates in infancy and childhood).

Overloading the environment

Human communities exploit local natural resource stocks: soil, water, and plants and animals for food and materials. This exploitation, in time, tends to deplete and ultimately degrade environments. Often, the local consequences have been the restriction or decline in human numbers, and impairment of nutritional status and health.

The extent to which humans are disrupting their environment has increased rapidly over the past two centuries, as numbers have expanded and as the material and energy intensities of productive activity have increased. Over the past century or so, adverse environmental effects have mostly been of a localized kind, such as urban-industrial air pollution, chemical pollution of waterways, and urban squalor. Today, human effects on the environment are being played out on a much larger scale—and the longer-term consequences for health could be commensurately more serious. Recent global assessments point to a significant and increasing 'ecological deficit', with manifest decline in natural environmental and ecological resource stocks.

Further, some of these environmental stresses are likely to cause tensions between human communities, leading to armed conflict—another potential source of damage to health. For example, Ethiopia and the Sudan, upstream of Nile-dependent Egypt, increasingly need the Nile's water for their own crop irrigation.

The central issue in all of this is that the ecological underpinnings of human health are being perturbed or depleted. The sustained good health of any population, over time, requires a stable and productive natural environment that: (i) yields assured supplies of food and fresh water, (ii) has a relatively constant climate in which climate-sensitive physical and biological systems do not change for the worse, and (iii) retains biodiversity (a fundamental source of both present and future value). For the human species, as a 'social animal'in the extreme, the richness, texture, and stability of the social environment (i.e. 'social capital') is also important to population health.

A Malthusian perspective on sustainability

Two hundred years ago, Thomas Malthus, responding to the utopian views of William Godwin, de Condorcet, and others about the perfectibility of human institutions, foresaw a potential crisis arising from excessive human numbers within a food-limited environment. The exponential power of population growth would, he concluded, tend always to outstrip the (arithmetic) power of growth in food production. He grimly predicted that population excess in Europe would lead to starvation and die-off—that is, to nature's 'positive checks' that would bring human numbers back in line with food supplies.

In fact, the crisis did not materialize in Europe. Malthus could not have foreseen the remarkable increase in food-producing capacity that the second agricultural revolution, underwritten by mechanization and fossil-fuel energy, would bring during the nineteenth century—or the bonanza of imported grain and meat that Europe's newly-established colonies would provide. Nor could he have foreseen the marked decline in fertility rates that emerged in European populations during the nineteenth century as social modernization occurred and as contraceptive possibilities became widely understood.

Today, nevertheless, a 'Malthusian' perspective is relevant at another level of analysis. In the past quarter-century we have begun to see the evidence that there are limits to the carrying capacity of the globe as a whole. There is mounting evidence, for example, of a damaged stratosphere and of human-induced climate change. These are signs that we are exceeding the carrying capacity of the world as a whole. What might lie in store?

In the natural world, the tendency of plant and animal species to exponential growth is generally constrained by predation, by limits to food supplies, by infectious disease, and, in many animals, by density-dependent changes in reproductive behaviour. As numbers increase, one of the following patterns operates:

1. logistic (asymptotic) growth, responding to immediate negative feedback, as carrying capacity is approached;

2. domed or capped growth, responding to deferred negative feedback, necessitating compensatory die-off; or
3. irruptive growth, with a chaotic post-crash pattern.

Our recognition, today, of the risk of overshoot and collapse (patterns 2 and 3) underlies the increasing attention being paid to the need for 'environmentally sustainable development'. Simplifying, there are two main adverse outcomes to which an excess of human numbers might contribute: (i) recurrent subsistence crises on a subnational or national level, or (ii) 'planetary overload'.

Local subsistence crises

The focus of concern with 'overpopulation' in much of the latter half of the twentieth century was the likelihood that the growth of many local populations would overload local carrying capacities. Chronic food shortages would ensue and undernutrition would force mortality rates up towards equilibrium with fertility, both at unfavourably high levels. The emiserating effects of population pressure would prevent economic development, prolong population growth, and leave such populations 'demographically entrapped'.

So far, however, there appear to have been few developments in this direction. The famines that have occurred in recent decades, the most serious being the Chinese famine of 1959 to 1961 with around 15 to 20 million deaths, have not been attributable primarily to the progressive reduction of food-producing resources per person. Rather, they appear to have arisen from either economic mismanagement (as in the case of the Chinese 'great leap forward') or warfare (as in parts of Africa)—although the contributory causes of some of that strife may include local population pressures on dwindling natural resources. The recent generally favourable trends in per-person food supplies may not be sustainable as populations double (or more) in size in poor countries such as Bangladesh that already have less than one-tenth of a hectare of cropland per person.

Planetary overload

While local subsistence pressures persist or increase in many parts of the world, there is a newer form of pressure arising at the global level. Human population size and the material intensity of our economies are now so great that, at that global level, we are beginning to disrupt some of the biosphere's life-support systems. The clearest evidence of the occurrence of 'global environmental change' is the documented destruction of stratospheric ozone, particularly in polar and subpolar regions, over the past quarter-century and the apparent incipient changes in world climate due to greenhouse-gas accumulation in the lower atmosphere. There is a net ongoing loss of productive soils on all continents; we have overfished most of the ocean fisheries; we have severely depleted many of the great aquifers upon which irrigated agriculture depends; we are extinguishing at an unprecedented overall rate whole species and many local population;, and, increasingly, persistent human-made organic (especially chlorinated) chemicals are pervading the biosphere.

These various changes are perturbing or weakening systems in the biosphere that provide the stabilization, replenishment, organic production, cleansing, and recycling that our predecessors were able to take for granted in a less populated, less degraded, world. Manifestly we no longer live in such a world. This weakening of Earth's basic life-supporting processes poses a spectrum of long-term risks to human population health. The currently foreseeable risks from these environmental changes include: (i) an anticipated increase in skin cancer rates (and perhaps in ocular disorders and immune system suppression) due to the approximately 10 per cent increase in ultraviolet radiation levels that has now accrued at middle latitudes; (ii) a likely increase in geographical range and seasonality of vector-borne infectious diseases such as malaria and dengue fever under conditions of climate change; (iii) increased exposure, in some parts of the world, to weather extremes and disasters, consequent upon climate change; and (iv) malnutrition and hunger in local populations whose agricultural productivity is adversely affected by changes in climate, soil fertility, freshwater supplies, and the ecology of pests and pathogens.

Contribution of population increase to environmental disruption

The World Wildlife Fund for Nature has analysed in detail the trends over the past three decades in the vitality and function of major categories of ecological systems, including freshwater, marine, and forest ecosystems. Overall, the 'Living Planet Index' has declined by 30 per cent since 1970. Assessments by other international agencies approximately concur.

The three main determinants of human disruption of the environment are population size, the level of material wealth and consumption, and the types of technology. The ongoing climate change debate illustrates well the relativities between the environmental effects of increases in population and consumption. Historically, during the twentieth century, as population increased by just under fourfold the annual fossil fuel emissions of carbon dioxide increased 12-fold. In 1995, the 20 per cent of world population living in high-emission countries accounted for 63 per cent of carbon dioxide emissions, while the lowest-emitting 20 per cent of population contributed just 2 per cent. Over the coming century the projected world population growth will contribute an estimated 35 per cent of growth in carbon dioxide emissions, whereas economic growth would account for the remaining 65 per cent.

If the world were to limit carbon dioxide build-up to a doubling of its preindustrial concentration (i.e. from 275 to 550 p.p.m.)—a level which climatologists think would be tolerable to most ecosystems—then the United Nations medium population projection of 10 to 11 billion by 2100 would allow per-person carbon dioxide emissions similar to those of the 1920 to 1930s. That is approximately two-thirds less than today's level of emissions (see Fig. 1). While that looms as a very demanding task, we actually already have much of the necessary technology to reduce emissions greatly without forfeiture of material standards of living. The real challenge is political—to transform current technologies and economic practice.

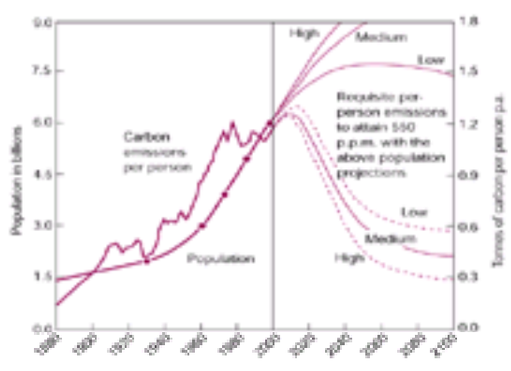

Fig. 1 This shows the configuration of relationships between economic activity, wealth distribution (especially poverty), population size, environmental conditions, and human health. Note that poverty and the material (natural and social) environment are major determinants of health.

Overall, then, the larger potential threat is not from the increase in human numbers *per se* but from mildly environmentally disruptive humans becoming highly disruptive humans—in other words, from a 'development' process that would generalize the patterns of production and consumption typical of today's rich countries. Current practices in rich countries cannot be applied to a human population likely to exceed 10 billion and demanding a higher average standard of living. The Netherlands requires an estimated area 15 times greater than its national size to support its population's way of life. It has been estimated that citizens of high-income countries today each require approximately 4 to 9 ha of the Earth's surface to provide the materials for their lifestyle and to absorb their wastes—while India's population gets by on 1 ha per person. There is not enough Earth to allow more than 1 ha of 'ecological footprint' per average-person when the world population reaches 10 billion during the coming century—and yet that future world population will presumably wish to live like Californians, not Calcuttans.

Serious investment in the development and deployment of less environmentally disruptive technologies, and a much greater commitment to international equity, will be required if a smooth and timely transition to an ecologically sustainable world is to be achieved. Because rich countries remain the main source of new knowledge and new technologies, responsibility for finding paths to sustainability rests mainly with them. Minimizing the probabilities of long-term harm to health will be a major consideration. Indeed, this is now becoming the most important health-related aspect of the 'population debate'.

'Green accounting'

We cannot predict, with certainty, how the adverse health effects of ecological disruption will unfold. It therefore makes sense to concentrate, in the short term, on our society's direction of travel, on whether we are moving closer to, or further away from, sustainable paths of economic development. To this end we need to devise and implement new indicators of material progress.

Sustainability has recently been defined by the Environment Department of the World Bank as leaving to future generations 'as many opportunities as we ourselves have had, if not more'. Sustainability can be more readily expressed in operational terms using measures of economic 'stock' (i.e. capital, including natural capital and human resources) than using measures of 'flow' (income). In this context, conventional national income accounts are both biased (they treat living off natural capital as income) and insensitive (they provide little indication of legacies for the future). A broad measure of wealth would combine the estimated values of natural and human resources with those of produced assets (capital as traditionally considered). Human resources include the 'human capital' embodied in individuals (augmented by health and education levels) and 'social capital' embodied in institutions, customs, and knowledge.

Employing these categories, a pattern of economically sustainable development can be envisaged as one that conserves natural capital while rebuilding (with 'green' technology) the stock of produced assets, and augmenting human and social capital. This shift of emphasis from flows to stocks accords with recent analyses of health trends. For example, in low- and middle-income countries, indicators such as school attendance rates for girls and literacy among adult women are correlated more strongly with the level of child mortality than is income. Countries at similar levels of income may have several-fold differences in child mortality, with the 'better performers' typically showing higher levels of relevant aspects of social capital.

For rich countries, this approach recognizes that health depends less on the consumption opportunities provided by income than on personal and social capacities to protect and enhance health— reflecting, at the individual level, determinants such as schooling and, at the social level, determinants such as food cultures (for example the protection against vascular mortality in Mediterranean populations) and elements of the built environment such as sewers, water supplies, and safe roads. Given that life expectancy differences among high-income countries are, at most, very weakly related to income, it makes little sense to see increasing national income as an important path to sustainable improvements in health.

Conclusion

Over the last two centuries new knowledge of disease and its control, improvements in material conditions, and the enhancement of individual capabilities through education and of social capacities through development of new institutional forms have yielded previously unimaginable improvements in health and longevity. During the historical gap between the fall in the death rates and the fall in birth rates, populations increased rapidly—and are still doing so in many poorer countries. Meanwhile, in high-income countries, attention should be substantially redirected from achieving yet higher local levels of health to developing the conditions necessary to both generalize and sustain good health worldwide.

A first essential is birth control, for without it death control is unsustainable. A second task is to revise our expectations of 'progress' and to reconstruct the milestones by which we measure it, so that the interests of future generations are safeguarded. Physicians are well placed to foster greater public understanding of why large-scale environmental disruption is likely to jeopardize the health of our grandchildren.

3.3 The pattern of care: hospital and community

Anthony Harrison

Introduction

Changes in the treatments available over the last 100 years have transformed the care of individuals. Conditions once untreatable, can now be successfully dealt with, while advances in public health have transformed the pattern of disease confronting the health care system, eliminating or virtually eliminating some diseases. These developments have had a strong influence on the pattern of health care delivery. For much of the twentieth century they led to an expansion of the role of hospitals, but towards the end of the century the scope for moving care to other settings was increasingly recognized.

In 1920, a committee chaired by Lord Dawson set out a blueprint for the way that health care services should be delivered in England. The pattern it proposed consisted of primary and secondary care centres, the first located as near as possible to the local population, and the second in any sizeable urban area. If that area was not large enough to support a teaching hospital, the secondary centre and the teaching hospital should be linked professionally. The primary care centres would provide for a wide range of services including general practice and dentistry and, despite their modest size, inpatient beds. Their location in a single facility would, it was hoped, encourage professional interchange and collaboration. This early attempt to set out a vision for the pattern of health care delivery across all services forming a defined geographical area was not implemented even in the country for which it was devised. However, two central issues were presented that continued to preoccupy policymakers ever since.

1. Exactly which clinical services should be provided locally and which regionally or even nationally?
2. How should the various elements be persuaded to work together?

These questions face any health system but the way they are approached varies according to the way that health care is organized and financed. To outside observers, the British National Health Service (**NHS**), funded almost entirely from a single source and under the control of a single central body, in contrast for example to the pluralist systems obtaining in the United States or Germany, has seemed ideally placed to resolve these issues in a systematic way. In practice, however, solutions have remained elusive in all health care systems.

Since Lord Dawson put forward his proposals, the expansion of clinical knowledge, the specialization that goes with it, and the introduction of expensive diagnostic hardware created pressures for larger concentrations of clinical skills within hospitals. That trend was further strengthened by the growth of clinical research in close association with the patient care and teaching functions of the large acute hospital. Hospital development and clinical progress appeared almost synonymous.

Towards the end of the twentieth century, however, that perception began to change. Although the acute hospital has retained a central role in the health care system, its relative importance has begun to decline. Table 1 sums up some of the key changes within England: similar trends are apparent and indeed are in some cases more advanced in other countries.

The growth in activity as measured by the number of patients treated reflects the massive increase in the scope of hospital work brought about by developments in medical technology such as imaging and endoscopy and the vast new range of surgical procedures such as joint replacement, from which a wide range of the population can benefit.

The large acute hospital has been the physical expression of modern medicine through most of the twentieth century, but it became obvious, towards the end of the century, that technological development was allowing effective care to be provided off the hospital site for conditions once treated within it. Consequently, the scale of some elements of hospital care could be reduced.

A combination of developments in clinical technology, particularly in anaesthesia and surgical techniques, and financial pressures imposed by those paying for care, whether government or private insurers attempting to control health care spending, has resulted in continuing losses of bed capacity even while the numbers of treated patients have gone up. Loss of beds was particularly noticeable in surgical specialties as, from the early 1990s onwards, the proportion of patients treated as day (ambulatory) cases rose rapidly. Medical specialties also lost beds, as lengths of stay fell. Thus the acute hospital sector has continued to expand throughout the twentieth century, but its physical capacity, as defined by its bed-stock, has begun to decline. Turnover has become increasingly rapid. This in turn has meant that its efficient operation is increasingly dependent on effective links with community-based services offering aftercare and other forms of support.

These changes in the acute hospital in themselves implied some degree of shift of care to community settings. Rapid discharge schemes and hospital at home schemes have been developed, often administered by community-based nurses. They complemented the hospital's drive to reduce length of stay and use its remaining bed-stock more intensively. Similarly, other parts of what was once the hospital's role, such as check-ups following an inpatient admission, have tended to become the responsibility of general practice.

These changes were part of a wider and more fundamental development—the dispersal of a wide range of hospital activities to other settings, inspired by developments in technology, changes in clinical practice, and the search for lower costs of provision. The rapid introduction of new drugs from the 1950s onwards allowed general practitioners to deal with a large number of conditions which at one time would have been part of the hospital's workload. In some cases, such as diabetes, technological developments—in this case simple self-monitoring devices—allowed some care to be effectively transferred to the patient's own home. Hospitals were needed only for emergencies.

Lord Dawson's proposal for primary care centres was not widely adopted in its country of origin, but the idea that general practice should be the universal front-line of the health service was, in England and many other countries, seen as the foundation of a properly organized health service. General practice offers ready access and continuity of care, but also some control via the gatekeeping function, to the high-cost services of the hospital. This restriction of patient choice has not been universally accepted. Germany for example continues to allow patients to consult specialists directly. The United States has not had the same tradition of general practice and has, until recently, offered freedom of choice. However, financial pressures have led to the creation of managed care organizations aimed at restricting access to specialist, hospital-based care.

The general practitioner or community-based physician has assumed a co-ordinating role. The range of professional services, closely connected to the practice, has grown and with it the concept of an integrated primary care team emerged, reflecting the range of services, such as nursing, physiotherapy, and counselling, that come within the ambit of general practice or work in close association with it.

While the pattern of acute care was changing, an even more dramatic change was taking place in long-stay hospitals housing the elderly, the mentally ill, and those with learning disabilities. Clinical developments, particularly new drugs for the control of severe mental illness, played their part. However, the main explanation for this switch from hospital to community was the perception, which became widespread in the 1980s and 1990s, that most people housed in these institutions did not need to be there. With appropriate support from housing and social services as well as clinical staff, they could perhaps live reasonably normal lives in the community.

However, problems remain. The switch of some care to the community has not been wholly successful. The transfer of care for the mentally ill away from large isolated institutions to smaller local units supported by a network of health care and other community-based services has led to the emergence of a different pattern. Many patients reach specialist care by self-referral or other routes, and for many, the main point of contact is a community nurse and/or social worker rather than a general practitioner. Their roles are central to the creation of community support networks which provide access to housing, and recreational and other facilities essential to everyday life. Such networks have proved hard to manage and, in practice, the necessary liaison between their various elements has not always been

possible, particularly in times of crisis.

The switch of care for long-stay groups into the community has led to closures of the large hospital institutions that once housed them. These trends have led to the closure of smaller acute hospitals—or a drastic reduction in the scope of their activity through, for example, the transfer of inpatient admission facilities to other sites. This has been bitterly resisted by local communities, but the combination of cost pressures and clinically based arguments in favour of concentration of services has often proved decisive.

Such rationalizations have been based on the presumption that larger hospitals are better, both economically and clinically. The evidence on both is limited. What exists is often of poor quality since confounding factors make it hard to disentangle the effects of size on the outcomes of care. Overall the available evidence does suggest that specialization of clinical roles with concentration of hospital work in fewer sites produces better results. How far this process should go remains unclear and in some areas of care it may already have gone too far.

Working together

Although most episodes of care are 'singletons' consisting of a visit to one health care professional such as a general practitioner or dentist in the community or the accident and emergency department of a hospital, many are complex, involving many different professionals even within a single hospital institution and extending for long periods. Modern medicine has virtually eradicated some diseases and has contributed, with the social and economic trends associated with the growth of personal incomes, to prolonging life. This has meant that a large part of clinical practice is taken up with chronic conditions and with treating frail elderly people who often need continuing support after, for example, an episode of acute hospital care.

An effective health care system requires that these various contributions are made by the most appropriate professionals and are co-ordinated to prevent the patient falling through gaps between different organizations or professionals. These requirements have proved difficult to fulfil. Even within the British National Health Service funded from a single central source and under unified management, there are frequent failures of the various elements to mesh together properly. Failures often occur at the interface between different organizations. A persistent area of difficulty has been hospital discharge, particularly for those requiring postoperative support. Delays have given rise to the notion of the 'blocked bed'. Blocks can sometimes be attributed to poor internal communications within the hospital. They also reflect failure to co-ordinate the hospital discharge process with provision of community health and social care services. This failure reflects differences in source of funding, which create a division—artificial from the viewpoint of the patient—of responsibility for closely related care functions.

Research has revealed important gaps in the care system, particularly in rehabilitation after stroke or heart attack. As a result, too many people may be prematurely admitted to community long-stay institutions. Again the difficulties can in part be attributed to the failure of the financial mechanism to match clinical and patient requirements.

The search for better service integration has stimulated a number of initiatives. In hospitals, these range from large-scale re-engineering of the hospital as a whole to more modest attempts to improve the care pathways for specific groups of patient such as those receiving new joints or other procedures where some degree of care after discharge is required. In some cases, such pathways extend across care providers. The British government has recently introduced the concept of a national service framework. This is intended to define both the elements required from all forms of provision—hospital and community—and the way they should work together to form a clinically integrated system of care. In principle, this should ensure a correct balance between preventive and curative means and should enable patients needing care to be correctly and promptly routed to an appropriately equipped and trained clinical team. In the United States and elsewhere, disease management programmes have been developed with similar objectives.

Cost pressures have meant that the orchestration of the various contributions of complex episodes of care has been combined with a search for the best combination of professional contributions, where necessary across the boundaries of existing disciplines. It is increasingly accepted that different professional roles are to some extent interchangeable. Many health care systems are experimenting with mixtures of different skills, allowing nurses and in some cases technicians to take over roles which were once exclusively medical.

The emphasis on clinical integration has led to the creation of new professional roles such as liaison nurses. They are intended to co-ordinate contributions by different organizations, for instance that hospital and community professionals co-operate at the point of discharge and that the various elements required for post-discharge support are put in place.

The search for the effective integration of care across the boundary of the hospital and the community continues. In the United Kingdom, the Labour Government's first white paper on health policy, *The new NHS*, suggested ways in which health and social care providers might work together harmoniously.

Conclusions

The pattern of health care services will continue to change, as a result of continuing technical developments within medical and information technology and as a result of social and financial pressures for new forms of service delivery. The balance between hospital and community and between hospitals of different sizes and structure will vary according to the relative advantages in access, cost, and clinical effectiveness of treatment in different locations.

For clinicians, the most important development is the move towards the definition of care pathways and whole systems of care for broad disease groups running across the boundaries of individual hospitals and those of community- and hospital-based organizations. While the bulk of medical training and practice will remain focused on the individual intervention and the patient encounter, the vision of health care delivery is of a series of integrated pathways or networks. Clinicians must start to take responsibility for system management as well as patient care.

Critical future developments may lie as much with the user as the professional. Many health systems have been introducing a new front line—the telephone. In England, after a series of experiments in different parts of the country, the first steps were taken in 1998 towards the introduction of a national network of nurse-provided advice lines. Information technology is making it easier to gain access to knowledge that was once the preserve of the professional. Many large health care institutions in the United States now have websites which are accessible worldwide. The NHS has recently opened a site of its own: NHS Online. Patients are becoming better informed. If these developments succeed in changing the balance between professional and user, new patterns of care will emerge that suit the user rather than the professional. In some areas, such as maternity care and mental health, this is already happening.

3.4 Preventive medicine

D. Mant

In his millennium address, Nelson Mandela reminded the world that 'we close the century with most people still languishing in poverty, subjected to hunger, preventable disease, illiteracy and insufficient shelter'. The health gap between rich and poor nations is shameful. For example, life expectancy in Malawi is 34 years compared with 79 years in Sweden. But even in the economically developed world many people still die prematurely. In England and Wales almost 1.4 million years of working life are lost each year due to death before age 65 years. Again, there is a marked gap between rich and poor—the death rate from lung cancer in males aged 20 to 64 years is almost three times as great in social classes IV/V (SMR 151) as in I/II (SMR 58). It is naïve to think that medicine will remedy this situation. The fundamental step in achieving good health remains the elimination of poverty, with consequent access to food, sanitation, education, and shelter. But the power of medicine lies in the scientific understanding it provides of the disease process. Preventive medicine uses this understanding both to try to reduce the risk of disease and to detect and treat appropriately emergent disease before it does damage.

What is the scope for prevention? Figure 1 shows the number of women expected to die at different ages if 10 000 were subject to the age-specific death rates in England and Wales of today compared with the1870s (the pattern is similar for men). The dramatic fall in deaths during childhood and early adulthood has meant that the modal age of death is now over 80 years. However, what medicine cannot offer is immortality. The proportion of women surviving to age 65 who live on to age 100 is still very low, about 0.5 per cent. So there seems to be a reasonable expectation that effective preventive medicine might make death before age 70 or 80 years uncommon—but the objective is delay of death, and hopefully better quality of life before death, rather than absolute prevention of death.

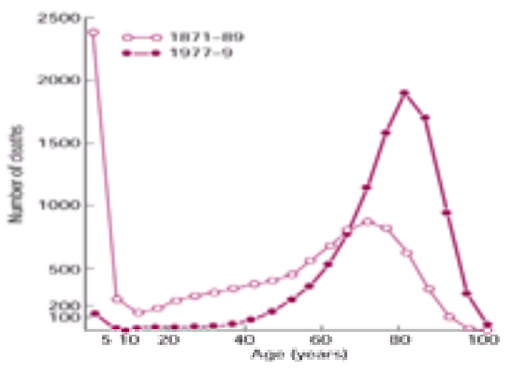

Fig. 1 Numbers of women dying at different ages if 10 000 were subject from birth to the mortality rate current in 1871 to 1880 compared with that in 1977–9. (Figure originally drawn by Doll R. *British Medical Journal*, 1982; **286**: 445–53.)

Preventive strategies

The prevention paradox

The main difference between preventive and curative medicine is the focus on risk. Preventive medicine aims to reduce the risk of disease and the risk of further morbidity and mortality in those who develop disease. It offers hope for the future rather than immediate benefit. The benefit from preventive medicine is the absence of future disease. This is a difficult benefit to champion, particularly to the individual. As Geoffrey Rose pointed out many years ago, not only is the benefit intangible but many people must take precautions in order to prevent illness in only a few. Even in a country where diphtheria is common, several hundred children must be immunized to prevent one death. Rose called this the prevention paradox—a preventive measure which brings large benefits to the community may offer little to each participating individual.

The risk paradox

Epidemiological studies define risk factors for disease—the personal or environmental characteristics which increase the likelihood of developing the disease. One of the risk factors for cardiovascular disease is a high level of cholesterol in the blood. Figure 2 shows the prevalence of high cholesterol in the United Kingdom population, the death rate associated with each cholesterol level, and the proportion of all deaths attributable to cholesterol occurring at each level. The risk paradox is that although those with a blood cholesterol of 7.5 mmol/l or greater are at highest individual risk of disease, the population at highest risk is that associated with a cholesterol level of 5.5 to 6.0 mmol/l. This is simply because of the number of people at risk—there are far fewer people in the high than in the moderate risk group. Targeting just the high-risk group will have relatively little impact on the total number of deaths.

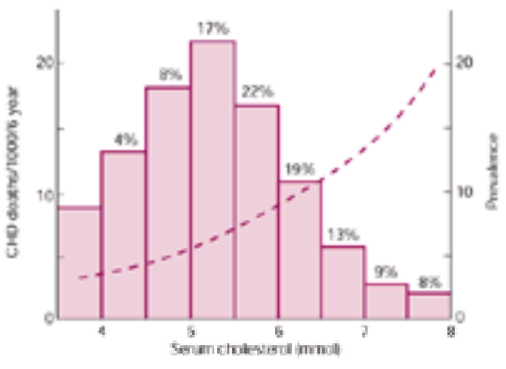

Fig. 2 Proportion of coronary heart disease deaths attributable to raised serum cholesterol occurring at each level (figures above columns). Columns show the

prevalence of different levels of cholesterol in the population. The broken line shows coronary heart disease mortality at each level. (Reproduced from Rose G. *Strategy for prevention.* Oxford University Press, 1992: 23.)

Defining the at-risk population

As preventive medicine seeks to reduce future disease, its patients are usually identified by characteristics which predict risk of developing the disease. It is usual to define this risk in one of three ways—demographic, phenotypic, or familial. Within each category, further subpopulations may be identified as at particularly high risk.

Demographic risk

This is the most common way to define the target group for preventive medicine. Both the United States and Canadian task forces on prevention (see further reading) classify preventive interventions by the age of the target population. Screening programmes, which often target gender-specific diseases (e.g. breast and cervical cancer), may also specify the target population by sex. Geographical specification of risk tends to reflect health-care system boundaries but some preventive programmes target specific ethnic or socially disadvantaged groups.

Phenotypic risk

A phenotype is a set of observable characteristics of an individual or group. Most epidemiological risk factors for disease (e.g. smoking, obesity, hyperlipidaemia) are phenotypic. Other phenotypic categories used to define at-risk populations are behaviours (e.g. smoking, driving), disease states (e.g. diabetes, angina), and physical characteristics (e.g. obesity, cholesterol level). As phenotypic risks are sometimes interactive (i.e. more than one risk factor influences a specific disease risk), multiple risk assessment is an increasingly common practice.

Familial risk

Recent advances in genetic technology have increased our ability to characterize familial risk accurately, and further advance is likely in the next few years. At present, most preventive medicine programmes in this area use genetic assessment to refine assessment of individual risk in phenotypically identified high-risk families (e.g. cystic fibrosis, neurofibromatosis) or populations (e.g. Down's syndrome). However, the characterization of risk based on population-based genetic screening is already technically feasible in the economically developed world.

Identifying the at-risk population

Some public health interventions can be applied without identifying the at-risk population—you can pass seat belt legislation and increase the tax on tobacco without identifying either drivers or smokers. However, most interventions in clinical preventive medicine are delivered to individuals. It is therefore necessary not only to define the at-risk population but also to identify the individuals within it. You don't just need to know that smokers are at risk, you need to know who smokes. Again, this is usually done in one of three ways—registration, screening, and case-finding.

Registration

Most socialized health systems keep registers. These may be simply demographic (e.g. age, sex, and address) or contain phenotypic or genetic details of individuals. Effective preventive medicine is much easier where registration exists and its accuracy is systematically maintained.

Screening

This topic is covered in Chapter 3.6. The objective is to identify early disease or high risk of disease (e.g. neoplastic dysplasia) before significant morbidity occurs. Its most important feature is that it can do harm as well as good (it may generate 'false alarms' and detect disease which would not otherwise present during the patient's lifetime) and benefit needs to be carefully assessed, normally in a randomized trial. Population screening is most efficient when based on an accurate population register.

Case-finding

This involves identifying at-risk individuals during routine clinical work (normally in clinical consultations, but sometimes through contact or family tracing). It is less efficient than systematic population screening, but sometimes provides better access to socially disadvantaged groups who may respond poorly to screening invitations or have no registered address. It also allows some interventions to be given at a particularly appropriate moment (e.g. smoking cessation advice at a consultation for cough or contraceptive advice after termination of pregnancy).

Interventions to modify risk

The marked improvements in health which have been achieved in economically developed countries over the past 200 years are not attributable to medicine. Life expectancy has doubled mainly because of environmental control of infectious pathogens (through sanitation and control of insect vectors) and a lifestyle which reduces individual susceptibility to infectious disease (better food, shelter, and education). So although medical science can play an important role in guiding public health policy by improving understanding of the mechanisms of disease, and specific medical interventions allow us to treat disease when it occurs, the role of preventive medicine should not be overestimated. In particular, the medical profession should not take upon itself responsibilities for public health which are more appropriately assumed by governments and other social and environmental agencies.

However, preventive medicine is an important and integral part of good curative medicine. All doctors have a responsibility to think about why someone is ill. Whatever cause is identified (physiological, social, or psychological) the question of whether the cause can be prevented (and the risk of future disease reduced) should be addressed. Doctors who work in a primary care role (particularly those with a registered population) have the added responsibility to ask themselves whether the risk should be addressed at a population rather than just an individual patient level.

Primary and secondary prevention

Preventive interventions have traditionally been categorized as primary, secondary, and tertiary depending on their objectives. However, the term secondary prevention is now commonly used to cover both secondary and tertiary categories. According to this common usage, primary and secondary prevention can be defined as follows.

1. Primary prevention—interventions to reduce the risk of disease in healthy people (e.g. use of seat belts to prevent injury in car accidents; tobacco control to prevent the occurrence of smoking-related disease; immunization against infectious disease).
2. Secondary prevention—interventions to prevent avoidable morbidity in people with disease (e.g. treatment of vascular disease with aspirin; screening for early cancer).

It is immediately obvious that the distinction between primary and secondary is sometimes difficult. Some interventions can fall into more than one category (e.g. stopping smoking reduces the progression as well as onset of many smoking-related diseases) and the definition of disease is not absolute (e.g. many apparently healthy people will have undetected disease). Nevertheless, the pragmatic categorization of preventive interventions into primary and secondary is often useful in practice.

Immunization

Immunity can be induced against many pathogenic bacteria and viruses. Active immunity is usually achieved by stimulating antibody production by vaccination with an inactivated organism (pertussis, hepatitis A/B), an attenuated live organism (measles, rubella), an antigenic component of the organism (influenza, pneumococcus) or an inactivated toxin (tetanus, diphtheria). Long-lasting immunity can be induced with a single dose of live vaccine. At least two and sometimes three doses are needed for other vaccines, although once an IgG antibody response has been induced, antibody levels are likely to remain high for months or years and can usually be reinforced by a single booster dose. Passive immunity is achieved by injection of human immunoglobulin and therefore protection lasts only a few weeks.

Vaccination can be a very effective preventive strategy. Vaccination against smallpox has led to global eradication of the disease; eradication of polio seems a feasible global objective in the next decade. Vaccination against many other diseases, particularly diseases of childhood such as measles, diphtheria, and polio, has led to rapid and dramatic falls in disease incidence. Figure 3 shows the impact of introduction of the Hib vaccine in 1992 on the incidence of *Haemophilus influenzae* infection in England and Wales.

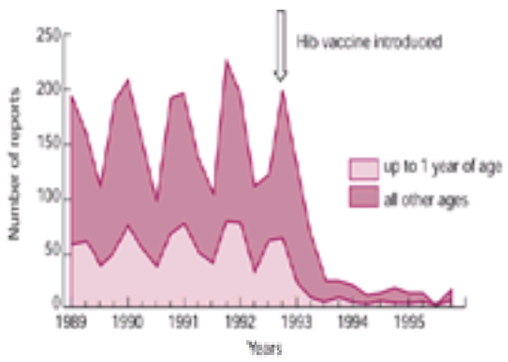

Fig. 3 Laboratory reports of *Haemophilus influenzae* type b before and after introduction of the Hib vaccine (England and Wales 1989 to 1995). (Reproduced by permission of the Controller, Her Majesty's Stationery Office.)

A number of new and important vaccines are on the horizon—for example, a malaria vaccine. But the existence of an effective vaccine does not guarantee the success of an immunization programme. This depends on the effective delivery of the vaccine to the at-risk population. Vaccination programmes are often limited in their effect by affordability (many vaccines are too expensive for developing countries), acceptability (parental anxiety about the adverse effects of pertussis vaccine has limited its uptake in many countries), and deliverability (vaccines may lose potency if stored outside a refrigerator). There are also potential problems with the antigenic variability of organisms (e.g. influenza) and the difficulty of immunizing at an age young enough to prevent morbidity but old enough to stimulate an immune response (e.g. measles). Nevertheless, immunization is probably the most important medical contribution to primary disease prevention.

Prophylactic treatment

Although most people think of medicines as cures for current illness, many medicines are prescribed with a view to preventing future illness. Antibiotics are given before surgery to prevent postoperative infection, antimalarials to prevent malaria in travellers, anticoagulants to prevent stroke in people with atrial fibrillation, and lipid-lowering agents to prevent heart attacks in people at high risk of cardiovascular disease. The duration of treatment may also be extended beyond the initial treatment phase to achieve a preventive effect. Antidepressants are continued after cure to prevent relapse, ACE inhibitors to prevent worsening of ventricular dysfunction, and uricosuric agents to prevent further episodes of gout.

It must be clear from these examples that many, perhaps most, drugs have the potential to be used for prevention as well as cure. In some cases (e.g. treatment of diabetes) the distinction between prevention and cure is unhelpful—treatment aims to prevent morbidity in both the short and long term. However, in all the examples given, prescribing is limited to a defined high-risk group. Prophylactic treatment with drugs is less helpful when a high-risk population cannot be easily defined. It is almost always inappropriate to use prophylactic treatment to reduce population risk for three reasons: the strategy is seldom cost-effective, increasing the reliance of the population on medicine is an adverse social outcome, and uncommon adverse effects can easily outweigh any clinical benefit. The last point has been repeatedly demonstrated in clinical trials, including the use of lipid-lowering agents to prevent heart disease and antioxidants to prevent the development of cancer.

Changing behaviour

Environmental factors contribute substantially to differences in premature morbidity and mortality. Many of these environmental factors reflect individual behaviour. Eating more healthily, taking more exercise, and avoiding riding on a motorcycle are all effective ways of preventing disease. People do listen to doctors, and a number of clinical trials have shown advice on behaviour modification to be cost-effective, even though the effect size may be small (e.g. in most studies only about 1 in 20 to 30 smokers given brief advice to stop smoking actually quit). Brief advice is most effective if practical in nature (giving guidance on how change can be achieved) and if backed up by written advice to take home. More intensive interventions tend to be less cost-effective. Time spent on alternative preventive activities (e.g. effective management of chronic disease) may reap greater rewards.

Environmental change

Many environmental causes of disease are best modified on a public health rather than an individual basis. Such factors include the safety of the workplace, environmental pollution, transport safety, food hygiene, and provision of clean water. However, a number of diseases have environmental causes which need to be recognized and avoided by the individual patient. On a global scale, avoidance of insect and other disease vectors (e.g. by netting) and attention to nutritional hygiene (e.g. by filtering water) are probably the most important. In economically developed countries the most common diseases amenable to individual environmental intervention are those associated with atopy—such as asthma and eczema. Not all patients have an identifiable allergenic cause for their symptoms and, even if one is identified, avoidance (e.g. of house dust mite in asthma) may not be easy. But dramatic improvement can occur, and treating contact dermatitis without giving advice on contact avoidance, or treating louse bites without giving advice on how to rid clothes of lice, is bad medical practice.

What interventions work?

It is impossible in a single chapter to cover every possible preventive intervention. It is also undesirable, because many preventive interventions are better seen as part of good routine clinical care (and are included in the relevant chapters on specific diseases). Nevertheless, it is worth listing the preventive interventions which may not be included elsewhere, and for which there is very good evidence of effectiveness from clinical trials. The best sources of evidence are the task force reports from Canada and the United States (see further reading). The evidence cited below is based on the last (1997) update of the Canadian report on clinical preventive health care. It focuses on issues of importance in economically developed countries in which most of the research has been done.

Table 1 lists the preventive interventions shown to be effective for mothers and babies. The target for all but one intervention (screening for haemoglobinopathies) is the whole population. Many of the interventions are usually delivered by midwifery or nursing staff (health visitors in the United Kingdom), but medical staff may be involved in child development and antenatal examinations and it is very important that they reinforce the advice and guidance given by other staff.

Table 2 deals with children and adolescents. Immunization, dental care, and protection of hearing are interventions which should be offered to all children. All other interventions are targeted at specific high-risk groups, particularly children living in conditions of social disadvantage or with families identified as being at 'high risk' of providing unacceptable levels of child care. Chemoprophylaxis is effective for child contacts of open tuberculosis and for immunocompromised children exposed to influenza. Screening for sexually transmitted disease has been shown to be effective in at-risk adolescents and children.

Table 3 deals with interventions for adults, including the elderly. Only two (hearing impairment and dental care) are targeted at the whole population, although post-fall assessment is targeted at all elderly patients and mammography at all women in the relevant age group. The effectiveness of mammography has again been questioned recently, but the balance of evidence remains in its favour. All other interventions are aimed at high-risk groups. It must be stressed that the omission of

many secondary preventive interventions (e.g. management of high blood pressure; rehabilitation after myocardial infarction) reflect their inclusion in other chapters rather than lack of evidence of effectiveness.

What is achievable?

Programme effectiveness

The interventions cited above are known to work because they have been tested in clinical trials. However, clinical trials are often done in settings far removed from everyday life—participants are compliant, those delivering the intervention are highly trained, the technology is of high specification, and quality control is rigorous. These conditions will not hold on a wet Tuesday morning in the boondocks. When preventive interventions fail, the most common reason is lack of effective implementation of the implementation programme, rather than lack of effectiveness of the intervention itself.

The importance of considering programme effectiveness is seen most vividly in relation to immunization and screening programmes. The three most important issues which determine programme effectiveness are the following.

1. Coverage—What proportion of the population at risk receives the intervention?
2. Delivery—Are factors which effect the delivery of the intervention (like the maintenance of equipment, the training of staff, and the storage of biological materials) up to scratch?
3. Quality control—Are standards set and monitored for key indicators of the intervention process (e.g. immune response or predictive value of screening)?

The effect on programme effectiveness of failure in just one of these areas is well documented in the United Kingdom in relation both to immunization (e.g. the resurgence of pertussis after media publicity about potential adverse effects of the vaccine led to a fall in uptake) and to cervical screening (e.g. lack of quality control in cervical sampling and cytological assessment led to false-negative results and avoidable mortality).

Cultural constraints

Many preventive interventions aim to change behaviour. Most behaviour has a strong sociocultural component and reflects prevalent attitudes and norms in society. Preventive interventions are severely constrained by this social context—convincing individuals to stop smoking, eat less salt, drink less beer, or drive more slowly is difficult if everyone else is doing the opposite. For example, the mean blood cholesterol level in Finland is almost twice that in Japan (Fig. 4). Migrant studies suggest that this difference is dietary rather than genetic in origin and so medical advice to reduce fat consumption should have the potential to reduce substantially blood cholesterol level. However, even in the context of a clinical trial, dietary advice from health professionals in a community setting seldom achieves a reduction in blood cholesterol of more than 3 to 5 per cent. Studies of salt restriction (to lower blood pressure) show a similar result—intensive intervention and support is needed for an individual patient to achieve a physiologically significant reduction in intake, with many finding such a diet unpalatable. Countercultural change is difficult to achieve.

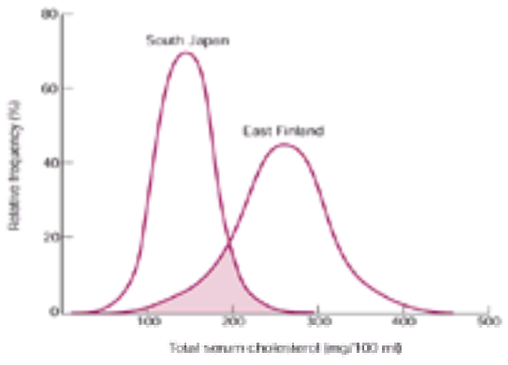

Fig. 4 Distribution of serum cholesterol in southern Japan and eastern Finland. (Reproduced from Rose C. *Strategy of prevention*. Oxford University Press, 1992: 57.)

Time effects

Things change over time. The North Karelia project was a large-scale long-term programme to reduce mortality from cardiovascular disease in northern Finland started in 1972 which involved both public health and individual intervention. Figure 5 compares mortality from cardiovascular disease in North Karelia with that in 10 other provinces in Finland before and during the intervention by plotting two regression lines. The difference in slope of these two lines shows that the intervention was to some extent effective. However, far more impressive in magnitude is the absolute fall in mortality over time in both North Karelia and the other provinces. The lessons for preventive medicine are twofold: the effect of medical intervention may be small in relation to the effect of other economic and social influences; and the change in baseline risk and social context over time may be so rapid that it will substantially influence the absolute benefit of any preventive intervention.

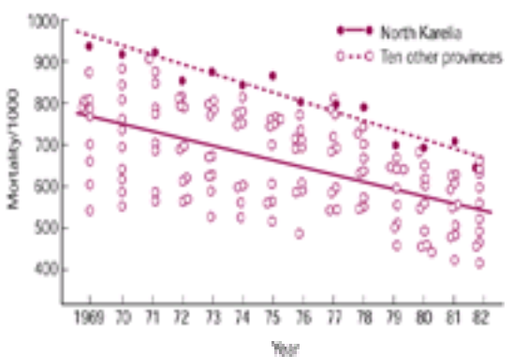

Fig. 5 The North Karelia project. Age-standardized annual mortality from cardiovascular disease in men aged 35 to 64 in Finland, 1969 to 1982. (Redrawn from original data published by Tuomilehto J *et al*. *British Medical Journal,*1986: **293**: 1068–71.)

Conclusion

Preventive medicine is an integral part of clinical practice for all doctors. It is our responsibility as clinicians not only to cure the presenting illness but also to take action where possible to prevent future morbidity. However, we must display both humility and assertiveness in our approach. We need to be humble in our approach to patients and to recognize that medicine is not the main determinant of health. At the same time we must display assertiveness in our advocacy of prevention. In the United Kingdom, the Royal College of Physicians' reports, the campaigning of medical charities, and the decision of virtually all doctors to stop smoking have played a major role in influencing both public and political opinion against tobacco use. As a profession, we can make a unique and powerful contribution to prevention by identifying the existence and causes of ill health. We also have a unique and powerful responsibility to act as advocates for our patients in seeking to ensure that these causes are addressed and the risk to their health is minimized. Good clinical practice entails preventive medicine, but good preventive medicine is more than just good clinical practice.

3.5 Health promotion

Keith Tones and Jackie Green

Health promotion

Health: meaning and aetiology

Health: the positive dimension

Health promotion is a controversial concept—it means different things to different people. This is not surprising since the notion of health itself is open to many interpretations. The definition of health embodied in the Constitution of the World Health Organization (1946) confirmed that health is not just the absence of disease and infirmity. It is also concerned with positive well being and has mental and social as well as physical dimensions. Although there is a temptation for medical practitioners to dismiss such preoccupations with well being as vague philosophizing, medicine cannot, and should not, discard these broader concerns. For instance, the notion of tertiary prevention has traditionally acknowledged that medicine should aim to maximize the quality of life of those it cannot cure. There is also increasing evidence that life expectancy, in addition to well being, can be influenced by a number of 'positive' individual and social attributes. For instance, the notion of 'social capital' is currently very popular with health policy-makers—it is argued that a high level of social capital supports health through giving access to a range of social networks which provide support and foster a sense of social connectedness. People will be healthier if they feel they are in control of their lives and that their lives are meaningful and make sense emotionally—in other words, they have a 'sense of coherence'. The central concern of health promotion should be not only to add years to life but life to years!

Determinants of health

Whether health is defined as the absence of disease or as a broader more holistic state, it is widely agreed that four major factors determine the extent to which people are or are not healthy. These are shown in Fig. 1.

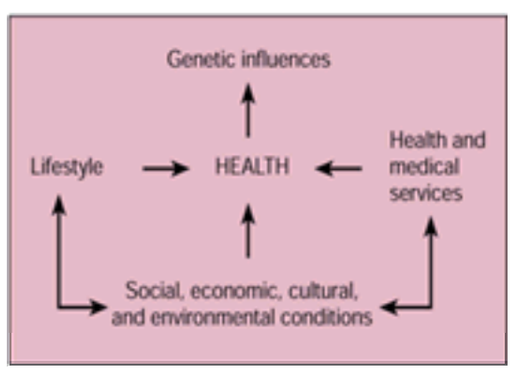

Fig. 1 Determinants of health

Traditionally, the individual's lifestyle has been the main target of health education—together with exhortations to make proper use of medical services. The current view is that the environment in which we live, work, and play has the most powerful influence, either directly or through the mediation of individuals' behaviour. Accordingly, the most effective health promotion strategies are those that modify the environment to make it safer and more health-enhancing and, most important of all, those which tackle the social and economic factors that cause health inequalities. Environmental circumstances may make it more or less easy for individuals to adopt healthy behaviours. For this reason a central concern for health promotion is to go beyond merely providing education about healthy choices. It should provide a supportive environment such that the 'healthy choice becomes the easy choice'. Of course, changing the environment often requires substantial changes in public policy and associated political action. Health promotion is therefore considered to include both health education and 'healthy public policy'.

Human behaviour in health and illness

Although some medical practitioners have been involved in a wide range of different health promotion activities—including community development and creative arts projects—the face-to-face encounter between doctor and patient is the most common focus of interaction. Every such encounter offers an opportunity for one-to-one health promotion. However, quite often this face-to-face interaction fails to capitalize on the potential offered.

Lessons from failure

Promoting healthy lifestyles is not an easy task and requires a thorough understanding of human behaviour at the social and individual level. The interaction between health professionals and their clients has been subjected to extensive research. This research confirms that, on average, as many as 50 per cent of people fail to co-operate with health advice of any kind, and changes in lifestyle are particularly challenging. A variety of reasons accounts for this failure, for example:

- recipients of, or participants in, health promotion often misinterpret the information provided and a smaller proportion forget key points;
- many people do not believe the information provided because it conflicts with their own ideas and beliefs;
- people may want to change lifestyle but do not believe they can change—because of real or perceived obstacles to action;
- environmental circumstances may be such that there is an absolute barrier to change.

We can and must draw lessons from examples of failure. Typically they are due to inadequate and naïve attempts at health promotion and lack a sound theoretical foundation. There is, however, considerable evidence that allows us to state categorically that health promotion can be effective—provided that appropriate and sufficiently sophisticated interventions are employed. Such interventions should be derived from analysis of the determinants of health and health behaviour, and must be based on a thorough understanding of the psychological, social, and environmental factors that influence people's behaviour in health and illness.

The psychosocial and environmental determinants of health actions

Figure 2 summarizes the important factors that determine whether or not individuals will adopt a new and healthier course of action.

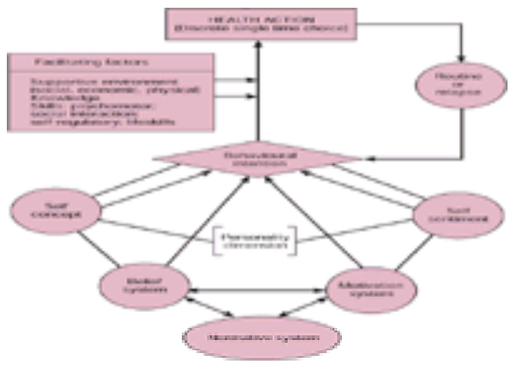

Fig. 2 Determinants of health actions.

Three major systems influence individuals' intention to act, that is the strength of their determination to adopt new types of behaviour or change old habits. These comprise the sum total of their beliefs about carrying out the action, together with their level of motivation to take action. This, in turn, will be the product of all their values and attitudes relating to the action and other emotional states. Finally, their intentions will also be determined by the cumulative influence of social pressures. These pressures will range from the relatively unimportant effect of general norms, conveyed by mass media, through the more powerful community norms, to the much greater influence of close friends, peers, and family.

Even quite firm intentions to adopt a healthy course of action will only be translated into practice if the environment and social circumstances are supportive and there is adequate provision to overcome the various barriers that often stifle action. In other words, it is essential to identify those circumstances that 'make the healthy choice the easy choice' and help avoid relapse into earlier unhealthy habits. The psychosocial and environmental prerequisites for adopting and routinely using condoms as part of a package of safer sex practices provide an illustration of what is required.

Beliefs and motivation

Certain key beliefs will contribute to the intention to use condoms with a sexual partner. First of all, individuals must believe they are susceptible to infection. Furthermore, they must accept that using a condom really will prevent HIV infection (and other sexually transmitted diseases). This belief will, in turn, depend on their having sufficient understanding about the nature of the virus and its mode of transmission—and by accepting that a condom's thin membrane is an effective barrier to the virus. More importantly, they must be persuaded that using a condom will neither be expensive nor inconvenient. Unfortunately, there is a common belief that condoms reduce sensitivity and gratification, interrupt lovemaking, and generate embarrassment!

A number of key motivational factors may militate against safer sex. Most people value health and are worried about the risk of disease—especially fatal disease. However, many women have been conditioned to believe that casual sex is immoral, a powerful disincentive to taking anticipatory action. This may well create a situation in which a powerful moral value may rule out precautionary action, but be insufficiently powerful to resist sexual passion and their partner's preference.

Social pressure

It is widely recognized that intentions are influenced not only by personal beliefs and values but also by various pressures, real or imagined, from other people. These pressures will include the general influence of social norms in defining 'normal' sexual behaviour, peer expectations and pressures, and also the particularly powerful influence of the partner or potential partner.

Skills and the environment

Good intentions will rarely be implemented unless barriers to action have been minimized and appropriate support has been provided. Three kinds of supportive strategy may be necessary. The first and simplest of these involves access to the information needed to adopt the health action. In this specific example—where to obtain and how to use condoms.

The second prerequisite for making healthy choices is to acquire essential skills:

- assertiveness to negotiate condom use with a partner;
- interpersonal skills and associated confidence needed to obtain condoms;
- psychomotor skills needed for safe and efficient use of the condom.

Third, the provision of a supportive environment is essential. A range of environmental measures will be relevant, including physical measures such as access to condoms and social measures that will create a climate in which condom use is acceptable.

However, the most difficult environmental barriers of all are the socioeconomic circumstances associated with poverty and its accompanying feelings of hopelessness and helplessness. It is no coincidence that the prevalence of preventable disease worldwide—including AIDS—is highest in the lowest socioeconomic groups.

The principle of reciprocal determinism

The principle of reciprocal determinism—drawn from social psychology—has proved to have great explanatory value for understanding efficient health promotion interventions. It asserts that there is typically a continuing interplay between the environment and individual action. On the one hand, social, material, and economic circumstances can facilitate or inhibit individual choice and action; on the other hand, individuals are capable of taking action to change their environment thus effecting change in those circumstances. Health promotion, therefore, is concerned both to reduce environmental barriers to action and, at the same time, strengthen individuals' capacity to challenge and modify their environmental circumstances. For these reasons, empowerment occupies a central place in the philosophy and practice of contemporary health promotion.

Health promotion as 'empowerment'

The World Health Organization has defined the main purpose of health promotion as helping people to take control of their lives and their health by:

- providing individuals with those 'empowerment' skills that generate competence and confidence; and
- removing at least some of the environmental barriers to action.

We noted earlier that health promotion involves a close relationship between health education and 'healthy public policy'. Health education should not be concerned primarily with persuading and cajoling to gain compliance, but rather with reassuring and supporting people to gain their co-operation. A supportive environment will be dependent on healthy public policy, including fiscal and economic measures, environmental engineering, and legislation. The pursuit of healthy public policy itself requires education and lobbying of key figures and activists in the policy arena.

However, it is clear that although lobbying and advocacy are essential to successful health promotion, they will have little impact on entrenched power structures—especially if there are major financial implications—unless they are supported by public pressure. Accordingly, one of the main functions of health education is to create 'critical consciousness'—a process that involves:

- building a sense of community;
- raising people's awareness of, and indignation about, major social and health problems, and developing the skills they need to exert political pressure on

government or organizations.

In some instances, this dual process may be sufficient in itself to bring about change but frequently the public's efforts must be supplemented by advocacy on their behalf—and the powerful voice of the medical profession can be especially important in this context.

Furthermore, medical services can contribute in a more general way to both individual and community empowerment and provide a model of good practice for other agencies. The service offered should be 'user-friendly' and responsive to the felt needs of communities.

Settings for health promotion

The 'health career'

The 'health career' is one of the most useful devices for identifying the cumulative influences on health behaviour—and for devising appropriate intervention strategies. In short, it plots key influences that operate over a lifetime. Figure 3 describes its main features. It identifies key agencies, such as the family, and more general influences, such as the community or mass media, that shape beliefs and motivations about health, exert social pressure, and erect barriers to action or, alternatively, provide support for healthy choices.

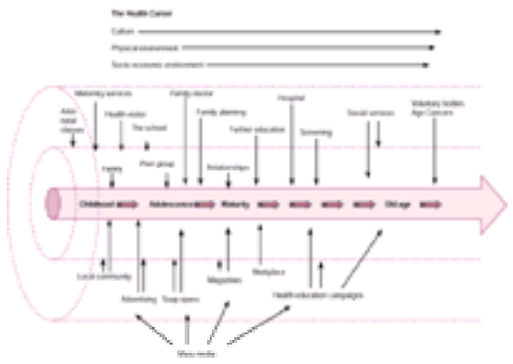

Fig. 3 The Health Career.

Settings, alliances, and mass media

The 'health career' analysis makes it possible not only to identify negative influences on health, but also, more positively, to identify agencies, organizations, and settings that can be used to 'deliver' health promotion. For instance, particular interest has been shown recently in the Health Promoting School, the Health Promoting Workplace, and the Health Promoting Hospital; three points merit emphasis:

- the whole ethos of an organization should be health promoting and empowering;
- the impact of any one organization will be maximized by intersectoral working and the creation of healthy alliances;
- mass media can support community health programmes but cannot act as a substitute for interpersonal working.

The doctor's role

It should by now be self-evident that health promotion is a multidisciplinary endeavour. What is the doctor's role? It is clear that the medical profession enjoys a high level of credibility with public and politicians. They are also uniquely placed to have awareness of the broad range of psychosocial and environmental factors influencing the health and well being of patients. Their major contribution may be summarized as follows:

- providing advice on lifestyle;
- delivering medical services in ways that are empowering and contribute to a sense of control;
- acting as advocates for social change—by lobbying and by using creative epidemiology (presenting health data in a dramatic, readily understandable, and compelling way) to create public concern and pressure for political action.

Health promotion methods: the consultation

Ultimately, the effectiveness of health promotion will be directly related to the quality of the specific methods used by health workers. It is clear that the achievement of certain important goals—such as remedying health inequalities—depends on the strength in unity that results from the kinds of alliance and political action mentioned above. However, individual practitioners and organizations such as hospitals can make a substantial impact—if the right techniques and strategies are employed. Box 1 provides guidelines for a health promoting consultation that helps clients take charge of their lives and their health. This approach should avoid the kinds of failure mentioned earlier in this chapter and maximize the chances of achieving real change.

Box 1 The health promoting consultation

Needs assessment

- Establish and maintain rapport using appropriate counselling skills.
- Check patients' state of readiness. Have they given any thought to changing their behaviour? Do they think they have a problem? Do they feel it is important for them to change? Are they committed to change but just need some support?

Communication phase

- Provide information at a level appropriate to the patient.
- Ensure that patients pay attention to the message.
- Check that patients have correctly interpreted the message—and fully understood key points. Take account of non-verbal communication.
- Try to ensure that patients remember important points—and provide a written aide-memoire.
- Ensure that any written material has been checked for 'readability'.

Motivation phase: helping patients to change

- Explore patients' existing beliefs and attitudes and those skills necessary for the proposed behaviour change.
- Analyse patients' environmental and social circumstances.
- Seek to modify beliefs and attitudes where appropriate and provide skills training.
- Negotiate and agree a 'contract'.
- Check that the relevant changes in beliefs, attitude, and skills have taken place. Are patients now committed to action?

Support phase

- Provide opportunities for patients to acquire any extra knowledge and skills necessary for translating good intentions into actual practice.
- Help mobilize social and environmental support.
- Consider particularly any skills or support needed to minimize the chance of relapse.
- Keep a check on patients' progress.

Where consultation time is limited, the task outlined above may appear daunting. However, the following points should be noted:

- The full procedure would be necessary in only a few cases.
- Many interactions with health professionals are continuing and cumulative. A series of meetings may be needed to cover the full 'recipe' for a successful outcome.
- Careful assessment of the stages of readiness to change will allow selection of only those strategies which are pertinent.
- It is frequently possible and desirable to delegate some or all of the task to other staff who may have more time.
- Different methods may be combined to achieve the various subtasks described above, e.g. a support group may use lay 'peer leaders' as health educators.
- Although the consultation offers only limited opportunities for addressing major socioeconomic problems, some action is possible. For instance, a number of health centres have offered 'welfare benefits clinics' in collaboration with a social worker to ensure that patients claim their full entitlement to financial help. Furthermore, by acting as advocates for patients, health workers as a professional group can and should seek to influence local and national policy.

3.6 Screening

J. A. Muir Gray

All screening programmes do harm; some also have the potential for doing good. In this respect screening is no different from the rest of clinical practice, but there are important differences between screening and clinical practice.

First, the contract, implicit or explicit, between the person being screened and the screener is qualitatively and ethically different from the contract that exists between clinician and patient. A patient who presents with a problem is seeking help and is usually aware of the facts about the limitations of medicine, and does not expect a guaranteed cure or risk-free treatment. This is part of the deal that they make with the clinician when entering the process of care. When, however, a professional or health service, or indeed the government through one of its agencies, writes to a healthy member of the population and asks them to come along for screening, the responsibility on the person issuing the invitation is much heavier. The traditional principle and the first priority to do no harm is even more strongly reinforced when dealing with people who perceive themselves as being healthy. In addition, the limitations and risks of screening must be explicitly and clearly spelt out.

The second way in which screening differs from clinical practice is that screening focuses on populations or on subgroups of the population, although it is often delivered by an individual clinician to an individual member of the public.

Screening is defined by the National Screening Committee in the United Kingdom as 'The systematic application of a test or inquiry, to identify individuals at sufficient risk of a specific disorder to warrant further investigation or direct preventive action, among persons who have not sought medical attention on account of symptoms of that disorder'.

This definition emphasizes that a subgroup of the whole population is selected on the basis of gender, age, or other characteristics, and then offered a test or asked a question. The results of the test may be either positive or negative and both positive and negative results occur in people with the disease or risk factor, and in those without. The relationship between positive and negative test results and those who are positive and negative for the disease is most easily set out in a figure (Fig. 1).

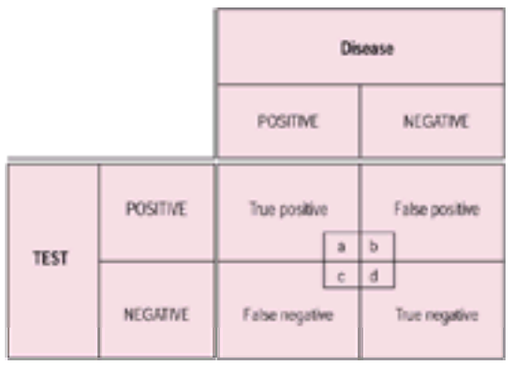

Fig. 1 The relationship between test results and the presence of disease.

On the basis of these results, it is possible to define certain characteristics of a screening test of which the most important are its sensitivity and specificity.

The sensitivity of a screening test is measured by the proportion of people who actually have the disease or the risk factors sought and who are detected by a positive test.

The specificity of a screening test is measured by the proportion of the people who do not have the disease who are classified as negative by the test result (Fig. 2)

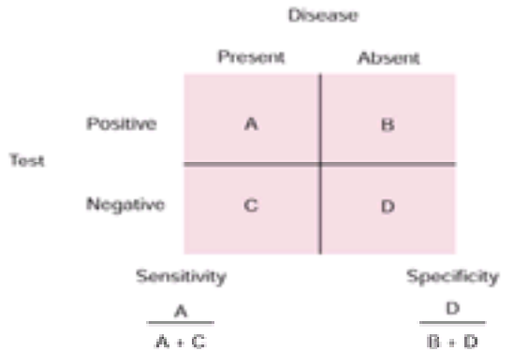

Fig. 2 The calculation of sensitivity and specificity.

These are the true traditional epidemiological parameters for a screening test, but one of the principles of screening is that screening consists not simply of tests but of a whole set of activities ranging from the identification of the population at risk right through to the diagnosis and treatment of affected individuals.

Appraising the balance of good and harm

The first step in deciding whether or not to introduce a screening programme is to appraise the balance of good and harm.

Screening is delivered as a programme and not as a single test. The sensitivity and specificity of the test, or tests, used in the screening programme are important but criteria have to be used to assess the programme as a whole.

The criteria proposed by the World Health Organization in 1968 have been widely used since then. However, the National Screening Committee in the United Kingdom considered that these criteria, sometimes called the Wilson–Jungner criteria, were not sufficiently robust for the twenty-first century because:

1. they did not emphasize the need to take into account the adverse effects of screening; and
2. they paid insufficient attention to the strength of the evidence on which decisions about screening were to be made.

Accordingly a new set of criteria, set out in Box 1 have been developed.

Box 1 Criteria for appraising the viability, effectiveness, and appropriateness of a screening programme

Ideally all the following criteria should be met before screening for a condition is initiated.

The condition

1. The condition should be an important health problem.
2. The epidemiology and natural history of the condition, including development from latent to declared disease, should be adequately understood and there should be a detectable risk factor, disease marker, latent period, or early symptomatic stage.
3. All the cost-effective primary prevention interventions should have been implemented as far as practicable.

The test

4. .There should be a simple, safe, precise, and validated screening test.
5. The distribution of test values in the target population should be known and a suitable cut-off level defined and agreed.
6. The test should be acceptable to the population.
7. There should be an agreed policy on the further diagnostic investigation of individuals with a positive test result and on the choices available to those individuals.

The treatment

8. There should be an effective treatment or intervention for patients identified through early detection, with evidence of early treatment leading to better outcomes than late treatment.
9. There should be agreed evidence-based policies covering which individuals should be offered treatment and the appropriate treatment to be offered.
10. Clinical management of the condition and patient outcomes should be optimized in all health care providers prior to participation in a screening programme.

The screening programme

1. There should be evidence from high-quality randomized controlled trials that the screening programme is effective in reducing mortality or morbidity.
2. There should be evidence that the complete screening programme (test, diagnostic procedures, and treatment/ intervention) is clinically, socially, and ethically acceptable to health professionals and the public.
3. The benefit from the screening programme should outweigh the physical and psychological harm (caused by the test, diagnostic procedures, and treatment).
4. The opportunity cost of the screening programme (including testing, diagnosis, and treatment) should be economically balanced in relation to expenditure on medical care as a whole.
5. There should be a plan for managing and monitoring the screening programme and an agreed set of quality assurance standards.
6. Adequate staffing and facilities for testing, diagnosis, treatment, and programme management should be available prior to the commencement of the screening programme.
7. All other options for managing the condition should have been considered (e.g. improving treatment, providing other services).

Measuring the benefits of screening

The first step in appraising a proposed screening programme is to try to measure or estimate the benefits that will result from that programme. But there are two traps that lie in the way of anyone wishing to assess the effectiveness of screening—lead-time bias and length time bias.

Lead-time bias

Proponents of the introduction of any screening programme sometimes base their argument on cohort studies, which are designed to follow a series of people who have had a screening test and compare their survival with that of the general population. However, this is a poor method of evaluating screening, principally because of what is called lead-time bias.

Imagine a disease that has a natural history of 10 years from its beginning to its fatal end, and that causes symptoms after 5 years, which usually prompt the sufferer to visit a doctor; the survival time from the point of symptomatic diagnosis is 5 years (Fig. 3(a)). A test that enables a diagnosis of the disease to be made at an earlier, presymptomatic, stage—for example, at 3 years—will apparently increase survival time (Fig. 3(b)). This apparent increase in survival time does not necessarily mean that screening is effective; it may simply mean that the person with the presymptomatic disease found by screening is aware of the condition for 7 years as opposed to 5—this is referred to as lead-time bias. It is essential that any screening programme is evaluated within a randomized controlled trial which has been designed with death as the outcome in order to control for lead-time bias.

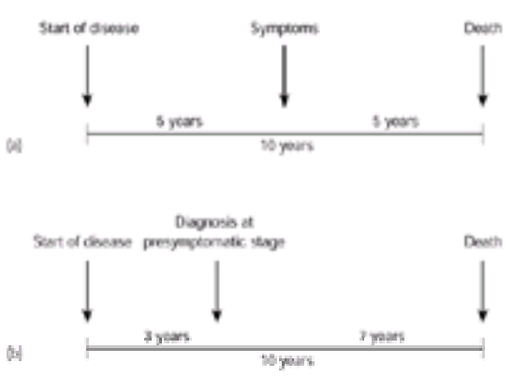

Fig. 3 Lead-time bias.

Length-time bias

Imagine a disease that consists of a number of subtypes; almost every disease has been shown to consist of subtypes when more sophisticated methods of diagnosis and classification have been developed. Imagine those subtypes are of two sorts, those that kill very quickly and those that kill very slowly. A screening programme based on regularly repeated tests is inevitably going to identify more of the slow-growing diseases. Thus it might be possible to describe an improvement in survival following the introduction of a screening programme, but if the only people whose survival has been estimated are those with slowly progressing disease, this does not warrant the conclusion that screening is effective.

This problem, sometimes called length-time bias, is classically demonstrated in the case of prostatic cancer. At the age of 80, about one-third of men have evidence of prostate cancer, but only about 8 per cent of men develop symptoms of prostate cancer. It is now thought that there are at least two types of prostate cancer, sometimes called the tigers and the pussycats, with the pussycats being very slow growing and the tigers very rapidly growing. One interpretation of the results of prostate cancer screening is that it is very good at diagnosing the pussycats but has little or no impact on the tigers.

For these reasons it is important to conduct randomized controlled trials of proposed screening programmes and to prepare a systematic review of the evidence from several trials if more than one has been done.

The harm from screening

No screening test is 100 per cent sensitive and specific; furthermore, initiatives to increase sensitivity almost always decrease specificity and, vice versa, initiatives to increase specificity decrease sensitivity.

People who are true positives, who have both the test and the disease, suffer least harm from a screening programme. However, not all the people identified with the disease will benefit from screening; for example, for a proportion of women whose breast cancer is detected by screening the outcome remains unchanged—they still die of breast cancer. The effect of screening on the whole population has been to increase the probability of survival but has also meant that when they die this subgroup will have known that they have had cancer for a longer period of time.

People who are false negatives can be said to be harmed by screening if they are falsely reassured, but that harm is minimal. The main harm from screening affects those who have false positive tests. People with false positive tests suffer psychological harm, usually short term, but some may also suffer physical harm from the additional tests or treatments that they undergo. In colorectal cancer screening, for example, it is inevitable that someone who does not have colonic cancer will die from colorectal cancer screening as a result of a complication of colonoscopy.

The special ethical issues of screening

All health care involves risk and many people suffer side-effects from treatment. The ethical difference in screening is, however, that screening tests and programmes are offered to people invited to come for screening by the health service, and the ethical contract between the screening programme and those who are screened is different from that which exists between a clinician doing the best that they can for a patient who has sought help.

The problems that might result from prostate cancer screening illustrate the ethical dilemma. Prostate cancer screening leads to the diagnosis of cancers that would not appear in the lifetime of the individual. In a country the size of the United Kingdom, more than 10 000 people would be identified each year whose cancer would never have become clinically evident in their lifetime. If those people were offered radiotherapy or radical prostatectomy, there would be a mortality of about 1.5 per cent from the effects of treatment alone, and about 30 per cent of those treated would suffer significant side-effects such as incontinence and impotence. Thus the screening programme will harm a large number of people with significant numbers dying as a direct result of screening. These harms must be clearly assessed before screening is started.

Special issues in antenatal screening

For antenatal screening, in which the ethical issues are heightened because the 'outcome' is often abortion, the randomized controlled trial is not necessarily the most appropriate design and for some screening this type of trial is impossible. Of crucial importance in appraising antenatal screening is the sensitivity and specificity of the diagnostic test. With this information it is possible to model the effects of a screening programme. The model for Down's syndrome screening is shown in Fig. 4.

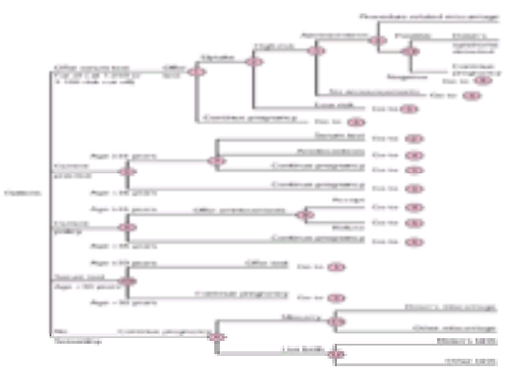

Fig. 4 Decision analysis to show implications of offering screening for Down's syndrome.

However, even the most elegant research study does not actually make a policy decision; policy-makers in public health have to take the best evidence available and then decide whether or not to introduce the screening programme.

Policy-making: assessing the costs

Once the benefits and harms that might result from screening have been assessed, it is necessary to consider whether or not the introduction of a screening programme that has been shown to do more good than harm is a reasonable use of resources for the population concerned, and policy-makers need to take into account a number of issues, as shown in Fig. 5.

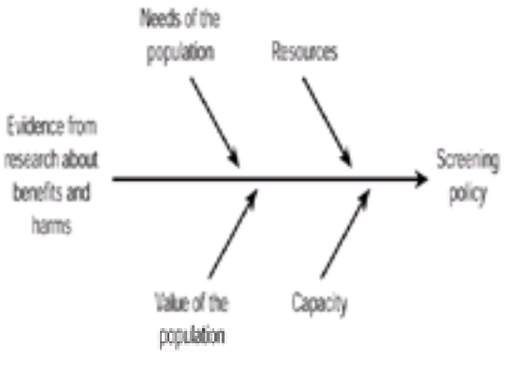

Fig. 5 The ingredients of a screening policy decision.

Research produces the evidence of benefit and harm but other factors are equally or more important.

The needs of the population

The needs of the population and the many other demands made on resources need to be taken into account. The decision about whether or not to screen antenatally for HIV infection should be influenced by the prevalence of HIV infection in the population. Similarly, the decision about whether or not to screen for haemoglobinopathies will be influenced by the prevalence of those disorders in the population.

Resources

The cost of the potential screening programme has to be taken into account. One way to think of screening is to think of opportunity costs, namely what else could be done for people with that disease with the money that is being invested in screening. For this reason it is sometimes useful not to think of the proposed screening programme in isolation—for example, not to ask 'shall we screen or not screen?', but to pose the question 'would the resources invested in screening obtain better results if they were put into primary prevention or treatment services for this health problem?'.

The values of the population

Like any other public health service, the values associated with screening are important. Society places a high value on prevention but, for example, if the values of the population are against abortion then many antenatal screening programmes will not even be considered.

Capacity

The results of screening done in research settings are helpful but have their limitation. For example, in considering the results from the Swedish Two Counties study of breast cancer screening, the Department of Health in the United Kingdom had to take into account not only the results of the research but also the facts that:

1. the research was being done by people who were among the best in the world at mammography and the management of early breast cancer; and
2. 100 screening teams of the same size as the research team would have to be recruited, trained, and supported for the results obtained in research to be reproduced in practice.

In considering the relevance of research to everyday practice, it is sometimes useful to pilot the proposed screening in an ordinary service setting, principally to see if a sufficient level of quality can be obtained, for without good quality management screening should not be introduced.

Quality management

The quality of a service, as defined by the guru of quality management, Avedis Donabedian, is that quality is measured by the degree to which the service conforms to preset standards of goodness.

The importance of quality assurance

The balance between the good and the harm of a clinician or a service is a function of the quality of the service. If the quality improves, the benefit increases and the harm decreases, and there comes a certain point, as shown in Fig. 6, where a service can do more harm than good.

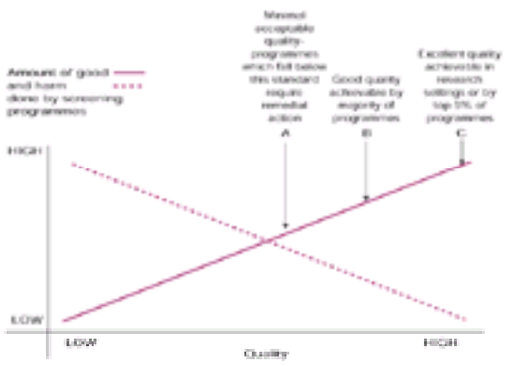

Fig. 6 The relationship between programme extremes and quality, showing the balance between good and bad effects at different levels of quality.

The challenge for the person responsible for a public health service such as screening is that they are presented with evidence from a research setting which usually has a very high level of quality and they have to ensure that they can achieve the quality standards at point B on Fig. 6, even if they cannot, immediately, achieve the quality standards at point A. Standards are arbitrarily chosen and different levels of standards can be set. The standard set by the research team working to a very tight protocol with highly committed and expert staff is a standard of excellence. The pursuit of excellence is obviously an objective of quality assurance but it is not realistic to expect every service to achieve the level achieved by the best in the world, and a second level, indicated at point B in Fig. 6, is usually defined as the achievable standard. It is also important to identify the minimal acceptable standard below which no service should fall, point C in Fig. 6, for it is important to ensure that of the hundred or so programmes covering an entire population not one of the programmes should fall below the minimal acceptable standard and do more harm than good.

Running screening programmes as systems

A system is a set of activities with a common set of objectives and once the objectives of the programme have been chosen it is possible to identify criteria that can be used to measure progress towards those objectives. Standards can also be set on the basis of the criteria with targets for annual quality improvement being selected.

This approach to systems thinking in screening programme management is shown in Table 1.

The objectives of quality management

Quality management of screening programmes has four objectives.

1. The prevention of quality failures, e.g. by good training and the appropriate choice of equipment.
2. To identify and resolve speedily quality failures that occur; failures in screening programmes are often the focus of intense press and media interest with public alarm being generated by the discovery that one screening programme has a higher number of false negatives than is acceptable.
3. To help all those involved in screening continually to improve their performance; screening is essentially a boring repetitive activity and a high level of

commitment is needed to ensure that staff remain motivated; this is particularly important in those screening programmes that depend on the perception of an observer, for example visual perception of cervical smears or mammograms, or the auditory perception of Koratkow sounds.

4. To reset standards regularly; it is not possible to stand still in screening programmes—unless one is constantly striving for improvement there is a risk that the programme will fail because boredom and loss of motivation may reduce quality. The resetting of standards provides new targets at which clinicians and managers can aim.

Achieving continuous quality improvement

Continuous improvement in quality is the objective of screening quality assurance and it requires:

1. an evidence-based screening system with objectives, criteria, and standards;
2. an information system that allows performance to be measured and compared with the standards; and
3. authority to drive quality improvement in all aspects of the programme and to take action if necessary if any part of the programme falls below minimal acceptable standards.

A screening programme requires careful management. The main responsibility for assuring quality rests with the clinicians and managers who are actually responsible for delivering the screening programme, but it is also important for management to invest in quality assurance, activities that are not directly under control of clinicians and managers but which play a part in helping the two groups assess their performance, compare it with the performance of others, and take action either to solve problems or improve performance.

The future of screening

Much has been written about 'genetic screening' but it is in fact hard to generalize about genetic screening for the term is not particularly useful. Certainly new knowledge about genetic risk is raising new opportunities for screening, either in hunting for a particular gene that increases risk or in considering the use of family history as a means of identifying subsets of the population that might be offered screening earlier than the general population, for example breast cancer screening before the age of 50; or offered more intensive screening, for example referral to a cancer genetic clinic. However, the same criteria as outlined above in the section on the good and harm of screening are as relevant to screening based on genetic risk factors as for any other risk factor.

Perhaps more important implications for the future are the changing social attitudes towards technology and risk. Certainly it appears to be much more important to inform people being offered a screening test about the possibility of risk and harm associated with screening. In the past, for example, people have simply been offered blood pressure screening or sometimes been given an antenatal screening test without the implications being fully explained to them. In the twenty-first century this will be unacceptable and all choice will need to be informed. The choice has hitherto been based on statistics defined for populations so people can be told, for example, that the benefits of screening for hypertension outweigh the risks. However, in the twenty-first century, with members of the public much better informed and the World Wide Web providing unprecedented access to knowledge, of both good and poor quality, people will increasingly want to know about how the risks relate to them as individuals. Screening is a public health service that focuses on individuals and which brings clinicians in contact with individuals in a manner analogous to traditional clinical practice. In the twenty-first century screening will be based on even sounder epidemiological evidence, derived from studies of whole populations, than has been the case in the twentieth century. Individuals offered screening will need help and advice in deciding whether or not to accept the clinician's proposal and will have an increasingly important part to play in helping them decide whether or not the screening programme offered is appropriate for them as individuals.

3.7.1 The cost of health care in Western countries

Joseph White

Reasons for interest

The countries conventionally called 'Western' (a term that refers to level of economic development, not geography) have the physical and financial resources needed to provide a high standard of health care to all citizens. Yet doing so at a socially acceptable cost is difficult. Efforts to limit cost may affect the quality of care, access to it, and the work and incomes of medical providers.

Defining the issues

One view of costs emphasizes health care's share of a national economy, and thus the economic 'burden' of care. Another view emphasizes costs relative to service or outcome, and therefore value for money. Those who object most to spending levels, such as employers who contribute to insurance, or government budget-makers, often claim they are concerned with value for money, to show that they are not trying to reduce needed care.

Cost control should be distinguished from 'cost-shifting'. If tight budgets for the British National Health Service cause many patients to 'go private', that is cost control from the government's perspective. From the patients' and providers' vantage point, some costs have been shifted, not reduced.

Why is cost a policy issue?

The cost of health care is more of a public issue than that of most other commodities or services because all Western countries remove much health care from the market's allocation processes. Markets allocate resources by price. A person who cannot afford an item then may save for it, borrow for it, do without, or buy a lower-quality alternative. All of these options can be impracticable or socially unacceptable for a large number of medical needs, so some other method of allocation is needed.

All advanced industrial countries free sick people from worrying (too much) about cost by combining individual contributions into pooled funds. Whether those pools are private or public, and cover all or part of the population of an area, their effect and intent is to protect members from the price constraints that otherwise would limit spending. Some other method of controlling spending on individuals' care is therefore needed, in order to limit contributions to the pool.

Spending trends

Table 1 shows health care spending as a percentage of national economies for 11 countries with constant borders from 1975 to 1995 (Germany is therefore excluded). Generally the 'burden' of health care spending has risen, but much more quickly in some countries than others, and at different rates over time within the same country.

One common explanation of spending increases emphasizes the ageing populations in Western countries. Yet careful analyses suggest that longer life expectancies explain only a small part of the trend, because greater life expectancy implies that mortality, and its attendant costs, are lower at each particular age.

Some analysts believe that individuals simply prefer health care to other goods so that, once other basic needs are met, higher income will lead to disproportionately higher consumption of health care services. The methods of payment, however, make it hard to determine to what extent spending represents individual preferences.

Rapid innovation in treatments and diffusion of knowledge about them usually interacts with pooled financing to encourage increases in cost. Particularly when policies promise a high standard of care, knowledge of a new, supposedly useful treatment creates pressures to make it available to everyone, as opposed to the norm with market goods, which can be rationed legitimately by price.

In spite of this generally upward trend, Table 1 shows that both spending levels and rates of increase vary greatly. A nation's cost level reflects its history: for instance, the development of national medical capacity, provider income expectations, and practice norms. Spending can also vary due to differences in underlying causes of illness, such as poverty, diet, smoking, alcoholism, violence, and genetic endowments. Yet these factors are unlikely to explain the different rates of growth.

Cost control policies

The main reason why trends in medical costs differ is that nations have made different efforts to restrain them. We can distinguish cost control efforts in terms of the targets of control and the systems of health care finance.

Targets

National policies vary in both the emphasis on and success of targeting different types of services, such as inpatient care or pharmaceuticals. Until recently, national medical norms and the economic and political power of different providers favoured, for example, surgery in the United States and pharmaceutical treatment in Japan. Sometimes advocates argue that higher spending on one service would reduce expenses for others: for instance, that expanded insurance for ambulatory care or pharmaceuticals would reduce hospital costs. Whether such expansions of insurance ever reduce total costs (as opposed to providing better value) is doubtful.

Policies may target different factors that influence spending for a given type of service. For example, they may focus on restraining prices per service or numbers of services or, somehow, both. Another common approach is to limit physical capacity to provide care, and so both volume and prices. For instance, fewer MRI machines per person will probably mean fewer scans and, since each machine is used more often, lower costs per scan.

Research showing that many procedures lack scientific support, and demonstrating wide, medically unexplained variations in practice among communities, encourages another type of policy: measures to make care more 'appropriate', such as treatment guidelines. Sometimes termed 'evidence-based medicine', these measures are promoted as offering savings without harm to patients.

Systems

Cost control is affected by the systems used to pool funds and pay for services.

The extent to which individuals pool their resources may range, in theory, from not at all (individuals pay all costs out of pocket) to total (all care is paid from a single pooled fund). In Western countries, the range is from most people being insured for most services, with some cost-sharing (as in the United States); to virtually

everyone insured, for most services, in a single pool (as in Canadian provinces, and the British National Health Service, **NHS**). Both the low and high ends of this continuum are likely to control costs better than some position in the middle. If people pay substantial amounts from personal funds they will face considerable price constraints. But extensive pooling can limit costs, because payment through a 'single pipe' provides a single point of control: limit the total flow, and you can limit spending.

A similar pattern of effectiveness can be seen in choices about how individual caregivers are paid. At one end of this payment continuum, virtually all providers of a given service are paid on the same terms, even if there are multiple payers. Such co-ordination gives the payer(s) dominant market power, which can be used to enforce (relatively) low prices. At the other extreme, payers contract selectively with providers. Then hospitals or doctors may agree to reduce their fees, or accept some outside management of their practices, so as to preserve access to patients. Co-ordinated payment is usual in most Western countries. Selective contracting is the basis of much of American 'managed care', and of 'internal market' reforms such as fundholding by British general practitioners (**GPs**). Unselective contracting by uncoordinated payers, as in the United States around 1990, seems to be the most costly possible approach.

Highly pooled funds tend to be associated with co-ordinated payment. Yet selective contracting may be implemented within a large pool, as in NHS GP fundholding, while high cost-sharing could be combined with standard fees. Thus distinguishing the two dimensions allows more careful analysis than a simple division into more 'market-like' or 'regulatory' approaches.

Choices about targets and systems affect only potential for cost control; performance depends on the specific measures chosen and the commitment of payers to control costs. Extreme positions on these two dimensions none the less have very different risks, both for other health care variables and interests. For example, higher cost-sharing is probably a more direct threat to equity of care, but a lesser threat to the incomes of providers, than some other cost control measures. The much-vaunted 'marketization' of Western systems has generally involved moves towards selective contracting rather than lesser socialization. The evidence does not yet show that highly selective contracting controls costs more effectively than highly co-ordinated payment.

Paying doctors

Cost control choices have many implications for doctors in particular. They tend to prefer higher cost-sharing to alternative cost control measures. But cost-sharing is particularly unpopular with voters, so policies tend to focus instead on the structure of doctors' compensation.

Economists worry that doctors may respond to fee restraints by encouraging patients to consume more services. Capitation or salary would not be vulnerable to that response, but may create incentives to provide fewer services than are necessary. Both private and public policy-makers therefore seek mixed compensation schemes that might limit either failure. In most countries doctors have much preferred fee-for-service payment. Yet methods that reduce fees automatically in response to increased services, as prevailed in Germany from 1985 to 1997, seem to counter the effect of any volume increases, leaving doctors as a group working more for the same money. In many countries, therefore, doctors' organizations are rethinking their preferences about payment methods.

Policy-makers virtually everywhere would like to get the medical profession to 'manage care', making it more appropriate, and to manage the balance among price, volume, and quality within a budget. Unfortunately, even German physicians, with a supportive tradition and institutions, find corporate self-management difficult.

As an alternative, some schemes make individual doctors or groups of doctors responsible for the cost of pharmaceutical, hospital, or other services. Unless these responsibilities are limited and spread across a large payment base, they can create dangerous incentives to deny necessary care.

Fairy tales and the future

Policy-makers and critics dream of more 'rational' measures than those discussed above. One is that policies to keep people healthy would save lots of money on acute care. There is little or no confirming evidence. Another is that societies could prioritize medical services within budgets, excluding those that science shows to be least cost-effective. But such general rules would not be appropriate for many individual cases. The state of Oregon's well-publicized prioritization of treatments in its insurance for the poor has contributed little to cost control, both because the covered list was quite extensive, and capitated providers found that distinguishing covered from uncovered treatments was not worth the trouble. Instead, each Western country must choose its own imperfect policy, with attendant consequences. The trend towards relatively increased spending on health is likely to continue, because longer, less painful lives seem desirable to most people, and modern medicine is believed capable of providing that. But systems will vary in both total costs and cost-effectiveness.

3.7.2Health in a fragile future

Maurice King

Politics is health. Health is also politics—the operation of power in society—to the grave disadvantage of today's poor and tomorrow's everybody. The traditional enemies of public health—infection, etc.—have been reinforced by those three serpents: the world, the flesh, and the devil, newly armed and globalized for the coming millennium. For 'the world' read 'Mammon'—the overarching quest for wealth, and the power that it brings. For the devil and the flesh read on.

This is written at the start of the new millennium. The human population of the earth has just exceeded 6 billion (12 October 1999), having tripled during the writer's lifetime. Mankind has already passed the highpoint in per capita oil consumption (1979) and in grain consumption (1985). The average human is unlikely ever to have so much energy at his disposal again, or to be so well fed.

Wealth

One superpower with 4.6 per cent of the world's population now dominates the earth. Half the world's health expenditure is spent there, and a quarter of its fossil fuel is burnt there. Most serious, that superpower dominates what the world thinks, and it dominates the United Nations system. Within it, money dominates. With a public 'dumbed down' by the media, power is increasingly concentrated, not in Congress and Senate, but in the Department of State, in lobbyists, in think tanks, and in the boardrooms of transnational corporations, especially those which control the media. Domestically, the proper functions of government are being increasingly abrogated to lucrative struggles between lawyers.

The market economy reigns supreme, with no credible alternative on the horizon. The market is now advertisement-driven to produce ever more luxurious resource consumption, and ever less sustainable lifestyles, to the point that tourism has now become the largest industry on earth. The rich become ever richer, and the gap between rich and poor ever wider. More and more wealth is in fewer and fewer hands. For the fortunate, wealth effortlessly creates more wealth as never before. Meanwhile, during the last 20 years, 60 countries have been getting steadily poorer.

With the coming of the new millennium, and the stock markets buoyant, the mood (for the fortunate) is bullish. Unfortunately, the prosperity bubble is fragile. Besides the technical problems of the stability of the global economic system, the bubble can only continue to swell if certain major problems are overlooked—population, global warming, global food, the rising energy costs of fossil fuel exhaustion, and the effects of the media on the stability of the family. One or more of these could prick the bubble and all have the gravest implications for health. In the United States, the market economy requires a per capita carbon dioxide production of 20 tonnes annually, and in the United Kingdom 10 tonnes. Globally, the sustainable fair share is probably about 1.4 tonnes. I argue for radical adaptations in lifestyle, North and South, for equity, frugality, ecology, economy, and for the intense dialogue that must accompany the solution of our major problems. Susan George reminds us that the fossil fuel based economic activity of the present 2 billion 'haves' who burn that fossil fuel, is destroying the world, and that the 9 billion, who by 2050 will want that economic activity, will destroy the world even more disastrously — with no adequate means of either controlling or sharing such economic activity as the world might support sustainably. Meanwhile, the 'have nots' who will not enjoy such benefits are likely to become increasingly violent, North and South. The market economy is therefore destroyed either way. She concludes that we cannot both sustain the liberal free-market economy and continue to tolerate 'the superfluous billions'. This was published in 1999. September 11 2001 has proved how right she is. Before discussing the difficulties of opening this dialogue on a sufficient scale, there is a more immediate problem for physicians.

Health as a free market commodity

Now that the service sector of the economy is growing faster than manufacturing, it has become a tempting source of profit, with the result that the unfettered free market is becoming increasingly perilous for those who cannot afford private health care. Traditionally, most governments have sought to provide some form of insurance-based and tax-supported 'national health service' which was available to everyone, and which strove to 'generalize the adequate' in health care. Of these, the British National Health Service was much admired.

High on the agenda of the World Trade Organization (WTO) is the privatization of education, health, welfare, and social housing. The race is on to capture that share of gross domestic product (GDP) which governments spend on public services, and to open the European public market to transnational competition to the disadvantage of universal coverage, of solidarity through risk pooling, of equity, of comprehensive care, and to the European tradition of democratic accountability—largely in the pursuit of profit.

Opposition to all this is disorganized and inchoate. Over a thousand non-governmental organizations (NGOs) opposed the WTO's 1999 meeting in Seattle. Out of this soup of opposition a coherent, high profile, alternative has yet to crystallize. The problem is that, whereas the WTO's objective is simple—profit—that of the 'the global new green left', if such it can be called, is complex, and lacks a tangible manifesto. It is part green, part animal rights, part local autonomy, part antitransnational, and part much else. It is also divided North/South. Since it is commonly at variance with itself, there is no single voice to articulate the opposition to the free market status quo, and to debate the many problems connected with it. The greatest of these is population.

Demographic disentrapment

Demographic disentrapment is the crux—communities exceeding the carrying capacities of their ecosystems with nowhere to go, and with economies that do not enable them to compete for food on the world market. The Belgian administration had long considered Rwanda trapped. The classic case of as yet peaceable entrapment is Malawi, which has outgrown the carrying capacity of its fragile ecosystem, and where chronic malnutrition is endemic. Half its children are stunted. Expert opinion considers (privately) that much of Africa is trapped. There are also grave doubts about the ability of India to feed a population which is expected to increase by 50 per cent and exceed that of China. Its per capita grain is already falling gently, and water is an even greater constraint than land.

Starvation permitting, Malawi's population, without AIDS, was set to have tripled by 2050, and eventually to have quadrupled. With AIDS it is expected to increase by only 50 per cent. Without AIDS, immediate one-child families would have been essential. Now that AIDS has removed Malawi's demographic momentum, two-child families may be sufficient. The tragedy of AIDS has made the disentrapment of Malawi possible. This opportunity has to be grasped courageously on a continental scale.

Demographic entrapment is tightly taboo to demographers, to development economists, and particularly to the United Nations system. It also taboo to most NGOs. There amounts to what the United States demographer Jason Finkle has termed a 'population policy lockstep', in which demography, the great foundations, and the United Nations agencies support the same policies, and in particular deny (publicly) that demographic entrapment exists. The Cairo population conference in 1994 avoided all population targets, and by 1999 at 'Cairo plus five', population control was even further out of fashion.

There are many reasons for this lockstep. The most politically sensitive one is that that the United States Department of State appears to be actively interested in maintaining it—presumably, since if the South is to restrict its fertility, the North will be expected to restrain its resource consumption, with the serious implications that this has for the market economy, and for United States resource consumption in particular (see www.leeds.ac.uk/demographic.disentrapment).

In effect, there appear to be many more 'Chinas' and 'Malawis' in urgent need of one-or-two-child families, if they are to avoid starvation and slaughter, but no demographer dare say so publicly. China's triumph is that one-child families have become the socially-responsible norm. Equity requires that if any community is to be counselled to reduce its fertility drastically, we all should. If therefore the United Nations is to suggest that any country should do so, it will have to be in the context of

a United Nations programme for 'a one-or-two-child world'—we are all in it together. This cannot be a tight directive, but has rather to be a 'general political direction' in which the world needs to go. In the uproar over population that would result, Italy for example, with a total fertility of 1.2, and which is afraid that it might disappear, might try to raise its fertility.

Demographic entrapment is only one of many problems in which population plays a part, often a large part. Others include poverty, hunger, malnutrition, increasing global inequality, deforestation, street children, and, indirectly, global warming. To make demographic entrapment taboo is also to hinder gravely the resolution of these other problems —in effect to obstruct the solution of all the major human problems. The consequences of doing this, particularly if the desire to preserve Northern levels of resource consumption, is ultimately the major factor, are diabolical—'overpowering evil' which, incidentally, the *British Medical Journal* saw fit to list as a technical term.

A common fear underlies all this—that of an anarchic, overcrowded world. '*Quand viennent les Africains?'*, a Swiss acquaintance asked, not 'if they come' but 'when are they actually coming?' Many have already come. Equity demands that more should come. Reason argues that all cannot come, say a billion from Africa which is having increasing difficulty feeding itself, and where the fertility of the land is falling widely, and perhaps another half a billion from Asia. The future of the world is brown. How brown? What does seem clear is that for the majority of the trapped, disentrapment will have to take place *in situ*, if they are not to starve or slaughter themselves on the spot. But there is another threat to the family, besides that to its size.

The flesh and the family

The most important institution for human welfare is the family—that cradle of the virtues, 'in sickness and in health', 'for richer for poorer'. The fact that the family is falling apart so widely is thus of the gravest consequences for health and human well being. Why is the family in such decline? Taboos, it seems, are important for maintaining the structure of society. The taboo on entrapment helps to preserve the current North/South power structure. It may well be that the many kinds of taboo with which all societies have surrounded sex—'who may say, or show what, when, where, and to whom', play an important part in maintaining the structure of the family, and that the weakening of the taboos, under the persistent attrition of the media, to which we are all increasingly exposed, from the age of three onwards—in effect 'anything goes'—bears a large part of the blame. We are each the recipients of many years of nurturing in the bosoms of our families. When we die we take these blessings with us. A society which fails to replace the 'social capital' generated by the family, does so at its peril. The consequences of this loss are all around us.

So where is the devil?

Any serious writer or *mediaste* hopes to influence what other people think. The devil lies in what he wants them to think—and not to think—and why, and on the scale and the means by which he does it. Even modest deviance from 'political correctness' becomes ever more difficult in an increasingly 'one-think', one-language, one-superpower, CNN world, with its ever more narrowly focused centres of wealth and power. Frances Stonor Saunders has documented the multifarious ways in which the United States Department of State manipulated the intelligentsia, both left and right, during the Cold War. There is no reason to think that this manipulation has ceased. The policing of the population policy lockstep is a particularly clear example. A really free unlockstepped press capable of debating anything, however alarming, and whatever implications it has for northern lifestyles, is critical.

The idea that, in a world of supposed free speech, the media need to be controlled in order to protect the family, and to prevent our behaviour being too gravely manipulated by scientifically crafted advertisement, and if so how, and by whom, is a thought so outrageous as to defy credulity. But so was the *contagium vivum,* and a spinning earth. We are just starting to think about tempering the free market, the proposed Tobin tax on financial transfers being the outstanding example. But this must be only the beginning.

So as we pore in triumph over the atoms in our chromosomes, let us not forget that we have no clue as to how those atoms bring us conscious minds, and that the devil is as busy as ever in influencing what those minds think, and in narcotizing our consciences so us to prevent our getting to grips with the terrifying problems that beset us—and those who come after us. The first millennium started with a command to care for all men. The important difference now is that we have 30 times as many to care for, and that for 'our fellow men' we should now read 'all terrestrial creation'. Such, then, is the fragile future of public health in a new millennium.

4.1 The genomic basis of medicine

Trevor Woodage and Francis S. Collins

Introduction

Much of the progress made in biomedical science in the past century has been due to an increasingly sophisticated understanding of the cellular and molecular mechanisms underlying disease processes. Deciphering the nucleotide sequence of the DNA molecules that make up the 46 chromosomes found within each human diploid cell will represent a major milestone in our ability to understand these processes. In particular, knowledge of the sequence of the human genome will help us understand the structure and function of the proteins and RNA molecules that control the developmental programmes and functions of human cells in health and disease. The Human Genome Project is a large, multinational effort that has among its goals determining the complete human genetic sequence by the year 2003, although most of the sequence was already available in 2000, and two groups published draft sequences in 2001. Along with its technical goals, the Human Genome Project has brought dramatic changes in the ways in which biological and medical processes are viewed. This chapter will discuss some of these influences on modern medical theory and practice.

The terms genetics and genomics are often incorrectly used interchangeably. Genetics refers to the study of inherited traits or characteristics, while genomics describes the study of the large-scale structure and composition of the material encoding these genetic instructions. Applying a genomic approach to medicine involves an appreciation of the complex set of interactions that govern the repertoire of genes that are expressed in different tissues under conditions of health and disease.

Scope of the Human Genome Project

Although initially met with widespread scepticism, proposals to determine the complete DNA sequence of the human genome began to circulate in the mid 1980s. This objective was ambitious both in its scientific scope and in its technological requirements. The suggestion that efforts to discover the sequence of individual genes, answering specific biological questions, were to be supplanted by industrial-scale programmes to analyse large numbers of genes or chromosome regions using novel methods and equipment was not well received in all quarters. Debates about the relative merits of gene-based (cDNA) versus whole genome sequencing projects eventually moved to a consensus (but not unanimous) position that both approaches were worth pursuing.

The development of several generations of semiautomated DNA sequencing apparatus that helped to drive down costs gave impetus to arguments that large-scale sequencing efforts were feasible. Even so, the international Human Genome Project was expected to require funding of 3 billion dollars over 15 years to sequence the estimated 3×10^9 base pairs (bp) making up the haploid genome. A substantial proportion of that expense was not directly attributable to DNA sequencing, but rather to providing infrastructure in the form of genetic and physical maps of the human genome, and work on the genomes of model organisms. Construction of these maps, in turn, depended upon the development of new DNA cloning and analytical methods, especially large-insert cloning vehicles such as yeast artificial chromosomes (YACs) and bacterial artificial chromosomes (BACs). YACs and BACs allow the propagation of extended regions of genomic DNA (100 000 to more than 1 million bp) in multiple copies in cultured yeast and bacterial cells respectively. Availability of these cloned DNA molecules allows analysis of large, but manageable, chromosomal fragments that encompass complete genes.

Exceeding expectations, and with the entry of private sector efforts to spur progress, it appears that the complete sequence of the human genome will be available substantially before the initial target date, 2005. In fact, in June 2000 announcements of the completion of the first draft of the human genome sequence were made, and in February 2001 publications appeared describing the draft sequence and its initial analysis. Both public and private sector sequencing efforts arrived at similar estimates of human genome size, at approximately 3.1×10^9 bp, remarkably close to earlier estimates based upon measurements of the amount of DNA contained in an average cell's nucleus. Continuing attempts to provide an essentially complete, ordered representation of the sequence of the human genome are now planned to be finished by 2003.

Generation of these huge amounts of DNA sequence is of little benefit if there is no effective way of interpreting what it means. The creation of large databases containing different kinds of genomic information together with sophisticated software algorithms that can detect protein coding regions, compare related sequences to each other and identify biologically relevant patterns or sequence motifs have given rise to the rapidly expanding discipline of bioinformatics. Although most public attention paid to the Human Genome Project has, naturally enough, been given to sequencing the human genome, early realizations that one of the most effective ways of interpreting sequence data was by cross-species comparison led to the establishment of parallel efforts to sequence a series of model organisms. The complete, or near complete, genomic sequence has been determined for over 20 bacterial species including *E. coli* (5 million bp); *Saccharomyces cerevisae* (12 Mb), a simple, unicellular eukaryote, the common baker's yeast; *Caenorhabditis elegans* (97 Mb), a simple multicellular nematode used in many types of basic research; and *Drosophila melanogaster* (120 Mb), the fruit fly used by biologists for almost 100 years as a model for studying genetics and development. Major efforts to sequence the genomes of the mouse, rat, and zebrafish are underway. These efforts are providing a solid foundation for understanding the genomic basis of many aspects of molecular and cellular physiology.

Implications of genomics for medical practice

Disease gene identification

Initial successes (prior to 1985) in cloning genes that were mutated in human genetic diseases required a detailed understanding of the pathophysiology of the disorder being investigated and the nature of the proteins whose sequences were altered (such as the roles of the a-globin and b-globin genes in the thalassaemias). Unfortunately, such approaches could not be applied in most cases. For example in cystic fibrosis, the most common serious autosomal recessive disease to affect Caucasians, little was known about the molecular causes of the respiratory and gastrointestinal problems that occurred in patients with this uniformly fatal disease. The lack of any detailed knowledge about the protein whose function was disrupted in cystic fibrosis meant that it was impossible to use standard methods to proceed from phenotype to protein to gene. In order to discover the gene that was mutated in cystic fibrosis, it was necessary to follow a novel strategy, which has become known as positional cloning.

Because of its pattern of inheritance, the gene that was mutated in cystic fibrosis was known to lie on one of the autosomes (chromosomes 1–22) rather than on a sex chromosome (the X or Y chromosomes). Cystic fibrosis carriers would have one abnormal copy of the gene and affected individuals would have mutations in both

copies of the gene. By examining the pattern of inheritance of a panel of variable DNA markers, it was possible to identify genetic markers lying on the long arm of chromosome 7 whose inheritance patterns correlated with carrier or disease status more often than expected by chance alone. These markers were thus said to show genetic linkage to the cystic fibrosis gene. The cystic fibrosis gene candidate interval was narrowed by identifying additional polymorphic DNA markers that were more finely distributed throughout this part of chromosome 7. Even when this process, linkage analysis, is successful, the chromosomal region containing the disease gene usually consists of several hundred thousand to several million base pairs, typically containing 10 to 100 genes. Clearly, this is a considerable improvement over individually investigating the 30 000 to 40 000 genes that the human genome is estimated to contain, but it is still a daunting target.

The DNA sequences that make up the protein-coding regions of genes occupy only 1.5 per cent of chromosomal DNA (the rest is largely repetitive DNA and spacer elements of unknown function). Thus, it is not a trivial matter to identify all of the genes in a candidate interval of a million or more base pairs. A number of techniques have been developed to identify the genes within a defined interval of chromosomal DNA, most requiring large cloned DNA molecules covering the chromosomal interval under investigation. Recent improvements in the ability to identify and obtain these cloned molecules using BACs and YACs have greatly facilitated gene identification, but all will soon be superceded by the availability of the complete, ordered, human DNA sequence, together with ever-improving annotations of gene location and structure.

Once the genes within the chromosomal segment containing the disease gene have been discovered, the laborious task of finding which of these genes contains the pathogenic mutation is undertaken. In some instances, easily recognized abnormalities such as large deletions or chromosomal translocations disrupt the genes, but in most cases subtle changes in DNA sequence produce disease. The most definitive subtle alterations are mutations that result in the premature termination of a growing peptide chain during the translation of an mRNA coding sequence into protein. Thus, the simple alteration C to A, changing the codon TAC (encoding tyrosine) to TAA (a stop signal) will prematurely terminate protein manufacture. Similarly, the deletion or insertion of a small number of bases (not divisible by three) will cause a frame-shift in which interpretation of codons downstream of the mutation site will be scrambled, and a premature stop codon is usually formed by chance. Simple sequence changes that do not produce premature termination signals may be harder to recognize as being responsible for disease. For example changing a TCG codon to TCA would be unlikely to result in a disease state because both of these nucleotide triplets code for the amino acid serine. Substituting ACG for TCG produces threonine instead of serine. These two amino acids are chemically closely related and substituting one for the other may or may not result in a significant functional alteration. A TCG to CCG change, however, produces proline instead of serine. This amino acid change is non-conservative and more likely to produce a protein that functions differently from the wild-type form. Other subtle mutations that may be difficult to recognize can involve alterations in the DNA sequences that direct the occurrence of normal messenger RNA splicing, or regulatory elements such as promoters, or enhancers which control gene expression.

There are several ways to distinguish between mutations that cause inherited disease and harmless genetic polymorphisms that do not significantly change protein function or patterns of gene expression. A mutation may segregate in families with the presence of disease but not be found in unaffected controls. Cases of highly penetrant autosomal dominant disease that arise spontaneously in pedigrees where the illness has not previously been noted should manifest mutations in the affected proband that are not present in germline DNA from either biological parent. Comparing amino acid sequences of homologous proteins from different species can also help to distinguish between disease-causing mutations and harmless polymorphisms. If the amino acid in question is conserved across a range of species then it is more likely that this specific amino acid residue performs an important role and that altering it would have a significant effect on protein function. Finding pedigree-specific mutations involving different amino acids in the same gene can also add confidence to the search. A more direct test of the significance of a particular sequence change is to examine its effect directly in a functional assay. It may be possible to introduce a copy of a gene containing the sequence change into an appropriate cell line and measure whether protein function has been altered. To perform this type of experiment meaningfully, the protein being studied must be sufficiently understood to develop an assay.

In the case of cystic fibrosis, one of the genes in the candidate interval of chromosome 7 being investigated was found to have a three base pair deletion that segregated with disease status in many affected pedigrees. This results in the absence of a phenylalanine residue at position 508 of the protein, named the cystic fibrosis transmembrane conductance regulator because of its potential effects on ion flow across cell membranes. Loss of the phenylalanine from the protein disturbs intracellular processing, preventing the mature protein from reaching the cell membrane.

In 1989, the feat of identifying the specific 3-bp sequence alteration represented by the mutation known as ‡F508, amidst a genome 3×10^9 bp in size, was a testament to the potential power of positional cloning. However, when practised without a pre-existing framework of polymorphic DNA markers and large-insert DNA clones spanning the genome, this process proved very laborious, time-consuming, and expensive. Fortunately, as a consequence of the Human Genome Project, high-resolution genetic maps now exist for all of the chromosomes. Thus, it is usually no longer necessary to identify novel polymorphic DNA markers when trying to narrow the chromosomal intervals containing disease genes. Further, once a candidate chromosomal interval has been identified, it is now a straightforward matter to obtain DNA clones and most of the sequence covering the region containing the disease gene. The identification of genes lying within a specific genomic interval was previously greatly facilitated by the mapping of a large number of genes to well-defined chromosomal intervals, and is now even more enhanced by the availability of richly annotated genomic sequence databases. Significant technical advances have also been made in the field of identifying sequence variants that represent disease-causing mutations although, in many ways, this area remains the rate-limiting step in positional cloning projects.

Common diseases as complex traits

While great advances have been made in the realm of identification of the causes of single-gene disorders, genetic factors contributing to the development of more common diseases are, on the whole, much less well understood. It is generally accepted that a hereditary component contributes to the aetiology of almost all types of disease. Evidence in support of this contention is provided by observations that family members of affected individuals have the same disease more often than do members of the general population. Of course, a portion of disease familiality may also be due to shared environmental exposures, and care must be taken to consider this when examining such statistics. Nevertheless, careful study designs have allowed the identification of substantial genetic contributions to such common diseases as diabetes mellitus (both types I and II), asthma, essential hypertension, atherosclerosis, degenerative neurological disorders such as senile dementia and Parkinson's disease, the major mental illnesses, and many forms of cancer. Unlike single-gene disorders, common diseases tend not to segregate in families in easily recognized mendelian patterns. For example first-degree relatives of someone with an autosomal dominant disease such as familial hypercholesterolaemia have a 50 per cent chance of carrying the same mutation in the LDL receptor and second-degree relatives have a 25 per cent chance of carrying the mutation. Risk of developing the disease falls with this predictable pattern, depending directly upon the degree of relatedness to the index case. In common polygenic diseases, however, disease risk declines much more rapidly with the genetic distance from the index case. For this reason, familial clusters tend to be fairly small, making them difficult to recognize and study. Such clusters can also be the result of chance, when the disease is common. It is at least partly for these reasons that intensive genetic analyses of many common diseases remain in relatively early stages.

Common diseases are often known as complex traits because they are thought to be due to complex interactions between multiple genetic and environmental factors. Thus, genetic factors that might contribute to type I diabetes mellitus include a locus within the HLA complex, a polymorphic region just upstream of the coding region of the insulin gene and over a dozen other as yet, uncloned genetic loci in addition to presumed environmental exposures such as Coxsackie virus infection. While the presence of HLA-DQw8 has been associated with type I diabetes, possessing this allele does not guarantee that an individual will develop diabetes. In fact, most people with HLA-DQw8 will not become diabetic unless they also carry other predisposing genetic variants and are exposed to certain, largely undefined, environmental factors. In the absence of a complete understanding of these interactions, it is not yet possible, in most instances, to develop models capable of describing precise risk patterns for complex trait inheritance. Nevertheless, a variety of parameters have been used to quantify the relative contribution of various genetic and environmental factors that play a role in the development of disease. One of these quantitative measures is denoted l, and represents the ratio between the risk of a relative of a patient developing disease compared with the risk of an individual selected at random from the general population. l_s refers to the l value for siblings of index cases. Thus, l_s for type I diabetes is approximately 20, representing the relative risk of a sibling of a diabetic patient developing the disease (6 per cent) compared to the population risk of developing type I diabetes (0.3 per cent). This compares with much higher values for genetic disorders displaying simple mendelian patterns of inheritance. For example the l_s for cystic fibrosis is approximately 750 in Caucasians (l_s will tend to be large for rare disorders with low population prevalence). It should be remembered that l measures the effect of combined genetic and shared environmental factors. Each individual component necessarily must confer a smaller relative risk than the total l. The manner in which distinct risk factors combine to yield the overall value of l for a condition can be additive or multiplicative depending upon whether they are independent of each other or synergistic. Values of l_s for a number of disorders are shown in Table 1. In any case, individual genes that play a role in the development of common diseases may only cause comparatively small increases in the relative risk of developing disease. Assessing the clinical importance of each of these effects may pose substantial challenges in individual patients and they will need to be interpreted in the context of the presence of other genetic variants, exposure to environmental risk factors, and the overall clinical setting. When considered in large populations, however, even sequence variants that are responsible for modest increases in disease risk can be associated with a major public health burden.

While the distinction between 'simple' and 'complex' diseases is a useful one in helping to understand their genetic underpinnings, it is an artificial division. For example approximately 1 in 10 000 individuals possess frame-shift mutations that produce truncated and non-functional versions of one copy of their APC genes, causing familial adenomatous polyposis. This condition is characterized by the development of hundreds to thousands of intestinal polyps. Without prophylactic

colectomy or other preventive measures, there is a high likelihood that one or more of these polyps will undergo malignant transformation. Untreated, most patients will develop cancer of the colon by 40 years of age. Approximately 7 per cent of Ashkenazi Jews carry a non-truncating T®A sequence variant in APC, rendering the gene unstable and prone to further mutation in dividing cells of the colonic epithelium. This APC mutation appears to be associated with a 1.5 to 2-fold increased risk of developing colorectal carcinoma. This contrast between levels of cancer risk for low-frequency, high-penetrance and high-frequency, low-penetrance alleles of the same gene is an important one, and helps to demonstrate the spectrum of risk associated with different disease-associated alleles. Moreover, it helps to remind us that, strictly speaking, genes do not cause genetic disease, specific alleles of genes confer risk.

The challenge of identifying sequence variants contributing to complex disease

Several of the factors that make it difficult to find DNA sequence changes associated with complex disease have already been alluded to above. They include the absence of large numbers of affected family members sharing identical mutations, the fact that many of the sequence variants found in chronic disease are likely to be subtle changes that are difficult to recognize, and the expectation that the predictive power of particular sequence changes will generally be quite low. Patients with the sequence variant may not have the disease (low penetrance) and some patients with the disease will not carry the sequence variant (phenocopies). In contrast to the situation for simple mendelian disorders in which it may be possible to identify pathogenic mutations by analysing DNA samples from only a small number of cases, for complex disease samples will be needed from hundreds or perhaps thousands of cases. Rather than being able to make simple decisions about whether or not a sequence variant is the causative allele, sophisticated statistical analyses will generally be necessary.

Several approaches are being used to search for disease-associated sequence variants. Instead of relying on collecting large pedigrees, one type of study analyses pairs of affected siblings looking for evidence of excess allele sharing at loci that might be linked to disease. Two siblings can have none, one, or two alleles in common at a particular polymorphic genetic marker, with an expected frequency distribution of 25 per cent, 50 per cent, and 25 per cent respectively. If a particular allele were associated with disease risk, then both siblings with the disease would be expected to carry this allele more often than by chance alone. In large sets of sibling pairs, this would be manifested by statistically significant deviation from the expected distribution of shared alleles.

It is believed that many DNA variants that predispose to common disease traits will be ancient, derived from a common ancestor at some time in the past. More recent examples of shared ancestral alleles causing disease have come from studies of monogenic disorders. For instance in the case of porphyria variegata, two apparently unrelated Afrikaaners with the disease are highly likely to have the same underlying mutation and be descended from a pair of Dutch immigrants who arrived in South Africa in the early seventeenth century. In more outbred populations, the sources of such founder mutations will generally lie in the more distant past. Individuals who carry disease gene variants with common origins will also carry the same alleles at nearby polymorphic markers that were present on the ancestral chromosome on which the mutation first occurred. The distance over which these shared polymorphisms will be observed depends, in part, on the age of the variant. The greater the number of generations that have passed, the greater the chance that meiotic chromosomal recombination will have occurred, creating new patterns of associated markers.

The concept of association between disease status and specific alleles at nearby polymorphic markers in apparently unrelated subjects is known as linkage disequilibrium. Although there remains some uncertainty relating to these estimates, it is likely that, in groups that have not gone through recent population bottlenecks, linkage disequilibrium will extend for regions estimated to be 25 to 30 kb, on average. This means that in order to perform genome-wide scans for disease-associated alleles, roughly 200 000 to 300 000 polymorphic markers will need to be examined (in contrast to the 300–400 markers that are often used to search for monogenic disease genes by linkage analysis in affected families).

Even though characterizing common variants in human DNA was not part of the original goals of the Human Genome Project, that goal has been added. The need for very large numbers of polymorphic markers has meant that a great deal of energy is now being devoted to identifying and cataloguing human genetic variation, and within the next 1 to 2 years it is expected that more than 1 000 000 variants will be found. On average, any two randomly selected chromosomes differ from each other in about one base pair in every thousand. Several efforts have been undertaken to establish databases containing very large numbers of single nucleotide polymorphisms (SNPs). Some methods identify SNPs that are randomly scattered throughout the genome while other approaches target SNP discovery to particular parts of the genome, such as protein coding regions. All of these SNPs may be useful for genetic mapping and linkage disequilibrium studies, though some would argue that focusing on coding region SNPs (cSNPs) will give a higher yield of sequence changes that are more likely to be associated with alterations in gene function. A number of issues relating to the technical and statistical challenges associated with SNP analysis, high through-put genotyping, and the mathematics underlying linkage disequilibrium analysis remain to be resolved. These issues are the subjects of active research.

Changes to medical practice in the age of genomics

Given the great effort needed to define allelic variants contributing to complex disease, it is reasonable to ask whether such a large investment of resources is warranted. To be able to answer in the affirmative, it is necessary to demonstrate that benefits will accrue to everyday medical practice and patient health. Understanding genetic factors that contribute to disease could help establish a more rational basis for many aspects of patient care by providing deep insights into molecular pathogenesis and through improved molecular diagnostic tools that allow individually tailored preventive and/or therapeutic regimens.

Better understanding of molecular mechanisms of disease

Despite the extraordinary advances in our understanding of the functions of cells and organ systems in states of health and disease, it is somewhat humbling that fewer than 5000 human genes have been functionally characterized—many in only a cursory fashion. Clearly, it is difficult to provide full descriptions of the ways in which disease processes perturb cellular function in the absence of a comprehensive catalogue of genes that are either affected by these disease processes or are involved in the response to disease. The Human Genome Project will provide such a catalogue, giving a complete description of the DNA and protein sequences of all of these genes.

The genome project is providing important tools that will help researchers discover functions of novel proteins. About half of the new genes identified by large-scale DNA sequencing bear some resemblance to other genes that have previously been studied, either in humans or in model organisms. Sequence similarity to previously characterized genes can provide important clues to protein function. In addition to comparisons of primary DNA and protein sequences, computerized approaches to predicting three-dimensional protein structures are becoming increasingly feasible, and may also allow generation of testable predictions about gene function.

Of course, many novel genes do not have any (or enough) similarity to known genes for useful predictions to be made, and direct experimental investigation may be required to determine their function. To deal with the large number of new genes that are being identified by the Human Genome Project, an innovative set of methods has emerged, known collectively as functional genomics, which explore the roles of many genes in parallel. Functional genomics experiments will obtain a great deal of information about patterns of gene expression, protein interactions, and metabolic pathways.

Diagnostic tests

One advance in genomics that is already finding its way into clinical practice is the use of diagnostic tests based on DNA sequence changes. Such tests can be used for several purposes. As with more conventional tests, genetic tests can confirm a specific diagnosis or contribute to the evaluation of problematic differential diagnoses. Presymptomatic diagnostic testing can also be performed in subjects without disease. However, even in the case of high penetrance mutations, such as those found in Huntington's disease, it may be difficult to predict the time at which clinical signs or symptoms will develop. In some cases, measures may be available that will prevent or ameliorate the onset or course of illness. Examples of such conditions include haemochromatosis, in which regular venesection can prevent the sequelae of iron overload, or hereditary non-polyposis colon cancer, in which case colonoscopic removal of premalignant lesions can help to prevent the development of cancer. In the absence of such effective interventions, especially careful consideration must be given to the circumstances in which predictive genetic testing is performed. Some patients find presymptomatic genetic diagnosis helpful because it gives them the opportunity to make long-term plans which include the likelihood (or not) of developing illness. Others prefer 'not to know' and would rather forego testing unless an intervention is available. In many centres, teams that include qualified genetic counsellors are in place to ensure that patients receive appropriate education and non-directive counselling before and after making decisions about whether to undergo testing for serious illnesses.

An important way that DNA testing can differ from conventional diagnostic investigations is in its implications for relatives of the tested proband. A positive (or negative) result may allow one to infer the genotype of individuals other than the proband. For example if a subject had a paternal grandparent with Huntington's disease and was found to have an expanded glutamine-encoding triplet repeat in the Huntington gene herself, then it is virtually certain that her father is also at risk of developing Huntington's disease. Even without his consent to be tested, the father's genotype could be inferred with a high degree of certainty. Such situations can

complicate issues relating to informed consent. It is not unusual for several members of a family with a history of a genetic disorder to present for presymptomatic evaluation. Genetic counsellors can help to explore complex issues related to the needs and expectations of different family members while respecting individual autonomy.

To date, most conditions being investigated with DNA-based tests are relatively uncommon, single-gene disorders, and the tests are usually carried out in specialized centres with considerable experience in their execution and interpretation. As the technologies needed to perform these tests become more widely available and the sequence changes being evaluated more frequent, attention will be needed to ensure that procedures relating to DNA-based diagnostics continue to be carefully executed. Such concerns include issues related to quality control, skills in the interpretation of complex test results, provision of adequate genetic counselling, and other matters such as control of record-keeping systems to ensure genetic privacy. As the use of predictive genetic testing becomes more widespread, the associated obligations will fall to an increasingly diverse range of health-care professionals and it is important that they receive adequate training in this area.

Pharmacogenomics

Although not generally thought of in the same way as DNA variations that predispose to complex disease, germ-line sequence changes can also be important determinants of response to pharmacological treatment. The study of DNA sequence polymorphisms affecting metabolism of, and response to, drugs has become known as pharmacogenomics. It has long been recognized that individuals metabolize pharmacological agents at different rates. A substantial proportion of this variation can be due to genetic effects. A classic example of this phenomenon was described well before the modern era of molecular genetics and genomics, with the division of the population into slow and rapid acetylator groups. Approximately 60 per cent of Caucasians, but only 5 to 10 per cent of Asians, show reduced rates of *N*-acetylation and elimination of a number of drugs, including isoniazid, hydralazine, and caffeine, compared with the remainder of the population who exhibit comparatively rapid *N*-acetylation. Although initially characterized by standard biochemical tests, the genotypic bases for these metabolic differences in drug metabolism are now known to be several polymorphic variants in the gene *N*-acetyl-transferase-2 or *NAT2*.

In addition to showing different rates of metabolism and clearance of drugs from the system, subjects are often found to show variable therapeutic responses to these agents. In some cases, this may be due to subtle changes in the structure of drug targets between subjects. For instance several studies have found that schizophrenics with the amino acid histidine at residue 452 of the 5-HT $_{2A}$ serotonin receptor have a poorer antipsychotic response to clozapine than do patients with a tyrosine at this position. In diseases such as essential hypertension that are treated symptomatically, rather than with specific measures, some patients respond better to certain interventions than to others. If the genetic factors that are responsible for different forms of hypertension could be identified, then it might prove possible to tailor treatment regimens specifically directed towards generating responses in the physiological pathways that are perturbed in particular patients. For instance we might be able to predict that a particular patient would be more likely to respond to the antihypertensive effects of b-blockers than ACE inhibitors. We may then be able to use relatively inexpensive, one-time DNA tests, to determine which drugs can be used safely and efficaciously in patients with chronic illness. Such approaches promise to be more effective than the trial and error processes that are now often needed to discover optimal drug treatment regimens.

Development of therapeutic agents

In parallel with the government-funded human genome project, much effort has been expended in the private sector to identify and sequence novel genes. A large part of the motivation behind these efforts is the expectation that new therapeutic agents and targets will be discovered. The distinction between therapeutic agents and targets is one that has important implications for the development strategies that must be used. Therapeutic agents developed from genomic sequence information are usually secreted proteins or hormones that can be made for direct *in vivo* administration. A prime example is the use of recombinant erythropoietin for the treatment of anaemia in chronic renal failure. On the other hand, therapeutic targets can potentially be any proteins that are involved in a disease process or a compensatory response to disease. Once such a target is identified, further effort is needed to develop agents (usually small molecules) that can affect function of the target. Although it remains difficult to predict the three dimensional structure of novel proteins based on amino acid sequence alone, improvements in computational analysis, X-ray crystallography, and nuclear magnetic resonance studies are making it possible to produce increasingly sophisticated models of the active sites of target proteins. Using principles of rational drug design, it will become a more straightforward and less expensive matter to develop new drugs for particular diseases than using the trial-and-error methods that were relied upon in the past. The use of genomic sequence information in identifying targets for drug development is also advancing rapidly in the field of new antibiotic discovery. The genomes of several important microbial pathogens including *H. influenzae*, *S. aureus*, *M. tuberculosis*, and *T. pallidum* have been completely sequenced. Newly identified proteins that are important for bacterial replication or virulence but that do not have close relatives in mammalian cells may provide excellent drug or vaccine targets.

Another exciting possibility that arises from an understanding of the genomic sequence of disease genes is the possibility that the expression of particular proteins might be able to be modulated by developing small molecules that interact specifically with promoter and enhancer elements of the genes coding for these proteins. Considerable advances have been made in both the understanding of factors that influence sequence-specific DNA-binding and the ways in which gene expression are controlled, and it is likely that this knowledge will be used to help develop drugs that can up- or down-regulate gene expression in useful ways for disease treatment or prevention.

Gene therapy

Though they have been slow to come to fruition, the concepts underlying somatic cell gene therapy predate the inception of the Human Genome Project. Initial plans to induce expression of normal proteins in patients with rare genetic defects, such as adenosine deaminase deficiency, have been broadened to include a range of more common diseases such as cancer, atherosclerosis, and AIDS. Achieving clinical benefits from gene therapy has proven to be problematic because of technical difficulties preventing sufficiently high-level expression of recombinant proteins in appropriate tissues. Substantial effort is now being directed to the development of viral and other vectors that will allow more effective delivery of introduced genes to the desired sites. The recent death of a patient involved in a clinical trial using adenovirus as the delivery system has underlined the risks of triggering an overwhelming immune response with such vectors. A full discussion of gene therapies is beyond the scope of this chapter; but clearly, as our understanding of the human and other genomes increases, the range of conditions that are amenable to treatment by various forms of somatic genetic manipulation will also increase.

Public policy implications

With the advances in medical and scientific knowledge that come from the recent, rapid developments in the field of genomics come a host of issues that require consideration by the broader community. Some of these issues have been faced before in other contexts, and some are peculiar to the fields of genetics and genomics.

Genetic privacy

In addition to issues relating to control of access to medical records that are shared with other forms of medical data, there are several privacy concerns that are particular to genetic and DNA sequence-based information. Most people would agree that individuals should have a high degree of control over who has access to information concerning the makeup of their genome. Because relatives share genetic markers, it may be possible to determine a person's genetic constitution without the knowledge or consent of that individual. This can lead to a conflict between one person's desire to be aware of their genetic makeup with another's desire that other people not know his or hers. Deciding 'ownership' of genetic information is not a simple matter and may be difficult to resolve if disputes occur within families. Such disputes also have the potential inadvertently to reveal previously known or unknown instances of non-paternity, with unsettling consequences for those involved.

The use of combinations of polymorphic markers for the purpose of uniquely identifying subjects has found increasing application in non-medical settings, especially forensic science. Privacy concerns have been raised about databases established by government agencies that record DNA profiles of large numbers of individuals. It is important that appropriate safeguards be instituted to ensure that databases that might be used for socially justifiable purposes, such as criminal forensic analysis or identification of deceased military personnel, are not abused.

Health insurance and employment discrimination

Especially in countries such as the United States that do not have universal health insurance programmes, there is concern that people will be denied access to affordable health care because of their genetic makeup. There have been occasional, but well documented, examples of denial of health insurance because patients are at risk of developing genetic illnesses. As the factors underlying genetic contributions to complex disease are elucidated, eventually the majority of people could

be found to be at an increased risk of developing one serious medical condition or another. It would be most unfortunate if the possession of an allele that predisposes to cancer of the colon put someone in the position of losing health insurance coverage, rather than the institution of a regular colonoscopy programme that could prevent them from dying of cancer. Legislative solutions are needed to ensure that the availability of health care does not depend upon genetic constitution.

Fears have also been expressed that potential employers could screen applicants for the presence of 'undesirable' genetic traits and use the results of these tests to decide who should be offered positions. Should someone be denied the chance to become an air traffic controller because they were more likely than average to abuse alcohol? Should a person possessing a neurotransmitter receptor variant that makes them prone to depression be prevented from carrying a firearm as a police officer? In general, however, predictions based on such correlations will be rather weak—and thus the strong consensus is that employment decisions should be made solely on the basis of ability to do the job. Here again, legislative protections are needed to prevent discriminatory practices from becoming widespread.

Regulation of novel genetic tests and therapies

Novel diagnostic tests and therapies arising from rapid progress in the field of genomics can pose substantial challenges to statutory regulatory agencies such as the Food and Drug Administration in the United States or the Committee on the Safety of Medicines in the United Kingdom. These authorities may need to acquire quickly the expertise to assess innovative modalities and ensure that they are used appropriately and safely. Many of these issues will best be considered within frameworks similar to those that have been used in other areas of medical practice. The establishment of the Secretary's Advisory Committee on Genetic Testing (SACGT) signals an era of increased scrutiny of predictive genetic tests in the United States.

Many aspects of the traditional drug approval process are being adapted to assess the safety of somatic cell gene therapy and recombinant biotherapeutic agents. Nevertheless, certain of these processes will need to be refined to cope with changes brought about by advances in genomics. Authorities responsible for the governance of genetic testing procedures must address issues relating to informed consent and genetic privacy. Techniques with potential to alter the makeup of the human genome, such as germ-line gene therapy and cloning, have already raised thorny moral and philosophical questions.

Education of medical and lay communities

Several factors appear to be responsible for the relatively little attention given by many medical schools to clinical aspects of genetics and genomics. In part because of the relatively large cost of establishing comprehensive research programmes in this area there, has been a tendency for cutting-edge genomics research to be carried out in only a few centres. This, together with the fact that most of the physicians and scientists with experience in genomics tend to be relatively young, has meant that few medical school curricula have received input from senior academics who appreciate the importance of the subject. Clinical genetics has often been taught under the auspices of paediatrics, and has focused on rare diseases. Given the cross-disciplinary nature of the topics that need to be covered to understand genomic aspects of human disease (including clinical medicine, pathology, biochemistry, epidemiology, and biostatistics) and its application to many common diseases of adult onset, it may be that the study of genomics should be considered within a broader context.

With the extensive amount of coverage that has been given to recent advances in genetics and genomics by the print and electronic media, it is not unusual for patients to ask their doctors questions on topics about which the physicians have little information. To meet their patients' needs, and to allow them to be more proactive in addressing preventive medicine and other health concerns, it is important that established medical practitioners and physicians in training have access to continuing medical education resources informing them about genomic aspects of human disease. In the United States, the recent formation of the National Coalition for Health Care Professional Education in Genetics (by the National Human Genome Research Institute, American Medical Association, and American Nursing Association) promises to fuel this effort. Several databases and other resources are already widely accessible on the world wide web. As a useful starting point, the National Center for Biotechnology Information site (*http://www.ncbi.nlm.nih.gov/*) provides access to On-line Mendelian Inheritance in Man (OMIM), a comprehensive collection of information related to inherited disease phenotypes. Other highly useful sites include GeneClinics (*http://www.geneclinics.org/*), which provides authoritative reviews on the diagnosis and management of specific genetic disorders, and GeneTests (*http://www.genetests.org/*), which provides a guide to availability of genetic testing services.

At the same time, members of the lay public will benefit from an increased understanding of how genetic factors might be important in managing their health. Challenges that have to be met in this arena include the sometimes technically complex types of information that need to be understood, as well as the probabilistic nature of many of the clinically relevant associations between genotype and phenotype under consideration. While many patients will take the initiative to try to learn about medical aspects of genomics for themselves, most will benefit from education from a number of sources, especially their physicians and other health-care providers.

Conclusion

It is not an exaggeration to assert that the field of genomics has revolutionized biomedical research in recent years. The process of transition from the laboratory to the clinic is still in its early phases but holds great promise. Insights into the pathological processes underlying many illnesses will expand the range of diagnostic and therapeutic options available to the clinician. Perhaps the most exciting near-term advance that the fruits of the Human Genome Project offers is the opportunity to develop personalized risk profiles based on the particular patterns of DNA sequence variation that individual patients exhibit. These profiles will give us many chances to ameliorate the effects of disease by instituting appropriate preventive health measures and tailoring treatment regimens to specific patients based on their genotypes.

We must be cautious, however, not to overestimate the power of genomics to explain clinical outcomes and other biological phenomena. A comprehensive understanding of the importance of genetic factors in human disease should only serve to highlight the significance of environmental factors as modifiers of genetically coded molecular processes. The effects of genes or DNA sequence variation should not be treated in too deterministic a manner but only regarded as one facet contributing to our understanding of the processes involved in human health and disease.

4.2 The human genome sequence

Sydney Brenner

The modern period in biological research began in 1953 when JD Watson and FHC Crick discovered the double helical structure of DNA. Within the very short period of time of about a decade, the new science of molecular biology uncovered the basic mechanisms of information transfer from genes to proteins in living cells. The nucleotide sequence of a gene was shown to be colinear with the amino acid sequence of the protein that it specified, the genetic code was found to be a triplet code and the correspondences of the three-base codons to each of the 20 amino acids was established. Although there were chemical methods for determining the amino acid sequences of proteins, the structure of the gene was accessible only through mutational changes as recorded by phenotypes. Such mutations defined genes, and these could be mapped by recombination. Research in molecular genetics proceeded most rapidly with bacteria and their viruses which could be handled easily in the laboratory. A beginning was also made to study more complex systems, such as *Drosophila* which had been long established as a laboratory organism for experimental genetics, and *Caenohabditis elegans*, a small, free-living nematode worm.

In the mid 1970s there were two revolutionary, technical innovations which changed the entire course of genetics. The first was a method of cloning and propagating fragments of DNA in bacteria and yeasts and the second was the invention of methods for sequencing DNA. Thus the genome of any organism could be obtained as a library of fragments and the sequences of these fragments could be determined. In principle, therefore, the complete sequence of the genome could be obtained, and since it was possible to clone and sequence cDNA copies of messenger RNA, the expressed genes could be identified and the amino acid sequences of their proteins inferred from the nucleotide sequences. cDNA characterization became important when it was quickly discovered, by the new techniques, that the genes of higher organism were interrupted by intervening sequences called introns which were removed by splicing leaving the coding exons to form a coherent sequence.

For some time the only complete genomes that were sequenced were small, of the order of 100 kb. In 1985, when it was suggested that the complete sequences of the human genome might be obtained, it was realized that not only would there have to be considerable technical improvements, but also the project would have to be on a large scale and require international co-operation. The technical improvements were the automation of many of the laborious steps of the sequencing process, and the availability of sequencing machines and their progressive enhancement in throughput. Larger genomes were tackled and an early accomplishment was the 14-Mb sequence of yeast. This was followed by the sequences of *C. elegans* and *Drosophila*, each of around 100 Mb. In 2001, two groups announced that they had more or less completed the first draft of the human genome sequence, and no doubt this will be subjected to much improvement in future years.

The human genome sequence was seen by many to provide new approaches to human biology and, in particular, to medicine. For example it was claimed that once all the genes were found, all the proteins specified by those genes would be known, and this would allow the uncovering of an enormous number of new targets for the development of new therapeutic agents. In the long run this may prove correct, but before we can use a protein as a drug target we have to know how it functions in the body, and whether any alteration of its activity will have the desired effects. Although the molecular function of a protein can often be specified by comparison of its sequence with proteins of known function, this is insufficient to decide how this activity is translated into a particular cellular process and how this is, in turn, integrated into the physiology of the whole human organism. Thus, for example, while we can readily identify domains with resemblances to proteases, we require additional information to decide what the proteolysis is doing; it may be involved in digestion, in gene regulation, in cell death, in blood coagulation, or the complement pathway. For any protein to be a target we must have something much more than the protein sequence, we must have a therapeutic hypothesis and this will be made possible only by the continuation of conventional biological and clinical research.

There can be no doubt, however, that knowing all or nearly all of the proteins made by cells will spur research on the biochemistry of cells. In particular, this has already had a profound effect on the development of knowledge about cell signalling pathways, DNA repair, protein traffic within cells, and ion channels, to name only a few. In addition, because many of these processes are common to other organisms such as *Drosophila*, the nematode, and even yeast and bacteria, we can draw on research in these organisms to illuminate function in mammalian cells. A whole area of research, called functional genomics by some, relies extensively on this comparative approach. Since mutations in genes are easily obtained in these model organisms, such mutant homologues can inform us about the cellular function of the gene, which can be carried over to the mammalian systems. The main experimental organism for functional analysis is the mouse, a mammalian model organism amenable to a special form of gene manipulation. A line of embryonic cells, ES cells, can be propagated in tissue culture, and when these are injected into a mouse blastula they become incorporated into the embryo and populate both the germline and somatic ells. In this way, transgenic mice can be constructed in which genes have been added or removed from the mouse genome. Mice in which genes have been deleted are called knockout transgenics and can reveal the contribution of the gene to the total phenotype. These methods were used to prove that prions cause the endogenous prion protein to adopt an incorrect form and so cause the neurological disease. Complete removal of the prion gene has no effect of its own but the animals become resistant to infection.

The most significant contribution made by the new genetics has been the identification of the genes involved in single gene mutations in humans. More than 1000 such monogenic, inherited disorders have been identified; some rare, others, such as cystic fibrosis, quite common. These provide the direct test of function and they throw light on the pathogenesis of disease and the underlying molecular causes. In certain areas, such as cholesterol metabolism, the analysis of the changes in certain monogenic diseases has revealed the connections between cholesterol and the ensuing cardiovascular pathology. In addition, even very rare monogenic diseases which resemble the much more common diseases, such as the cases of breast cancer or Alzheimer's disease, can lead us to understand the pathogenic pathways involved.

There are, however, several very common diseases which can be shown to have a genetic component but are not due to single gene mutations. Schizophrenia, diabetes, and Crohn's disease are common and are about 50 per cent correlated in identical twins. There is, therefore, a large environmental component and the fact that they are polygenic makes it difficult to discover the genes involved. However, the possibility that one might identify the genes with polymorphisms correlating with the disease state has led to the development of what is called predictive medicine or probabilistic medicine. We only have a few of these disease susceptibility marks, but the fact that genetic analysis may be predictive has raised many questions about the ethical, social, and legal consequences of genetic testing. There is very little established work in this field but already there are problems, mostly created by health insurance.

It is clear that in the rush to obtain the sequence, the understanding of the connections between genotype and phenotype has remained superficial. There is a tendency to talk about genes for homosexuality, alcoholism, criminality, and so on. The unravelling of the complex skein of connections between the genes and the final phenotype has only just begun and it will occupy biomedical scientists for the next few decades, at least. DNA sequencing is a unique technology; one can feed a machine with DNA derived from anything—plants, bacteria, humans—and the linear sequence of bases which is the essential information in the DNA can be extracted. There has been an explosion in the amount of data available and there will be much more to come. However, data are not knowledge and only knowledge can lead to understanding the meaning of the sequence and allow us to diagnose and treat human disease.

4.3Molecular cell biology

William M. F. Lee and Newman M. Yeilding

The molecular mechanisms underlying many cellular and biological functions have been unravelled in recent years and, with this, has come an understanding of the molecular basis of many pathological conditions. This progress promises to provide improved insights into disease pathogenesis, suggest novel opportunities for therapeutic intervention, and launch efforts to make these interventions a part of medical practice. In this chapter, we provide a synopsis of salient features of cell function at the molecular level. Important decisions and events that all cells undergo, such as proliferation, differentiation, and death, are then discussed in molecular terms. Finally, to provide a medical context for this information and illustrate the potential clinical relevance of the knowledge gained, we discuss emerging concepts of the molecular pathogenesis of two important human diseases, cancer and cardiomyopathy. Clearly, none of these sections can hope to be comprehensive given the mass of accumulated knowledge and relatively scant number of pages allotted to this chapter. Accordingly, emphasis has been placed on concepts and principles, with details and examples presented only to better illustrate these paradigms. A further reading list is provided for those seeking more in-depth discussions of the various topics. These are in the nature of review articles and books in order to limit the size of the bibliography. For those with greater interest in the science and who wish to know the details and read the primary articles, the bibliographies of the reviews and book chapters will provide the appropriate references.

Genetic information and information retrieval

No biological process is more universal or fundamental than the way cells store, access, and use the information that is needed for the all the processes involved in creating and sustaining life. Deoxyribonucleic acids (DNA) in the genes of the cell are the repository of this information. DNA is an unbranched, linear polymer constructed of deoxyribonucleotide monomers that are directionally, covalently linked by phosphate bonds between the 5' hydroxyl group of the deoxyribose sugar moiety of one deoxyribonucleotide and the 3' hydroxyl group of the deoxyribose moiety of the next deoxyribonucleotide (Fig. 1). Four different deoxyribonucleotides (adenine, A; guanine, G; cytosine, C; and thymine, T) comprise the genetic 'alphabet' with which genetic information is written. Cellular DNA usually exists in a double-stranded (duplex) helical configuration in which one strand is 'zippered' by hydrogen bonds to a second, fully complementary DNA strand. This bonding between complementary strands is established by the nucleotide on one strand interacting with the paired nucleotide on the opposite strand with which it forms the most stable hydrogen bonds: G bonds best with C, C with G, A with T, and T with A. The two strands in duplex DNA maintain full complementarity because, during DNA replication, the DNA polymerase enzymes responsible for synthesis use one strand as template while synthesizing the other through covalent addition of complementary nucleotides to the nascent strand. This type of replication is termed 'semiconservative' because each of the two new daughter DNA strands contains one newly synthesized strand and one previously synthesized strand derived from the original duplex.

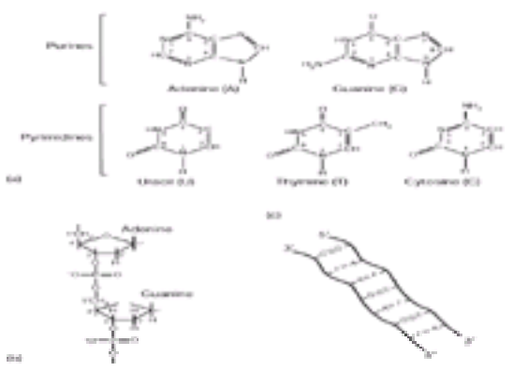

Fig. 1 Chemical structure of DNA and RNA. The chemical structures of the bases that comprise DNA and RNA are depicted in (a). In the nucleotides comprising DNA and RNA, the nitrogen atom at position 9 of purines or position 1 of pyrimidines is covalently bonded to the 1' carbon atom of a ribose or deoxyribose sugar. DNA and RNA polymers are directionally linked via a phophodiester bond of the 5' carbon of the sugar moiety of one ribonucleotide or deoxyribonucleotide and the 3' carbon of another (b). While RNA is most commonly single stranded, DNA primarily exists as a hydrogen-bonded antiparallel duplex between complementary DNA strands (c).

In eukaryotic cells, the library of genetic information is stored in chromosomes which consist of exceedingly long strands of DNA with associated proteins that help organize and compact the DNA. The most prominent proteins in chromatin, as chromosomal DNA with associated proteins is called, are the various types of histones. Certain histones form a core around which the DNA is more or less tightly wound, forming a structure called a 'nucleosome'. Nucleosomes are stacked, and stacks of nucleosomes are further organized to allow the very long DNA in chromatin both to fit in chromosomes and, importantly, to be accessible for information retrieval and replication. Arrayed on each chromosome are a multitude of genes, each of which contains the information necessary to synthesize a functional protein or RNA molecule. Normal somatic cells are diploid, meaning that they possess a pair of every non-sex chromosome (autosomes) and two sex chromosomes, which are either a pair of X chromosomes in cells from females or one X and one Y chromosome in cells from males. This means that two copies of every autosomal gene exist in each cell (one derived from each parent), two copies of X chromosome genes exist in female cells but only one copy in male cells, and one copy of Y chromosome genes exists in male cells and none in female cells. Human cells have 22 pairs of autosomes and two sex chromosomes, so they have 46XX chromosomes if they are female, and 46XY chromosomes if they are male.

An organism's genome contains a complete catalogue of the information required for its development, growth, and function. Proteins are the primary effector molecules responsible for carrying out the instructions written in the genome, and the properties, structure, and function of each protein is largely determined by its amino acid sequence. The principal information carried in the genome is the amino acid sequence of all the proteins produced by that organism. To create these proteins, genomic information is first accessed by transcribing DNA into ribonucleic acid (RNA) format, after which the information in RNA is translated into proteins. The process of gene transcription is carried out by complexes of proteins collectively termed transcription factors and involves the synthesis of RNA copies from DNA templates. RNA differs from DNA structurally in that the sugar moiety is ribose instead of deoxyribose, uracil (U) is incorporated where thymidine (T) is present in DNA, and RNA is usually single-stranded. The absence of a complementary strand means that nucleotides in RNA are free to form hydrogen bonds with other nucleotides in the same RNA (intrachain hydrogen bonding), a property that allows RNA to become highly folded and adopt secondary structures that are functionally important. The three major types of RNA present in cells are:

1. messenger or mRNA which encode the amino acid sequence of proteins;
2. ribosomal or rRNA which are components of ribosomes that translate mRNA into proteins; and

3. transfer or tRNA which actually decode the codons in mRNA transcripts into their respective amino acids during protein synthesis.

Information contained in mRNA for constructing proteins is deciphered through the process of translation. Proteins are polymers composed of 20 different amino acids covalently linked together by peptide bonds. Instructions for the sequence of amino acids in a protein are contained in sequential groups of three consecutive nucleotides, or codons, in mRNA (and the DNA from which it was transcribed), with each codon designating a specific amino acid. Thus, the sequence of specific codons defines the sequence of amino acids that are to be polymerized to create the encoded protein. Since each position in a given codon contains one of four possible nucleotides from which RNA and DNA are made, there are 4^3 or 64 possible nucleotide sequence combinations in a codon triplet. Of these 64 codons, 61 code for 20 different amino acids and 3 (TAA, TAG, and TGA) signal termination of translation. These numbers indicate redundancy in the genetic code, and, in fact, most amino acids are encoded by more than one codon.

The flow of information from DNA to RNA to protein just outlined is the fundamental basis upon which all life on earth is built. However, while this principle is relatively straightforward, the actual process of retrieving information from the genome is much more complicated. Consider that some proteins are needed in large quantities, others are needed in small quantities, and many are needed only some of the time. Yet, two copies of most genes exist in each diploid cell, regardless of the demand or lack of demand for the information they bear. To provide for this requirement that gene expression varies independently of gene copy number, cells have devised elaborate mechanisms for regulating the expression of genes and the activity of their products. That expression of genes is a highly regulated process is hinted at by the fact that the sequences that actually encode protein occupy only part of the DNA of most genes and only a small proportion of the human genome. Many non-coding regions of the genome have been shown to have important regulatory functions, such as regulating the transcription of genes.

The process of making mRNA transcripts suitable for translation into protein involves the initial synthesis of a primary mRNA copy of the gene and subsequent maturation of this primary transcript to ready it for translation (Fig. 2). Non-coding regions of genes near the start site of transcription or further upstream, termed promoters, initiators, and enhancers, regulate transcription. These elements act only on genes to which they are covalently linked (i.e. they act 'in *cis*') and function by interacting with proteins that regulate transcription, so-called transcription factors. These proteins non-covalently bind to specific DNA sequence motifs in gene regulatory elements and act 'in *trans*' to modulate expression of genes by assembling multiprotein complexes that start and control the process of transcription. The abundance and activity of many of these transcription factors are regulated by specific stimuli and environmental factors. Together, these *cis*- and *trans*-acting factors regulate mRNA production and determine which genes are expressed, when, and to what extent in different types of cells.

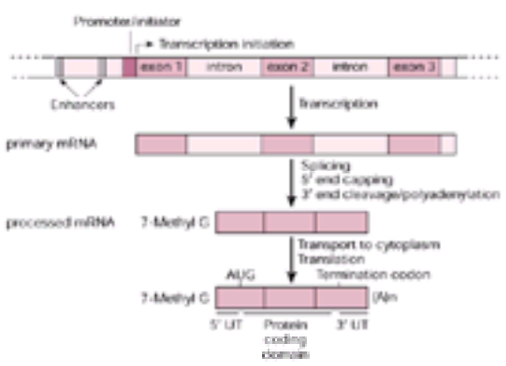

Fig. 2 Transcription and post-transcriptional processing of mRNA. Features of a gene transcriptional unit are shown. Following transcription and generation of a primary mRNA transcript, post-transcriptional processing converts this to a mature mRNA that is ready for export to the cytoplasm and translation. Landmarks in the mature mRNA relevant to translation are shown (UT, untranslated region).

After transcription, mRNAs must undergo additional processing to ready them for translation. The protein coding sequences of many eukaryotic genes are discontinuous and separated by intervening non-coding sequences (introns) which are transcribed and are part of the primary mRNA transcript. Introns must be removed by the process of splicing before the mRNA can be translated, resulting in a spliced mRNA that contains only exon sequences. While their origins are unclear, introns effectively divide protein coding regions of the gene into distinct segments. This gives rise to a form of modularity that can be envisaged as facilitating the modification of existing genes and proteins and the evolution of new ones if exons are moved, mixed, shuffled, duplicated, or deleted. Besides splicing out introns, mRNA maturation involves other events, such as the addition of a special nucleotide 'cap' (7-methyl G) at the proximal or 5' end, cleavage of the distal or 3' end and the addition there of an untemplated string of A residues (polyadenylation). These post-transcriptional modifications of mRNA protect it from degradation by nucleases and make it more translatable once it reaches the cytoplasm.

Mature mRNAs are transported from the nucleus to the cytoplasm where they are translated into the specified amino acid sequence. Ribosomes, which are macromolecular assemblages of multiple RNA and protein components, are the engines of translation and protein synthesis, while multiple species of tRNAs, each charged with its specific amino acid, 'read' the appropriate codons using complementary sequences in their structure. Mature mRNAs contain non-coding sequences preceding and following their coding sequences, and these have been shown to regulate both the efficiency of translation and longevity of the mRNA. During translation, ribosomes must exclude these 5' and 3' non-coding sequences from translation or, put another way, they must know where translation should begin and end. Current models of translation suggest that ribosomes attach to the mRNA via its 5' cap structure and 'scan' down the mRNA until they find the first AUG trinucleotide that is located in a nucleotide sequence context appropriate for translation initiation. This prevents false translation initiation by distinguishing the authentic translation initiation AUG from other AUG trinucleotides that are frequently present upstream. Translation is initiated at the authentic initiation AUG, which encodes methionine, then proceeds down the mRNA in the nucleotide triplet 'reading frame' established by the initiation AUG. Amino acids encoded by each subsequent trinucleotide are covalently added to the elongating polypeptide strand until an 'in-frame' termination codon (UAA, UGA, or UGA) is encountered, at which point translation stops. The reading frame is all important for correctly interpreting the message in mRNA nucleotide sequence and synthesizing the correct protein, since translation of the same sequence in either of the two alternate reading frames will produce totally different, incorrect proteins.

Mutations

Many systems have been built into cells to insure the fidelity of the genetic information transmitted from cell to progeny cell. If DNA errors arise, mechanisms exist to correct them, and if this is not possible, mechanisms exist to cull out the damaged cells. Despite these protective mechanisms, genetic changes and mutations do arise. This is not necessarily bad, for heritable changes drive diversity and the evolution of species. The prejudice against genetic mutations derives, justifiably, from a focus on the individual and the medical problems they may cause. In truth, however, most genetic changes probably have no detectable phenotypic consequences and give rise to so-called DNA sequence or genetic 'polymorphisms' that distinguish the genome of different individuals and have been used for a variety of purposes (e.g. forensics analysis, determining parentage, tracing inheritance of genes, etc.). Because they cause no problems, their occurrence goes unnoticed. On the other hand, mutations that cause disease soon come to medical attention and tend not to remain undetected, especially with the rapid pace of modern genetic analysis. These mutations can cause organ malfunction and developmental abnormalities, particularly those that arise in the germline and are inherited, because all cells in the organism are affected. More frequently, however, genetic mutations arise in somatic cells during a person's life. These may be spontaneous or induced by DNA damaging agents (e.g. gamma or UV radiation or chemical mutagens). Most somatic mutations probably have few if any consequences, because they affect only individual cells, and the vast majority are unaffected. However, when somatic mutations involve important regulatory genes, this may lead to aberrant cell behaviour which, if it involves loss of normal control over cell proliferation, can eventually cause disease, such as cancer.

The nature of genetic errors and their potential consequences are diverse. The complement of chromosomes in somatic cells may deviate from the normal diploid. Aneuploidy may involve either fewer (hypodiploid) or greater (hyperdiploid) numbers of chromosomes, and an aberrant complement of even a single chromosome can be pathogenic (e.g. trisomy 21 causes Down's syndrome). Segments of chromosomes rather than entire chromosomes may be amplified, which can give rise to visible cytogenetic abnormalities, such as chromosomes with 'homogeneously staining regions' (HSR). 'Double minutes' are amplified chromosomal segments that exist free in the nucleus, separated from their chromosome of origin. These cytogenetic abnormalities indicate the presence of genes that are present in many copies in the cell and whose expression may be deregulated. More common than gene amplification are gene deletions, which may or may not be detectable cytogenetically. Chromosomal translocations are yet another aberration and are frequently associated with lymphoid malignancies, probably because gene breakage and rejoining naturally occurs during certain stages of T and B cell development. Translocations juxtapose genetic elements that are normally separate and may cause aberrant regulation of gene expression or fusion of two different genes resulting in the production of a chimeric protein.

The genetic anomalies described so far are detectable cytogenetically, but most mutations are on a much smaller scale. Deletion of whole or portions of genes, which are usually not detectable cytogenetically, cause total loss of the protein product or creation of a truncated protein. Loss (or addition) on a much smaller scale (e.g. of one or two nucleotides), particularly if they occur in protein coding regions of genes, may produce equally devastating effects by shifting the reading frame during translation. Sequences downstream of the nucleotide loss or addition are normal but will be read by ribosomes in an alternate reading frame, resulting in incorporation of totally different amino acids from those intended. Needless to say, unless the frameshift mutation is near the end of the protein coding domain, functionality of the whole protein will be lost. Nucleotide substitutions or 'point' mutation can cause more or less profound disruptions of gene expression and protein function. At one extreme, substitutions may convert a codon for an amino acid into a termination codon ('nonsense' mutation) leading to premature termination of translation. Point mutations outside protein coding regions may also have profound effects if they occur in sequences important for exon–intron splicing or for binding of critical transcription factors. At the other extreme, nucleotide substitutions may be 'silent' when they occur in a nucleotide position that causes no change in the encoded amino acid (due to redundancy in the genetic code). Between these extremes, nucleotide substitutions may alter a codon so that it encodes a different amino acid. These 'missense' mutations may have little effect on the properties of the encoded protein (essentially becoming an amino acid sequence polymorphism) or may critically alter its function. The spectrum of genetic mutations briefly described here will assume greater relevance when the genetic aetiology of cancer is discussed.

Post-translational protein regulation

Cells are highly ordered structures and properly function only when their molecular assemblages and organelles function and interact appropriately. This organization requires that newly synthesized proteins are targeted to the areas of the cell where they are designed to function. For example haemoglobin must be retained within the cytosol of erythrocytes for optimal function, while insulin is secreted and carried via the vasculature to sites distant from the cell that produced it. The molecular beacons that designate the cellular location of proteins are contained in their amino acid sequence. Proteins that integrate in the cell membrane or that are destined for secretion contain a signal peptide, typically an amino-terminal peptide sequence containing one or more positively charged amino acids followed by six to 12 hydrophobic residues. The signal peptide targets proteins for translocation across the endoplasmic reticulum membrane into the lumen as they are being synthesized, after which the peptide is cleaved off, giving the mature protein a different amino terminus from the one initially produced by translation. Endoplasmic reticulum channels are lined by membrane that is contiguous with the plasma membrane, and their lumen is contiguous with the extracellular milieu, so that proteins translocated across the endoplasmic reticulum membrane have access to the cell surface and beyond. Transmembrane proteins are distinguished from secreted proteins by the presence of a transmembrane domain which is comprised of a linear stretch of about 22 hydrophobic amino acids that fixes the protein in the lipid bilayer of cell membranes as it transits into the endoplasmic reticulum during translation. Secreted proteins, in contrast, have no such domain and fail to arrest in the lipid bilayer during membrane transit. The orientation and topography of transmembrane proteins may vary and can be complex, such as in the case of proteins with multiple membrane spanning domains that weave in and out of the cell. Cytosolic and nuclear proteins do not have a signal peptide and are deposited during translation in the cytosol. Nuclear proteins are characterized by the presence of nuclear localization signals which consist of peptides with a preponderance of basic amino acids (lysine or arginines) that target the protein for transport to the nucleus.

Appropriate protein localization within cells and cellular subcompartments is critically important for function. During signal transduction, for example, signals received at the cell surface frequently need to reach the nucleus in order to transcriptionally reprogramme the cell to generate a response. The proper localization of proteins in these signal transduction pathways is crucial so that they are correctly positioned to receive and pass on these signal. As examples Ras and Src proteins function proximally in signal transduction pathways and are kept at the plasma membrane by covalently linked lipid moieties added after translation. Here, they are positioned to interact with upstream signalling molecules, such as transmembrane receptors. The functional importance of this localization is shown by the fact that loss of membrane attachment resulting in cytosolic localization renders Ras and Src inactive. Protein location may be used to regulate their biological activity. Transcription factors obviously have to be in the nucleus to modulate gene expression, and one such factor, NF_B, is kept inactive in the cytoplasm through binding to its inhibitor, I_B. When a signal for NF_B activation is received, I_B is phosphorylated, the complex dissociates, and free NF_B enters the nucleus where it can function. Keeping proteins out of the nuclear compartment until they are needed is a mechanism of regulation for several transcription factors.

Even after appropriate localization, many proteins must have their activity carefully regulated. This is frequently achieved by modifying proteins in one of a number of ways to alter their behaviour and function. Such post-translational modifications enable the cell to regulate protein activity without having to alter gene expression, resulting in faster, more responsive, and often reversible control. A variety of mechanisms have evolved to regulate protein activity. They may be proteolytically cleaved to generate fragments that have more or different activity from the uncleaved, parent protein. Many secreted enzymes are initially secreted in inactive, proenzyme form and require proteolytic modification for activation. Prime examples include blood coagulation factors which are widely distributed in inactive form and capable of being rapidly activated by proteolysis where and when clot formation is needed. Hormones provide additional examples, some being initially secreted in 'pre' or 'pro' form that require proteolytic processing to become active hormones. Protein function can be altered by covalently modifying the parent protein. For example phosphorylation (attachment of phosphate groups) of the hydroxyl groups of specific serine, threonine, and tyrosine amino acids modifies the activity of many proteins. The enzymes that catalyse such reactions are termed kinases; serine/threonine kinases catalyse phosphorylation of serine and threonine residues, and tyrosine kinases perform the same function for tyrosine residues. Phosphorylation confers a negative charge to these otherwise uncharged amino acids and can change the functional properties of the proteins in which they reside. For example many kinases are themselves substrates for phosphorylation which, in turn, activates their kinase activity. Phosphorylation can also confer upon proteins the ability to interact specifically with other proteins; phosphorylation of certain tyrosine residues allows proteins to bind proteins that have so-called SH2 domains, which are phosphotyrosine binding elements. Modification of proteins by phosphorylation can be reversed through dephosphorylation catalysed by protein phosphatases. The opposing activities of protein kinases and phosphatases and their antagonistic effects on substrate function clearly sets up a highly regulable system for controlling the activity of target proteins. Other examples of post-translational protein modifications with functional consequences include glycosylation, acetylation/deacetylation, ADP ribosylation, sulfation, and attachment of lipid groups (myristoylation, farnesylation, geranylation, etc.).

Signal transduction

Described above are the basic materials and processes important for the normal function of cells, but normal function of the body as a whole requires more highly co-ordinated, integrated, and orderly function of all of its constituent cells. Significant progress has been achieved in recent decades towards defining the molecular mechanisms involved in the complex and multifaceted inter- and intracellular signalling pathways through which cells and tissues communicate with each other. When functioning normally, these signalling networks allow us to perceive, integrate, and respond to local, environmental, and behavioural stimuli. Deregulated or dysfunctional signalling pathways, on the other hand, are pathogenically associated with many disease states. Cell-to-cell communication occurs through a variety of mechanisms, and the proximity of interacting cells dictates how such communications occur. Cells that are in direct contact with each other can establish direct lines of communication through plasma membrane junctions or pores that allow exchange of small molecules or the propagation of electrical signals to help co-ordinate metabolic, mechanical, or behavioural response. In the absence of direct contact, however, cell-to-cell communication occurs primarily via signalling molecules that are synthesized and released by a signalling cell and elicit a specific response in a target cell. Signalling may be paracrine, with the signalling and responding cells adjacent or nearby, as in the case of signalling at a neuromuscular junction where release of acetylcholine from a neurone elicits a contractile response from its target myocyte. Endocrine signals, on the other hand, use the circulatory system to target more distant cells and may elicit a tissue-specific or tissue non-specific response. For example release of follicle stimulating hormone from the anterior pituitary gland stimulates maturation of an ovarian follicle in a tissue-specific manner, while release of insulin from pancreatic islet cells elicits a more general physiological response from cells throughout the body resulting in their increased uptake of glucose. Cells can also respond to stimuli that they themselves elaborate through autocrine signalling pathways. For example interleukin-2 (IL-2) produced by activated T lymphocytes can stimulate their own IL-2 receptors, leading to autocrine stimulation of proliferation and clonal expansion. This section will address how cells perceive and respond to these signals.

Identification of many of the molecules mediating cell-to-cell communication has facilitated the use of molecular approaches to defining the mechanisms by which target cells respond to signals and modify their behaviour accordingly. Signals are perceived when signalling molecules or ligands bind their cognate receptors. The chemical characteristics of the signalling molecule dictate how and where this interaction occurs. Hydrophilic signalling molecules, for example peptide hormones and small charged molecules, such as epinephrine and histamine, that cannot freely diffuse across the plasma membrane bind receptors located on the cell surface. Some lipophilic signalling molecules, such as prostaglandins, also interact with cell-surface receptors. Others, for example steroid hormones, thyroxine, and retinoids, diffuse across the plasma membrane and interact with receptors located within the cell. Interaction of signalling molecules with their receptors initiates a cascade of chemical reactions that culminates in the modification of the cell's behaviour. These modifications may be rapid and transient, such as the contraction of a muscle cell, or they may be more prolonged, such as the metabolic response initiated by insulin. Some signals initiate a complete and irreversible reprogramming of the cell, as is seen when haematopoietic progenitor cells are induced to terminally differentiate into myeloid or erythroid cells.

The stimulus initiated when a ligand binds to its receptor is usually transduced by a variety of intermediary molecular mechanisms before it affects cell behaviour or produces its response. Conceptually, the most straightforward of these mechanisms is exemplified by the activities of receptors for most steroid hormones, thyroxine, and retinoids. Upon binding, the hormone–receptor complexes are induced to bind specific DNA sequences, called hormone response elements, and regulate the

transcription of associated genes (Fig. 3). Up- or down-modulation of the transcription of specific genes reprogrammes the cells toward a defined biological end. For example oestrogens stimulate endometrial growth in preparation for embryonic implantation and growth of the mammary ductal system in preparation for future lactation.

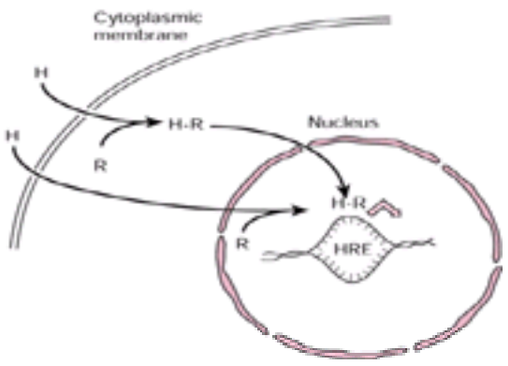

Fig. 3 Activation of gene transcription by hormones. After diffusing across the cell membrane, the lipophilic hormone (H) binds to its cytoplasmic or nuclear hormone receptor (R). This induces binding of the receptor to specific DNA sequences, called hormone response elements (HRE), which modulates transcription of associated genes and results in altered gene expression.

Signalling molecules that cannot diffuse across the plasma membrane are limited to interactions with cell-surface molecules. Therefore, the signals transmitted by hydrophilic ligands or by lipophilic ligands that interact with cell-surface receptors must be transduced by intracellular messengers. Cell-surface receptors transduce signals through three primary mechanisms: activation of ion transport channels; generation of small molecular intermediates ('second messengers') that modulate the activity of specific cellular proteins; or induction of covalent modifications of proteins, thereby modulating their enzymatic activity. The first mechanism, activation of ion transport channels, can alter the electrical potential across the cell membrane as seen when the nicotinic acetylcholine receptor is stimulated by acetylcholine resulting in activation of its Na^+/K^+ ligand-gated ion channel, membrane depolarization, and muscle contraction. This will not be discussed further, and attention will focus on the other two mechanisms by which cell-surface receptors transduce their signals.

Second messengers

Cell surface receptors modulate cell behaviour by activating intracellular signalling networks. Many of these signalling networks involve second messengers, intracellular signalling molecules whose concentration increases or decreases in response to activation of a cell-surface receptor. Second messengers transmit the signal by binding to and altering the activity of specific proteins that modulate cell behaviour. Ionized calcium, Ca^{2+}, serves as a second messenger, as do many small molecular weight intermediates, for example cyclic AMP (cAMP), cyclic GMP (cGMP), 1,2-diacylglycerol, and phosphatidylinositides, produced by enzymes activated directly or indirectly by cell surface receptors. An overview of the mechanisms by which second messengers transmit signals provides insight into the complexities of intracellular signalling networks.

Cyclic AMP

Cytosolic cAMP levels regulate many cellular metabolic responses. Increases in cAMP levels cause an increase in contraction rate in cardiac myocytes, increased gluconeogenesis in hepatocytes, increased thyroxine synthesis in thyroid cell, and many other cell type-specific metabolic responses. Levels of cytosolic cAMP are regulated by the enzyme adenylate cyclase, which is located on the inner surface of the plasma membrane and which, when activated, converts ATP to cAMP. Adenylate cyclase activity is regulated by members of a family of cell surface receptors, called G-protein-coupled receptors. These receptors are characterized by a primary amino acid sequence containing seven transmembrane domains that thread the receptor back and forth seven times through the plasma membrane (hence, they are sometimes called seven transmembrane-spanning proteins). These receptors regulate the activity of a family of GTP-dependent regulatory proteins (G-proteins) located at the plasma membrane, which, in turn, regulate adenylate cyclase activity (Fig. 4). Both stimulatory (G_s) and inhibitory (G_i) G-proteins exist which induce or inhibit the activity of adenylate cyclase, respectively, thus providing a mechanism for either increasing or decreasing cAMP levels.

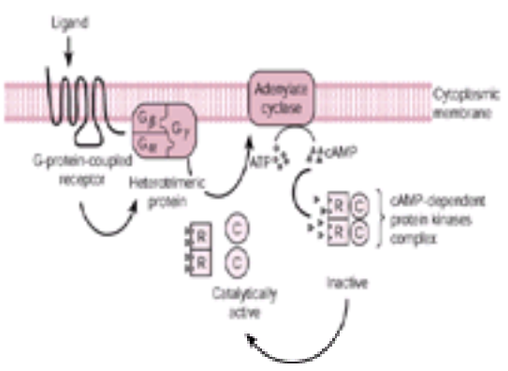

Fig. 4 Activation of cyclic AMP-dependent protein kinases by G-protein-coupled receptors. Ligand-induced activation of the G-protein-coupled receptor activates the heterotrimeric G-protein leading to dissociation of the Ga subunit from the Gb–Gg complex. Ga activates adenylate cyclase leading to the synthesis of cAMP from ATP. Two cAMP molecules bind to each of the two regulatory subunits of the heterotetrameric cyclic AMP-dependent protein kinase, causing dissociation and activation of the catalytic subunits.

Cytosolic levels of cAMP regulate the activity of a family of cAMP-dependent protein kinases, referred to as protein kinase A. These enzymes are composed of two regulatory (R) and two catalytic (C) subunits that form R_2C_2 tetramers. When cAMP binds to the R subunits, the C subunits dissociate and become catalytically active serine/threonine protein kinases. Phosphorylation of target proteins by protein kinase A modulates their enzymatic activity and leads to the downstream physiological consequences of receptor activation (Fig. 4). These effects of increased levels of cAMP persist until cAMP is hydrolysed to AMP by cAMP phosphodiesterase. The C and R subunits of protein kinase A then reassociate into a catalytically inactive R_2C_2 tetramer, and signalling is terminated.

The cascade of reactions initiated by the signalling network, from hormone to receptor to G-protein to adenylate cyclase to cAMP to protein kinase A activity to biological effect, permits amplification of the hormone signal, comparable to the amplification of chemical reactions initiated by activation of the blood coagulation cascade. One G-protein-coupled hormone receptor can activate as many as 100 G_s-proteins, and activated adenylate cyclase catalyses the production of many cAMP molecules. Such amplification can lead to dramatic augmentation of an initially small signal, and explains why epinephrine levels as low as 10^{-10} M can lead to the generation of as much as 10^{-6} M cAMP, an amplification of 10^4.

Adenylate cyclase is activated by a variety of hormone receptors, yet it leads to different metabolic responses depending on the cell type. For example activation of adenylate cyclase in adipocytes by epinephrine, ACTH, or glucagon results in decreased amino acid uptake and increases lipolysis. In contrast, its activation in hepatocytes increases amino acid uptake, as well as activating pathways that lead to increased gluconeogenesis, ketogenesis, and glycogenolysis. This observation leads to the question: How do an apparent limited number of signalling proteins generate such diverse cellular responses? While the mechanism of the diversity of biological responses is only partially understood, it is clear that cell context is a major determinant of the biological effect of second messengers. Different cell types express different repertoires of proteins, enzymes, and transcription factors. Second messengers can have diverse biological readouts depending on which factors they interact with, and furthermore, the same signal can have different effects depending on the strength with which it is delivered. Thus, subtle differences in gene

expression, signal strength, and amplification can have important biological and physiological consequences.

The clinical relevance of cAMP-mediated signalling pathways is highlighted by the mechanism by which *Vibrio cholerae* induces massive diarrhoea. These bacteria produce cholera toxin, a peptide that irreversibly activates G_s by covalently adding an ADP-ribose moiety to a specific arginine residue. This leads to continuous activation of adenylate cyclase and dramatic increases in cAMP levels in intestinal epithelial cells. Increased cAMP levels alter the activity of ion transport proteins and potentiate the flow of water through intestinal epithelial cells into the intestinal lumen leading to massive diarrhoea.

Other second messengers

The principles outlined above in which receptor activation leads to changes in second messenger concentrations which, in turn, alters the activity of specific effector proteins hold true for other second messengers, including cGMP, Ca^{2+}, and phosphatidylinositides. cGMP levels are regulated by soluble and membrane-bound forms of the enzyme guanylate cyclase. Guanylate cyclase is regulated by a broad spectrum of factors, including atriopeptins (e.g. atial natriuretic peptide, brain natriuretic peptide, and some enterotoxins) which regulate the membrane-bound form, and nitric oxide, nitroglycerine, nitroprusside, and sodium nitrite which diffuse across the plasma membrane to regulate the soluble form. cGMP levels and cGMP-regulated protein kinases play important roles in the regulation of vascular smooth muscle tone, endothelial cell permeability, cardiac contractility, platelet aggregation, intestinal motility and ion transport channel function, bone growth, and neuronal function.

The inositol-lipid signalling pathways are regulated by second messengers derived from two phospholipids located mainly in the inner layer of the plasma membrane lipid bilayer, PIP (phosphatidylinositol 4-phosphate) and PIP_2 (phosphatidylinositol 4,5-bisphosphate). This signalling pathway is activated when G-proteins, G_0 and G_q, activate the enzyme phospholipase C (PLC), which catalyses hydrolysis of PIP_2 to two second messengers, IP_3 (inositol 1,4,5-trisphosphate) and diacylglycerol (Fig. 5). IP_3 diffuses into the cytosol and stimulates Ca^{2+} release from the endoplasmic reticulum by activating IP_3-gated Ca^{2+}-release channels. Ca^{2+}, itself a second messenger, mediates many of its cellular effects through a calcium-dependent regulatory protein, calmodulin. The Ca^{2+}/calmodulin complex is an important regulator of ion transport channels, and structural elements of the cell, for example actin–myosin complexes in smooth muscle cells and microfilaments that mediate many processes such as cell motility, conformation changes, and mitosis. It also regulates a group of enzymes known as Ca^{2+}/calmodulin-dependent protein kinases (CaM-kinases) which affect glycogen breakdown and synthesis of catecholamine neurotransmitters.

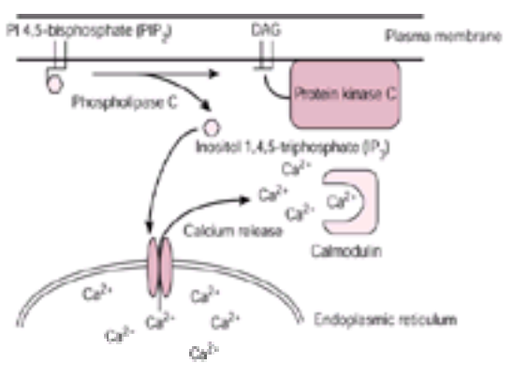

Fig. 5 Inositol–phospholipid signalling pathways. Activation of phospholipase C catalyses the hydrolysis of phosphatidylinositol 4,5-bisphosphate to inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 induces calcium release from the endoplasmic reticulum which acts as a second messenger binding to calmodulin and modulating the activity of CaM kinases. DAG activates protein kinase C which transduces the signal by modulating the activity of a number of downstream enzymes.

In addition to its effects on CaM kinases, increases in intracellular Ca^{2+} mediated by IP_3 stimulates the migration of a cytosolic protein, protein kinase C, to the plasma membrane where it is activated by diacylglycerol, the other product of PIP_2 hydrolysis. Protein kinase C regulates the activity of a number of enzymes complementary to those regulated by CaM-kinases in mediating glycogen breakdown. It also regulates various transcription factors, such as NF_B, to alter the transcriptional programme of the cell. Thus second messengers transduce signals that are important in regulating numerous cell functions, including metabolism, structure, function, proliferation, and differentiation.

Signalling via covalent modifications of proteins

Many recently identified signalling pathways are initiated and conducted by proteins with latent enzyme or functional activity. Stimulation of these pathways by ligand binding to cell surface receptors induces the activity of these signalling proteins. These signalling pathways are initiated by one of four classes of receptors: (1) receptor tyrosine kinases; (2) tyrosine kinase-associated receptors; (3) receptor tyrosine phosphatases; and (4) receptor serine/threonine kinases. Once activated, these receptors induce either phosphorylation or dephosphorylation of target proteins on specific tyrosine, serine, or threonine residues, thereby altering target protein structure and/or function, and initiating a cascade of downstream events.

Receptor tyrosine kinases

Receptor tyrosine kinases (RTKs) make up a family of cell-surface proteins with several common structural features: an extracellular domain that interacts with a specific ligand; a transmembrane domain; and a cytoplasmic domain with regulated tyrosine kinase enzymatic activity. When ligand binds to the extracellular domain, the kinase activity of its cytoplasmic domain is induced through a process involving dimerization or multimerization of the receptor. The kinase domains of the dimerized receptors phosphorylates specific tyrosine residues in the cytoplasmic domain of its dimerization partner, a process termed 'autophosphorylation'. These phosphorylated tyrosine residues serve as high-affinity binding sites for intracellular proteins that transduce the receptor signal.

Once activated, the RTK signal is transduced through two classes of proteins that bind to the receptor: adapter proteins that have no intrinsic enzymatic or signalling properties and enzymes involved in activating downstream events. These two classes of proteins share SH2 domains which are known to mediate binding to phosphotyrosine residues. Through their SH2 domains, adapter proteins and other signalling proteins bind the newly phosphorylated tyrosine residues on the RTK cytoplasmic domain (Fig. 6). The specific residue that each protein binds is determined by the distinct sequence of amino acids surrounding the phosphotyrosine residue. For example Src binds the amino acid sequences phosphotyrosine–glutamate–glutamate–isoleucine through its SH2 domain. By binding adapter proteins and other enzymatically active proteins, the RTK transduces its signal into the cell.

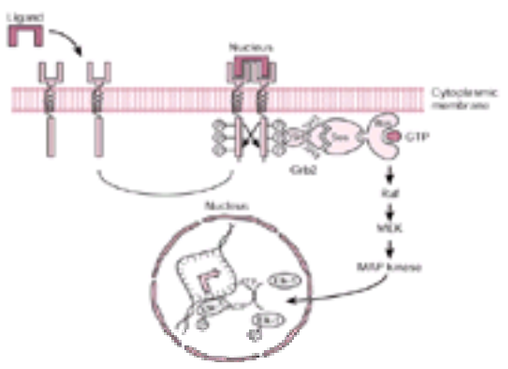

Fig. 6 Activation of intracellular signalling pathways by receptor tyrosine kinases. Ligand-induced dimerization of receptor tyrosine kinases leads to activation of latent kinase activity and *trans*-phosphorylation of the receptor's cytoplasmic domain. The adapter protein, Grb2, binds specific phosphotyrosine residues in the receptor via its SH2 domain, and it binds Sos via its SH3 domains. Sos functions as a guanine exchange factor, activating Ras by facilitating GDP–GTP exchange. The activated Ras signal is transduced in a linear fashion through Raf to MEK, to MAP kinase. MAP kinases translocate to the nucleus and modulate cell behaviour by regulating

the activity of transcription factors, for example Elk-1, and hence gene expression.

Intracellular signalling pathways activated by receptor tyrosine kinases

Many of the signals initiated by RTKs are transduced by Ras proteins, which are members of a family of low molecular weight proteins that bind guanine nucleotides and possess GTPase activity. They, in turn, regulate a cascade of serine/threonine kinases that control cell proliferation and differentiation. Ras proteins were initially identified through the role of mutant Ras proteins in carcinogenesis. Ras mutations are estimated to be present in about 30 per cent of human cancers and are among the most common molecular abnormalities found. Ras proteins cycle between an active 'on' state when GTP is bound and an inactive 'off' state when GDP is bound. Cycling between the on and off states is regulated by two classes of signalling molecules: GTPase-activating proteins (GAPs) which increase Ras hydrolysis of bound GTP to GDP, thereby inactivating Ras, and guanine-nucleotide exchange factors which facilitate dissociation of GDP from Ras (Fig. 7). Since the cytosolic concentration of GTP is approximately 10-fold higher than GDP, Ras will tend to bind GTP after dissociation from GDP, resulting in its activation. Many RTKs activate Ras through the actions of two cytosolic proteins, Grb2 and Sos. Grb2 is an adapter protein that contains an SH2 domain through which it bind the tyrosine-phosphorylated RTK, and two Src homology 3 (SH3) domains through which it binds Sos. Sos functions as a guanine-nucleotide exchange factor and activates Ras by facilitating GDP–GTP exchange. In many human cancers, Ras has been mutated so that it no longer hydrolyses GTP to GDP normally, resulting in a Ras protein that is continuously bound to GTP and a signalling pathway that remains turned on.

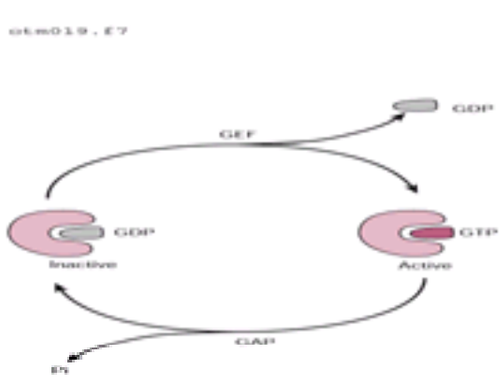

Fig. 7 Activation of Ras proteins. Ras proteins cycle between active and inactive forms. Ras becomes activated when guanine nucleotide exchange factor (GEF) facilitates its dissociation from GDP, enabling it to bind GTP, thus resulting in Ras activation. Ras binding to GTPase-activating proteins (GAP) induces hydrolysis of GTP to GDP resulting in Ras inactivation.

Many of the cellular changes induced by Ras are mediated by a family of proteins called mitogen-activated protein (MAP) kinases. These kinases are unusual in that they require phosphorylation of both threonine and tyrosine residues to stimulate their full activity, while most kinases catalyse phosphorylation of either tyrosine residues or serine and threonine residues, but not both. The dual function kinase that activates MAP kinase is called MAP-kinase-kinase (MKK, also known as MAPKK or MEK). MKK is activated by a serine/threonine kinase called Raf (also known as MAP-kinase-kinase-kinase or MKKK) which, in turn, is activated by Ras. Once activated by this linear cascade of reactions (Fig. 6), MAP kinases modulate cell behavior by phosphorylating other cellular proteins, including cytosolic proteins and other kinases. They also translocate to the nucleus where they phosphorylate and activate transcription factors, e.g. Elk-1 and serum response factor (SRF).

Transcription factors are final participants in afferent signal transduction pathways and initiators of cellular responses to these signals. In general, they are proteins that bind specific DNA sequences and modulate the expression of genes to which they bind. Most bind DNA as dimers, and different transcription factors use specific peptide motifs to dimerize with their partner(s), e.g. 'leucine zippers' and helix-loop-helix domains. Upon binding to DNA, they interact with the basal transcription machinery either directly or via intermediary proteins ('coactivators' and 'corepressors') to initiate, enhance, or inhibit transcription. Transcriptional gene regulation is highly complex, not only due to the multitude of transcription factors present in cells but also due to the ability of many factors to heterodimerize and form combinatorial pairs that have different DNA-binding, transactivation and/or regulatory properties. By transcriptionally reprogramming the cell, these factors regulate cell proliferation or differentiation, survival or apoptosis, and cell structure and function.

Organization of MAP kinase signalling pathways

The RTK–MKKK–MKK–MAP kinase cascade transduces many different signals from the cell surface to the nucleus. To date, 14 MKKKs, five MKKs, and 12 MAP kinases have been identified. Different signal transduction pathways are created by combining different components of each of these kinase families, thus generating diversity in cellular responses. However, some limitations exist in the different components that can be combined. For example MKKs show a fair amount of specificity for the MAP kinases that they activate and are generally coupled to a specific MAP kinase. The MKKs, MEK1 and MEK2, activate MAP kinases involved in cell growth and differentiation, for example ERK1 and ERK2, but they do not activate the MAP kinases involved in response to stress, for example JNK/SAPK kinases or p38 kinases. In contrast, MKKKs are quite promiscuous and can activate multiple MKKs. This promiscuity raises the question of how specificity in signal transduction pathways is generated. This mystery was recently solved by the discovery that scaffold proteins bring together specific components of the signalling cascade so that they are sequestered into a signalling unit. Scaffold proteins assure that when a MKKK is activated by a specific signal, only those MKKs and MAP kinases bound to the same scaffold protein are activated (Fig. 8). Thus scaffold proteins bring specificity to signalling pathways so that only the intended cellular responses are generated.

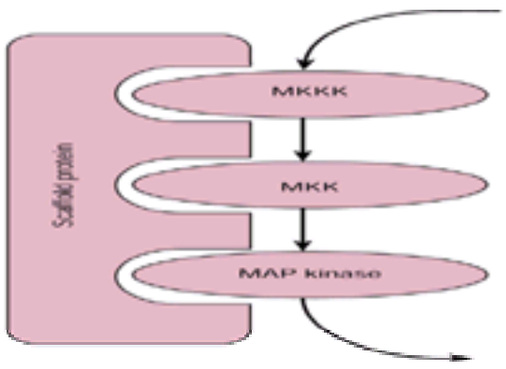

Fig. 8 Organization of MAP kinase signalling pathways by scaffold proteins. Scaffold proteins can bind multiple members of a signalling pathway, restricting their access to substrates and providing specificity in the signalling response.

Tyrosine kinase-associated receptors

While RTKs have latent enzymatic activity that is activated by ligand binding, receptors of the tyrosine kinase-associated receptor family lack intrinsic kinase activity, but associate via their cytoplasmic domains with tyrosine kinases located in the cytosol and/or the plasma membrane. Ligand binding induces activity of the associated kinase to transduce the receptor signal. This family includes antigen-specific receptors on T and B lymphocytes and receptors for many of the cytokines that regulate the proliferation and differentiation of haematopoietic cells. These non-catalytic receptors primarily associate with members of the Src family or the Janus family of cytosolic tyrosine kinases (JAK) to transduce their signals. Members of the Src family of tyrosine kinases play important roles in regulating the cell cycle,

regulating activation of immune effector cells induced by antigen and Fc receptors, and modulating osteoclast behaviour in bone remodelling.

The more recently described JAKs are involved in signalling pathways initiated by many cytokines, and mediate their effects by activating transcription factors from the STAT (signal transducers and activators of transcription) family. Binding of cytokines such as interferon a, b, or g or many interleukins to their cognate receptors activates the latent kinase activity of their associated JAKs which, in turn, phosphorylates specific members of the STAT family. Phosphorylation induces the STATs to dimerize and translocate to the nucleus where they activate transcription of specific cytokine-regulated genes.

Receptor tyrosine phosphatases

The currency of signal transduction initiated by RTKs and tyrosine kinase-associated receptors is phosphorylation of specific tyrosine residues. These signalling pathways illustrate the dramatic effect that an apparently simple modification, tyrosine phosphorylation, has on protein function. Receptor tyrosine phosphatases, in contrast, transduce signals by removing phosphate residues from, or dephosphorylating, specific proteins. The CD45 protein is a transmembrane protein expressed on the surface of leucocytes and plays an important role in lymphocyte activation. Upon activation, CD45 acts as a phosphatase to dephosphorylate target proteins. One such target is Lck, a member of the Src family of tyrosine kinases, whose kinase activity is induced when it is dephosphorylated.

Receptor serine/threonine kinases

The final class of receptors that transduce signals by inducing covalent modifications of target proteins is the serine/threonine kinase receptor family, which, upon activation, catalyses the phosphorylation of target proteins on specific serine and/or threonine residues. Receptors for the transforming growth factor-b (TGF-b) superfamily of ligands, including TGF-b proteins, activins, and bone morphogen proteins (BMP), contain serine/threonine kinase domains through which they modulate signalling pathways. These receptors activate members of the Smad family of proteins by inducing phosphorylation of target serine residues. Activated Smads form heteromeric complexes with other Smad family members, and translocate to the nucleus where they act as transcription factors.

Signalling networks

The events involved in transducing signals from cell surface receptors have been presented as simplified linear pathways leading to predictable cellular responses. However, biological systems are in actuality much more complex with numerous interconnections between the different signalling pathways. These interconnections enable a single signalling event to activate a network of signalling cascades and, thus, to orchestrate complex metabolic, structural, or functional cellular changes. For example activated RTKs typically phosphorylate several tyrosine residues in the RTK cytoplasmic domain which enables the docking of multiple proteins containing SH2 domains. Such proteins, in addition to Grb2, include the g isoform of phospholipase C (PLC), phosphatidylinositol-3 (PI-3) kinase, tyrosine phosphatases (e.g. Shp2 and Syp), RasGAP (a negative regulator of the Ras GTPase), Src family tyrosine kinases, and multiple adapters (including Shc, Grb7, Nck, etc.). Thus, in addition to activating the MKKK–MKK–MAP kinase pathway, RTKs can also activate numerous accessory signalling pathways (Fig. 9). Moreover, interconnections between signalling pathways exist distal to cell surface receptors. For example, protein kinase C can activate the Ras signalling pathway, and Ras can activate PI-3 kinase to activate the inositol–lipid signalling pathways. Thus complex interconnections exist between different signalling cascades that enable signalling proteins to build a multifaceted signalling network to marshal a cellular response.

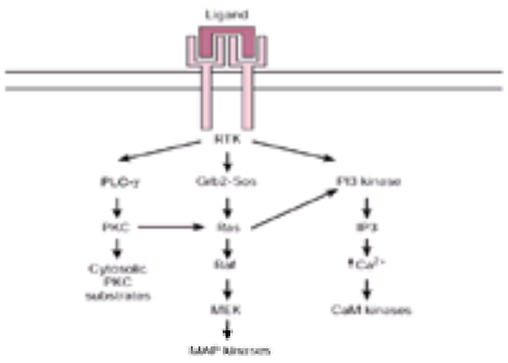

Fig. 9 Signalling networks. Signals from activated RTKs can be transduced via multiple signalling pathways, and numerous interconnections exist between different signalling pathways. Thus a single stimulus can orchestrate a complex biological response.

Fates of a cell: proliferation, differentiation, death

Somatic cells undergo one of three general fates: they (a) proliferate by mitotic cell division; (b) differentiate and acquire specialized functions; or (c) die and are eliminated from the body. Cell proliferation is necessary for growth of the organism and insures repletion of cells lost to terminal differentiation, death, or cell loss. In the immune system, lymphocyte proliferation serves the important function of amplifying responses to antigens. Differentiation provides the organism with cells that execute specific and specialized functions. Differentiation tends to be an incremental process, going through stages, but at the end may be 'terminal' so that further cell proliferation is precluded. Cell death as an active process, initiated by the cell itself, is apoptosis. Perhaps not obvious is the fact that this cell fate is as important physiologically as cell proliferation and differentiation. It allows tissue renewal and changes in cellular composition without undesirable or harmful cell accumulation. In the event of exposure to toxic agents, apoptosis eliminates the damaged cells, preventing them from being a burden or harmful to the organism. In complex multicellular organisms, when any of these three cellular processes becomes deregulated and unbalanced, the consequences are usually dire and result in either functional insufficiency or neoplasia. In recent years, some of their mechanisms and regulation have been defined at a molecular level.

Cell proliferation

The cell cycle

Somatic cells proliferate by mitosis, a process that produces two identical progeny from one parental cell. Mitotic cells pass through an ordered series of states collectively termed the 'cell cycle' (Fig. 10). This cycle has four sequential phases, labelled G_1, S, G_2, and M, which are defined biochemically, morphologically, and on the basis of cellular DNA content. S phase is the period of wholesale DNA synthesis during which the parental diploid cell with a '2N' complement of DNA replicates its entire genetic content and becomes a cell with 4N DNA content. M phase or mitosis is the period of nuclear and cell division during which the duplicated DNA complement of the 4N parental cell is divided equally between the two progeny cells which are consequently 2N. M phase is morphologically obvious as the period during which chromosomes condense into their familiar, microscopically visible forms, the nuclear envelope breaks down, the chromosomes segregate into two identical sets, the nuclear envelopes reforms (which completes nuclear division or 'karyokinesis'), and the two progeny cells separate (which completes cell division or 'cytokinesis'). G_1 and G_2 phases were originally conceived as 'gaps' between the distinctive M and S phases of the cell cycle. G_2 is the period between S and M, when cells have finished replicating their DNA, have 4N DNA, and are preparing to divide. G_1 is the period between M and S when cells are 2N, have finished one round of cell division, and have not yet initiated the next.

The durations of S, G_2, and M tend to be relatively constant, in contrast to that of G_1 which can be highly variable depending on the cell type and is subject to regulation by environmental factors, such as the availability of mitogens and nutrients. It is the period of cell growth, and a certain increase in mass may be required before the cell can enter the next S phase. When conditions are unsuitable for cell proliferation, they arrest in G_1, and those that are already in S, G_2, or M usually complete the round they have entered and arrest only when they reach G_1 again. A point in late G_1 called the 'restriction point' or 'R' has special significance and is the point past which cells become committed to enter S, even if mitogens are withdrawn. Cells may withdraw from the cell cycle and remain for prolonged periods in a metabolically active but non-proliferative state. These cells have 2N DNA content and are described as being in G_0. Terminally differentiated cells are examples of cells in G_0. However, other cells reversibly enter G_0 and may be induced to return to G_1 and begin cycling again under certain conditions (distinction between cells in G_0 and prolonged G_1, admittedly, may be difficult). Hepatocytes are in G_0 unless partial hepatectomy or hepatotoxic insults induce them to proliferate to reconstitute

functional liver mass. Resting, antigen-specific lymphocytes remain in G_0 until antigen and cytokine stimulation induces them to proliferate.

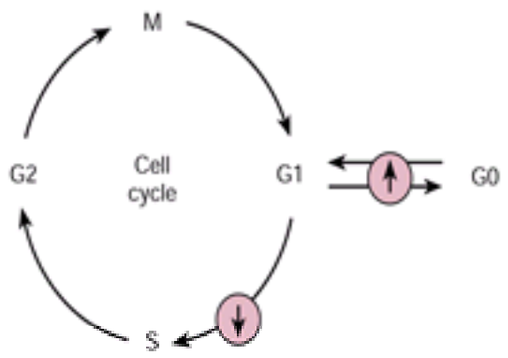

Fig. 10 Cell cycle. The sequential phases of the cell cycle, G_1, S, G_2, and M, are depicted, as well as the resting G_0 phase. Common regulatory points near the end of G_1 and between G_1 and G_0 are shown by circles with arrows within.

Adherence to the G_1–S–G_2–M sequence during normal progression through the cell cycle means that a cell must duplicate its DNA before dividing and that it must divide before duplicating its DNA again. This insures a normal genetic complement in the progeny cells and maintains genetic constancy. The dependence of later events in the cell cycle upon normal completion of earlier events is insured by 'checkpoint' control mechanisms that prevent a cell that has not successfully completed one phase of the cycle from entering the next. Checkpoint activity is seen after cell exposure to DNA-damaging agents, such as ionizing radiation, and is manifest as delayed cell entry into S and M by inducing temporary arrest in G_1 or G_2. This delay allows cells time either to repair its damaged DNA or, if the damage is irreparable, to execute a programme of self-destruction or apoptosis.

Cell cycle regulation: cyclins and cyclin-dependent kinases

Notable progress has been made in understanding the regulation of cell entry and progression through the cell cycle. In brief, cell cycling is regulated by serine/threonine kinases of the Cdk (cyclin-dependent kinase) family. As implied by their name, the catalytic activities of these kinases are dependent on associated regulatory proteins called cyclins. Cyclins were so named because levels of the first to be described were seen to fluctuate periodically with the cell cycle. Numerous Cdks and cyclins exist in the cell and form various combinatorial pairs with distinct activities. Control of cyclin/Cdk activity exists at many levels and occurs by the appearance and disappearance of the cyclins at specific phases of the cell cycle, by post-translational modification of Cdks, and by association with Cdk inhibitors. Cyclin/Cdks, in turn, regulate cell cycling by modulating the activity and behaviour of other proteins, such as transcription factors and structural proteins.

The function of cyclins and Cdks is best exemplified by their regulation of cell entry into M phase. Studies of mutant fission yeast called cdc2 (cell division cycle 2) that tended to arrest in G_1 or G_2 led to the cloning of a 34 kDa serine/threonine kinase ($p34^{cdc2}$) that is required for yeast to enter S or M phase. This protein is evolutionarily conserved, being present in a structurally and functionally similar form in humans. Another line of study showed that cytoplasmic extracts from mature frog eggs, when injected into immature oocytes, induced the oocytes to mature and undergo typical M phase changes. The 'maturation promoting factor' (MPF) activity in these extracts was found to reside in two proteins, frog $p34^{cdc2}$ and a B-type cyclin (Fig. 11). Cyclin B has no intrinsic enzymatic function and plays a regulatory role by associating with $p34^{cdc2}$ which then exhibits kinase/MPF activity. Cyclin B levels increase during S and G_2, and levels of the cyclin B/$p34^{cdc2}$ complex sufficient for the G_2/M transition are reached well before the onset of M. Mitosis is not prematurely triggered, however, because the complex accumulates in an inactive form. During S and G_2, the $p34^{cdc2}$ complexed with cyclin B accumulates as a multiply phosphorylated protein. In human $p34^{cdc2}$, phosphorylation of a specific threonine (thr161) stabilizes its association with cyclin B and is essential for activity. On the other hand, phosphorylation of another threonine (thr14) and a tyrosine (tyr15) in $p34^{cdc2}$ suppresses its kinase activity and keeps the cyclin B/$p34^{cdc2}$ complex inactive. Activation of this complex just prior to entry into M requires dephosphorylation of both thr14 and tyr15 which is accomplished by a dual-specificity phosphatase, Cdc25. The kinase and phosphatase that regulate $p34^{cdc2}$ activity and time cell entry into M are themselves regulated by phosphorylation (which inhibits the kinase responsible for tyrl5 phosphorylation and enhances the phosphatase function of Cdc25). Once activated, cyclin B/$p34^{cdc2}$ can phosphorylate Cdc25 and create a self-amplifying feedback loop that generates more oocyte MPF activity from a small initial amount of active MPF and the large pre-existing stock of inactive MPF. What starts this sequence of events by initially phosphorylating Cdc25 is unclear, although cyclin A/Cdks are candidates because they are active prior to cyclin B/$p34^{cdc2}$ activation and have MPF activity; also inhibition of cyclin A during S prevents entry into M.

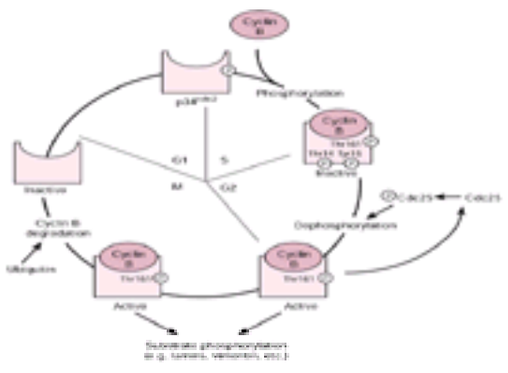

Fig. 11 Activation of mitosis. The G2–M transition activated by cyclin B/$p34^{cdc2}$ is depicted, as well as the phosphorylation and dephosphorylation events leading up to cyclin B/$p34^{cdc2}$ activation and cyclin B degradation during M phase.

As its name indicates, activated cyclin B/$p34^{cdc2}$ phosphorylates serine and threonine residues in cellular proteins. Discerning its physiological substrates is difficult, however, because there are many potential substrates and other cyclin/Cdk complexes and kinases are active at the same time. Candidates include the lamins and vimentin which are proteins important for the structural organization of cells. They are substrates for cyclin B/$p34^{cdc2}$ kinase activity *in vitro* and undergo M phase phosphorylation *in vivo*. Phosphorylation of lamins is important for nuclear lamina disassembly and envelope breakdown, and phosphorylation of vimentin may cause depolymerization of intermediate filaments in the cytoplasm. If these are physiological substrates, cyclin B/$p34^{cdc2}$ activity may initiate the structural reorganization that is part of mitosis. As M phase progresses, cyclin B/$p34^{cdc2}$ is inactivated by degradation of the cyclin B component. Mutant cyclin B that is resistant to proteolysis induces cell arrest in M, demonstrating that cyclin B degradation is important for cells to exit M.

Cyclins other than cyclin B and Cdks other than $p34^{cdc2}$ regulate other parts of the cell cycle. The behaviour and activity of these others resemble those of cyclin B and $p34^{cdc2}$, so that the activity of Cdks are regulated by the cyclins with which they pair, and the permitted partnerships determine where and how in the cell cycle the individual cyclin/Cdk complexes function. The portion of the cell cycle that has received particular attention is G_1 and the G_1/S boundary, because events here determine commitment to and rates of cell proliferation and have a bearing on neoplastic transformation of cells. Among cyclins, cyclin A and B are unlikely to be important in G_1 and the G_1/S boundary because they disappear during M and reappear only in S; cyclins D and E are better candidates from a timing standpoint, and D cyclins (there are three types, Dl, D2, and D3) may be especially significant because abnormalities in these have been implicated in the pathogenesis of parathyroid adenomas and certain B cell lymphomas. Cdks that associate with these cyclins are probably important in G_1/S regulation: Cdk4 and 6 associate only with cyclin D, and Cdk2 associates with cyclins A, D, and E. These cyclins and Cdks are thought to regulate the G_1/S transition through phosphorylation of Rb, the protein product of the retinoblastoma susceptibility gene (Fig. 12). In its hypophosphorylated state, Rb inhibits cell entry into S phase probably by binding to certain members of the

E2F family of transcription factors. However, during passage through G_1, Rb is phosphorylated on many serine and threonine residues, and hyperphosphorylated Rb releases E2F. E2F, in turn, activates transcription of genes needed for S phase activity and other aspects of cell proliferation (dihydrofolate reductase, thymidine kinase, myc, myb, etc.). Thus, Rb's ability to bind E2F is determined by its phosphorylation state and, in turn, regulates E2F transcriptional activity and cell cycling. Cyclin D/Cdk4 and 6 are among the kinases that can phosphorylate Rb with substrate specificity being conferred, at least in part, by the ability of cyclin D to bind Rb. Others cyclin/Cdk complexes may play important roles in cell cycle regulation as well. For example cyclin E associates primarily with Cdk2, and in G_1 cells is found in a quaternary complex with Rb-related p107 protein, E2F, and Cdk2. This complex disappears as cells enter S, just as a similar complex containing cyclin A instead of E makes its appearance. Cyclin E can also phosphorylate Rb and reverse the G_1 growth arrest induced by hypophosphorylated Rb. The appearance of cyclin A at the beginning of S, its decline in G_2 and M, and its presence in S phase in a quarternary complex with Cdk2, E2F, and p107 suggest that cyclin A plays a role in driving S phase events. Cyclin A in complex with $p32^{cdc2}$ may trigger the G_2/M transition by phosphorylating Cdc25 and initiating cyclin B/$p32^{cdc2}$ activation.

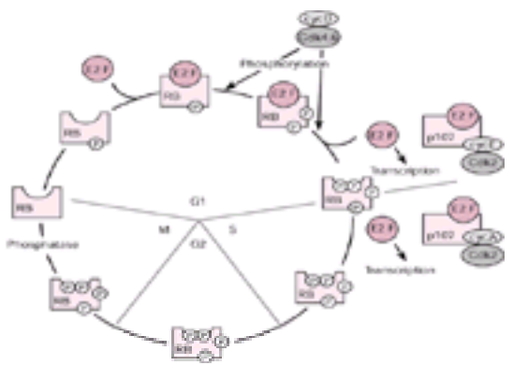

Fig. 12 Rb regulation of cell cycling. Cell cycle regulation by Rb and its association with E2F is depicted, as well as the regulation of the Rb/E2F association by cyclin D/Cdk4,6 phosphorylation of Rb on serine and threonine residues. Other potentially important kinase and transcription factor complexes involving E2F and Rb-like p107 are shown.

Cell cycle regulation: cyclin-dependent kinase inhibitors

Another layer of cell cycle regulation complexity has been revealed with the discovery of inhibitors of Cdk and cyclin/Cdk complexes. The first inhibitor identified and cloned was p21 (Waf1, Cip1, Sdi1) which binds several different cyclin/Cdk complexes and has been classified as a 'universal' inhibitor. While this and other properties of p21 (such as its ability to inhibit the process of DNA replication) account for its ability to induce cell cycle arrest, the regulation of p21 expression sheds the most light on its cellular function. Its expression is transcriptionally induced by p53 which is a transcription factor activated following DNA damage. This suggests that p21 is responsible for halting cell proliferation after DNA damage and allowing the cell time for damage assessment and repair. Other Cdk inhibitors similar to p21 exist. These include p27 (Kipl) which, like p21, bind and inhibit multiple cyclin/Cdk complexes. Upregulation of p27 is thought to mediate the growth arrest of cells under crowded conditions (contact-inhibition of cell growth) or after treatment with TGF-b, a growth arrest cytokine. Other Cdk inhibitors are more specific and inhibit specific Cdks. For example, p16 (INK4a, MTS1, Cdk4I) and p15 (INK4b, MTS2) are Cdk inhibitors that bind Cdk4 and Cdk6 exclusively, and binding inhibits their association with cyclin D and kinase activity. Since Rb is an important target of cyclin D/Cdk4,6 kinase activity, p15 and p16 may inhibit cell proliferation by preventing Rb phosphorylation by cyclin D/Cdk4,6. The observation that p16 overexpression inhibits proliferation of cells expressing Rb but not of cells devoid of Rb supports this idea.

Pathophysiological relevance

Evidence from a variety of spontaneously arising and experimental cancers indicate that Rb/E2F and their regulation by cyclin/Cdk play a central role in cell cycle regulation. In many types of human cancer cells, both copies of the *Rb* gene are disrupted, normal Rb protein is not made, and Rb regulation of E2F activity does not occur. The prototypic tumour in which Rb is pathogenically involved in this manner is retinoblastoma, but Rb abnormalities occur in other, more common cancers as well. Inactivation of Rb regulatory activity can also be achieved by means that do not alter the gene. In tumours induced by certain DNA tumour viruses, oncogenic proteins produced by the virus bind to and functionally inactivate Rb. Large T antigen (the transforming protein of SV40 virus), E1A (one of two transforming proteins of adenovirus), and E7 (one of two transforming proteins of human papilloma virus) proteins all bind Rb in its hypophosphorylated form and prevent it from inhibiting E2F activity. These examples of disruption of Rb cell cycle regulation by different viral oncoproteins provide compelling evidence that transforming viruses 'recognize' the importance of this pathway for maintaining normal cell behaviour and the need to disrupt it if they are to induce neoplasia.

Cell differentiation

Proliferation may provide organisms with the cells needed for growth, replacement, and repair, but differentiation endows these cells with the specialized characteristics and functions that make them useful. Cell differentiation to ultimate form and functionality does not occur in a single step but, rather, is an incremental process. In many tissues, cells, such as haematopoietic or intestinal epithelial cells, go through discernible stages of progressive lineage commitment leading up to full differentiation. In some differentiation lineages, the earliest cells are so-called 'stem cells' which display few if any signs of lineage commitment but have the potential for proliferation and self-renewal. Following cell division, progeny of stem cells undergo one of two fates—they either remain as stem cells or begin to commit to differentiate. The former path maintains the size of this critical pool of cells, while the latter supplies the organism's need for differentiated cells. Once stem cell progeny commit to differentiate, a process that may be progressive, incremental, and span several cell generations, they begin to express proteins that make them recognizable as 'blast cells' of their particular lineage. These remain largely undifferentiated but are fully committed and restricted to particular paths of differentiation. Though blast cells proliferate, they and their progeny inevitably acquire more differentiated characteristics and become fully differentiated cells of their type, that is they lack self-renewal potential and have limited or singular differentiation potential.

This model of progressive cell commitment and differentiation is well illustrated by haematopoietic differentiation. The elusive pluripotent haematopoietic stem cell is believed to divide infrequently, but when it does, it self-renews and gives rise to lymphoid progenitor cells and/or myeloid progenitor cells. These progenitors have the potential to develop into one of several lineages but, as their names imply, do not retain the full potential of the haematopoietic stem cell. Further along and perhaps some cell generations later, lymphoid and myeloid progenitor cells give rise to more committed progeny which are unipotential, that is they can differentiate only along one specific lineage, and show discernible features of differentiation. For example lymphoid progenitors may become T or B lymphocyte precursor cells (which are identifiable by evidence of T-cell receptor or imunoglobulin gene rearrangement), while myeloid progenitors give rise to erythroid, megakaryocytic, granulocytic, or monocytic precursors (which are identifiable as erythroblasts, megakaryoblasts, myeloblasts, monoblasts, etc. by special stains of bone marrow or *in vitro* colony forming assays). Even after reaching this stage, several days and a few cell divisions elapse before their progeny appear in the bloodstream as terminally differentiated blood cells. This multistep process of haematopoiesis clearly involves many fateful decisions about self-renewal, lineage commitment, restriction of potential, and differentiation. Through it, however, the stem cell pool is preserved as a resource for the life of the organism, and mitotic amplification of committed and differentiating cells supplies the body's huge requirement for the end products—an estimated 10^{10} to 10^{11} erythrocytes and granulocytes are normally produced every day.

The molecular switches that determine commitment, lineage-specification, and differentiation are incompletely understood. What is not in doubt is the involvement of transcriptional reprogramming of cells during this process, evidenced by the fact that cells committed to differentiate express a different complement of genes from their uncommitted counterparts. A stochastic model proposes that the stem cell decision to self-renew versus commit is based on probability. What determines this probability is unknown but, based on the likelihood that it involves transcriptional reprogramming, processes involved may include 'opening up' of critical regions of the genome so that they are permissive for gene transcription and binding of a requisite combination of transcription factors to their cognate sites in regulatory genes. When all these conditions are met, the cell may move to the next phase of differentiation (e.g. commit) but, otherwise, will remain as it was (e.g. self-renew). An alternative model is an inductive model of differentiation which suggests that environmental signals, perhaps originating from neighbouring cells and/or the cell stroma, induce stem cells to commit. However the decision is made, embarking on commitment and differentiation involves expression of lineage-specific genes. Among these genes are those encoding receptors for growth and survival factors pertinent to the development of that lineage. These may be crucial for the further progress of differentiation, because they provide the ability to receive instructions that promote the further proliferation, survival, and differentiation of cells of that lineage. For example erythropoietin signalling through its receptor promotes the survival, proliferation, and differentiation of cells of erythrocytic lineage, so that

production of the erythropoietin receptor is an essential component of erythrocyte lineage-specific gene expression. The signals generated by these lineage-specific factors often provide an autocrine feedback loop by inducing specific transcription factors which activate *cis*-regulatory sequences and expression of additional genes that contribute to the survival and differentiation of cells committed to these, but not other, lineages.

Many of our current insights into the molecular basis and transcriptional regulation of cell differentiation have been gained from the study of cell culture systems and gene knockout mice to examine myogenic differentiation. *In vitro* studies of myogenesis indicated that certain mesenchymal cells without detectable features of myocyte differentiation could become myoblasts and differentiate into myocytes following treatment with agents (e.g. 5-azacytidine) that can derepress expression of certain silent cellular genes. Transfer of genomic DNA from these 5-azacytidine-induced myoblasts conferred myogenic differentiation on the parental cells, indicating that the myogenic phenotype was heritable. Identification of mRNAs expressed in myoblasts but not in the parental cells led to the cloning of the *MyoD* gene which was subsequently shown to be sufficient for myogenic conversion of the parental cells. MyoD is a basic–helix–loop–helix transcription factor that activates expression of muscle-specific genes by binding to consensus DNA sites present in enhancer elements of muscle-specific genes. It is a member of a family of myogenic transcriptional regulators, including Myogenin and Myf-5, that can induce development of the myogenic phenotype in certain undifferentiated mesenchymal cells. MyoD binds its DNA sites preferentially as a heterodimer with another basic–helix–loop–helix transcription factor, E2A. The ubiquitous presence of E2A suggested that myogenic differentiation and transcriptional regulation of muscle specific genes are regulated by the abundance of MyoD, but this was contradicted by the presence of MyoD in undifferentiated myoblasts. his led to the discovery of the *Id* (inhibitor of differentiation) gene whose protein resembles MyoD in having a helix–loop–helix domain that allows it to dimerize with MyoD or E2A, but differs from MyoD in that it lacks a basic region for binding DNA. Heterodimers containing Id are unable to bind DNA, and Id antagonizes myogenic differentiation by inhibiting the ability of MyoD to activate expression of muscle-specific genes. Expression of Id decreases in cells undergoing myogenic differentiation and cell cycle withdrawal, allowing MyoD to function unhindered in these cells. Neat though this model may be, myogenic differentiation is more complex, because other transcriptional regulators, such as Myogenin and Myf5, can also induce muscle differentiation programs *in vitro.* Furthermore, the finding that mice lacking either MyoD or Myf5 (generated by knocking out both germline copies of these genes) had normal skeletal muscle development, whereas those lacking both MyoD and Myf5 had no signs of skeletal muscle development indicated that MyoD and Myf5 either function redundantly or act in separate myogenic cell populations that can compensate for the other's absence. In mice lacking Myogenin, skeletal muscle differentiation is blocked, even though MyoD and Myf5 are expressed and myoblasts are present. Thus, Myogenin is needed to activate myocyte differentiation following myogenic commitment that seems to depend on MyoD and Myf5 activity.

Apoptosis (see also Chapter 4.6)

Apoptosis is the process of cell death, also called 'programmed cell death', in which the mechanism of cell killing is instituted from within the cell itself. Apoptotic cells undergo fairly stereotypic changes characterized morphologically by early compaction of nuclear chromatin and condensation into clumps at the nuclear periphery. Nuclear and cellular outlines become mildly convoluted, the nucleus fragments, and the dying cell sheds or breaks up into membrane-enveloped 'apoptotic bodies'. These bodies are taken up by adjacent cells or nearby phagocytic cells, and apoptosis typically engenders little or no inflammatory response *in vivo.* Biochemically, the genomic DNA of apoptotic cells undergo strand breaks due to cleavage between nucleosome loops. Since each nucleosome loop is about 180 base pairs in length, this fragmentation leads to a characteristic 'laddering' of DNA fragments in size increments of 180 base pairs on gel electrophoresis. The presence of so many free genomic DNA ends in apoptotic cells allows them to be detected sensitively by DNA end-labelling techniques.

Cell death by necrosis is different and generally occurs when cells are exposed to severe physical, thermal, or other injury imposed from without. In necrosis, nuclear clumping may also be evident, but the most obvious changes involve marked swelling of the cell and organelles, such as mitochondria, and eventual internal disintegration of the nucleus and other structures. Genomic DNA of cells undergoing necrosis is degraded without regard to nucleosomal organization and, upon electrophoresis, appears smeared (indicating random cleavage) rather than laddered. Necrosis tends to be accompanied by inflammatory responses *in vivo*. It is important to point out that when pathologists use the term 'necrosis' to describe areas of cell death in tissues and organs, these terms are histopathology descriptors and are not generally meant to convey death mechanism, which may be apoptosis, necrosis, or a combination of the two. Indeed, apoptosis, rather than necrosis, is the most common mechanism by which cells die in the body, for example during tissue remodelling, after immunological attack, following cytotoxic chemotherapy or radiation therapy, and in pathological states such as congestive heart failure.

Cells can be induced to undergo apoptosis by a variety of factors and stimuli. Death programmes may be initiated following exposure of cells to toxic insults. The insults may be metabolic, such as severe hypoxia, acidosis, or a combination of the two stemming from ischaemia. They may be genotoxic, such as exposure to radiation that damages DNA beyond the point of repair. Chemotherapy-induced cell death is also attributed to apoptosis. Apoptosis can also be induced by factors unrelated to toxins and insults. Many cells thrive only in the presence of specific survival signals, and absence of these signals leads to apoptosis. These signals may come in the form of soluble factors, such as cytokines and interleukins, and 'permission' for cell survival may work hand in hand with cell differentiation mechanisms to establish specific populations of differentiated cells. For example erythropoietin induces development of late erythroid precursor cells but also promotes the survival of these precursors. Survival signals may also come from interaction of cell surface receptors, such as integrins, with specific components of the extracellular matrix in the cell's environment. Presumably, this insures that cells survive when they are in their 'correct' location or environment and not otherwise. In the last few years, specific receptor–ligand systems have been identified that function specifically to receive or stimulate cell death signals, and these provide another way that apoptosis can be induced. Among the best studied of these is the Fas/Fas ligand system. Fas is a member of the tumour necrosis factor (TNF) receptor 1 family of cell surface receptors which exist as trimers. Present only on certain cells, its interaction with crosslinking anti-Fas antibodies or Fas ligand (FasL; also a cell surface protein) induces apoptosis. Fas is conditionally expressed on lymphocytes and Fas/FasL interaction is known to be important for deletion of autoreactive lymphocytes (to prevent autoimmunity), following activation by antigen (to control immune responses and limit the number of antigen-reactive lymphocytes following antigen clearance), and in immunological sanctuary sites. The physiological importance of this system for maintaining lymphocyte and immune homeostasis is shown by the development of lymphoproliferative disease and autoimmunity in mice deficient in either Fas *(lpr* mice) or FasL *(gld* mice). Other members of this family of ligands and receptors, such as the prototypic TNF and TNF receptor 1, also generate apoptosis signals.

Cell killing during apoptosis is accomplished by members of the caspase family of cysteine proteases with specificity for aspartic acid residues in their substrates (Fig. 13). Upon activation of apoptosis, caspases cleave critical cellular proteins causing irreversible cell damage and death. Caspases exist in cells in inactive single-chain proenzyme form, and activation involves limited proteolytic cleavage of the proenzyme into a large and a small subunit, both of which are needed for catalytic activity. In some caspases, this proteolysis also removes an N-terminal regulatory domain, called the prodomain. Two large and two small caspase subunits assemble into a tetramer which form an active complex that possesses full proteolytic activity and executes cell death programmes. Caspases are activated in a hierarchical order, with caspases 8 and 9 activated first and cleaving procaspases 3, 6, and 7 to activate them so that they, in turn, can cleave and inactivate target cellular proteins (e.g. poly(ADP-ribose) polymerase or PARP, DNA-dependent protein kinase, actin, etc.). Thus the mechanism of caspase 8 and 9 activation provides the link between apoptosis stimulation and apoptosis execution. In the case of apoptosis signalling initiated by Fas ligation, a cytoplasmic domain of the receptor, termed the 'death domain', binds a similar domain in an adapter protein known as FADD. FADD also contains a 'death effector domain' which binds the prodomain of caspase 8. Assembly of this multiprotein complex brings several procaspase 8 molecules into close proximity, which may allow its very low level of proteolytic activity to cleave and activate nearby procaspase 8 molecules (i.e. 'autoactivation'). This would generate fully active, soluble caspase 8 and the subsequent cascade of downstream events. Procaspase 9, on the other hand, interacts via a 'caspase recruitment domain' in its prodomain with a similar domain in a protein called Apaf1 (apoptotic protease-activating factor 1). Apaf1 also self-associates, but this and procaspase 9-Apaf1 binding occur only in the presence of cytochrome c, which is made available by release from damaged mitochondria. Thus, mitochondrial release of cytochrome c triggers clustering and autoactivation of procaspase 9.

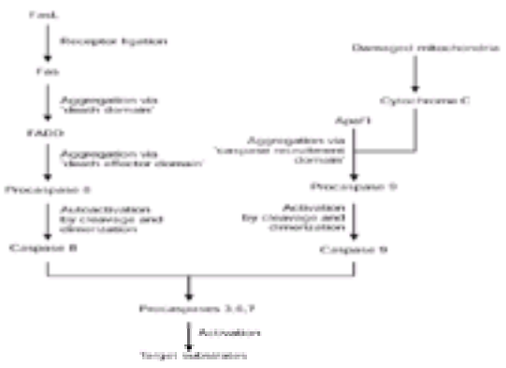

Fig. 13 Apoptosis mechanisms involving caspases. Apoptosis pathways leading from Fas death receptor activation and from cytochrome C release from damaged mitochondria to the hierarchical activation of different caspases are shown.

A system for activating efficient and irreversible self-destruction mechanisms cannot exist safely in cells without safeguards and regulators. A family of regulators exists in the Bcl-2 family of proteins. *Bcl-2* was identified as the gene juxtaposed to the immunoglobulin heavy chain gene in the t(14;18) translocation present in human follicular lymphomas. This type of lymphoma is characterized by a low growth fraction and indolent clinical behaviour early in its course. The accumulation of lymphoma cells in patients is attributable to their decreased rate of cell death due to decreased rates of apoptosis resulting from deregulated *bcl-2* expression. Bcl-2 is the prototypic member of a complex family of proteins, some of which are antiapoptotic (e.g. Bcl-2 and Bcl-X_L) and some of which are proapoptotic (e.g. Bax). Bcl-2 family proteins influence cellular responses to apoptosis signals by as yet poorly defined mechanisms but which may involve formation of solute channels in mitochondrial membrane and/or modulation of release of mitochondrial contents, including cytochrome c. Alternatively, certain antiapoptotic Bcl-2 proteins appear to bind Apaf 1, while certain proapoptotic Bcl-2 proteins dissociate this complex and allow Apaf 1 to activate caspase 9. Other proteins are also important in regulating apoptosis, including the tumour suppressor protein, p53. It is a regulator of gene transcription that becomes activated by DNA strand breaks and induces G_1 cell cycle arrest. Overexpression of p53 in cells has been associated with enhanced apoptosis, while inactivation of p53 seems to confer resistance to apoptosis. However, p53 only appears to affect apoptosis induced by certain stimuli and not others, for example p53 null thymocytes undergo less apoptosis following ionizing radiation but have unchanged apoptosis following exposure to glucocorticoid. These observations suggest that some pathways to apoptosis are p53-dependent, while others are p53-independent. This has great clinical relevance to cancer therapy, because many chemotherapy agents kill tumour cells by inducing apoptosis. p53 is believed to be the most frequently inactivated gene in human cancers (an estimated 50 per cent), and the p53 status of tumours may be an important determinant of chemotherapeutic response. Other regulators of apoptosis may also exist, but the Bcl-2 family of proteins and p53 are clearly clinically important regulators of apoptosis.

Molecular basis of cancer (see also Chapter 6.3)

Molecular studies have been applied to the study of cancer pathogenesis with notable success. The knowledge gained has led to a much better understanding of the mechanistic basis of cell transformation and promises to improve our ability to categorize, diagnose, and treat cancer. The problem of cancer pathogenesis may be viewed from the perspective of cell fate determination. As described above, all cells in the body undergo one of three general fates: proliferate to produce more cells, differentiate to carry out specialized functions, or die by the process of apoptosis and be eliminated. Organisms require an appropriate balance of cells undergoing each of these fates for normal function and homeostasis, and neoplasia arises when proliferation consistently and aberrantly exceeds apoptosis in a clonal population of cells, leading to their inappropriate and pathological accumulation. To the extent that cell differentiation and proliferation are opposing cell fates, the deregulation of cell proliferation associated with neoplasia is generally accompanied by a loss of differentiation. While this reductionist view greatly oversimplifies the pathogenesis of cancer which proceeds through multiple stages (e.g. dysplasia, adenoma, carcinoma *in situ,* invasive carcinoma, etc.) and involves complex interactions with the host environment (e.g. induction of angiogenesis, invasion, metastasis, evasion of immune response, etc.), it has directed research towards mechanisms that deregulate cell proliferation and apoptosis. This effort has led to the discovery of a rich cache of cellular genes that normally regulate cell behaviour and have the potential to contribute to neoplastic transformation when they go awry (Table 1). The underlying lesson of these discoveries is that cancer has a genetic basis. It results when cells lose or deregulate the function of genes responsible for their normal behaviour and it is heritable. While the transformed phenotype is transmitted from cell to progeny cell, it is not done without modification. Genetic mutability is a characteristic of many, perhaps all, cancer cells, and evidence suggests that selective forces operate on these cells *in vivo* to allow those with selective growth advantage to thrive and predominate, much as 'natural selection' acts at the organism and species levels. Cancer involves a cell evolutionary process in which the end product is the result of multiple genetic anomalies accumulated as once-normal cells progress to malignancy.

Oncogenes

Cellular genes potentially involved in neoplastic cell transformation have been identified by a number of approaches. Some were identified by their close relationship to transforming genes or oncogenes present in rapidly oncogenic retroviruses (e.g. *src* from Rous sarcoma virus, *myc* from avian myelocytomatosis virus, *ras* from Harvey and Kirsten sarcoma viruses, etc.). These retroviral oncogenes were originally derived from normal host genes present in infected cells by a process of gene capture ('retroviral transduction') that can occur during the retrovirus life cycle because they integrate into the host genome. This aetiology explains the close homology between retroviral oncogenes and their cellular precursors or 'proto-oncogenes' and makes the case that the latter have latent transforming potential. Cellular proto-oncogenes were also identified through study of genome integration sites of slowly transforming retroviruses. These retroviruses typically cause specific types of tumours in certain species (e.g. mouse mammary tumour virus or MMTV causes mammary tumours in mice, avian leukosis virus or ALV causes bursal or B cell lymphomas in chickens, etc.) but do not possess oncogenes. Instead, they transform by integrating into the host genome near specific cellular proto-oncogenes, deregulating their expression and activating their transforming potential (e.g. *int* in the case of MMTV mammary tumours, *myc* in the case of ALV bursal lymphomas, etc.). A different approach that identified cellular oncogenes employed experimental transfer of genomic DNA from cancer cells into phenotypically normal cells. Rare recipient cells acquired the transformed properties of the donor cells, and cloning of the donor genes in these recipients led to identification of the cellular oncogenes responsible. Finally, cancer cells commonly have chromosomal anomalies that are pathogenically significant because they are frequently or consistently associated with certain cancers (e.g. chromosomal translocations) or with aggressive clinical behaviour and advanced stage of disease (e.g. chromosomes with homogeneously staining regions, double minute, etc.). Cloning of the genes involved in these anomalies led to identification of additional oncogenes and proto-oncogenes.

The genes identified by the approaches outlined are transforming or have the potential to transform cells. One only has to consider that many proto-oncogenes produce proteins that participate in mitogenic signalling and cell cycling or are highly related to proteins that do to get a sense of their nature, that is proto-oncogenes are cellular genes whose products promote cell proliferation. More specifically, the types of genes that have been found to have oncogenic potential include genes that encode growth factors (e.g. platelet derived growth factor), growth factor receptors with tyrosine kinase activity (e.g. epidermal growth factor receptor or its homologue, Her2/neu), non-receptor tyrosine kinases (e.g. Src), Ras proteins (e.g. H-, K- and N-Ras), serine/threonine kinases (e.g. raf-1), transcription factors (e.g. Myc, Fos, Rel, etc.) and cyclins (e.g. cyclin D). While scores of candidate transforming genes have been revealed through the study of avian and rodent tumours and cells, only a few of these have actually been shown to contribute to human cancer pathogenesis *(ras, myc, Her2/neu* are examples of these). As indicated previously, genes regulating cell death may also play a role in oncogenesis, and an inhibitor of cell apoptosis (*bcl-2*) is involved in the pathogenesis of certain human lymphomas.

The importance of proto-oncogenes for maintaining normal control of cell proliferation and apoptosis indicates that cell transformation is not an expected result of their normal function. Indeed, their oncogenic potential is only unveiled through 'gain-of-function' or activating gene mutations that release the proto-oncogene or its protein from normal regulation of their activity (Table 2). These genetic alterations tend to upregulate or deregulate gene expression or to enhance or alter the function of their protein products. For example deregulation can result from chromosome translocations which involve breakage and aberrant rejoining of chromosomes to link genetic segments that are not normally juxtaposed. If translocation breakpoints occur in the coding region of genes, it may result in the synthesis of truncated or chimeric proteins with altered regulatory or functional properties. Examples include the chimeric proteins produced by the *bcr–abl* [t(9;22) or 'Philadelphia' chromosome] translocation characteristic of chronic myelogenous leukaemia and the PML–RARa [t(15;17)] translocation characteristic of acute promyelocytic leukaemia. If the translocation breakpoint is outside the coding region of genes, it may bring genes under the regulation of alien transcriptional control elements and alter gene expression. Examples are common in B-cell and T-cell lymphomas where immunoglobulin gene or T-cell receptor gene enhancers and promoters, respectively, become juxtaposed to proto-oncogenes, such as *myc* and *bcl-2.* Other genetic alterations, such as gene amplification, produce multiple copies of genes which may augment or deregulate their expression and activate oncogenic potential. Clinically relevant examples include amplification and overexpression of N *-myc* in neuroblastoma and of *Her2/neu* in breast and ovarian cancer, both of which are associated with a worse prognosis. Point mutations in coding regions of genes can result in amino acid substitutions that alter protein functional properties. The oncogenic potential of *ras* proto-oncogenes typically become activated by this mechanism. Finally, viruses whose genomes integrate into the cell's genome as part of their life cycle (e.g. retroviruses) can activate nearby genes by insertion of their foreign transcription regulatory elements. While retroviral insertional activation of proto-oncogenes is important in the pathogenesis of several types of animal tumours, it has yet to be shown to be a significant mechanism of human oncogene activation.

Tumour suppressor genes

The transforming genes or oncogenes just described generally promote cancer by favouring cell proliferation. Tumour suppressors are entirely different kinds of genes involved in cancer causation. They are cellular genes that normally function to restrain cell proliferation and contribute to cell transformation only following 'loss-of-function' or inactivating mutations. Since the activity of only one copy of a tumour suppressor gene is generally sufficient for function in a diploid cell, the function of both copies must be lost before they promote transformation. Thus, tumour suppressor genes act recessively at the cellular level and stand in marked contrast to oncogenes, which act dominantly (only one activated copy of an oncogene has to be present in a cell to promote transformation). Discovery and identification of tumour suppressor genes came much later than discovery of oncogenes because of the difficulties inherent in tracking down genes that produce effects only when they are absent or functionless. Almost all known tumour suppressor genes have been identified through laborious genetic mapping studies of cancer-prone kindreds. The telltale sign of tumour suppressor genes is loss of heterozygosity (LOH; loss of one of the two alleles normally present in diploid cells) at specific genetic loci in cancer cells that are not present in the normal cells of an individual with cancer. When the two copies or alleles of a gene in an individual's

cells can be distinguished molecularly (e.g. by restriction fragment length polymorphisms (RFLP) or microsatellite repeat length polymorphisms), LOH can be detected by molecular analysis. A given LOH found in tumour cells can be an incidental occurrence of little or no pathogenic significance, because these cells tend to be genetically unstable and may have lost alleles of many cellular genes as a consequence. If, on the other hand, LOH at a particular genetic locus is found in tumour cells from many different patients, the probability is high that the loss is pathogenically significant. With LOH, the remaining alleles are physically present but, when these have been studied, they have been found to contain inactivating mutations (e.g. small deletions or premature termination and frameshift mutations). Thus, non-random LOH at specific loci in the cancer cell genome suggests the functional loss of tumour suppressor genes at these sites and provides the starting point for more precise localization studies and eventual cloning.

Inherited cancers and cancer-prone kindreds have been instrumental in providing insights into the presence and identity of tumour suppressor loci and genes. *Rb* (retinoblastoma susceptibility gene), *APC* (adenomatous polyposis coli gene), *WT1* (Wilms' tumour gene), *p16*$^{INK4\varepsilon}$(melanoma susceptibility gene), and *BRCA1* and *BRCA2* (breast cancer susceptibility genes 1 and 2) are examples of tumour suppressor genes that were identified through study of families whose members had strong predispositions to developing the respective tumours. In each case, the inherited predisposition to cancer results from functional loss of one allele of the corresponding tumour suppressor gene in the germline (either through complete or partial deletion of the gene or the presence of inactivating mutations). Examination of the actual tumours in affected family members reveal that these have lost or inactivated the remaining, functional tumour suppressor allele and, thus, have undergone the obligate functional loss of both alleles for cancer pathogenesis. Thus, the high incidence of specific cancers in affected individuals in these kindreds is attributable to the pre-existing loss of one tumour suppressor allele, so that, as these individuals go through life, their cells have only to lose the remaining allele to embark on cancerous changes. Cells of normal individual, in contrast, need to lose both alleles before they embark on similar changes. While this obviously happens, attested by the fact that sporadic (non-familial) retinoblastomas consistently lose both copies of *Rb* and sporadic colon and breast cancers frequently lose both copies of *APC* and *BRCA2*, respectively, the likelihood must be substantially less given the much lower incidence of these tumours in the general population than in affected families. Finally, the vastly greater chance of cells losing one versus both tumour suppressor alleles accounts for the dominant inheritance pattern of cancer predisposition in families, despite the fact that the defect inherited resides in a gene that acts recessively at the cellular level. Thus, in familial retinoblastoma, children who inherit a defective *Rb* gene are virtually assured of developing these tumours, indicating that at least one retinoblast in their eyes will almost certainly lose its remaining good copy of *Rb*.

The number of known tumour suppressors is quite small compared to the number of putative oncogenes, but most if not all of the former have a role in human tumour pathogenesis. They are functionally diverse, act in seemingly distinct cellular pathways, and defy ready categorization. The function of Rb and pl6 ^{INK4a} as a negative regulator of the cell cycle was described previously. WT1 is a transcriptional repressor that inhibits expression of genes that encode certain growth factors and growth factor receptors. The APC protein binds b-catenin (among other proteins) and targets it for degradation. b-Catenin is a protein with many functions, one of which is to interact with transcription factors of the Tcf (T cell factor)/Lef (lymphoid enhancer factor) family and activate transcription of genes that probably stimulate proliferation or inhibit apoptosis. In colon carcinoma cells deficient in APC, b-catenin levels are high and activity of b-catenin-transcription factor complexes is constitutive, which leads to activation of target genes and the beginnings of cell transformation and polyposis. Interestingly, the tumour suppressors responsible for hereditary non-polyposis colon cancer (HNPCC; a familial syndrome characterized by right-sided colon carcinomas without antecedent polyposis) are entirely different. Defects in several related genes and proteins are responsible for HNPCC, with defects in *hMSH2* and *hMLH1* being the most common. These proteins repair DNA that contain mismatches arising from errors during DNA synthesis, and defects in these proteins impede repair of these replication errors and allow them to accumulate. This 'mutator' phenotype presumably begins the process of cell transformation and colon carcinogenesis when errors affect genes that influence cell proliferation or apoptosis. These mismatch repair tumour suppressors differ from oncogenes and tumour suppressors, such as *Rb* and *APC*, in that the function of their products does not directly affect cell proliferation, apoptosis, or differentiation. Rather, they are responsible for maintaining the fidelity of genomic information transmitted from cell to progeny cell, and their absence contributes to tumourigenesis by favouring mutagenesis of genes that affect cell fate directly.

The relevance to cancer causation of genes that allow cells to repair defective DNA is reinforced by the role of the *p53* tumour suppressor in human cancers. Originally described as the gene producing a 53 kDa protein that is overexpressed in many transformed cells, *p53* was believed to be an oncogene, because overexpression of *p53* cloned from cell lines had transforming properties. Subsequently, comparison with normal *p53* cloned from fetal tissues revealed mutations in the *p53* genes previously used, and normal *p53* was found to suppress rather than promote cell transformation. These studies and findings of frequent *p53* LOH in tumours have led to the current view that *p53* is a tumour suppressor gene with a negative effect on cell proliferation. It is probably the most frequently deleted or mutated cancer-associated gene (involved in about 50 per cent of human tumours), and Li–Fraumeni syndrome kindreds, who are prone to developing a variety of cancers, are heterozygous for mutant *p53* in their germline. The observation that mutant *p53* transforms is explained by its 'dominant negative' effect: p53 modulates transcription of genes to which it binds as a tetramer, and mutant p53 not only loses this ability but prevents normal p53 from functioning when they are together in a mixed tetramer. Thus, a mutant *p53* allele may be transforming despite the presence of a normal *p53* allele in cells, especially since mutant p53 proteins are frequently longer lived and more abundant than normal p53 protein. Given the importance of p53 in preventing oncogenesis, it was somewhat surprising to find that mice with both their *p53* alleles deleted developed normally and were abnormal only in being prone to developing tumours. How p53 prevents tumourigenesis but is not essential for normal growth and development is explained by the conditional requirement for its activity. When DNA is damaged, for example by exposure to radiation or chemotherapy agents, p53 becomes functionally activated and modulates transcription of genes that induce cell cycle arrest, apoptosis, and repair of damaged DNA. Cell cycle arrest presumably allows the cell time to repair damaged DNA before it is replicated, passed on to progeny cells and becomes a ongoing source of genetic misinformation. Alternatively, induction of apoptosis presumably eliminates cells that are genetically damaged beyond repair. Cells without functional p53 fail to cell cycle arrest following DNA damage, are predisposed to genomic instability, and are less likely to be eliminated by apoptosis. These p53 functions obviously are not needed for normal growth and development but are needed for protection against DNA damage leading to cell transformation.

Regulatory pathways disrupted during cell transformation

As more and more oncogenes and tumour suppressor genes are identified, the proteins of many have been found to interact with each other and function in the same cell regulatory pathways. This suggests that these regulatory pathways are important for maintaining normal cell behaviour and must be disrupted for neoplasia to occur and that cells undergoing transformation may achieve this by altering one pathway participant or another (Fig. 14). For example p53, activated by DNA damage, transactivates expression of a gene, *mdm2*, whose protein binds p53, promotes its degradation, and inhibits its transcription regulatory function—that is Mdm2 is a negative regulator of p53 activity. Interestingly, Mdm2 is an oncogene that induces cell transformation when overexpressed in cells, and in tumours that overexpress Mdm2, p53 is normal. Thus, inactivating p53 is important for cell transformation, but this can be achieved either by inactivating p53 directly or activating Mdm2 expression. More recently another protein, p19 ^{ARF}, has been found to interact with Mdm2 and inhibit its ability to counter p53. The genetic locus of p19 ^{ARF} (which coincides with the gene for the Cdk4,6 inhibitor, p16 ^{INK4a}, but is in an alternative reading frame) is disrupted in familial melanomas and other types of cancers, suggesting that it is a tumour suppressor gene affecting the p53 functional pathway.

The APC-b–catenin interaction provides another example of the importance of disrupting certain regulatory pathways during cell transformation, no matter the means. Many sporadic colon carcinomas resemble carcinomas arising in those with familial adenomatosis polyposis in that the tumour cells have no functional APC. In these carcinomas, both alleles have been inactivated by somatic mutations. Other cases of sporadic colon carcinoma, however, have normal APC. A substantial proportion of these cases have mutant b-catenin genes that produce proteins that do not interact with APC but retain the ability to interact and function with Tcf/Lef transcription factors, that is b-catenin is a mutationally activated oncogene in these cells. One can infer that deregulated expression of genes regulated by b-catenin–Tcf/Lef is important for colon carcinogenesis, and less important is whether this is achieved by eliminating APC, an inhibitor of b-catenin activity, or mutating b-catenin so that it is no longer susceptible to APC regulation.

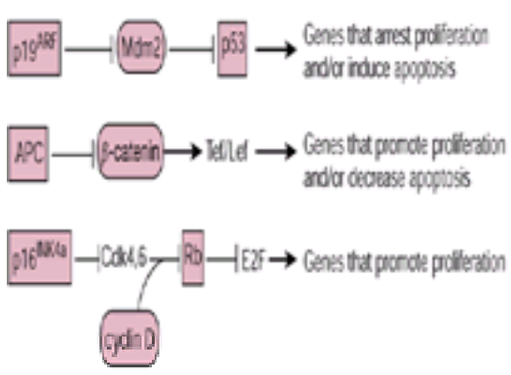

Fig. 14 Regulatory pathways targeted for deregulation in cancer. Three pathways important for the regulation of cell proliferation and apoptosis which are frequently deregulated during neoplastic cell transformation are shown. Components of these pathways that are frequently activated or inactivated by mutations in cancer cells are surrounded by ovals and rectangles. Rectangles designate tumour suppressor genes that are subject to loss-of-function mutations, and ovals designate

proto-oncogenes that are subject to gain-of-function mutations.

The pathway of cell cycle regulation involving Rb perhaps best illustrates the importance of certain regulatory pathways for controlling cell behaviour and how these pathways may be subverted in a number of different ways during cell transformation. In many types of human cancer cells, both copies of the *Rb* gene are inactivated, and there is no functional Rb. While this may be the most effective way to eliminate Rb regulation, other events pushing cells towards neoplasia may achieve a similar effect without altering Rb itself. Enhanced cyclin D expression due to chromosome translocation is seen in certain neoplasms. As cyclin D/Cdk4,6 phosphorylates Rb and prevents it from regulating E2F, deregulating cyclin D expression produces an oncogenic effect resembling Rb inactivation. p16 ^{INK4a} inhibits Cdk4,6 function, and loss of this Cdk inhibitor has been shown to result from gene deletion or epigenetic mechanisms in different tumour types. Its loss eliminates a regulator of cyclin D/Cdk4,6 activity, allowing the latter to phosphorylate Rb when it should not and producing an effect similar to Rb inactivation (note that disruption of p16 ^{INK4a} is likely to disrupt the p19^{ARF} gene as well, in which case two important pathways, Rb and p53, are disrupted by one genetic event). The complexity of the Rb regulatory pathway—p16^{INK4a} inhibiting cyclin D/Cdk4,6 activity which inhibits Rb control of E2F function—allows inactivation of p16 ^{INK4a}, deregulation of cyclin D/Cdk4,6, or inactivation of Rb to effectively deregulate E2F function and cell cycling. Recall that DNA tumour viruses (SV40, certain adenoviruses, and certain human papilloma viruses) also know the importance of this pathway and produce viral proteins that neutralize Rb function. Together, these argue compellingly for the central importance of the Rb pathway for maintaining normal cell regulation and preventing neoplastic behaviour, and cells on the path to transformation need to find a way to subvert it.

Limitations and uses of the information available

No one questions that investigations into the molecular basis of cell transformation over the past two decades have radically altered and refined our view of cancer pathogenesis. Major concepts and important subtleties now known were not even suspected two to three decades ago. However satisfying this may be, clearly much more needs to be learned. Cancer as a clinical entity is the product of many changes undergone by the cancer cell, not only intrinsically but also in terms of how it relates to the host. Our understanding of the molecular mechanisms involved in cell transformation, the initial steps in pathogenesis, have outpaced our understanding of how the neoplastic cell masters its environment, the steps responsible for most of the symptoms, signs, and clinical character of cancer: how transformed cells evade the host immune system and invade the surrounding extracellular matrix, induce host blood vessel growth necessary to supply the demands of enlarging tumours, enter and exit lymphatic and blood vessels to initiate metastasis, and thrive in distant, ectopic sites to form metastases.

Despite these gaps in our understanding, the knowledge gained so far has proved clinically useful. Knowing the oncoproteins involved in cell transformation, specific inhibitors of their function are being developed. Fortunately, even though neoplastic transformation involves multiple steps and has many participants, interrupting only one of these steps may be sufficient to inhibit transformed behaviour. Perhaps the closest to clinical application are putative inhibitors of Ras function, the farnesyltransferase inhibitors. Ras and related G-proteins must attach to cell membranes to function and do so by adding lipid groups (e.g. farnesyl and geranyl moieties) post-translationally. Compounds that inhibit this modification prevent proper localization and function of Ras and relatives of Ras. Tumour suppressor proteins, in contrast, are generally missing in tumour cells, and consideration is being given to functional reinstatement of these proteins in tumour cells to reverse their neoplastic behaviour. Currently, most attempts have focused on gene transfer technologies ('gene therapy') to accomplish this goal. Tumour-associated proteins that are mutant or overexpressed in transformed cells are potential neoantigens and have been suggested as targets for tumour-specific immunological attack. Mutant Ras proteins, novel Bcr–Abl fusion proteins, overexpressed HER2/neu receptors, and abundant mutant p53 proteins have each been suggested as the basis for tumour vaccine formulations. Whether these ideas and approaches turn out to be practical and therapeutically useful will probably be determined with another decade of research, but, in that interval, many additional new ideas and approaches will undoubtedly surface.

The genetic changes and molecular participants in neoplastic transformation also may be used for diagnostic and classification purposes. With the extreme detection sensitivity of polymerase chain reaction (PCR) technology, genetic alterations characteristic of certain cancers may be detected even when they are present at extremely low frequency. For example this has been applied to the *bcr–abl* translocation that characterizes chronic myelogenous leukaemia and used to detect minimum residual disease in patients following therapy. The association between this translocation and this leukaemia is so strong that the presence of the *bcr–abl* translocation is considered diagnostic of chronic myelogenous leukaemia, whether or not a t(9;22) Philadelphia chromosome is detected on cytogenetic examination. For many cancers, the molecular 'genotype' may affect and even define clinical behaviour and, perhaps, therapeutic response. For example the t(15;17) *PML–RARa* translocation is responsible for the distinctive phenotype of acute promyelocytic leukaemia and its initial dramatic response to all *-trans* retinoic acid therapy. The influence of genotype on therapeutic response may be especially important with regard to the p53 status of tumours. Mutations in p53 are so common in human cancers and its influence on apoptosis seems so likely to affect the killing of cancer cells by certain chemotherapy agents that tumour p53 status may become an important factor in deciding between different types of cancer therapy. These examples just begin to illustrate the potential applications and utility of molecular genotyping of tumours in the future.

Molecular basis of dilated cardiomyopathy

Defining the molecular mechanisms by which cells respond to environmental stimuli and communicate with each other has led to greater understanding of the role played by intracellular signalling pathways in the pathogenesis of many common diseases. While it is intuitive that deregulated signalling might lead to uncontrolled cell growth, and hence malignancy, it is increasingly recognized that signalling cascades also play a significant role in the pathogenesis of many non-malignant conditions. For example the molecular events that culminate in dilated cardiomyopathy and congestive heart failure are mediated by signalling cascades initiated by increases in biomechanical stress.

Cardiomyocytes respond to increased biomechanical stress by increasing myocardial mass commensurate with the increase in work load. This increase in mass, or hypertrophy, is characterized by an increase in the number of contractile protein units contained in individual cardiomyocytes, but not an increase in the number of cells. Depending on the inciting event, the level of work required, and the physiological state of the functioning myocardium, this adaptive response can result in physiological hypertrophy (a proportional increase in the length and width of cardiomyocytes), concentric hypertrophy (increases in width of cardiomyocytes out of proportion to increased length), or eccentric hypertrophy (increased length relative to width). For example, in normal individuals, exercise can lead to physiological hypertrophy in response to increased cardiac workload. Loss of myocardium, as occurs following myocardial infarction, similarly increases the workload on residual cardiomyocytes and initiates compensatory hypertrophy. The magnitude of myocardial loss, and hence the level of biomechanical stress on residual cells, is a major determinant of whether the heart responds with physiological or eccentric hypertrophy. Increased biomechanical stress can also result from defects intrinsic to cardiac myocytes (e.g. genetic abnormalities of cytoskeletal proteins as seen in some forms of muscular dystrophy) or from extrinsic defects (e.g. haemodynamic overload resulting from chronic hypertension).

The molecular events that induce cardiac hypertrophy are only beginning to be defined. Biomechanical stress is known to induce release of a number of growth factors and cytokines, including proteins that activate G-protein-coupled receptors (e.g. endothelin-1 and angiotensin II), receptor tyrosine kinases (e.g. insulin-like growth factor I or IGF-1), and tyrosine kinase-associated receptors (e.g. the interleukin-6-related cytokine, cardiotrophin 1). Furthermore, each of these receptors transduce signals that induce cardiac hypertrophy. Receptors for endothelin-1 and angiotensin II induce hypertrophy by activating the heteromeric G $_q$ protein, which, in turn, activates protein kinase A and specific isoforms of phospholipase (PLC-b and phospholipase D) and protein kinase C. Activation of these pathways leads to transcriptional reprogramming of cardiomyocytes and produces compensatory hypertrophy through, as yet, poorly characterized mechanisms (Fig. 15). Factors activating receptor tyrosine kinases induce cardiac hypertrophy through multiple, different MAP kinases, including the ERKs and the stress-activated MAP kinases, JNK/SAPK and p38, each of which has been shown to be capable of activating hypertrophy programmes. The tyrosine kinase-associated receptor for cardiotrophin, gp130/LIF, activates specific JAK and STAT isoforms (JAK1, JAK2, and Tyk2; and STAT1 and STAT3) that regulate cardiac hypertrophy. These same growth factors and cytokines have pleiotropic effects in various other tissues, but they all activate signalling cascades that lead to hypertrophy in cardiomyocytes. Whether these different pathways represent functional redundancy and how they interact is unclear.

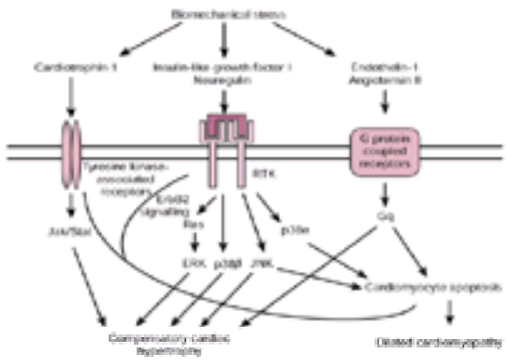

Fig. 15 Signalling pathways activated by biomechanical stress that mediate cardiac hypertrophy and heart failure. Biomechanical stress activates multiple signalling pathways that converge to induce compensatory cardiac hypertrophy, including signals mediated by receptor tyrosine kinases, tyrosine kinase-associated receptors, and G-protein-coupled receptors. However, many of these same pathways can also stimulate apoptosis pathways. Loss of cardiomyocytes through apoptosis results in increased biomechanical stress on residual cell and leads ultimately to a dilated cardiomyopathy and congestive heart failure. The end physiological response to biomechanical stress depends on the balance of these two opposing signal transduction pathways.

Prolonged, uninterrupted biomechanical overload ultimately leads to a dilated cardiomyopathy which is characterized by eccentric hypertrophy, loss of cardiac contractile function, and loss of cardiomyocytes due to apoptosis. The molecular events that tip the balance from adaptive hypertrophy to eccentric hypertrophy and heart failure are poorly understood, but increasing evidence implicates activation of apoptosis pathways in the development of dilated cardiomyopathy. Like most other cells, cardiomyocytes survival depends on activation of cell survival signals, and withdrawal of survival signals can induce apoptosis. This important property is highlighted by the unanticipated clinical observation that patients with metastatic breast cancer who received therapy with herceptin (a monoclonal antibody that blocks signalling via the receptor tyrosine kinase, ErbB2) had an approximately 15 per cent incidence of dilated cardiomyopathy, with patients previously exposed to anthracyclines being at greatest risk. The molecular basis of the heart failure seen in these trials is unclear, but was thought to result from apoptosis of cardiomyocytes. If true, this observation suggests that cardiomyocyte survival is dependent on ErbB2 signalling cascades and that apoptosis results when cardiomyocytes are deprived of these signals.

Interestingly, many of the signalling pathways that induce cardiac hypertrophy also regulate cell survival and cell death signals. The receptor for cardiotrophin-1, gp130/LIF, and the beta isoform of p38 transduce cell survival (antiapoptotic) signals, while the alpha isoform of p38, JNK/SAPK, and G_q all transduce proapoptotic signals. The balance of these pro- and antiapoptotic signals is likely to play a critical role in the adaptive response of the heart. When cell survival signals predominate, the heart responds with an adaptive hypertrophy, but a predominance of apoptotic signals induces cardiac decompensation with eccentric hypertrophy and heart failure. The magnitude and duration of biomechanical stress may play an important role in determining whether pro- or antiapoptotic signals predominate. For example moderate overexpression of G_q induces cardiac hypertrophy, but high expression results in cardiomyocyte apoptosis.

As heart failure progresses, signalling pathways are activated that appear to further exacerbate biomechanical overload and accelerate cardiac decompensation. To compensate for depressed cardiac function, b-adrenergic signalling pathways are activated in an attempt to augment cardiac contractility. While b-adrenergic signalling transiently improves contractility, prolonged stimulation depresses calcium fluxes resulting in impeded cardiac contractility. In this setting, b-adrenergic blockade improves calcium transport from the cytosol to the sarcoplasmic reticulum, and, in so doing, improves both cardiac relaxation and contractility. This observation provides the rationale for using b-adrenergic blockade in the treatment of patients with congestive heart failure.

Defining the signalling pathways that lead to cardiac hypertrophy has begun to provide a clearer understanding of the molecular basis for heart failure and the molecular events that link mechanical factors (e.g. workload) to biological effect. This understanding of what has traditionally been considered in mechanical and physical terms promises not only to provide important new mechanistic insights into these processes but also to suggest novel approaches for prophylactic and therapeutic intervention.

4.4 Cytokines: interleukin-1 and tumour necrosis factor in inflammation

Charles A. Dinarello

The biology of cytokines

Cytokines are small, non-structural proteins with molecular weights ranging from 8000 to 40 000 Daltons. Originally called lymphokines and monokines to indicate their cellular sources, it became clear that the term 'cytokine' is the best description since nearly all nucleated cells are capable of synthesizing these proteins and, in turn, responding to them. There is no amino acid sequence motif or three dimensional structure that links cytokines; rather, their biological activities allow us to group them into different classes. For the most part, cytokines are primarily involved in host responses to disease such as infection and inflammation; involvement with homeostatic mechanisms is primarily at the level of host defence mechanisms in order to combat the constant challenge of micro-organisms from the environment. For example mice deficient in specific cytokines will spontaneously develop inflammatory bowel disease but when maintained in a germ-free environment, the disease does not occur.

It is not accurate to think of cytokines as hormones. First, hormones tend to be constitutively expressed by highly specialized tissues whereas cytokines are synthesized by nearly every cell. Hormones are the primary synthetic product of a cell (e.g. insulin, thyroid, ACTH), but cytokines account for a rather small proportion of the synthetic output of a cell. In addition, hormones are expressed in response to homeostatic control signals, many of which are part of a daily cycle. In contrast, most cytokine genes are not expressed unless specifically stimulated by noxious events. For example ultraviolet light, heat shock, hyperosmolarity, or adherence to a foreign surface activate cytokine gene expression. One concludes, then, that cytokines themselves are produced in response to 'stress' whereas most hormones are produced according to a daily, intrinsic clock.

Cytokine responses to infection and inflammation

There are at present 23 cytokines termed 'interleukin' (IL). Other cytokines have retained their original biological description such as 'tumour necrosis factor' (TNF). Most cytokines possess more than one biological activity and hence are often called 'pleiotropic'. Some cytokines clearly promote inflammation and are called proinflammatory cytokines whereas others suppress the activity of proinflammatory cytokines and are called anti-inflammatory cytokines. For example IL-4, IL-10, and IL-13 are potent anti-inflammatory agents. They are anti-inflammatory cytokines by virtue of their ability to suppress the expression of genes for proinflammatory cytokines such as IL-1 and TNF. Interferon-g (IFNg) is an example of the pleiotropic nature of cytokines. IFNg is an activator of the pathway which leads to cytotoxic T cells. However, IFNg is considered a proinflammatory cytokine because it augments TNF activity, upregulates vascular endothelial adhesion molecules, and induces nitric oxide (NO). Therefore, listing cytokines in various categories should be done with an open mind in that, depending upon the biological process, any cytokine may function differentially.

The concept that some cytokines function primarily to induce inflammation whereas others suppress inflammation is fundamental to cytokine biology and also to clinical medicine. The concept is based on the observation that during inflammation, the expression of genes coding for enzymes that synthesize small mediator molecules is upregulated. Examples of these proinflammatory enzymes are phospholipase A2 type-II, cyclo-oxygenase-2 (COX-2), and inducible nitric oxide synthase (iNOS), which synthesize platelet activating factor and leukotrienes, prostanoids, and nitric oxide. Another class of genes code for chemokines, small, proinflammatory peptides (8000 Daltons) that facilitate the passage of leucocytes from the circulation into the tissues. The prototypic chemokine is the neutrophil chemoattractant IL-8. IL-8 also activates neutrophils to degranulate and cause tissue damage. IL-1 and TNF are inducers of endothelial adhesion molecules, which are essential for the adhesion of leucocytes to the endothelial surface prior to emigration into the tissues.

Cytokine-mediated inflammation involves a cascade of proinflammatory gene products that are usually not produced in health. What triggers the expression of these genes? Although inflammatory products such as endotoxins can act directly, the cytokines IL-1 and TNF (and in some cases IFNg) are particularly effective in stimulating the expression of these genes. Moreover, IL-1 and TNF act synergistically in this process. Whether induced by a infection, trauma, ischaemia, immune-activated T cells, or toxins, IL-1 and TNF initiate the cascade of inflammatory mediators by targeting the endothelium. Figure 1 illustrates the inflammatory cascade triggered by IL-1 and TNF.

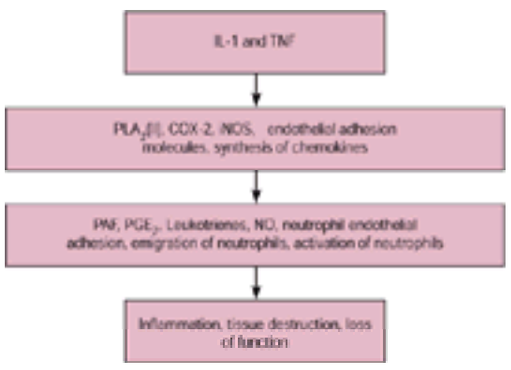

Fig. 1 The scheme of inflammatory cascade triggered by IL-1 and TNF.

IL-1 and TNF

The two cytokines discussed in detail here, IL-1 and TNF, have been selected because of their association with the pathogenesis and progression of disease, particularly autoimmune/inflammatory diseases such as rheumatoid arthritis and inflammatory bowel disease. IL-1 and TNF are the primary members of two 'families' of cytokines. Thus, seven cytokines have been identified as members of the IL-1 family; each has a different but related primary amino acid sequences and different but related receptors. The TNF 'family' and TNF receptor family is considerably larger (over 16 members). For the purposes of this chapter, IL-1 is used to denote IL-1b and IL-1a, the two major IL-1 agonists and TNF is used to denote TNFa, the major member of the TNF family. The case for a causative role of any cytokine in a particular disease can not be deduced from an association with production levels but can be proven only by specific inhibition of that cytokine in controlled, human trials. Fortunately, such trials are increasingly taking place since neutralizing antibodies to TNF and soluble receptors for TNF, which bind TNF in the extracellular

space, have been approved for clinical use. The IL-1 receptor antagonist IL-1Ra is likely to be approved for use in patients with rheumatoid arthritis.

The biology of IL-1 relevant to disease

Although animal experiments revealed that IL-1 was a highly proinflammatory cytokine, a great deal of information has been learned from studies in which humans were injected with either recombinant IL-1a or IL-1b. Results from trials for treating cancer or bone marrow suppression in which humans received IL-1, suggested a role for IL-1 in those conditions. Although there was no reduction in tumour growth, IL-1 treatment resulted in a more rapid recovery of platelets in subjects given high-dose chemotherapy. However, patients receiving 30 to 50 ng/kg of IL-1 developed fever, hypotension, and profound systemic, flu-like symptoms. Acute toxicities of either IL-1a or IL-1b were greater following intravenous compared to subcutaneous injection; subcutaneous injection was associated with significant local pain, erythema, and swelling. Chills and fever were observed in nearly all patients, even in the 1 ng/kg dose group. The febrile response increases in magnitude with increasing doses and chills and fever were abated with indomethacin treatment. In patients receiving IL-1a or IL-1b nearly all subjects experienced significant hypotension at doses of 100 ng/kg or greater. Systolic blood pressure fell steadily and reached a nadir of 90 mmHg, or less, 3 to 5 h after the infusion of IL-1. At doses of 300 ng/kg, most patients required intravenous pressors. By comparison, in a trial of 16 patients given IL-1b from 4 to 32 ng/kg subcutaneously, there was only one episode of hypotension at the highest dose level. These results suggest that the hypotension is probably due to induction of NO and elevated levels of serum nitrate have been measured in patients with IL-1-induced hypotension.

At 30 to 100 ng/kg of IL-1 patients exhibited a sharp increase in cortisol levels 2 to 3 h after the injection. In addition, there were increases in ACTH and thyroid stimulating hormone but a decrease in testosterone. No changes were observed in coagulation parameters such as prothrombin time, partial thromboplastin, or fibrinogen degradation products. This latter finding is in contrasted to TNFa infusion into healthy humans which resulted in a distinct coagulopathy syndrome. Not unexpectedly, IL-1 infusion into humans significantly increased circulating IL-6 levels in a dose-dependent fashion. These elevations in IL-6 are associated with a rise in C-reactive protein and a decrease in albumin.

Patients receiving only 3 ng/kg IL-1, given by intravenous infusion over 30 min, exhibited elevated IL-6 and IL-8 levels after 1 to 2 h; IL-6 reached a peak of 25 pg/ml after 1 h, IL-8 reached a peak of 311 pg/ml at 2 h, and nitrite/nitrate peaked after 10 h at 89 µmol/l (all statistically significant). If one calculates the maximum possible plasma concentration of IL-1b in these patients, the range would be 50 to 65 pg/ml. However, this calculated concentration is falsely high since the cytokine was given as a 30-min infusion rather than a bolus injection. Nevertheless, at 3 ng/kg, maximal plasma levels of IL-1b is 3 to 4 pM which is the same concentration of IL-1b needed *in vitro* for a biological response. Of interest is that the concentration of soluble IL-1R type II in healthy subjects is about 175 to 200 pM. When IL-1b is injected intravenously, it immediately encounters a 50-fold molar excess of soluble receptor to ligand. Why is there any biological effect to IL-1b given the high affinity of IL-1b for the soluble receptor? And the biological effect is dramatic with fever, hypotension, increased IL-6, IL-1Ra, IL-8, etc. There are two possibilities: the soluble receptor is already bound or the biological response is seen even at low concentrations.

Effects of TNFa injected into humans

Similar to IL-1, TNF is a highly proinflammatory cytokine when injected into humans. Unlike IL-1, TNF induces cell death, particularly in tumour cells. TNF has been injected as part of anticancer protocols, either systemically or regionally, in order to bring about death of tumour cells. Similar to the effects of IL-1 in humans, TNFa induces fever, headaches, myalgias, nausea, vomiting, and profound hypotension. Similar to IL-1 administration, elevated levels of IL-6, other cytokines, soluble cytokine receptors, and acute phase proteins are observed. In fact, the systemic responses to TNFa and IL-1 are mostly indistinguishable. However, activation of the coagulation pathways is observed with TNFa but not IL-1. The injection of TNF, 50 µg/m ^{2} body surface area, induced an early and short-lived rise in circulating levels of the activation peptide factor X and an increase in prothrombin fragment F1+2. These findings demonstrate that a single injection of TNF elicits a rapid and sustained activation of the coagulation pathway, probably induced through the extrinsic route. In these subjects, TNF induced a short-term increase in circulating plasminogen activator activity with rises in the antigenic levels of urokinase-type plasminogen activator and tissue-type plasminogen activator. This was followed by an eight-fold increase in plasminogen activator inhibitor type I and a sustained coagulation activation for 6 to 12 h. These findings may explain the microvascular thrombosis seen in septicaemia. Sequential measurement of the plasma concentrations of von Willebrand factor antigen was determined after a bolus intravenous injection of TNF (50 µg/m^2) in six healthy men. TNF induced a marked increase in von Willebrand factor antigen plasma levels, becoming significant after 45 min and peaking after 4 h (351 per cent increase). This increased von Willebrand factor secretion may explain the release observed in acute and chronic inflammatory disease and in systemic infection.

TNF also induced a transient stress hormone response, associated with an early and sustained rise in plasma glucose, free fatty acid, and glycerol concentrations. Resting energy expenditure showed a transient rise after TNF injection. In six healthy males, an intravenous bolus injections of TNF (50 µg/m ^{2}) produced the characteristic changes in circulating thyroid hormones and TSH observed in the sick euthyroid syndrome. In these subjects, TNF elicited a neutropenia after 15 min, followed by a neutrophilia. Decreased numbers of lymphocytes and monocytes were observed for several hours. There were increases in the concentrations of elastase–a1-antitrypsin complexes, lactoferrin levels, and neopterin, suggesting neutrophil and monocyte activation.

Diagnostic and prognostic value of measuring cytokines

Studies in human subjects have consistently revealed that circulating levels of pro- and anti-inflammatory cytokines as well as soluble cytokine receptors are elevated; moreover, levels may correlate with disease severity and outcome. In addition, spontaneous gene expression for certain cytokines in peripheral blood leucocytes or bone marrow cells are present in patients with various inflammatory and malignant disease whereas cells from healthy subjects rarely exhibited spontaneous cytokine production. A variety of animal models of infection, inflammation, or autoimmunity reveal that nearly all pro and anti-inflammatory cytokines are produced during disease and, as in humans, correlate with disease intensity. The best correlations of cytokine levels with disease activity are reported for IL-6 and IL-1Raa rather than with IL-1 or TNF; this includes patients with local infection, sepsis, and autoimmune diseases such as rheumatoid arthritis. Both IL-6 and IL-1Ra are considered 'acute phase reactants' and other correlate with C-reactive protein measurements. In addition, soluble receptors for IL-1 or TNF are better markers of disease intensity than the IL-1 or TNF itself. In patients with sepsis or septic shock, IL-6 and IL-1Ra levels correlated with mortality. In a study of patients with acute coronary artery syndromes, the admission and 48 h levels of IL-6 and IL-1Ra indicated which will undergo a corrective procedure such as angioplasty or by-pass graft and which patients will respond to conservative therapy and be discharged. In patients with rheumatoid arthritis who receive anti-TNF or anti-IL-1 therapy, the levels of IL-6 fall and are associated with a decrease in disease activity. Since IL-1 and TNF are the primary inducers of IL-6 and IL-1Ra, it is not surprising that therapeutic interventions to reduce IL-1 or TNF activity are associated with a decrease in IL-6 and IL-1Ra.

Reducing IL-1 and TNF activities in human disease

The reduction of the biological activity of any cytokine is based on a class of heterogeneous agents termed 'anticytokine-based therapies'. Treating patients with agents designed to reduce the production of cytokines or their biological effects has entered clinical medicine. Therapeutic strategies for reducing the effects of proinflammatory cytokines such as IL-1 or TNF are either specific or non-specific. This is an important distinction. For example corticosteroids inhibit the synthesis of proinflammatory cytokines but also suppress T-cell function as well as several metabolic pathways. Thalidomide also suppresses the synthesis of TNF, IL-1, and other cytokines and has been used to treat refractory multiple myeloma and the oral aphthous lesions of HIV-1 disease. IL-10, an anti-inflammatory cytokine, suppresses the synthesis of IL-1 and TNF but also of IL-6, IL-12, IFNg, and the entire family of chemokines. In contrast, a specific anticytokine therapy targets only one cytokine or closely related members of a single cytokine family. Neutralizing antibodies, soluble cytokine receptors, or receptor antagonists have the advantage of specificity, preventing the activity of a single cytokine in a particular disease. The first anticytokine-based therapy for rheumatoid arthritis employed a monoclonal anti-TNFa antibody which neutralizes only TNFa. IL-1 receptor antagonist blocks the IL-1 receptor; in doing so, it prevents the binding of either IL-1a or IL-1b. Soluble IL-1R type I binds IL-1Ra as well as IL-1a. Nevertheless, soluble receptors for TNF, the IL-1 receptor antagonist, and soluble IL-1 receptors (either type I or type II) are examples of specific anticytokine therapies.

Specific anticytokine-based therapies usually require parenteral administration. Non-specific agents, even when their primary mode of action is anticytokine based, are usually administered orally. The precursors for IL-1b, TNFa, and IL-18 each require cleavage by specific proteases before they are active molecules. Therefore, inhibiting these proteases is a logical anticytokine-based, anti-inflammatory strategy. Cleavage of the IL-1b or IL-18 precursor molecules is carried out by the cysteine protease IL-1b converting enzyme (ICE, also known as caspase-1); inhibition of this enzyme is effective in reducing the secretion of biologically active IL-1b and IL-18. For cleavage of the TNFa precursor, a specific metalloprotease is needed. Small, orally-active molecules, which inhibit these proteases specifically, reduce disease activity in animals and are at present undergoing clinical trials.

In animals, blocking either IL-1 or TNF reduced disease severity despite the fact that several cytokines were overexpressed in the disease model. This finding led to the concept that IL-1 and TNF are 'upstream' from many of the other cytokines produced in disease. Thus, IL-1 or TNF, or the combination of IL-1 plus TNF acting

synergistically, induce chemokines, IL-6, and several other 'downstream' cytokines. These observations explaines why blocking just one cytokine (either IL-1 or TNF) reduces disease. Moreover, of these two cytokines, TNF induces IL-1 production. Thus, in patients with rheumatoid arthritis who receive neutralizing monoclonal antibodies to TNFa, there is a rapid fall in circulating IL-1b as well as IL-6 within 24 h of the initiation of the antibody treatment.

Treating rheumatoid arthritis with IL-1Ra

IL-1Ra was initially tested in a trial in 25 patients with rheumatoid arthritis. In patients receiving 4 mg/kg per day for 7 days, there was a reduction in the number of tender joints from 24 to 10, the erythrocyte sedimentation rate fell from 48 to 31 mm/h and C-reactive protein decreased from 2.9 to 1.9 µg/ml. In an expanded double-blind trial, IL-1Ra was given to 175 patients. After 3 weeks, a significant reduction in disease parameters such as number of swollen joints, the investigator and patient assessments of disease activity, pain score, and C-reactive protein levels. Optimal improvement was in patients receiving 70 mg/day.

A double-blind, placebo-controlled, multicentre trial of IL-1Ra in 472 patients has been reported. There were three doses of IL-1Ra, administered subcutaneously: 30, 75 and 150 mg/day for 24 weeks. After 24 weeks, 43 per cent of the patients receiving 150 mg/day of IL-1Ra met the criteria for response (the primary efficacy measure), 44 per cent met the Paulus criteria, and statistically significant (p=0.048) improvements were seen in the number of swollen joints, number of tender joints, investigator's assessment of disease activity, patient's assessment of disease activity, pain score on a visual analogue scale, and duration of morning stiffness. In addition, there was a dose-dependent reduction in C-reactive protein level, and erythrocyte sedimentation rate.

Importantly, the rate of radiological progression in the patients receiving IL-1Ra was significantly less than in the placebo group at 24 weeks, as evidenced by the Larsen score and the erosive joint count. The reduction in new bone erosions was assessed by two radiologists who were blinded to the patient treatment as well as blinded to the chronology of the radiographs. This finding suggests that IL-1Ra is blocking the osteoclast activating factor property of IL-1, as has been reported in myeloma cell cultures. This study confirmed both the efficacy and the safety of IL-1Ra in a large cohort of patients with active and severe rheumatoid arthritis.

A trial of IL-1Ra in combination with methotrexate in patients with rheumatoid arthritis has also been reported; 419 patients were randomized to receive either placebo or increasing doses of IL-1Ra. Patients were also being treated with methotrexate (mean 17 mg/week). After 24 weeks, patients taking IL-1Ra (1.0 mg/kg) had significantly decreased parameters of disease compared to the placebo. For examples the proportion of patients with a 50 per cent reduction in disease activity was significantly greater in the IL-1Ra treated group (24 per cent) compared to the placebo (4 per cent). These studies suggest that the addition of IL-1Ra to optimal methotrexate treatment results in a further decrease in disease.

Treating rheumatoid arthritis with soluble IL-1R type I

Soluble IL-1R type was administered subcutaneously to 23 patients with active rheumatoid arthritis in a randomized, double-blind study. Patients received subcutaneous doses of the receptor at 25, 250, 500, or 1000 µg/m^2 per day or placebo for 28 consecutive days. In patients receiving 1000 µg/m^2 per day, only one showed improvement in measures of disease activity. One possible explanation for the lack of clinical response despite efficacy in suppressing immune responses could be the inhibition of endogenous IL-1Ra. This was observed in volunteers receiving soluble IL-1R type I before challenge by endotoxin.

Neutralizing TNF in rheumatoid arthritis

Strategies for reducing the biological activity of TNF have focused on neutralization by either monoclonal antibodies or soluble TNF receptors. The initial studies on the efficacy of blocking TNF in rheumatoid arthritis were carried out with the monoclonal antibody cA2 which is specific for neutralization of TNFa. Using a double-blind, placebo-controlled trial, increasing amounts of the antibody clearly showed that specific neutralization of TNFa in rheumatoid arthritis reduced the severity of both clinical and laboratory parameters of the disease. There were dramatic reductions in the circulating levels of IL-1b, IL-6, soluble vascular adhesion molecules, and other markers of systemic inflammation such as C-reactive protein and erythrocyte sedimentation. When combined with methotrexate, the efficacy of monoclonal anti-TNFa in this disease is improved over either agent alone. The biological basis for the effectiveness of blocking TNFa in rheumatoid arthritis is experiments showing a unidirectional cascade of cytokines in explants of synovial tissues in which the presence of anti-TNFa antibody inhibited the spontaneous production of IL-1, IL-6, and IL-8. IL-1Ra reduced IL-6 and IL-8 production but not TNFa production.

Treating rheumatoid arthritis with soluble TNFR p75-Fc

There are two distinct receptors for TNF termed p55 and p75, based on their molecular size. The extracellular forms of these receptors (also termed 'soluble' receptor), which circulate in healthy humans, can be administered in pharmacological concentrations in order to neutralize TNF. To increase the affinity of TNFa and to prolong its plasma concentration, the p75 receptor was synthesized as a fusion protein linked to human Fc domain of the IgG1 (TNFR p75-Fc). A randomized, double-blind, placebo-controlled trial involving 234 patients with active rheumatoid arthritis was carried out using soluble TNFR p75-Fc administered twice-weekly by subcutaneous injection. After 3 months of treatment, there was a improvement in 62 per cent of the patients compared to 23 per cent of the placebo using a 20 per cent ACR response. After 6 months of treatment, 59 per cent of the treated group but only 11 per cent of the placebo group achieved a 20 per cent ACR response. Clearly, blocking TNF using this construct resulted in a significant and sustained benefit in patients with active rheumatoid arthritis. However, similar to monoclonal anti-TNFa, the inflammatory component of the disease returned upon cessation of therapy.

When combined with methotrexate, the use of TNFR p75-Fc resulted in a ignificant reduction in disease activity using a lower-dose of methotrexate. Eighty-nine rheumatoid arthritis patients were treated for 24 weeks with a stable dose of methotrexate and randomized to receive placebo or TNFR p75-Fc; 71 per cent of the patients receiving TNFR p75-Fc plus methotrexate but only 27 per cent of the placebo group plus methotrexate showed a reduction in the ACR 20 criteria. TNFR p75-Fc has also been used to treat patients with juvenile rheumatoid arthritis and Still's disease.

Treating patients with Crohn's disease with anti-TNFa

Animal and clinical studies suggest a role for TNF in the pathogenesis of inflammatory bowel disease, particularly Crohn's disease. During a12-week multicentre, double-blind, placebo-controlled trial of a single infusion of anti-TNFa monoclonal antibody treatment in patients with moderate-to-severe Crohn's disease, 64 per cent of those given the antibody had a clinical response, as compared to 17 per cent of patients in the placebo group. Thirty-three per cent of the patients given the antibody went into remission. After 12 weeks, 41 per cent of the antibody-treated patients exhibited a clinical response as compared with 12 per cent of the patients in the placebo group. On the basis of this and other trials, the use of anti-TNFa monoclonal antibody to treat Crohn's disease was approved. In another study, 94 patients with enterocutaneous fistulas of draining abdominal or perianal fistulas of at least 3 months' duration were randomly assigned to receive placebo or anti-TNFa antibody; 38 per cent of the patients who received the antibody had closure of their fistulas compared to 13 per cent of the patients in the placebo group.

Neutralizing TNF in the treatment of congestive heart failure

Initial studies measuring biologically active TNF in the circulation of patients with severe (New York Heart Association class III and IV) congestive heart failure showed that the levels of TNF correlated with the severity of cachexia and exercise tolerance. Therefore, treating patients with severe heart failure with strategies to block TNF activity were tested. To date, 18 (class III) heart failure patients have been treated with p75-Fc, given as a single intravenous infusion, in a randomized, double-blind trial. A significant overall increase in quality-of-life scores, 6-min walk distance, and ejection fraction was observed in the cohort that receiving p75-Fc. There was no significant change in these parameters in the placebo group. It should be noted that in these studies, the patients were already receiving optimal treatment for heart failure with ACE inhibitors and b-blockers.

The biological basis for TNF and IL-1 in heart failure is well-established. Using strips of human atrial heart tissue *ex vivo*, the presence of concentrations of TNFa or IL-1b as low a few pg/ml results in depression of contractility. Moreover, the effect of these two cytokines to depress myocardial function is highly synergistic.

Blocking IL-1 and TNF in patients in septic shock

The great promise of anticytokine therapy in human disease was to reduce the mortality of sepsis and particularly septic shock. Despite the impact of intensive care units and optimal physiological support, the mortality in septic shock remain high at 35 to 40 per cent. A great number of animal models of septic shock provided overwhelming data that blocking IL-1 or TNF activity would reduce mortality in these patients. Over 10 000 patients have been studied in carefully designed trials to examine IL-1Ra, neutralizing monoclonal antibodies to TNFa, soluble TNF receptor p55, and soluble p75 TNF receptor, the same agents described above as showing efficacy in the treatment of rheumatoid arthritis, Crohn's disease, and congestive heart failure. There has been no statistically significant improvement in all cause

mortality 28 days after the onset of anticytokine treatment. However, in a meta-analysis of these trials, it was concluded that anticytokine intervention resulted in a small but consistent reduction (2–6 per cent) in all-cause 28-day mortality. In only one trial, mortality increased as a result of the anticytokine therapy. Some conclusions can be made from these trials since they offer insights into the effect of the same anticytokine agents as in patients with rheumatoid arthritis. First, despite being infected, the vast number of patients did not worsen or become vulnerable to more infection. There was one exception, the p75-Fc which is effective in treating rheumatoid arthritis was associated with a dose-dependent increase in 28 day all cause mortality. In each study, there was a subgroup with clear benefit but the overall group did not benefit significantly. The heterogeneity of the patients probably prevented the detection of a statistically significant improvement. Fortunately, these anticytokines are now receiving considerable attention for use in local inflammatory diseases.

4.5 Ion channels and disease

Frances M. Ashcroft

Ion channels are membrane proteins that act as gated pathways for the movement of ions across cell membranes. They are found in both surface and intracellular membranes, and play essential roles in the physiology of all cell types. An ever-increasing number of human diseases are found to be caused by defects in ion channel function. Ion channel diseases may arise in a number of different ways:

- From mutations in the coding region of the gene, or its control elements, leading to the gain, or loss, of channel function (Table 1). Diseases that result from ion-channel mutations are often known as 'channelopathies'. As with all single-gene disorders, their frequency in the general population is usually very low. Many channelopathies are genetically heterogeneous and the same clinical phenotype may be caused by mutations in different genes, as is the case for Long-QT syndrome. Conversely, mutations in the same gene may produce different phenotypes. For example, gain-of-function mutations in the epithelial Na^+ channel produce Liddle's syndrome, whereas loss-of-function mutations cause psuedohypoaldosteronism type-1. Disease severity may also vary with different mutations in the same gene.
- From defective regulation of channel activity by intracellular or extracellular ligands, or by channel modulators, due to mutations in the genes encoding the regulatory molecules themselves, or defects in the pathways leading to their production. For instance, glucokinase mutations cause one type of maturity-onset diabetes of the young (**MODY2**), by impairing the metabolic regulation of ATP-sensitive K^+-channels in pancreatic b-cells.
- From autoantibodies to ion channel proteins, which may either downregulate or enhance channel function (see Table 2). These diseases are discussed elsewhere.
- From ion channels that act as lethal agents. These are secreted by cells and insert into the membrane of the target cell to form large non-selective pores that cause cell lysis and death. Examples include bacterial toxins such as staphylococcal a-toxin and the amoebopore of *Entamoeba histolytica.* The membrane-attack complex of complement, perforin, and the defensins also act in this way.

To understand how ion channel defects give rise to disease, it is helpful to understand how these proteins work. The next section therefore considers what is known of ion channel structure, explains the properties of the single ion channel and shows how single-channel currents give rise to action potentials and synaptic potentials.

Properties of ion channels

Ion channel structure

Some ion channels consist of a single subunit, as in the case of the Ca^{2+}-release channel of the sarcoplasmic reticulum. In other cases, the channel pore is formed from a single (a) subunit but associated regulatory subunits may modify the ion channel properties, as in the case of voltage-gated Na^+ and Ca^{2+} channels. Yet other ion channels are multimeric and several subunits are involved in pore formation—the nicotinic acetylcholine receptor comprises five subunits (2a, b, g, †), while the voltage-gated K^+ channels are composed of four subunits (which are sometimes, but not invariably, identical). Mutations in both pore-forming and regulatory subunits can cause disease.

The multimeric nature of an ion channel may influence whether or not a channelopathy is inherited in a dominant or recessive fashion. Individuals who are heterozygous for voltage-gated K^+ channel mutations will express both mutant and wild-type subunits in the same cell. If the mutant subunits co-assemble with wild-type subunits to form heteroligomeric channels that are non-functional, the resulting K^+ current will be much smaller than if heteromultimerization does not occur. This is known as the 'dominant negative' effect, and may give rise to a disease that is dominantly inherited.

Single-channel properties

An ion channel can either be open or closed. When it is open, permeant ions are able to move through the channel pore. The current flowing through the open pore is known as the single-channel current. Its magnitude is determined by the ion concentrations on either side of the membrane (the chemical gradient), by the membrane potential (the electrical gradient), and by the ease with which the ion can move thorough the channel pore (its permeability). At the equilibrium potential of an ion, the electrical and chemical gradients are equal in magnitude but opposite in direction, and thus there is no net ion flux. The single-channel conductance g is a measure of the permeability of the ion and is given by the single-channel current (i) divided by the membrane potential ($g = i/V$).

Ion channels are often highly selective in the ions they conduct. K^+ channels, for example, are about 100 times more permeable to K^+ than Na^+ ions, while Na^+ channels conduct Na^+ ions but discriminate against K^+ ions. Ion selectivity takes place within a narrow region of the pore known as the selectivity filter. The basis of ion selectivity is only just beginning to be understood, but it is clear that while some ions are excluded on the basis of their size or their charge, hydrophobic interactions and the energy required to remove the waters of hydration are also important.

The fraction of time the channel spends in the open state is known as the open probability. Some channels open and close at random, but gating is regulated in other channels. In voltage-gated channels, the open probability is determined by the membrane potential, whereas in ligand-gated channels it is regulated by the binding of extracellular or intracellular ligands. Gating may also be subject to modulation, a process in which channel opening or closing is modified, usually by one of a number cytosolic substances (for example, by Ca^{2+} binding, phosphorylation, etc.). Gating is believed to involve conformational changes in the channel structure that result in the opening or closing of the pore.

At the resting potential of the cell, most voltage-gated channels are closed. In response to a membrane depolarization, the open probability of the channel is increased. This voltage-dependent activation may be followed by a further conformational transition (inactivation) to an inactivated state in which the channel no longer conducts ions. Recovery from inactivation occurs after a variable period following repolarization to the resting potential. Although most voltage-gated ion channels are opened by depolarization, a few types of voltage-gated channel are activated by hyperpolarization. Ligand-gated channels are opened (or more rarely closed) by binding of an appropriate ligand to a specific site on the channel protein, which induces a conformational change that allosterically opens the ion pore. The channel may open and close several times while the ligand remains bound to its receptor, but this intrinsic gating ceases on ligand dissociation.

There are numerous different types of channel. For example, even among the inwardly rectifying K^+ channels, there are seven subfamilies, most of which have several members. In general, ion channels are named after their gating and/or selectivity properties.

Single-channel currents summate to produce macroscopic currents

The cell membrane contains many hundreds of ion channels. The macroscopic current (I) flowing through all ion channels of the same type is determined by the

product of the number of channels in the membrane (*N*), the channel open probability (*P*), and the single-channel current (*i*); in other words *I = NPi.* Disease-causing mutations may affect any or all of these parameters and thereby influence the macroscopic current.

Cell membranes also contain several different types of channel. The total current that flows across the cell membrane (the membrane current) represents the sum of the ion fluxes through all the different kinds of ion channel open in the membrane. If it is sufficiently large, the membrane current may cause a change in membrane potential. The size of this voltage change is given by Ohm's law (*V = IR*) and is therefore influenced by both the current amplitude (*I*) and by the membrane resistance (*R*) (which in turn reflects the number of open channels). A change in the membrane potential to a more positive value is known as 'depolarization'; 'hyperpolarization' is a change to more negative potentials. The resting potential of most cells lies between –60 to –100 mV.

Action potentials

In excitable cells, a depolarizing stimulus may elicit an action potential. In nerve axons and skeletal muscle fibres, the action potential results from the initial activation of voltage-gated Na^+ channels followed shortly afterwards by activation of voltage-gated K^+ channels. Because Na^+ channels open rapidly on depolarization, there is an initial inward Na^+ current. If this is greater than the outward current flowing through (voltage-independent) K^+ channels which are open at the resting potential, it will produce a further depolarization. This activates more Na^+ channels and depolarizes the membrane even more. In this way, a regenerative increase in membrane potential (an action potential) is produced. The membrane is returned to its resting level by inactivation of the Na^+ channels (which reduces the inward current) and the opening of K^+ channels (which produces an outward, hyperpolarizing current).

The potential at which the inward Na^+ current exactly balances the outward resting K^+ current through resting K^+ channels is known as the threshold potential. It is a critical potential: any increase in the Na^+ current will elicit an action potential, while any reduction in the inward current (or increase in the outward current) will prevent action-potential generation. Ion channel mutations may increase nerve or muscle excitability either by enhancing the inward current (as in hyperkalaemic periodic paralysis), or by reducing the outward current (as in benign familial neonatal convulsions). This will produce a larger depolarization, so that the threshold potential is reached more easily and a subsequent action potential is initiated. Other mutations produce a depolarizing block of action-potential activity. This results from a maintained membrane depolarization of sufficient amplitude to inactivate the voltage-dependent Na^+ channels.

In some cells, additional types of ion channel contribute to the action potential—the ventricular action potential is mediated by voltage-dependent Na^+, Ca^{2+}, and at least four kinds of K^+ channel; several different kinds of K^+ channel contribute to the repolarization of action potentials in mammalian neurones; and chloride channels play an important role in the electrical activity of skeletal muscle. The functional importance of these different ion channels is exemplified by the fact that mutations in the genes which encode them produce a range of nerve and muscle diseases.

Synaptic potentials

When a nerve impulse arrives in the presynaptic terminal it opens voltage-gated Ca^{2+} channels, producing a rise in the intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) that triggers the exocytosis of synaptic vesicles. The amount of transmitter released varies with $[Ca^{2+}]_i$ and thus with the magnitude of the presynaptic Ca^{2+} current. In turn, this is influenced by the duration of the membrane depolarization and thus by the amplitude of the voltage-gated K^+ current that underlies membrane repolarization. A reduction in the presynaptic K^+ current therefore leads to excess transmitter release and postsynaptic hyperexcitability, as in episodic ataxia type 1 and acquired neuromyotonia. Conversely, a reduction in the presynaptic Ca^{2+} current is associated with reduced transmitter release, as occurs in the Lambert–Eaton myasthenic syndrome when the density of presynaptic Ca^{2+} channels is decreased by receptor internalization induced by the binding of autoantibodies.

Once released, the transmitter diffuses across the synaptic cleft and binds to receptors in the postsynaptic membrane. At the neuromuscular junction, for example, acetylcholine (**ACh**) binds to the nicotinic acetylcholine receptor (**AChR**), and opens an intrinsic ion channel. The resulting synaptic current produces a depolarization of the postsynaptic membrane (the endplate potential) which, if it is sufficiently large, triggers an action potential in the muscle fibre. A reduction in AChR density, as in myasthenia gravis, decreases effective transmission and leads to muscle weakness. Gain-of-function mutations in AChR may also induce myasthenia, by causing prolonged depolarization of the postsynaptic membrane and thereby Na^+ channel inactivation. This depolarizing block is the basis of the slow-channel syndromes. Mutations in the voltage-gated Na^+ channel of skeletal muscle may cause paralysis, or myotonia.

In skeletal muscle, the action potential is conducted into the interior of the fibre via invaginations of the surface membrane known as the transverse tubules (**T-tubules**). Depolarization of the T-tubule membrane stimulates the opening of Ca^{2+}-release channels (**RyR**) in the membrane of the sarcoplasmic reticulum (**SR**), the intracellular Ca^{2+} store. The T-tubule and SR membranes are not directly connected and the precise mechanism by which they interact is not fully understood. However, there is evidence that the a_1-subunit of the voltage-gated Ca^{2+} channel in the T-tubule membrane acts as the voltage sensor for the Ca^{2+}-release channels in the SR membrane. Mutations in the Ca^{2+}-release channel of skeletal muscles cause malignant hyperthermia and central core disease.

The channelopathies

This section provides brief descriptions of a range of channelopathies. Additional details may be found elsewhere in the *Oxford textbook of medicine* or in the books and Websites referenced.

Neuronal channelopathies

Generalized epilepsy with febrile seizures

Generalized epilepsy with febrile seizures (**GEFS**) has been linked to a mutation in the gene (*SCN1B*) that encodes the b_1-subunit of the voltage-gated Na^+ channel. Affected individuals exhibit febrile seizures in childhood and afebrile generalized epilepsy in later life. The presence of the b-subunit accelerates both the rate of inactivation, and the rate of recovery from inactivation, of the voltage-gated Na^+ channel. This modulatory effect is abolished if the b_1-subunit carries the GEFS mutation. It is predicted to cause a persistent inward Na^+ current that leads to neuronal hyperexcitability and seizures.

Benign familial neonatal convulsions

Benign familial neonatal convulsions (**BFNC**) is characterized by neonatal convulsions within the first 3 days after birth that show spontaneous remission by the third month of life. There is an increased risk of epilepsy in later life in 10 to 15 per cent of individuals. Mutations in the voltage-gated K^+ channel genes *KCNQ2* and *KCNQ3* are associated with BFNC.

KCNQ2 and KCNQ3 associate in a heteromeric complex to form the M-channel. This channel plays a critical role in determining the electrical excitability of many neurones. It is slowly activated when the membrane is depolarized to around the threshold level for action potential firing, thereby hyperpolarizing the membrane back towards its resting level. This reduces neuronal excitability by limiting the spiking frequency and decreasing the responsiveness of the neurone to synaptic inputs. All BNFC mutations studied to date result in reduced expression of the mutant protein. This may be expected to lead to neuronal hyperexcitability, accounting for the epileptic seizures. Because the M-channel is a heteromer of KCNQ2 or KCNQ3, mutations in either gene will disrupt channel function and cause BNFC.

Episodic ataxia type-1

Episodic ataxia type 1 (familial periodic cerebellar ataxia with myokymia) is an autosomal dominant disorder that causes ataxia accompanied by myokymia, nausea, vertigo, and headache. It results from mutations in the voltage-gated K^+ channel $K_V1.1$, which is expressed in the synaptic terminals and dendrites of many brain neurones. These mutations either prevent the formation of functional channels or result in a reduced K^+ current. This is expected to prolong the neuronal action potential, inducing repetitive firing and excessive and unregulated transmitter release, and thereby produce the clinical symptoms of ataxia and myokymia.

Familial hemiplegic migraine, episodic ataxia type-2, and spinocerebellar ataxia type-6

There are three human diseases with different phenotypes that are associated with mutations in the same Ca^{2+}-channel gene, *CACNL1A4*. These are familial hemiplegic migraine (**FHM**), episodic ataxia type-2 (**EA-2**), and spinocerebellar ataxia type-6 (**SCA-6**). FHM is associated with missense mutations, EA-2 is caused by truncation of the protein within the third repeat, and SCA-6 is produced by expansion of a polyglutamine repeat in the C-terminal coding region of the protein. All three diseases result in progressive cerebellar atrophy, but they differ in the extent and rate of progression of neuronal degeneration, with SCA-6 showing the greatest, and FHM the least, atrophy. Migraine-like symptoms also occur in all three diseases, and are most severe in patients with FHM. EA-2 and SCA-6 are also characterized by ataxia and nystagmus. It remains unclear how the different mutations in *CACNL1A4* give rise to the different phenotypes.

Startle disease (hyperekplexia)

Glycine is the major inhibitory transmitter in the brainstem and spinal cord. It binds to a ligand-gated Cl^- channel, producing an increase in Cl^- permeability that reduces the membrane depolarization and neuronal firing induced by excitatory neurotransmitters. The glycine receptor is a pentamer of three a-subunits, which contain the glycine-binding site, and two b-subunits. In humans, two types of the a-subunit have been identified. Mutations in the gene encoding the a_1-subunit of the glycine receptor give rise to startle disease (hyperekplexia). This is an autosomal dominant, neurological disorder characterized by muscle spasm in response to an unexpected stimulus. It manifests as facial grimacing, hunching of the shoulders, clenching of the fists, and exaggerated jerks of the limbs. Startle disease mutations produce a dramatic decrease in glycine-activated currents. Because glycinergic interneurones are important for normal spinal cord reflexes, muscle tone, and the pattern of motor neurone firing during movement, this leads to excessive and uncontrolled movements.

Charcot-Marie-Tooth disease

Charcot-Marie-Tooth disease type 1 (CMT1) causes progressive degeneration and demyelination of the peripheral nerves. It is genetically heterogeneous, but the X-linked form of the disease results from mutations in the gap junction channel connexin 32 (Cx32). It shows incomplete dominant inheritance, with heterozygous females being affected less severely than hemizygous males. The phenotype may vary from mild, in which the patient has a normal gait, to a severe form which may necessitate the use of a walking stick or wheelchair.

Over a hundred mutations in *CX32* have been identified. These fall into two main groups–those in which the protein never reaches the plasma membrane, and those where the protein reaches the membrane but forms channels with altered functional properties. The former give rise to a severe phenotype, whereas the latter may be associated with either mild or severe phenotypes, according to whether they partially or completely disrupt channel function.

The Cx32 protein is primarily expressed in the Schwann cells of peripheral myelinated nerves, at the nodes of Ranvier and at Schmidt–Lanterman incisures. In these regions, the myelin is not complete and there is a thin layer of cytoplasm between each of the enveloping turns of the Schwann cell. This suggests that Cx32 may serve as short-cut pathway for nutrients and other substances moving to the innermost layers of the Schwann cell, and perhaps also to the axon itself. This might explain why loss of Cx32 function causes axonal degeneration and demyelination.

Cardiac muscle channelopathies

Long-QT syndrome is a congenital cardiac disorder associated with an abrupt loss of consciousness and sudden death from ventricular arrhythmia in children and young adults. It is characterized by an abnormally long QT interval in the electrocardiogram, which reflects the delayed repolarization of the ventricular action potential. The duration of the cardiac action potential is determined by the balance between the inward and outward currents flowing during the plateau phase. Prolongation of the action potential can therefore be caused by a persistent inward current or by a reduction in outward K^+ currents.

Some six different genetic loci for Long-QT syndrome have been mapped, five of which have been identified and shown to encode cardiac ion channels. The I_{Ks} channel is a complex of two different proteins, KCNQ1 and minK, and mutations in these genes cause LQT1. Likewise, I_{Kr} is a complex of HERG and Mirp1, and is associated with LQT2. Mutations in these four genes either abolish, or markedly decrease, the repolarizing K^+ currents I_{Ks} and I_{Kr}, and are therefore expected to prolong the cardiac action potential and increase the QT interval. Mutations in the cardiac muscle sodium-channel gene (*SCN5A*) cause LQT3. These mutations affect Na^+-channel inactivation, producing a sustained inward current that results in an increased action potential duration. The larger the component of non-inactivating current, the more severe the phenotype.

In many cases, LQT syndrome is not inherited but acquired. For example, drugs that block I_{Kr} or I_{Ks} currents prolong the cardiac action potential and induce the Long-QT syndrome. Among these are class III antiarrhythmic agents such as sotalol, dofetilide, and quinidine, which selectively block I_{Kr}, and the antihistamine H_1-receptor antagonists terfenidine and astemizole, which block HERG. In most people, terfenidine does not produce cardiac problems as it is rapidly broken down in the liver and its metabolite, terfenidine carboxylate, does not block I_{Kr}. However, if the activity of the P-450 enzymes that break down terfenidine is impaired (due to liver disease or drugs such as ketoconazole and the macrolide antibiotics), there is a risk of *torsade de pointes.*

Skeletal muscle channelopathies

Myasthenia and slow-channel syndromes

Myasthenia gravis is produced by autoantibodies directed against the nicotinic acetylcholine receptor (**nAChR**), as discussed elsewhere. These antibodies lead to receptor internalization and thus to a smaller endplate potential that fails to reach the threshold for action-potential initiation.

Slow-channel syndrome (**SCS**) is a congenital myasthenia that results from mutations in the muscle nAChR channel. These mutations have been found in all four types of adult nAChR subunits (a, b, †, e) and result in protracted channel activation by acetylcholine. The increase in channel open probability produces a prolonged synaptic current and endplate potential. Consequently, temporal summation of endplate potentials can occur at physiological rates of stimulation, leading to prolonged depolarization of the muscle membrane, inactivation of voltage-gated sodium channels, and failure of muscle excitability. This explains why patients with SCS experience muscle weakness and rapid fatigue. A similar 'depolarization block' is observed with acetylcholinesterase inhibitors or with AChR agonists like suxamethonium.

The prolonged endplate potential also causes enhanced Ca^{2+} entry, which may account for the progressive destruction of the postsynaptic neuromuscular junction observed in SCS—loss of junctional nAChRs and destruction of the junctional folds has been reported. Abnormal channel openings in the absence of acetylcholine may also contribute to the 'endplate myopathy'. This may explain why the SCS mutations that cause spontaneous openings are often associated with a more severe phenotype.

In contrast to myasthenic gravis, the symptoms of SCS are exacerbated by acetylcholinesterase inhibitors and patients do not respond to immunotherapies.

The periodic paralyses

Hyperkalaemic periodic paralysis, paramyotonia congenita, and the potassium-aggravated myotonias result from mutations in the a-subunit of the human skeletal muscle Na^+ channel. All are inherited as dominant traits and usually present within the first or second decade of life.

Hyperkalaemic periodic paralysis (**HyperPP**) may occur spontaneously, but attacks are commonly precipitated by exercise, stress, fasting, or eating K^+-rich foods. Paralysis is often preceded by signs of muscle hyperexcitability such as myotonia or fasciculations. The duration is variable (minutes to hours) and may be so severe that the patient is unable to remain standing. It is associated with a raised blood K^+ concentration (5–7 mM). Paramyotonia congenita is precipitated by cold and (in contrast to most classical myotonias) aggravated by exercise. In some patients, the myotonia may be followed by prolonged paralysis. Potassium-aggravated myotonia is characterized by myotonia without muscle weakness or paralysis. It can be distinguished from classical myotonias by the fact that the myotonia is exacerbated by a mild elevation of the plasma K^+ concentration.

All three types of disorder result from mutations in the a-subunit of the skeletal muscle Na^+ channel (*SCN4A*), which disrupt Na+-channel inactivation. As a consequence, they produce a persistent inward current that causes a tonic depolarization of the muscle membrane (the larger the current, the greater the

depolarization). The magnitude of the depolarization determines whether myotonia or paralysis occurs. A small depolarization causes membrane hyperexcitability by lowering the action-potential threshold, whereas a large depolarization can lead to Na^+-channel inactivation and thereby paralysis. It is still not understood how cold or an elevated plasma potassium level precipitate attacks.

Myotonia

Loss-of-function mutations in the gene (*CLCN1*) encoding the skeletal muscle Cl^- channel produce two forms of myotonia—the autosomal dominant myotonia congenita (Thomsen's disease) and the autosomal recessive generalized myotonia (Becker's disease). Clinical descriptions of the disease can be found elsewhere.

In normal skeletal muscle, the Cl– conductance accounts for between 70 and 80 per cent of the resting membrane conductance. Mutations in *CLCN1* that result in a loss of functional Cl^- channels will therefore produce a marked increase in the input resistance of the muscle fibre. Consequently, muscle excitability will be enhanced (because a smaller Na^+ current will be sufficient to trigger an action potential). The elevated input resistance also produces a reduced rate of action potential repolarization, which enhances muscle excitability. An important role of the muscle Cl^- conductance is to counteract the depolarizing effect of K^+ accumulation in the transverse tubular (T-) system that accompanies muscle activity. During an action potential, K^+ ions leave the muscle fibre. In normal muscle, the amount of K^+ entering the T-system during a single action potential is not sufficient to alter the membrane potential, because the tubular Cl^- conductance is very high. But in myotonic muscle, the Cl^- conductance is very low and a small rise in tubular K^+ produces a significant depolarization following an action potential. If several action potentials occur in rapid succession, summation of the after-depolarizations may be sufficient to trigger spontaneous action potentials and thereby myotonia.

Mutations in *CLCN1* give rise to both recessive and dominant forms of myotonia. This may be because the muscle Cl^- channel comprises more than one subunit. In heterozygotes, mutant subunits might combine with wild-type subunits to form heteromeric channels. The extent to which the mutant subunit reduced the function of the heteromeric channel would thus dictate the severity of myotonia. Total inactivation of the channel by a single mutant subunit (the dominant-negative effect) would produce dominant myotonia, whereas recessive myotonia might occur if the heteromeric channel was unaffected by the mutant subunit.

Malignant hypothermia and central core disease

Mutations in the ligand-gated Ca^{2+} channel of skeletal muscle cause malignant hyperthermia and central core disease. This channel mediates Ca^{2+} release from the sarcoplasmic reticulum (SR), allowing Ca^{2+} to enter the cytoplasm and activate the contractile proteins. It is also known as the ryanodine receptor (or RYR1) because it binds the alkaloid ryanodine with high affinity.

Malignant hyperthermia (**MH**) is one of the main causes of death due to anaesthesia. In susceptible individuals, common inhalation anaesthetics or depolarizing muscle relaxants trigger accelerated skeletal muscle metabolism, muscle contractures, hyperkalaemia, arrhythmias, respiratory and metabolic acidosis, and a rapid rise in body temperature (as much as 1°C every 5 min). It is thought that this is due to stimulation of Ca^{2+} release from the SR, which produces a sustained increase in intracellular Ca^{2+}. This activates both metabolic and contractile activity; the former results in respiratory and metabolic acidosis and the latter produces the elevation in body temperature. The syndrome can be treated with dantrolene sodium, which blocks Ca^{2+} release from the SR. Malignant hyperthermia is genetically heterogeneous and is not linked to *RYR1* in all families.

Central core disease (**CCD**) is an autosomal dominant, non-progressive myopathy that presents in infancy as proximal muscle weakness and hypertonia. Diagnosis is by muscle biopsy, which reveals that regions of type 1 skeletal muscle fibres (known as 'central cores') are depleted of mitochondria and oxidative enzymes. The disease is often associated with a predisposition to malignant hyperthermia and results from mutations in *RYR1*. Thus CCD and MH are allelic disorders of the same gene. It is not clear how the different phenotypes arise, especially because the same mutation can give rise to MH in some individuals and CCD in others. Because all CCD patients are MH-susceptible, it is possible that additional factors are necessary for the development of central core disease.

Kidney channelopathies

Liddle's syndrome

Liddle's syndrome is a congenital form of salt-sensitive hypertension characterized by a very high rate of renal Na^+ uptake despite low levels of aldosterone, secondary hypokalaemia, and metabolic acidosis. It is caused by gain-of-function mutations in the epithelial sodium channel (**ENaC**). This channel consists of three subunits (a, b, g), and disease-causing mutations have been identified in both the b- and g-subunits. All are located in the C-terminus of the protein and result in constitutive channel hyperactivity.

The increase in ENaC current causes enhanced Na^+ uptake. This is accompanied by increased water uptake, thereby producing a chronic increase in blood volume and ultimately hypertension. An increased Na^+ uptake also has secondary consequences: in particular, K^+ secretion into the tubule lumen is stimulated because the apical membrane depolar*ize*s and so increases the driving force for K^+ efflux. In addition, more K^+ enters the cell due to the enhanced activity of the Na+/K+-ATPase. This explains why excess ENaC activity in Liddle's syndrome is associated with hypokalaemia and, conversely, why reduced ENaC activity (as in pseudohypoaldosteronism type 1 (**PHA-1**) disease) is accompanied by hyperkalaemia.

Pseudohypoaldosteronism type 1

While gain-of-function mutations in ENaC cause enhanced Na^+ uptake and hypertension, loss-of-function mutations produce salt-wasting, hypotension, and dehydration in newborns and infants. Pseudohypoaldosteronism type 1 (PHA-1) results from loss-of-function mutations in the a, b, or g ENaC subunits. The marked reduction in ENaC activity leads to decreased Na^+ absorption by the kidney. This stimulates renin and aldosterone secretion, but salt reabsorption cannot be augmented as ENaC is not functional. The high Na^+ concentration in the tubular fluid causes water to be osmotically retained in the tubule lumen, leading to diuresis and dehydration.

Bartter's syndrome

Bartter's syndrome is characterized by severe salt-wasting, with elevated plasma renin and aldosterone levels. The syndrome is both phenotypically and genetically heterogeneous, and several subtypes have been distinguished. Antenatal Bartter's syndrome or hyperprostaglandin-E syndrome presents *in utero* with a marked fetal polyuria. Newborns fail to thrive and show severe salt-wasting, moderate hypokalaemia, and metabolic acidosis, and elevated urinary excretion of prostaglandins. There is also marked calcinuria, osteopenia, and nephrocalcinosis.

Antenatal Bartter's syndrome results from loss-of-function mutations in the genes encoding proteins involved in salt transport in the cells of the distal kidney tubules. These include the inwardly rectifying K^+ channel Kir1.1 (*KCNJ1*; Bartter's syndrome type II), the NaK2Cl cotransporter (*SCL12A1*, Bartter's syndrome type I), and the voltage-gated Cl^- channel CLC-Kb (*CLCNKB*, Bartter's syndrome type III). These variants may be distinguished clinically, because hypokalaemia is less pronounced (3.0–3.5 mM) in patients with mutations in *KCNJ1*, and the course of the disease is less severe. And in contrast to patients with Bartter's syndrome types I and II, patients with mutations in *CLCNKB* do not suffer from nephrocalcinosis, despite elevation of the urinary calcium concentration.

Disease-causing mutations in Kir1.1 or CLC-Kb impair NaCl uptake in the distal tubules by impairing channel function or decreasing protein expression. This leads to a high salt concentration in the urine and thus to an osmotic diuresis, which accounts for the salt-wasting, polyuria, and low plasma volume characteristic of Bartter's syndrome. A similar phenotype is observed with loop diuretics, such as frusemide (furosemide), which inhibit the NaK2Cl cotransporter.

Nephrolithiasis

Mutations in the voltage-gated, renal chloride channel gene, *CLCN5*, cause Dent's disease, a congenital form of congenital nephrolithiasis. It is usually associated with proteinuria. Different mutations may produce phenotypically distinct syndromes (Table 1), but there is as yet no clear explanation for how this occurs. The mechanism by which mutations in a Cl^- channel impair calcium handling by the kidney is also not fully resolved.

Nephrogenic diabetes insipidus

Familial nephrogenic diabetes insipidus (**NDI**) results from impaired water uptake by the kidney tubules. The diseases manifests within the first few weeks of life and is characterized by the excretion of large amounts of hypotonic urine and excessive thirst. In early infancy these may not be noticed and the disease is often recognized by signs of dehydration, such as poor feeding, poor weight gain, irritability, and fever. In most cases, familial NDI is caused by a mutation in the vasopressin receptor, but in some families it results from loss-of-function mutations in the aquaporin 2 (*AQP2*) gene. AQP2 is expressed exclusively in the collecting duct of the kidney and plays a fundamental role in the production of a concentrated urine because it acts as a water channel. Vasopressin stimulates water uptake by causing the insertion of AQP2 channels into the apical membranes of the principal cells of the collecting duct, thereby enhancing water uptake. Loss-of-function mutations in *AQP2* result in a dramatic reduction in water channels, thereby accounting for the polyuria.

Other channelopathies

Cystic fibrosis

Of all the channelopathies, the best known is probably cystic fibrosis (**CF**). Its clinical features are described in Chapter 17.10. Cystic fibrosis results from mutations in an epithelial chloride channel known as the cystic fibrosis transmembrane conductance regulator (**CFTR**). Although its primary sequence is highly homologous to that of the ATP-binding cassette transporters, it is now well established that CFTR functions as a chloride channel. It also regulates the activity of the outwardly rectifying Cl^- channel and the epithelial Na^+ channel.

All disease-causing CF mutations result in the complete absence or a marked reduction in CFTR function. Those which result in the total loss of channel activity, either because the protein does not reach the plasma membrane or because it is present but completely inactive, give rise to a severe form of the disease. Mutations that result in a reduced Cl^- current are associated with a milder form of the disease. Compound heterozygotes carrying one allele with a severe mutation and another with a mild mutation will have significant residual channel activity and therefore a mild form of the disease.

While a large number of mutations (more than 450) have been identified in CFTR, it is still far from certain how the loss of Cl–-channel function gives rise to the clinical features of the disease, especially, in the lungs.

Congenital hyperinsulinaemia

Familial congenital hyperinsulinaemia (**CHI**) is characterized by an unregulated insulin secretion and profound hypoglycaemia that presents at birth or within the first year of life. Some patients respond to treatment with diazoxide, but in others the most effective treatment is resection of the pancreas (more than 90 per cent is usual). Many patients develop diabetes in later life.

CHI results from mutations in the genes encoding the pancreatic b-cell ATP-sensitive K^+ (K_{ATP}) channel. This channel plays a key role in glucose-stimulated insulin secretion. When the plasma glucose level is low (less than 3 mM), the channel is open and keeps the b-cell membrane potential at a hyperpolarized level. When plasma glucose levels rise, increasing glucose uptake and metabolism by the b-cell, the K_{ATP} channels close. This produces a membrane depolarization that activates voltage-gated Ca^{2+} channels, increases Ca^{2+} influx, and so stimulates insulin release. Two classes of therapeutic drugs modulate insulin secretion by interacting with K_{ATP} channels. Sulphonylureas inhibit channel activity and are used to enhance insulin secretion in patients with type 2 diabetes mellitus, whereas K-channel openers (for example, diazoxide) activate K_{ATP} channels, hyperpolarizing the b-cell and preventing insulin release.

The K_{ATP} channel consists of two types of subunit: a pore-forming subunit Kir6.2, and a regulatory subunit SUR1. Mutations in either subunit can cause CHI, but those in SUR1 are more common. CHI mutations result in the loss of K_{ATP} channel activity, even at low blood glucose levels. This results in a continuous depolarization of the b-cell, that leads to persistent Ca^{2+} influx and thus constitutive insulin secretion.

Non-syndromic deafness

About 70 per cent of all cases of prelingual deafness are non-syndromic. The disorder shows marked genetic heterogeneity, but in some families it results from loss-of-function mutations in the gene (*GJB2*) encoding the gap junction channel connexin 26. Both recessive and dominant mutations have been described. Connexin 26 (Cx26) is expressed in the cochlea, but the mechanism by which the lack of functional Cx26 leads to hearing loss remains obscure. In some individuals, mutations in Cx26 are associated with Vohwinkel's syndrome, a disorder characterized by keratoderma. Many patients also suffer from deafness.

4.6 Apoptosis in health and disease

Andrew H. Wyllie and Mark J. Arends

Introduction

Apoptosis is the process by which single cells die in the midst of living tissues. It is responsible for most—perhaps all—of the cell-death events that occur during the formation of the early embryo and the sculpting and moulding of organs. It continues to play a critical role in the maintenance of cell numbers in those tissues in which cell turnover persists into adult life, such as the epithelium of the gastrointestinal tract, the bone marrow, and lymphoid system including both B- and T-cell lineages. It is the usual mode of death in the targets of natural killer (**NK**)- and cytotoxic T-cell killing, and in involution and atrophy induced by hormonal and other stimuli. It also appears in the reaction of many tissues to injury, including mild degrees of ischaemia, exposure to ionizing and ultraviolet radiation or treatment with cancer chemotherapeutic drugs. Excessive or too little apoptosis plays a significant part in the pathogenesis of autoimmunity, infectious disease, acquired immunodeficiency syndrome (**AIDS**), stroke, myocardial disease, and cancer. When cancers regress, apoptosis is usually part or all of the mechanism involved.

Structural changes in apoptosis

Apoptosis can be recognized because of its characteristic, stereotyped sequence of structural changes (Fig. 1). The dying cells lose contact with their neighbours. They undergo a rapid loss of volume, often of the order of 50 per cent. There is explosive blebbing from the cell surface, in which multiple cytoplasmic protrusions extend and are immediately withdrawn, and this is followed by fragmentation into a cluster of subcellular bodies (apoptotic bodies) each membrane-bounded and containing a variety of compacted cytoplasmic organelles. The nucleus undergoes similar distortion and fragmentation. Chromatin condenses under the nuclear membrane in granular aggregates with a knob-like, hemilunar or toroidal distribution. Nuclear membranes overlying residual uncondensed chromatin are rich in pores but these are absent adjacent to condensed chromatin, suggesting that redistribution takes place. The nucleolus segregates so that its argyophilic fibrillar centre lies close to the peripheral aggregates of chromatin, whilst the osmophilic particles that are associated with transcription complexes disperse in the central nucleoplasm. Eventually the nuclear membrane disappears and the entire nuclear remnant becomes a mass of condensed granular chromatin.

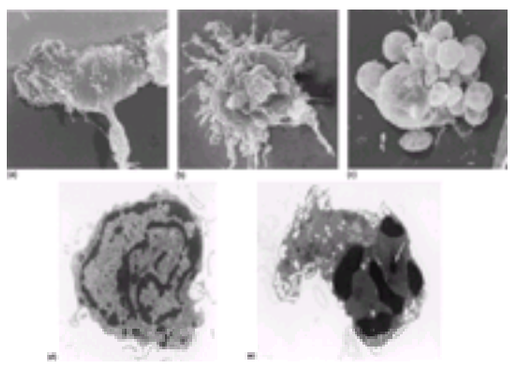

Fig. 1 The structure of apoptosis. (a) Scanning electron micrograph of a normal macrophage shows its surface sprouting many pseudopodia. In (b), the cell has been injured (in this case by oxidized lipid of the type often present in high concentration in atheromatous plaques) and is throwing out and retracting multiple surface blebs. In (c) the whole cell has fragmented into roughly spherical apoptotic bodies. Some of these are cratered by the orifices of the dilated endoplasmic reticulum. (d) Transmission electron micrograph of a thin section. The condensed chromatin (arrowheads), nucleolar remnant (arrow), and highly convoluted surface are clearly visible. The scale bar in μm. (Micrographs by courtesy of Dr Jeremy Skepper and Dr Jing Xia, Cambridge School of Biology Multi-imaging Centre.)

Within the cytoplasm, bundles of microfilaments often appear in a side-to-side configuration. Sometimes free ribosomes pack into semicrystalline arrays. There is dilatation of the endoplasmic reticulum. The cell surface loses any pre-existing microvilli or other indices of polarity. The shrunken cell and the apoptotic bodies into which it fragments tend to become spherical.

Isolated apoptotic cells lose the ability to maintain ionic homeostasis within an hour or so, lose density, swell in volume, and permit the entry of various dyes classically used to mark dead cells (such as Trypan blue and propidium iodide) to which they had been previously impermeable. Within tissues, however, this phase is seldom seen, because the apoptotic cell and its fragments undergo phagocytosis. Often this is undertaken by 'professional' phagocytes—the resident tissue macrophages—but where unusually large numbers of apoptotic cells are generated, other cell types share in ingesting them, including their viable neighbours. Once within the phagosome of the ingesting cell, the apoptotic cell and its fragments rapidly become indistinguishable from the contents of any other large secondary lysosome.

For reasons to be expanded later, the process of apoptotic-cell phagocytosis inhibits the neutrophil-dominated inflammatory reaction that is often seen when macrophages are activated in other circumstances. Cell loss by apoptosis can therefore be effected with little disruption of the tissue concerned. Moreover, apoptosis, once initiated, is completed swiftly. Although the interval from the initial application of a lethal stimulus to the first manifestations of shrinkage and blebbing can vary greatly, phagocytosis may be complete within an hour thereafter. Hence, the evidence for cell loss by apoptosis is transient and often surprisingly scanty relative to the reduction in cell number it effects.

Apoptosis is not the only mode of cell death. Dying cells sometimes show a very different pattern of change, dominated by volume overload and, eventually, plasma membrane breakdown and leakage of intracellular contents into the extracellular space. At first, the nucleus retains its general structure, although the chromatin patterns coarsen. Usually there is an associated acute inflammatory reaction. This pattern of death is frequently found when tissues are overwhelmed by high

concentrations of toxic substances or in severe ischaemic damage, where vascular perfusion has been arrested. Classically, it is called necrosis.

Later, following equilibration of the cytosol with extracellular calcium, and the resultant widespread activation of degradative enzymes such as cathepsins, vestiges of nuclear structure fade away (karyolysis) and only ghost-like cellular outlines remain.

Caspases: effectors of apoptosis

Many of the morphological features of apoptosis are attributable to activation of a family of proteases called 'caspases', because of the presence of the amino acid **c**ysteine in their catalytic site, and their preferential cleavage of peptides immediately C-terminal to **asp**artate residues. There are at least 12 mammalian caspases. All are initially synthesized as relatively inactive proenzymes and undergo proteolysis to generate two fragments of around 10- and 20-kDa molecular weight, together with a fragment of variable length from the original N-terminus (Fig. 2). These 10- and 20-kDa fragments oligomerize in pairs to form a tetramer, which is the active enzyme. Long N-terminal sequences provide the opportunity for regulation through interaction with various binding proteins.

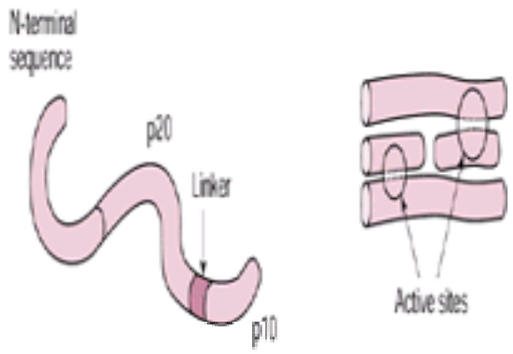

Fig. 2 Schematic diagram of caspase activation. The proenzyme is on the left. Following processing, as shown on the right, the N-terminal sequence and the linker are lost. The active sites of the enzyme each contain elements from both p10 and p20 subunits.

Caspases recognize 4-amino acid motifs that are present in many proteins. Significantly, such caspase target sites are often highly conserved between species, and frequently occur in strategic intramolecular locations, such that caspase cleavage would radically alter the function of the substrate protein. In particular, the cleavage of caspase substrates accounts for many of the structural changes of apoptosis already described. Particularly interesting substrates include proteases, structural proteins of the cytoskeleton, members of various signalling pathways, proteins involved in DNA damage and repair, and molecules of importance in the regulation of the cell cycle. Some caspase substrates appear to be intermediates in self-amplifying positive feedback systems required to complete the death process.

Caspases and proteases

For most caspases, the cleavage sites are themselves typical caspase target sequences, indicating that caspase activation might proceed by cascade-like autocatalysis. There is very good evidence for this, the initiator caspases with long N-terminal sequences (caspases 8–12 and probably 2, 4, and 5) being activated prior to the short effector caspases (3, 6, and 7). Caspases can also activate other proteases. There is, for example, a caspase site in the calpain-inhibitor protein, calpastatin. The inhibitor is rendered inactive by cleavage, so turning on calpain digestion within the dying cell.

Caspases and cytoskeletal proteins

Actin (the major protein of the cytoskeleton), fodrin (which provides the deformable shell underlying the plasma membrane), vimentin (an intermediate filament protein of the cytoskeleton), and the lamins (which form a major component of the nuclear envelope) are all caspase substrates. Caspase cleavage of these large polymeric proteins provides a means whereby they can be rapidly disassembled to the monomers of which they are composed. Gelsolin, a further caspase substrate, is an actin-binding protein that cleaves actin filaments in a calcium-dependent manner. Caspase cleavage of gelsolin separates the calcium-sensitive negative regulatory domain from the protease domain, and hence actin-filament cleavage is effected under normal intracellular calcium concentrations. These cytoskeletal proteolytic events probably contribute to the rounded shape of apoptotic bodies and to the eventual dissolution of the nuclear membrane.

Caspases and signalling proteins

The small G-protein, rho, regulates the mobility of the cell surface. Two rho-dependent kinases, PAK2 and ROCK-1, are rendered constitutively active by caspase cleavage, through excision of their negative regulatory domains. PAK2 activity is a factor in the early retraction of the apoptotic cell from its neighbours or from substrate attachment, whilst ROCK-1 activity is responsible for the enhanced action of a myosin light-chain kinase that drives the phase of cell-membrane blebbing that immediately precedes fragmentation of the apoptotic cell.

FAK^{p125} is the kinase associated with focal adhesion plaques. It is a critical element in the signalling pathway that links cellular awareness of substrate attachment (through integrins) to other cellular functions, including movement, attachment, and new transcription. FAK^{p125} is cleaved and inactivated by caspases, hence isolating the cell from such signals, many of which would normally promote survival. Somewhat similarly, the adenomatous polyposis coli protein (**APC**) and b-catenin are both elements in the wnt-1 signalling pathway, connecting cell-to-cell signals with regulation of cell function. Both are cleaved by caspases, although the precise significance of this is still speculative.

Certain members of the MAP kinase pathway are also targets of caspase cleavage. In particular, MEKK1 (MAPK/ERK kinase kinase; MAPK is mitogen activated protein kinase; ERK is extracellular signal-related kinase; all these enzymes form part of an autocatalytic cascade) a kinase upstream of the p38 stress-associated protein kinase, is activated through the removal, by caspase proteolysis, of an N-terminal inhibitory domain. As p38 itself initiates apoptosis, which would lead in turn to further activation of MEKK1, this could generate a positive feedback loop ensuring that the process of death is executed swiftly and effectively.

DNA damage and repair

ICAD (inhibitor of caspase-activated DNase) is a cytoplasmic chaperone that binds a double-stranded nuclease, **CAD** (caspase-activated DNase). The ICAD–CAD complex is normally cytoplasmic. ICAD, however, is a caspase substrate and once cleaved can no longer retain CAD in the cytoplasm. On translocation to the nucleus, CAD initiates the digestion of DNA, first to large fragments of around 50 kilobase pairs (**kbp**), and eventually—through cleavage of chromatin at internucleosomal sites—to a series of fragments that are multiples of the 180- to 200-bp unit wrapped around each nucleosome. These DNA fragments can be extracted from apoptotic cells and, on electrophoresis, produce the characteristic ladder pattern that historically was one of the distinctive signatures of apoptosis. Intranuclear DNA cleavage is still the basis of a variety of diagnostic methods that depend on the presence of large numbers of free double-stranded DNA ends. A further protein, acinus, also apparently activated by caspases, contributes to the extreme condensation of chromatin seen in the nuclei of apoptotic cells.

DNA-PK, ATM, PARP, and Rad51 are all DNA repair proteins concerned with the recognition and response to double-strand breaks. Significantly, all are cleaved in apoptosis at sites that separate their DNA-binding and catalytic domains, thus ablating their ability to effect non-homologous end-joining. This may be important in preventing re-ligation of the heavily digested DNA of the apoptotic nucleus, so avoiding the generation of large numbers of undesirable recombinant DNA molecules. Cleavage of PARP (poly-ADP-ribose polymerase) may have an additional function. PARP normally responds to DNA breaks by adding poly-ADP ribosyl tails. It is an abundant nuclear protein and has the capacity to exhaust cellular adenine nucleotide stores if presented with the large number of free DNA ends in the apoptotic nucleus. Apoptosis is an energy-requiring process, and it may therefore be advantageous to conserve adenine nucleotides, even during the process of death.

Caspases and cell-cycle proteins

Unexpectedly, several proteins that normally inhibit movement around the cell cycle are targets for caspase cleavage. These include p21 ^{WAF1} and p27^{KIP1}, inhibitors of cyclin-dependent kinases that catalyse movement through the G_1 and S phases of the cell cycle. Wee-1 is a further caspase substrate: normally it blocks movement from G_2 to mitosis. CDC27, a component of the anaphase-promoting complex which destroys cyclin B and hence inhibits entry into mitosis, is also subject to caspase cleavage. The purpose of this reactivation of elements of the cell cycle during the process of death is still quite obscure. It occurs during the apoptosis of cells such as neurones which have long since ceased movement around the cycle.

Pathways that activate caspases

Two well-documented pathways converge on and activate the effector caspases, one leading from cytokine-activated, death-signalling receptors on the cell surface, the other from mitochondria.

Death-signalling receptors coupled to caspase activation

The death-signalling receptors are all members of the tumour necrosis factor-a (**TNF-a**) receptor family. They are type 1 membrane receptors (that is, with the N-terminus on the external surface), containing a series of cysteine-rich incomplete repeats in the ligand-binding domain, a single transmembrane domain, and a cytoplasmic moiety with one or more signalling domains (Fig. 3). Their ligands are homologues of the cytokine TNF-a. The prototype death-signalling receptor is fas (also called CD95 or Apo-1). On binding its ligand, FasL, this receptor trimerizes and immediately recruits to its cytoplasmic moiety a cluster of proteins collectively called the death-initiating signalling complex (**DISC**). The aggregation of DISC proteins is the result of protein–protein interaction at an a-helical region called the death domain (**DD**), because without it fas signalling is ineffective. Through the DD, fas interacts with an adapter protein called **FADD** (fas-associated protein with death domain) that contains a further interactive region called **DED** (for death-effector domain). Through DED, FADD recruits procaspase 8 to the DISC, an initiator caspase with two DEDs in its N-terminal sequence. Because they are at high local concentration in the DISC, the procaspase 8 molecules can catalyse their own activation, and so initiate the proteolytic cascade that ultimately turns on the effector caspases. Whilst fas is widely expressed in many tissues, fasL expression is largely restricted to cytotoxic lymphocytes and to cells in immunologically privileged sites. In this way, the fasL/fas system plays a major role in cell killing by cytotoxic T-cells (**CTLs**) but can repulse CTLs at immunologically privileged sites. As will be described, upregulation of fas may play a much wider role in the sensitization of damaged cells to other types of apoptotic stimuli. Caspase 8 is not the only output from fas activation. A DISC component called daxx acts as an adaptor, connecting fas activation to the apoptosis signal-regulating kinase-1, **Ask-1**. This links fas signalling to the stress-activated kinases JNK and p38 (Fig. 3 and Fig. 4).

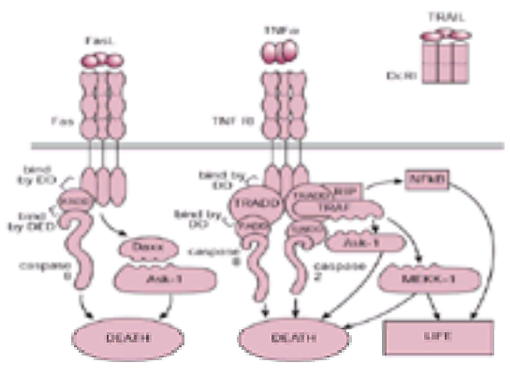

Fig. 3 Death-signalling receptors, shown diagrammatically. The fas receptor, with its ligand and DISC, signalling exclusively to death, is shown on the left. The more complex TNF-a receptor 1 is shown in the centre. Both prosurvival and proapoptosis signals can emanate from this receptor. On the right is shown one of the decoy receptors for **TRAIL** (TNF-related apoptosis-inducing ligand), DcR1. This receptor has no membrane anchor and so competes for TRAIL with the death-signalling membrane receptors, DR4 and DR5.

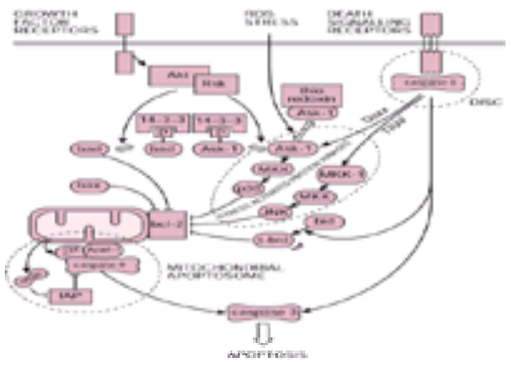

Fig. 4 Interaction between membrane receptors and mitochondrial signals coupled to apoptosis. In this summary diagram, proapoptotic elements are shown with rounded profiles, whilst prosurvival elements have rectangular borders. Cyt c, cytochrome *c*; t-bid, truncated bid.

TNFR1, the high-affinity TNF-a receptor, also trimerizes and signals to caspase 8 through FADD, in a DISC, but its action is substantially more complex. TNFR1 first recruits an additional DD-containing adaptor protein called TRADD. TRADD then recruits FADD, but can also bind other proteins into the DISC, including TRAF2 and a serine–threonine kinase called RIP. TRAF2 activates MEKK1 and Ask-1, elements of the MAP kinase pathway that transmit activation signals to JNK and hence the jun-containing transcription factor AP-1. RIP activates the transcription factor NF_B. NF_B provides a consistent survival signal, whilst JNK activation can be either prosurvival or proapoptosis. TNFR1 can also signal through yet another DD-containing adaptor protein, RAIDD, that in turn activates procaspase 2. Hence TNFR1-mediated signals can be interpreted as proapoptotic (through activation of caspase 8, caspase 2, or the p38 kinase), prosurvival (through NF_B), or ambivalent (through JNK and AP-1). This design means that incoming cytokine signals can be interpreted in opposite ways—for life or death—depending on precise conditions in the cell at the time.

DR3 is a receptor closely similar in structure to TNFR1 but with a narrower tissue distribution. Whereas TNFR1 is ubiquitous, DR3 is expressed predominantly in the lymphocytes of spleen, thymus, and peripheral blood. Interestingly, the expression of the ligands appears to adopt the opposite pattern, with TNF-a being a product predominantly of activated macrophages and lymphocytes, whereas the DR3 ligand (variously also called Apo3L and TWEAK) is expressed in many tissue types.

DR4 and -5 are similar receptors that bind a ligand called TRAIL (TNF-related apoptosis-inducing ligand). The downstream signalling appears to involve both FADD and caspase 8, although the possibility that certain cell types may couple DR4 and -5 to other signalling molecules is not excluded. Both TRAIL and its receptors are expressed in many tissue types. TRAIL has excited particular attention because it is frequently cytotoxic to tumour cells under conditions in which normal cells are unharmed. Variant receptors that lack the cytoplasmic signalling moieties are expressed in many normal tissues and appear to act as inhibitory decoys for TRAIL.

The death-signalling receptor pathway has the capacity to integrate several different types of environmental information in formulating its ultimate message to the caspases. Although its primary function is response, through the TNF-a family of receptors, to death-inducing ligands, its connection to the stress-activated kinases through Ask-1 also allows it to be sensitive to the redox status of the cell. Ask-1 binds to thioredoxin in a reversible, redox-sensitive manner. Hence the conditions under which Ask-1 is available for signalling are also redox-sensitive. Further, Ask-1 is inactivated, through binding to the chaperone 14–3–3, when serine phosphorylated. In this way the Ask-1 signalling pathway may be taken out of circuit by serine phosphorylation, as would pertain under conditions of growth-factor stimulation through raf kinase, PI3 kinase, and protein kinase B (Akt).

Mitochondrial signals coupled to apoptosis activation

The mitochondrial pathway depends upon the release of cytochrome *c*, together with dATP, from the intermembranous space of mitochondria. Cytochrome *c* and deoxyATP (**dATP**) bind to and effect a conformational change in a protein of the outer mitochondrial membrane, Apaf-1, so that it exposes a protein-binding domain (generically called a **CARD**, for caspase-activating recruitment domain) capable of recruiting and activating procaspase 9. This molecular assembly has been called the apoptosome, although other procaspase-containing complexes exist, including the DISC and probably others, referred to below. This then activates the effector caspases (Fig. 4). Triggers for the release of cytochrome *c* include reactive oxygen species, cellular redox stress, pH changes, and proteins of the BCL-2 family.

BCL-2 is a protein with a C-terminal hydrophobic domain that allows it to anchor to intracellular membranes, of which the outer mitochondrial membrane is one. It was first identified because of its consistent activation (through a chromosome translocation) in follicular B-cell lymphoma. In this sense, BCL-2 can function as an oncogene, but it differs from most other oncogenes in failing to stimulate cell proliferation—indeed, when expressed in isolation it inhibits cell-cycle progression. Its major role, however, is that of a survival factor, and thus it can cooperate with other oncogenes to sustain the life of clones of cells that otherwise might be deleted by apoptosis. This survival factor function appears to be a basic property of metazoan cells. The normal development of the nematode *Caenorhabditis elegans*, for example, depends on a BCL-2 homologue (ced 9), without which the embryo undergoes widespread apoptosis at an early stage. Transgenic mammalian BCL-2 can rescue the development of ced 9-deficient nematode larvae.

The mammalian BCL-2 family contains at least 15 members in three major branches, distinguished on the basis of their function, which can be either prosurvival or prodeath, and the presence or absence of certain conserved domains (called BH1–4). Amongst the prosurvival molecules are BCL-2 itself, BCL-xL, and BCL-w, all of which share all four BH domains, MCL-1 which lacks the BH4 domain, Boo which lacks BH3, and A1 which lacks both BH4 and BH3. In contrast, bax, bak, and bok form a branch of the BCL-2 family that possesses BH3, BH2, and BH1 domains but exerts prodeath functions. The third family branch consists of proteins whose sole region of homology with the others is a BH3 domain (sometimes amounting to no more than an 8-amino acid motif): bid, bad, bim, blk, hrk, and BNIP3. The BH1, BH2, and BH3 domains form part of a hydrophobic pocket in the molecule, into which another BH3 domain can fit in much the same way as a ligand binds to its receptor. Through this interdomain binding, BCL-2 family members can homo- and heterodimerize with each other. Whilst the prodeath action of the BH3-only proteins is known to depend upon such heterodimerization, the mechanism of action of the prolife and bax-related proteins is still uncertain.

Proteins in the prosurvival and bax-like prodeath branches of the BCL-2 family have a tertiary structure similar to bacterial haemolysins such as diphtheria toxin, suggesting that they could form transmembrane pore-like structures. Moreover, the majority of the members of the extended BCL-2 family possess C-terminal membrane anchors, and some (notably BCL-2 itself, BCL-xL, and bax under conditions of apoptosis activation) clearly localize to the mitochondrial outer membrane. Superficially at least, this could provide an explanation for the regulated escape of cytochrome *c* from mitochondria, through opening or closing of transmembrane channels formed from the BCL-2 proteins. This proposition is supported by the observation that BCL-2 family proteins can insert into artificial lipid membranes, thereby changing their electrical conductance. Further, the voltage gradient across the mitochondrial membrane (‡jm) collapses around the time of apoptosis activation. There remains some doubt, however, both over the capacity of such channels to permit the exit of molecules as large as cytochrome *c* and whether the relationship between the collapse of ‡jm and the initiation of apoptosis is cause or effect. Another model proposes that BCL-2 family members modify the function of the mitochondrial permeability transition pore (a multimolecular transmembrane structure containing a voltage-dependent anion channel and an adenine nucleotide translocator) leading eventually to rupture of the outer membrane.

BCL-2 possesses an important regulatory serine site that, on phosphorylation, neutralizes the prosurvival function. This critical phosphorylation can be effected by the stress-activated kinase pathways mentioned above, that lead from Ask-1 to activation of the JNK and p38 kinases. In this way, cellular stresses of many kinds, including exposure to reactive oxygen species and ultraviolet light, can negate the survival functions of BCL-2 family members and so swiftly lower the cellular threshold for apoptosis.

The BH3-only, prodeath members of the family appear to play important roles in coupling the powerful mitochondrial pathway to lethal stimuli in the cellular environment (Table 1). Notably, bid is activated through cleavage by caspase 8 of a small peptide from its N terminus. The truncated, activated bid translocates from the cytosol to mitochondria and effects the mitochondrial release of cytochrome *c*. In this way, stimuli too small to activate the effector caspases directly can be amplified by recruitment of the mitochondrial pathway through bid. Put another way, bid can lower the threshold at which cytokines trigger apoptosis. Somewhat similarly, bad is involved in a mechanism to raise the threshold at which apoptosis is engaged, depending on the availability of cytokine growth factors. The bad protein is phosphorylated by the kinases Akt (protein kinase B) and Rsk, both in turn dependent on PI3 kinase and the growth factors responsible for its activation. Normally, phosphorylated bad is sequestered in the cytoplasm by the chaperone 14–3–3. In conditions of growth-factor deprivation, however, unphosphorylated bad becomes available, translocates to the mitochondria, and activates cytochrome *c* release. BNIP3 is a mitochondrial protein that accumulates under conditions of hypoxia. It may thus provide a trigger linking hypoxia to apoptosis. Normally, bim binds to the light chain of dynein, a cytoskeletal protein. It may act as a sensor, triggering apoptosis under conditions of cytoskeletal disruption.

Perhaps surprisingly, BCL-2 itself is a caspase substrate: caspase 9 can cleave it to produce a C-terminal peptide with proapoptotic function. This is a further example, along with activation of the mitochondrial pathway through caspase truncation of bid and activation of MEKK1 as a proapoptotic stress-responsive pathway, that emphasizes the subtle strategy embodied in the caspase cascade. Mechanisms of this type would have no meaning if activation of initiator caspases inevitably led to commitment to death through the effector caspases. Rather, the initiator caspases can adjust a threshold, influenced by and integrated with many other incoming stimuli, that determines whether the death sentence will be enacted or repealed. Cells under stress of various types may start nearer that threshold, but the system is designed to process and interpret the continuous arrival of potentially lethal stimuli from around and within the cell.

Additional pathways for caspase activation

Despite the importance of the mitochondrial and death-receptor pathways in activating the effector caspases, it is clear that other means of caspase activation exist. Procaspase 12 localizes to the endoplasmic reticulum, whilst procaspase 2 can be found in the Golgi apparatus and the nucleus. The nucleus also contains CARD-proteins, that are recruited to foci of DNA damage, and BCL-2 is anchored to nuclear and ER membranes as well as mitochondria. Thus the death and survival of the cell, as modulated by caspase activation, may depend upon the synthesis of signals arising at many intracellular sites: some resulting from cell injury, others reflecting physiological stimuli. Damage to nuclear DNA is a particularly important source of injury-related stimuli for caspase activation.

A remarkable set of DNA-binding nucleoproteins is responsible for the recognition of DNA damage of different types, and for the initiation of repair. Thus, separate molecular mechanisms exist for responding to the presence of inappropriately inserted bases (base excision–repair, **BER**), nucleotides that have become modified through crosslinking or the formation of covalently bonded adducts (nucleotide excision–repair, **NER**), nucleotide mismatch or abnormal methylation (mismatch repair, **MR**), and double-strand breaks (homologous recombination or non-homologous end-joining, **HR** or **NHEJ**). In MR, MSH-2 and MLH-1 are recruited sequentially into a molecular complex at the injury site, which activates p53, effects cycle arrest, and, in the meantime, initiates repair at the site of damage. Similarly, amongst the first molecules to bind to DNA double-strand breaks in NHEJ are the DNA kinases ATM, ATR, and DNA-PK. In turn, these recruit and activate p53 and other molecules (for example, chk1 and chk2). In surviving cells, these effect arrest at a variety of points around the cell cycle, so ensuring that there is an opportunity to load the repair machinery on to the damaged DNA template before this is further altered by passing through DNA replication or chromatid separation.

A profoundly different means of limiting the effect of genome damage, however, is to commit the damaged cell to apoptosis; activation of the repair complex in both MR and NHEJ can also do this. The molecular basis for the decision between apoptosis or survival with repair is still unknown: indeed, there are circumstances in which repair is activated despite clear evidence that the decision to engage the machinery of apoptosis has already been taken. Activation of p53 is common to both outcomes, and it is therefore reasonable to search in this molecule for clues to the nature of the life or death decision. Activated p53 alters the transcription of a large number of genes. Some are well-known inhibitors of cell-cycle progression, such as p21waf1/cip1, but others (for example bax, fas, and a membrane protein called PERP) are associated exclusively with apoptosis. The situation is further complicated by the fact that p53 also signals to the apoptosis effector process by non-transcriptional means, via an N-terminal sequence that does not appear to be instrumental in effecting cell-cycle arrest. Phosphorylation provides one of the critical signals for p53 activation, and there are several different phosphorylation sites that respond preferentially to the various kinases. Thus the precise phosphorylation status of p53 could provide a molecular signature indicative of the nature, and perhaps the outcome, of the DNA damage.

Another potential factor in controlling DNA injury is a kinase (called **DAP** kinase because it was originally discovered as a death-associated protein) that influences the selection of $p14^{ARF}$ rather than $p16^{INK4A}$—alternative splice forms from the same gene. Whereas $p16^{INK4A}$ is a cell-cycle regulator, inhibiting the cyclin-dependent kinases, $p14^{ARF}$ displaces p53 from its inhibitor, MDM2, so generating a sustained p53 signal that may favour apoptosis. Curiously, DAP kinase normally docks on to the actin cytoskeleton. It is possible therefore that it affects the threshold at which apoptosis is triggered by DNA injury, depending on cytoskeletal-related factors such

as cell-to-cell and cell-to-substrate contacts.

Further clues to the way in which a variety of factors may be integrated in the response to DNA injury have emerged from detailed study of the injured nucleus. Within an hour of DNA damage, very large molecular complexes form around the damaged site. The first arrival is the phosphorylated histone gH2AX, which may recruit later members. These complexes contain molecular species that appear to generate platforms on which many injury-response proteins can associate, including p53, ATM, MSH-2, and Rad50 and -51. One type of platform is constructed from a protein called **PML** (so-called because of its abnormal synthesis in association with promyelocytic leukaemia). PML polymerizes to form intranuclear bodies (called PML bodies) into which p53 and many other proteins in the DNA-injury response are recruited. Indeed, nuclei without PML cannot mount the expected p53-dependent responses to DNA damage, even though p53 itself is available. Another such injury-related subnuclear body (the BASC body) incorporates the large DNA helicases BRCA1 and -2, proteins often defective in inherited susceptibility to breast cancer. These molecular platforms may provide the means whereby complex decisions, including the appropriate response to injury, are informed and initiated.

The replicative status of the cell is a further important determinant of its sensitivity to apoptosis following DNA injury. The proto-oncogene c-*myc* is normally amongst the earliest gene products to be synthesized when cells are stimulated by growth factors to leave quiescence and enter their replicative cycle. Thereafter, continuous expression of c-*myc* is required to sustain repetitive re-entry to the cycle following each cell division, rather than return to quiescence. Paradoxically, however, c-*myc* expression is also a powerful factor lowering the threshold for apoptosis. In particular, c-*myc* expression without concurrent molecular evidence of external growth-factor stimulation (such as PI3 (phosphatidylinositol-3) kinase and Akt activation) is interpreted as a death signal. Similarly, other early regulators of cell-cycle entry, including inhibition of function of the retinoblastoma protein and the release of the transcription factor E2F-1 from its binding pocket, also trigger apoptosis in the absence of concurrent evidence of external mitogenic stimulation. Perhaps this represents a means whereby tissues are protected from autonomous cell replication: survival of replicating cells is made conditional on the presence of appropriate stimuli in the cellular environment. The benefits of removing cells that show a tendency for such replicative autonomy are obvious, but the precise mechanism that couples replication to death except in acceptable circumstances is far less clear. It seems probable that the cell cycle itself includes checkpoints at which the decision to engage the apoptosis machinery can be taken should any of the appropriate conditions for replication be absent. Indeed, it is possible that injured cells may force the activation of such checkpoints as one way to access their apoptosis programme. This might explain the paradoxical activation of cyclin-dependent kinases by caspases in cells such as neurones that normally do not engage in replicative cycles at all, as mentioned earlier.

Inhibitors of caspase activation

The role of the BCL-2 family proteins in the activation and inhibition of apoptosis has been described, but there are other powerful endogenous inhibitors of caspase-associated cell death. One is FLIP, a DED-containing version of procaspase 8 that lacks caspase activity. High local concentrations of FLIP compete with procaspase 8 for recruitment into the DISC and so inhibit further propagation of death signals originating from the TNF family of receptors.

The heat-shock proteins hsp70 and hsp90 inhibit caspase processing and block mitochondrial cytochrome *c* release. The hsp90 forms a complex with Apaf-1, which is required for the inhibition of procaspase 9 processing, and is reversed by exposure to lethal doses of DNA-damaging agents.

IAPs (inhibitors of apoptosis proteins) inhibit caspase activity after autocatalytic processing of the procaspase has begun. All contain an element called a BIR domain, that binds to the N-termini of the short fragment of partially processed caspases, in such a way that adjacent elements of the IAP molecule drape across the caspase active site and sterically hinder substrate attachment. There are several such proteins—IAP1 and -2, ILP, the neuronal NAIP, and an X-linked family member X-IAP, all of which possess several BIR domains, and livin and survivin which contain a single BIR domain. One manifestation of the importance of IAPs is the presence of an IAP inhibitor, variously called smac or DIABLO, which is released from mitochondria along with cytochrome *c* during caspase activation by the mitochondrial pathway. The inhibitor smac has an N–terminal sequence that competes with partially processed caspase for the binding site in the BIR domain, and so allows the caspase to escape from the inhibitory embrace of the IAP (Fig. 5).

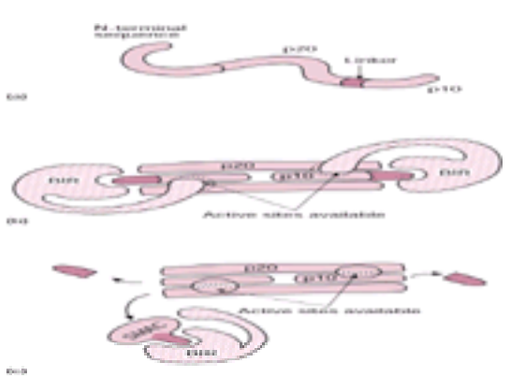

Fig. 5 Representation of the mode of action of IAPs. Following partial processing of the caspase, shown in (a), the IAP binds through its BIR domain, which identifies the newly exposed N-terminus of the linker region between the p20 and p10 caspase fragments. Thus bound, adjacent parts of the IAP molecule drape across the caspase active site (b). The inhibitor smac displaces the BIR domain, by presenting as a bait its own N-terminus, which is closely homologous to that of the partially processed caspase (c). With its active site now empty, the caspase can complete its processing and becomes fully active.

The IAPs provide a further example of the extraordinary interconnections between the cell cycle and cell death. Survivin, apparently associated with caspase 9, forms a complex with and is phosphorylated by active **cdk1** (cyclin-dependent kinase-1) during mitosis. Loss of phosphorylation leads to dissociation of the survivin–caspase-9 heterodimer, activation of caspase 9, and apoptosis. As normal mitosis proceeds, survivin associates with kinetochore proteins, the spindle microtubules, and finally, at cytokinesis, with the mid-body. Complexes of survivin with cyclin-dependent kinases active earlier in the cycle (for example, cdk4) have also been identified and promote transit through G_1. Thus, survivin may form part of the cell-cycle checkpoint system postulated earlier, providing a means whereby apoptosis can be activated by abnormalities in progression through the cell cycle. Finally, IAPs are themselves potential substrates of caspase attack, transactivators of the survival factor NF_B, and downstream products of NF_B-directed transcription. They thus form part of positive-feedback systems for both survival and death.

Recognition of apoptotic cells

Macrophages recognize and bind to the surface of apoptotic cells by virtue of multiple molecular 'eat me' signals (Fig. 6). The disposition of phosphatidyl serine (**PS**) residues on the apoptotic cell surface is one of the most characteristic of these. Normally PS appears only on the inner leaflet of the cell membrane, but this strict polarity is lost very early in apoptosis: around the time of rounding up, substantially earlier than chromatin condensation and DNA cleavage, and probably prior to evidence of caspase activation. Macrophages possess a PS receptor that binds to the exposed PS residues. The exposed PS residues may also bind to molecules in the extracellular environment that then form linkers to receptors on macrophage surfaces. Thus thrombospondin helps bind PS on the apoptotic cell surface to b_1, b_3, and b_5 integrins on the macrophage surface. Similarly, the complement fragment iC3b links to macrophage b_2 integrins, whilst the near-ubiquitous extracellular molecule b_2 glycoprotein-1 links to a macrophage receptor specific for it. In the same way, extracellular complement component C1q links specific binding sites on the apoptotic cell surface to receptors on the macrophages. A group of scavenger receptors (SRA, CD36, CD68, LOX-1) may tether directly to poorly defined oxidized lipid groups (similar to those in oxidized low-density lipoproteins) exposed on the surfaces of apoptotic cells. CD14 on the macrophage binds to ICAM3, exposed on apoptotic cells. Endogenous macrophage surface lectins also bind to sugars (such as *N*-acetyl glucosamine) selectively exposed on apoptotic cell membranes.

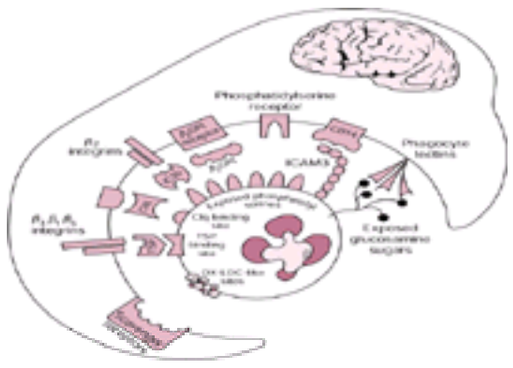

Fig. 6 Receptor–ligand interaction in the recognition of apoptotic cells by macrophages.

A distinctive feature of macrophage binding to apoptotic cells is the concurrent effect on macrophage function. Macrophages that engage in the phagocytosis of particles opsonized by immunoglobulin or complement component C3b engage in a sharp increase in oxygen usage (the respiratory burst), generation of reactive oxygen species and nitric oxide, and the release of inflammatory cytokines such as TNF-a. these recruit other acute inflammatory cells to the site. In contrast, macrophages that ingest apoptotic bodies show suppression of proinflammatory responses, mediated through the release of different cytokines, such as TGF-b. The basis of these contrasting effector responses appears to be the different signalling pathways that are activated by the macrophage receptors engaged by apoptotic bodies as opposed to opsonized particles.

Are caspases necessary and sufficient for cell death?

Although caspase activation appears to play a dominant role in the effector phase of apoptosis, it is clear that it is not responsible for all the phenomena of apoptosis. One striking example is the surface exposure of 'eat me' signals described above: this is not affected by pharmacological blockade of caspases using inhibitors that are unquestionably effective in blocking other aspects of apoptosis. These inhibitors are usually molecules that jam the caspase catalytic site through presentation to it, in uncleavable form, of a motif similar to the caspase target tetrapeptide. Inhibitors of this type, applied to lethally injured cells *in vitro*, often prolong cellular lifespan, but seldom totally reverse the cellular commitment to death. Moreover, developmentally programmed cell death can sometimes occur on schedule in embryonic tissues in which caspases have been inhibited, or key members of the caspase activation system (such as Apaf-1) are rendered deficient through germline gene knockout. In all these circumstances, the morphology of the caspase-free death is not that of apoptosis. The nuclei swell rather than undergoing the widespread condensation of chromatin. The cytoplasm shows signs of fluid overload, sometimes with the formation of dramatic fluid-filled vacuoles. Some of these changes are reminiscent of necrosis rather than apoptosis. Rather similar changes take place during the developmental death of phylogenetically ancient multicellular organisms that do not possess recognizable close homologues to the caspases, such as the slime mould *Dictyostelium discoides*.

These observations suggest that caspase activation, although intrinsic to the subtle and highly co-ordinated death process recognized as apoptosis, may not be the only event that commits cells to die. The existence of at least one caspase-independent death pathway is highlighted by a flavoprotein released from the mitochondria of injured cells called 'apoptosis-inducing factor' (**AIF**). AIF translocates to the nucleus, where it can effect chromatin cleavage to large fragments, but not the extreme condensation observed in apoptosis. It also appears to reproduce the cellular volume overload described above, even in the presence of caspase inhibition. Phylogenetically it is found in bacteria and plants as well as invertebrate and vertebrate animals.

Apoptosis and disease

There are few disease processes in which apoptosis does not feature, but the examples below are chosen because they exemplify how various steps in the apoptosis pathways may be critical for, or are subverted in, the course of disease pathogenesis.

Immunity and its disorders

Apoptosis is used extensively in the normal function of the immune system to facilitate the process of clonal selection. Antigen stimulation of T-cell proliferation is usually followed by expression of both fas and fasL, a recipe for apoptosis on a grand scale (called activation-induced cell death, **AICD**) unless there is rescue by a survival stimulus. This can be provided by co-stimulation from the immediate environment—adhesion molecules or cytokine receptors. A particularly important route for co-stimulation is through CD28, a receptor on T cells for signals transmitted from antigen-presenting cells, which increases the expression of several cytokines and their receptors. Similarly, clonally expanded populations of stimulated B cells in the bone marrow or those undergoing affinity maturation in lymph-node follicle centres are deleted by fas signalling, but can be selectively rescued by co-stimulation through CD40.

Cytotoxic T cells (CTLs) kill their targets by delivering to them the contents of their granules. Amongst these are perforin, which creates regions in the target-cell membrane of enhanced permeability at the points of contact with the CTL, and granzyme B, a protease that directly activates the caspases of the target cell. In this way, CTLs induce target-cell apoptosis.

The importance of apoptosis for the normal function of the immune system is underscored by the effects of genetic defects. Strains of mice with deficiency in the fas or fas ligand (called *lpr* and *gld*, respectively) show similar immunological phenotypes, characterized by massive lymphoproliferation and autoimmune disorders. The human homologue is the rare condition of the Canale–Smith syndrome (childhood autoimmune lymphoproliferative syndrome or **ALPS**) in which there is a mutation in the DD of fas. Inherited deficiency in C1q also leads to an autoimmunity syndrome: affected individuals almost always develop systemic lupus erythematosus. The pathogenesis here appears to be ineffective recognition and phagocytosis of endogenous apoptotic cells, so that their intracellular antigens are inappropriately processed.

Infective disorders

Shigella dysentery is due to pathogenic strains of *Shigella flexneri*. Pathogenicity is conferred by plasmid-borne genes that neutralize the primary host defence: phagocytosis and destruction of the bacteria by macrophages in the intestinal lamina propria. The plasmid-encoded protein Ipa B activates macrophage caspase 1, so annihilating the defence by inducing macrophage apoptosis. This strategy appears to be successful, because the bacterium that would normally be destroyed if it persisted within the phagosome of the ingesting macrophage, can escape from the cytoplasm of macrophages that undergo apoptosis.

The initial response to *Trypanosoma cruzi*, the parasite responsible for Chagas' disease, is dominated by T-lymphocyte activation. The resultant AICD generates a population of apoptotic lymphocytes. These impinge upon the macrophages that, suitably armed by proinflammatory cytokine stimulation, would be one of the most effective elements in the host defence against the parasite. As described earlier, sustained macrophage phagocytosis of these large numbers of apoptotic cells leads to suppression of proinflammatory cytokine release. The parasite subverts this aspect of the physiology of apoptosis into a source of protection from the host-defence reaction.

Viruses engage with the machinery of apoptosis in many ways. Even lytic viruses have strategies designed to conserve the life of their host cells for some time. DNA viruses, in particular, require means to abort apoptosis, as they must activate the cellular DNA synthesis machinery in order to replicate their own genomes, yet must then avoid the apoptosis that would otherwise follow DNA synthesis unaccompanied by commensurate external stimuli. The *E6* gene of human papillomavirus 16 (**HPV16**) encodes a protein that targets p53 for ubiquitination and subsequent degradation, and so permits cellular survival as the viral *E7* gene inactivates Rb and initiates entry into S-phase. The transforming genes of adenoviruses pair up to effect rather similar outcomes: whilst E1A binds Rb and initiates DNA synthesis, the 55-kDa subunit of E1B binds and inhibits p53, and the 19-kDa subunit neutralizes proapoptotic members of the BCL-2 family. Human herpesviruses such as HHV8 encode their own version of FLIP (v-FLIP). They also have their own prosurvival BCL-2 family members, such as BHRF1 in the Epstein–Barr virus (**EBV**) and KS-BCL2 in HHV8. The HHV8 strategy is particularly subtle, because the virus also destroys the endogenous BCL-2. Unlike endogenous BCL-2, this viral surrogate lacks an internal caspase site, and cannot be converted into a killer peptide by caspase cleavage. Baculovirus encodes a 35-kDa protein with BIR domains that is a prototypical IAP.

Apoptosis plays a key role in the pathogenesis of AIDS. The progressive loss of circulating CD4+ T cells, by which the course of HIV-1 infection to clinical AIDS can be charted, involves numbers of cells that are several orders of magnitude greater than the numbers that ever carry the virus. It is therefore clear that the overwhelming majority of the dying cells must be bystanders, sensitized to apoptosis by the presence of infection but not infected themselves. Viral proteins, released from infected cells, effect this sensitization by several parallel routes. The HIV proteins Tat and Nef induce fas, fasL, and TRAIL. Tat alters the cellular redox equilibrium in a manner that may activate Ask-1. Vpr binds to the mitochondrial permeability transition pore. A type of AICD may be induced by stimulation of CD4 and the cytokine receptor CXCR4 (both of which bind HIV epitopes). In infected cells, however, Nef inhibits ASK-1, and so may selectively protect these from apoptosis. Rather similar mechanisms underlie the deletion of neurones in HIV-associated dementia.

Cardiovascular disease

Pathogenetic mechanisms that interface with apoptosis are relatively poorly understood in cardiovascular disease, but there are several observations of potential relevance. Laminar flow inhibits Ask-1 in endothelium, whilst the generation of reactive oxygen species (**ROS**) induces the p38 and JNK stress kinase pathways. Thus, turbulence and the presence of ROS generators such as oxidized low-density lipoproteins—both known risk factors in the genesis of atheroma—are liable to promote apoptosis in endothelium. Other elements of the vascular wall are also abnormal in atheroma. Vascular smooth muscle cells from atheromatous vessels express p53, induce fas, and undergo apoptosis in increased numbers, particularly in the shoulders of the plaque, thus weakening attachment of the fibrous cap and rendering plaque rupture more probable. Macrophages also undergo apoptosis in response to the oxidized lipids that are present in atheromatous plaques. Death of the lipid-filled macrophages (foam cells) produces extracellular depots of oxidized lipid in the plaque core, a key step in plaque progression.

Whilst necrosis is the pattern of the cell death that immediately follows episodes of infarction, there is now substantial evidence that apoptosis occurs in the surrounding tissue over several hours thereafter, probably in response to relative ischaemia and the local generation of ROS. In animal models of stroke, this apoptosis can be downregulated by a variety of manoeuvres, including caspase inhibition, with objective evidence of improved cerebral function. These observations have generated enthusiasm for the development of antiapoptotic drugs for use following stroke and myocardial infarction. Another approach, potentially applicable to ischaemic myocardium, is to promote angiogenesis, perhaps by the use of angiogenic stem cells. Experimental models suggest that this improves the remodelling of the peri-infarct tissue, including decreased apoptosis of myocytes and improved cardiac function.

CNS degeneration

Despite the importance of the subject, there is still much doubt over the role of apoptosis in the chronic degenerative disorders such as Alzheimer's and Parkinson's diseases. Much of the problem stems from the relative inaccessibility of the brain for sequential studies following injury. In both conditions there is clear evidence of a loss of neurones, and those that remain accumulate abnormal cytoplasmic material, such as presenilins 1 and 2, and amyloid protein Ab in Alzheimer's disease. Cell culture and animal models suggest that the presence of these proteins may induce oxidative stress, which can lower the threshold for apoptosis. The protective effect of BCL-2 and caspase inhibition has also been recorded. The difficulties are compounded by the fact that neurones that undergo severe overstimulation (for example, by local high concentrations of the neurotransmitter glutamate) can also be induced to die (a phenomenon called excitotoxicity), but it is not clear whether the pathways involved overlap with or are identical to those of apoptosis.

Genetic studies of the inherited disorder, spinal muscular atrophy, provided what might have been the most definitive evidence linking the apoptotic pathways to CNS degeneration. A nearly consistent germline mutation has been identified that involves the IAP neuronal apoptosis inhibitory protein, **NAIP**. Unfortunately, another gene of quite different properties is also mutated in a high proportion of cases and it is still not clear which is responsible for the progressive loss of spinal motor neurones in this condition.

Tumour biology

Malignant tumours almost invariably show evidence of genomic instability. This commonly manifests itself as a tendency to undergo repeated episodes of chromosome breakage and recombination, or of mutation at microsatellite sites. The latter is due to defective function in the mismatch repair genes such as *MSH2* or *MLH1*, but there is less certainty over the basic causes of the former. Both can be associated with the loss of a p53-controlled checkpoint, chromosome instability more consistently so than microsatellite instability. Since MSH-2, MLH-1, and p53 are all connected to the activation of apoptosis, it follows that cancer cells inappropriately survive checkpoints normally controlled by these molecules. This gives cancer cells the opportunity to explore the consequences of genomic rearrangements that are denied normal cells. Some of these prove incompatible with continuing life but others lead to selective growth advantage (Fig. 7).

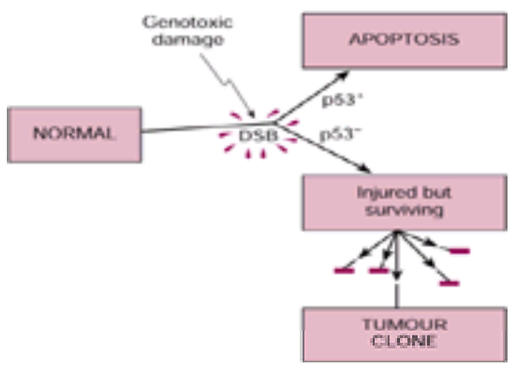

Fig. 7 Failure to activate apoptosis following damage by a genotoxic carcinogen, because of the absence of functional p53, leads to the inappropriate survival of clones of cells bearing double-strand breaks (DSB) and illegitimate recombination events. Whilst some of these clones may fail to proliferate further, others survive to become the founder clones of tumours. Constitutionally, these survivors have unstable genomes, as on further exposure to similar genotoxic stimuli they will again fail to enact apoptosis. Whilst the example given is for cells lacking p53, and hence unable to respond appropriately to DNA DSBs, exactly the same argument applies to cells that fail to identify nucleotide mismatch through defective MSH-2 or MLH-1. Such cells sustain extremely high mutations rates, as mismatches occur (and are normally recognized and repaired) in the course of normal DNA replication, even in the absence of genotoxic carcinogens.

An apoptotic view of carcinogenesis has implications for tumour management. The earlier sections of this chapter have indicated how proapoptotic pathways can cooperate. The activation of p53, for example, increases fas expression and this in turn, perhaps through daxx, Ask-1, and p38 kinase, sensitizes cells to the action of many xenobiotics. By contrast, however, cells lacking a critical signal that couples DNA damage to apoptosis (in this case p53) may often survive further damage by these agents. Whatever other changes occur in the course of tumour progression, the entry to malignant behaviour is likely to involve the loss of one critical link to the apoptosis effector pathway rather than loss of the pathway itself. Thus there are few cancer cell lines, and no reported primary tumours, in which, for example, caspase activity is absent, and levels of caspases appear to bear no relationship to tumour chemoresistance. Restoration of the links that couple DNA damage and other cellular stresses to the effector pathways of apoptosis is thus a real objective for cancer drug discovery.

5.1 Principles of immunology

A. J. McMichael

Introduction

There are two features which distinguished immune responses from the non-specific defence mechanisms such as inflammation. The first is the specificity of the reaction, which is easiest to appreciate in terms of antibody responses but it is also true of the cellular immune responses; an essential part of this specificity is the remarkable ability to distinguish between self and non-self. The second is memory by which a second challenge with a stimulus provokes a more rapid and more vigorous immune response. These concepts began to be formulated by Jenner and were developed by Pasteur, Erlich, Landsteiner, Medawar, Burnet, and many others. In the last 30 years, the cellular and molecular basis of these two characteristics has become much clearer.

Immune reactions play important roles in most disease processes. Much of what is observed at the bedside involves immune responses, although the visible, palpable, or audible end-result can be quite distant from the primary event. End-immune reactions can be divided into two: those dependent on antibody (humoral responses) and those on T lymphocytes (cell-mediated immune responses, CMI). Antibody reactions themselves are normally quite silent *in vivo* (e.g. neutralizing virus infectivity), but sometimes antibodies may trigger various secondary events that become literally visible (e.g. anaphylaxis) or revealed on investigation (e.g. haemolysis). Cell-mediated immune responses may also be silent (e.g. clearing of some virus infections by T cells lysing infected cells or releasing interferon) or visible (e.g. delayed hypersensitivity reactions in the skin) or revealed by investigation (e.g. kidney graft rejection).

These two different types of immune response are indicative of the basic division of lymphocytes into two types, B and T cells. They interact with each other and with a third important cell, the antigen presenting cell. The following sections explain how these cells work, as far as possible at a molecular level.

Antigens

Both B and T lymphocytes make the fundamental distinction between self and non-self. This is quite remarkable; for example each species will make antibody to cytochrome c of other species but not self, even though they are closely related proteins differing in very few amino acids. Similarly, T cells respond to all HLA (transplantation) antigens of other members of the species but not self. The mechanisms that underlie this self tolerance are complex and will be explained later. First, the nature of antigens recognized by B and T cells need to be examined, because there are important differences.

Antigens recognized by B cells

B lymphocytes recognize antigen through their surface antibody receptors. In chemical terms, the recognition is identical to that by secreted antibody. The antibody reacts with the native proteins. The availability of large amounts of purified antibodies, particularly monoclonal antibodies secreted by hybridomas, has facilitated detailed analysis of how protein or carbohydrate macromolecules are recognized. By inhibiting antibody reactivity with polysaccharides with small sugars, Kabat was able to show that an antibody binds to a small part (epitope) of a macromolecule, about the size of seven sugars. For protein antigens, knowledge of their sequence has helped to define their epitopes. A good example is the haemagglutinin (HA) of influenza A virus. The amino acid sequence and three-dimensional structure of this molecule are known. In addition, the amino acid sequence of variant HA molecules that react with different antibodies are known. It is possible, thereby, to locate the parts of the molecule that bind to antibody. Four have been identified in this way, situated on the outside of the globular head of the molecule, each involving less than ten amino acids; because the antibodies bind to a folded molecule these amino acids are not in continuous sequence. Thus for both protein and polysaccharide the epitopes that react with antibodies and B cells are discrete and small.

A protein antigen must be greater than about eight amino acids in size to stimulate an immune response. It is possible, however, to make antibodies to smaller molecules if these are coupled to larger carrier proteins. In this way antibodies can be made to virtually all drugs and other small chemical (hapten) groups. This implies a further, very special feature of the humoral immune response; it can recognize molecules that do not occur in nature or that have not been previously synthesized. This is because of the spatial configuration of many small molecules may be similar in the sense that they fit antigen binding sites of antibodies. Such molecular mimicry has been invoked to explain some autoimmune reactions, for instance the cross-reaction between streptococcal and cardiac antigens in rheumatic carditis.

B cells can react with antigen in its natural form, and special processing is not required. However, the signal delivered to B cells by antigen is on its own insufficient to activate them to proliferate and secrete antibody. Growth and differentiation factors must be provided by helper T lymphocytes. As discussed below, T lymphocytes respond to processed antigen. Certain carbohydrate antigens, however, which have multiple repeating units that can function as epitopes, can stimulate B cells directly to divide and secrete IgM antibody. Some polysaccharide carbohydrate antigens facilitate this by non-specifically activating cells to which they bind (lipopolysaccharide from Gram-negative bacteria for example).

Antigens recognized by T cells

In principle, T cells can recognize as antigen the same range of molecules that are seen by antibodies. However, they are more fastidious about the nature of antigen and its presentation; they do not respond to soluble or free antigen, but to antigen at cell surfaces. On the presenting cells the antigen has to be associated with histocompatibility antigens, HLA (inappropriately standing for human leucocyte antigens) in humans. As foreign antigens are invariably presented *in vivo* with self HLA antigen, the T cells show specificity for self HLA plus foreign antigen. T cells so activated will not recognize the same foreign antigens if presented with foreign HLA *in vitro*. However, foreign HLA antigens provoke very strong immune reactions and these alloreactive T cells do not have to see foreign HLA in association with self HLA. There is therefore something very special about T cell recognition of HLA antigens.

Foreign protein antigens are presented to Th cells (helper T cells that will stimulate B cells to make antibody) by specialized antigen presenting cells. When the parts

of the protein molecule that T cells respond to are analysed it is clear that these are often different from those seen by antibody. Using the same example as above, the T cells can recognize parts of the influenza A virus HA that are buried in the molecule. They respond well to short (15–20 amino acid residues) synthetic peptides that represent fragments of the known amino acid sequence. Experiments have indicated that if antigen presenting cells (macrophages) are lightly fixed with paraformaldehyde they will successfully present peptide fragments but not whole protein antigens to helper T cells. All this implies that helper T cells see digested fragments of protein antigens, rather than native proteins, in association with self major histocompatibility complex (MHC) antigens. The role of the antigen presenting macrophage or monocytes is to capture protein, or other antigen, ingest it, and present it in processed form on its surface in association with HLA antigen (Fig. 1). B lymphocytes, by binding antigen to their antibody receptors, can also process antigen and present to Th cells.

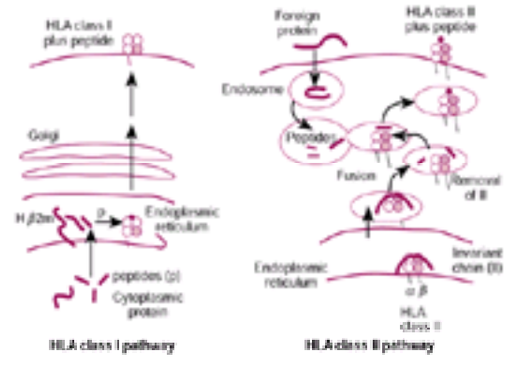

Fig. 1 Antigen processing: the two pathways are shown, through HLA class I on the left and through HLA class II on the right. For the class I route, cytoplasmic (e.g. virus) proteins are degraded to peptides in the cytosol. The peptides are transported to the lumen of the endoplasmic reticulum. Here, nonamer peptides bind to the newly synthesized class I molecules, stabilizing folding with b_2-microglobulin. The stable complex is translocated to the cell surface where foreign peptides, as well as self peptide, are displayed. For the class II route, foreign protein antigen is ingested by the cell and degraded to peptides in the endosome. The newly synthesized class II molecules fold in the endoplasmic reticulum and the groove is protected by binding to a polypeptide, 'invariant chain'. As the complex formed is transported towards the cell surface the invariant chain is digested away by proteases exposing the groove. HLA class II-containing endosomes fuse with peptide-containing vesicles and peptide binds to the class II HLA groove, stabilizing the structure. The HLA class II molecules reach the cell surface and display foreign peptides. (For further details see Townsend A and Trowsdale J (1993). The transporters associated with antigen presentation. *Seminars in Cell Biology* **4**, 53–61.)

The other chief subset of T cells, the cytotoxic T lymphocytes, see foreign antigen at the surface of non-specialized presenting cells, particularly virus antigen at the surface of infected cells. Cytotoxic T cells recognize peptide fragments of virus antigens at the surface of target cells bound to HLA class I molecules. In this form, antigen would not be recognized by antibody specific for the intact protein. This suggests a reason for this apparently complicated process of T-cell recognition. If T cells could react with native antigen free from cell surfaces they would be inactivated because the receptor would be engaged but the secondary signals needed for T cell activation, provided by the antigen presenting cell, would be lacking.

Histocompatibility antigens

These antigens, HLA in humans, play a central role in T lymphocyte function because, as described above, they associate with foreign antigen to stimulate T cells. HLA antigens are controlled by the major histocompatibility complex (MHC) which is a cluster of genes on the short arm of chromosome 6 (Fig. 2). There are two types of MHC antigen: class I and class II.

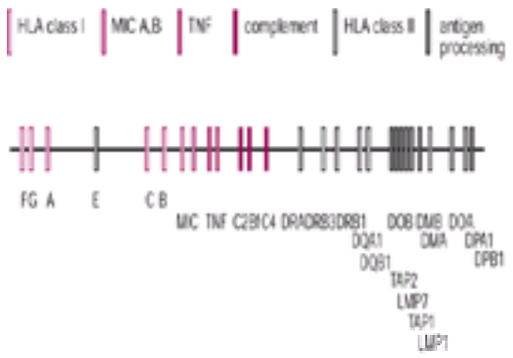

Fig. 2 Gene map of the HLA complex on the short arm of chromosome 6, showing the immunologically important genes. Shown are the HLA class I loci, the related MIC A and B loci, genes relevant to inflammation including the complement components C2, C4, and Bf, the HLA class II loci, and genes relevant to antigen processing. The map is based on that published by Aguado *et al*. 1999.

Class I antigens are dimers with a 45 000 molecular weight heavy chain, encoded in the major histocompatibility complex (MHC) of genes on the short arm of chromosome six, and an invariant light chain, b_2-microglobulin (b_2m), that is coded on chromosome 15. In 1987, the three-dimensional structure of HLA A2 was determined by Bjorkman, Strominger, Wiley, and colleagues, a finding that has had a profound impact on our understanding of T cell recognition. The heavy chain is divisible into three extracellular domains of about 90 amino acids, of which the membrane-proximal a3 domain resembles an immunoglobulin domain. Together with b_2-microglobulin, which is also immunoglobulin like, these form a stalk on which sits a structure made up by the a-1 and -2 domains. The molecule is folded to form a groove, bounded on its sides by two alpha helices and on its floor by an eight-stranded beta sheet; nearly all of the amino acids that differ between different class I molecules contribute to the fine structure of this groove. The ends of the groove are closed and contain tyrosines and threonines that are conserved in nearly all class I molecules. The crystal structure showed that the groove contains bound peptides, now known to be derived from degraded cytoplasmic proteins. Because different class I molecules (HLA types) have different shaped grooves they bind different peptides. The peptides are usually nine amino acids in length and are bound as extended chains with the amino- and carboxy-termini bound in pockets at either end of the groove. Between two and four of the amino acids that make up the peptides are involved in binding to the HLA molecule with their side chains fitting into other pockets in the groove. These anchoring residues are different in different class I molecules; for instance all peptides that bind to HLA B27 have arginine at position two, those binding to HLA A2 usually have leucine at this position, compared to proline for peptides binding to HLA B35. The class I molecules on a given cell probably bind several hundred peptides, sharing the common anchor residues; these give the cell a 'signature' that is monitored by T cells which are tolerant to normal self peptides. If a foreign peptide, derived from an intracellular parasite or mutated self protein enters the system, T cells can react and destroy the cell. The class I molecules thus serve the function of displaying abnormalities within the cell at its surface.

Most nucleated cells express the classical class I HLA antigens (HLA-A, B, and C) although trophoblast is negative and very low amounts seem to be expressed on hepatocytes, muscle cells, and nerve cells. Some tumours are negative, which may be one way in which they evade T-cell immunity. However, expression on many cell types is increased by the action of g-interferon released by activated T cells.

HLA class I heavy chains are encoded in the MHC. Products of two loci, HLA A and B, are expressed on cell surfaces in large amounts (10–100 000 molecules per cell); a third series, HLA C, is expressed at much lower levels. There are, in addition, three loci that express non-classical HLA class I molecules. HLA G is expressed almost exclusively on extra villous trophoblast and probably serves to inhibit natural killer cells and macrophages that might attack the foreign trophoblast. HLA E also inhibits natural killer cells; its surface expression is controlled by the availability of a particular peptide derived from the leader sequence of the classical HLA A, B, and C class I proteins, as well as HLA G. HLA E binds to a receptor CD94-NKG2 on natural killer (NK) cells that delivers inhibitory signals. Other receptors on NK cells (killer inhibitory receptors, KIR) detect the presence on classical HLA class I molecules, particularly HLA C, on the potential target cell but deliver an inhibitory signal that protects the target from lysis. Cells that fail to express HLA, such as certain tumour cells selected to evade T cell attack, are lysed by NK cells. Thus the

HLA class I molecules are intimately involved in the maintenance of cell survival.

The HLA A, B, and C antigens are highly polymorphic with multiple alleles at each locus (Table 1). As their structure implies, class I antigens present peptide fragments of foreign antigens, usually virus, on the surface of normal cells to cytotoxic T lymphocytes (CTL). The polymorphism of HLA A, B, and C means that, when tested *in vitro*, cytotoxic T cells (primed to virus *in vivo*) will only recognize virus antigen on self cells or HLA matched cells (HLA restriction). It is likely that the extreme degree of HLA polymorphism results from evolutionary selection of multiple HLA alleles by pathogens. Individual HLA molecules show varying efficiency in presenting particular antigens to CTL, thus affecting the quality of the immune response to various intracellular pathogens.

HLA class II proteins have two chains, a and b. Each is around 30 000 daltons molecular weight and is composed of two extracellular domains (Fig. 2). At least four different members of the family are expressed on cells and most are polymorphic. The best studied series are the DR antigens, which have a highly polymorphic b-chain (encoded by the DRB1 locus) giving rise to over 20 DR types (Table 1). There is a second, less polymorphic DR-b chain that gives the specificities DR 51, 52, and 53, encoded by the DRB3, DRB4, and DRB5 loci respectively. The DQ molecules are polymorphic in both a and b chains, which means that hybrid molecules can occur in heterozygotes. The DP molecules are polymorphic in the b-chain and are expressed in smaller amounts. The HLA class II molecules are expressed on a limited set of cells that includes B lymphocytes, monocytes, dendritic cells, activated T cells, and some endothelial and epithelial cells. They can be induced on many more cell types by interferon-g.

The crystal structure of HLA DR1 is remarkably similar to HLA class I. The main difference is that the groove is open-ended allowing the bound peptides to hang out; thus the peptides are longer, 12 to 16 amino acids. Like the peptides that bind class I, there are anchor residues, determined by the fine structure of the groove. There is a particularly prominent pocket in the floor at the left hand end of the groove which binds large aromatic side chains in some instances.

The function of the class II antigens is to present foreign processed antigen to helper T cells. As discussed above, this process is mediated by specialized antigen presenting cells, although the wider expression of class II antigens induced by interferon suggests that other cells may be able to process and present under certain circumstances. A particularly important antigen-presenting cell type is the dendritic cell; this expresses large amounts of HLA class II as well as important costimulatory molecules. Dendritic cells appear to be particularly good at processing antigen for both the class I and class II pathways.

Human individuals differ in the epitopes of an antigen that they recognize, according to their HLA class II type. The effects of this could be manifest, for instance, in the degree of cross-reactivity between related viruses that stimulate antibody responses. Similarly, HLA class II type could determine whether antigens that differ from self in only a few epitopes are recognized. Self antigens that are slightly altered could fall into this category and it is striking that several organ-specific, autoimmune diseases are associated with HLA DR3. However, the exact reasons for this and other HLA and disease associations (Table 2) remain unresolved. It should be noted that the disease associations imply either a direct role for the HLA molecule or that there is a nearby disease-susceptibility gene in linkage disequilibrium with the HLA marker. In the case of HLA-DR3, there is strong linkage disequilibrium with HLA B8 and everything in between, including a complement C4 null allele and at least 50 other genes, most of which are non-polymorphic and many of unknown function.

The action of HLA class II antigens in presenting antigens to helper T cells gives them a key role in initiating immune responses. In contrast, class I antigens are involved at a later and more specialized stage. This is important in transplantation, where matching class II antigens is more important than matching class I, although the final damaging activity of cytotoxic T cells and antibody is directed at class I antigens.

Antigen processing

There are two pathways of antigen processing, generating the peptides that bind to HLA class I and II molecules, recognized by cytotoxic T lymphocytes (CTL) (which carry the CD8 surface marker) and Th (CD4 positive) respectively.

As indicated above, class I HLA molecules present short peptides derived from cytoplasmic proteins. The most likely pathway by which this happens is given in Fig. 1. Proteins in the cell are naturally turning over, broken down by cytoplasmic proteases. The multicatalytic proteasome complex is a major contributor to this process. It degrades cytoplasmic proteins that have been coupled to ubiquitin and digests them to small fragments. It is made up of 28 components; two of these are encoded in the MHC in the class II region, are interferon-g inducible and they may affect the protease specificity. The peptides generated are transported by an ATP-dependent transporter (TAP, transporters associated with antigen processing), made up of two chains encoded in the class II region of the MHC, into the endoplasmic reticulum. Here the peptides are degraded further unless they bind to newly synthesized class I HLA molecules. The latter take the peptide to the cell surface bound in the groove. Expression of most class I molecules at the cell surface is dependent on the integrity of this pathway. Patients described recently who have a deficiency in the TAP, display very low levels of HLA class I molecules on their cell surfaces; interestingly, they suffer from recurrent bacterial infections and a severe granulomatous vasculitis with highly activated NK cells.

Processing of antigens to be presented by class II HLA takes place in specialized antigen-presenting cells, particularly monocytes, dendritic cells, and B lymphocytes. Protein antigens are taken into the cell from outside. Monocytes may take up antigen passively by endocytosis or by receptor-mediated uptake, acquiring proteins bound through complement or Fc receptors. The latter bind to the constant regions of antibodies and so mediate uptake of proteins bound to cells as immune complexes—antigen may bind to small amounts of 'natural antibody' or the early specific antibody (giving an early positive feedback). Also B lymphocytes with specific antibody receptors can bind foreign proteins directly, endocytose, and process antigen to present peptides bound to class II molecules. Digestion of proteins takes place in an endosome compartment; these fuse with class II HLA-carrying vesicles bringing class II molecules from the endoplasmic reticulum. The newly synthesized class II molecules do not bind peptides in the ER; instead they bind to a third chain the 'invariant chain'. This protects the groove from peptide binding and the complex is exported through the Golgi complex where glycosylation is completed and addition of sialic acid residues to both the class II molecules and the invariant chain takes place. In a late endosomal compartment, at low pH, the invariant chain is degraded and removed from the class II molecules. This process involves another HLA class II molecule, HLA DM that somehow facilitates the exchange of invariant peptide for foreign peptide. Binding of peptide stabilizes the class II structure and the class II molecule containing the peptide reaches the surface. As for class I HLA, several peptides derived from normal proteins are displayed and elicit no T cell response because of tolerance. Foreign peptides that stimulate T cells with appropriate receptors initiate Th responses.

Priming the immune response

It is becoming clear that antigen presentation by class I or class II HLA on its own is insufficient to initiate a T-cell immune response. Specialized cells play a role, particularly B lymphocytes, dendritic cells, and others of the monocyte series. In addition to presenting peptides on their MHC molecules, they display other accessory molecules on their surface important for cell–cell interactions. In addition to the adhesion molecules, such as LFA-1 and CD2 that are also necessary for T cell recognition of target cells, the B7 molecule (CD80 and not to be confused with HLA B7) seems especially important. This binds to the T-cell marker CD28 and delivers a signal to naive T cells initiating the T-cell response. Once activated in this way these T cells can interact with antigen-presenting cells, such as virus-infected epithelial cells, and react; from here on, CD28 may be less crucial though it can inhibit activation-induced cell death and so ensure the responding T cell remains alive. The importance of the CD28–CD80 pathway is that there can be cells in the body that display antigenic peptides but because they lack CD80 do not initiate an immune response and suffer immune attack. However, a virus infection could sometime initiate a cross-reacting T-cell response and trigger an autoimmune response.

Antibodies

Structure

The basic structure of an antibody molecule is illustrated in Fig. 3. An IgG molecule consists of four chains, two identical heavy chains (50 000 daltons) and two identical light chains (25 000 daltons). The immunoglobulin molecule can be broken into segments by enzymes, giving the peptides illustrated in Fig. 3. Sequence analysis of light and heavy chains and crystallographic studies have revealed that they are composed of domains of about 100 amino acids, held by a disulphide loop between two cysteines (a domain structure that has been found to be present in many other cell surface molecules). There are two for each light chain (L) and four for an IgGg heavy chain (H). The N terminal domains of both L and H chains are highly variable when different antibody molecules are compared; they contain the antigen binding site. The constant domains of the heavy chain define the isotype of the antibody, IgG, A, D, M, or E, each of which has particular functions. The main differences between the various heavy chain constant regions are described in Table 3. The isotypes determine essential properties of the antibodies, particularly binding of Clq of the complement system, binding of Fc receptors that enable antibody to cross the placenta, and binding of Fc receptors on macrophages, mast cells, and basophils. IgA binds to a specific Fc receptor, known as a secretory component, which is on epithelial membranes. The antibody can then be endocytosed and transported across these cells and released on the outside, that is the gut lumen, biliary tract, respiratory tract, or milk duct. Light chain constant regions are one of

two classes, _ or l, but there are no known differences in function between the two.

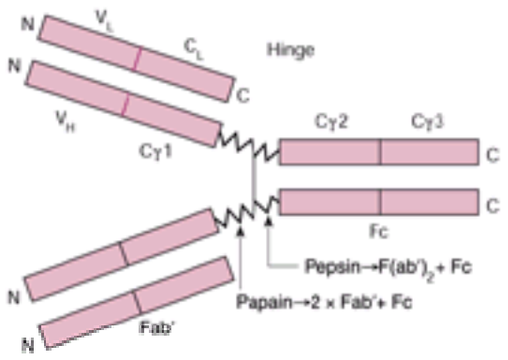

Fig. 3 Basic structure of an immunoglobulin, IgG, molecule. Two identical light (L) and two identical heavy (H) chains are shown. At the amino terminal (N) there is a variable (V) domain of 110 amino acids. In the light chain (L) this is connected to one constant domain of 100 amino acids which is one of the two types: l or _. The heavy-chain variable domain links to three constant-region domains, Cl1, Cl2, and Cl3. Between Cl1 and Cl2 is the hinge region, which gives the binding site (VL+VH) flexibility and contains interchain disulphide (—S—S—) bridges (see Table 3). The site of cleavage by the proteolytic enzymes papain and pepsin are shown, which give the antigen-binding fragments Fab and F(ab)$_2$ and the constant fragment Fc.

The N-terminal domains of L and H chains are variable regions. They vary between different antibodies to a remarkable degree. Sequence comparison of several variable regions has shown that there are three short, hypervariable patches between amino acids 28–34, 45–56, and 91–97 in both light and heavy chains. The crystalline structure of antibody indicates that these hypervariable regions form a surface to which antigen binds. In agreement with the studies on antigen epitopes, this is about the right area to bind to six amino acids on the surface of the antigen. Sequence analysis has also revealed that there are hundreds of genes for variable regions, explaining some of the enormous variability. Estimates, by various methods, agree that an individual must be capable of generating over several million different antibody molecules, probably nearer 10^8. As the variability is controlled by both the L and the H chains, which appear to associate independently, this means that there should be several hundred VL and VH sequences. How these are generated is discussed below.

Polyclonal or monoclonal antibodies

A normal antibody response includes multiple antibody molecules that bind to each epitope on a given antigen. B-cell activation requires binding of antigen, so any B cell that binds with affinity above a certain threshold stimulates B cells (with appropriate signals from helper T cells) and ultimately antibody secretion. A single antigen epitope can evoke a response comprising several hundred antibody molecules. This means that each antibody must be capable of binding more than one antigen, which is not surprising considering that antibodies recognize surfaces rather than sequences. An antiserum made up of hundreds or thousands of antibodies maintains its specificity because the immunogen is the common denominator. As each antibody molecule is the product of a single clone of B lymphocytes, and many are involved, this type of response is known as polyclonal (Fig. 4).

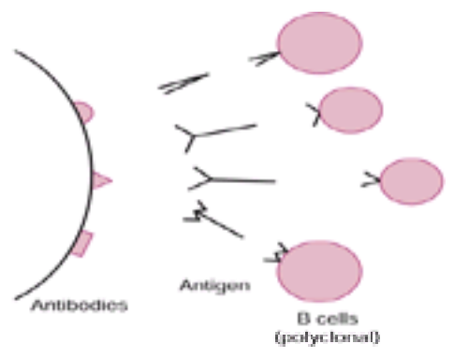

Fig. 4 Polyclonal antibodies. An antigen such as a protein has many antigenic sites (epitopes) on the surface of the molecule. To each can bind a set of antibodies with a range of affinity depending on the amino acid sequence of their variable regions. These are indicated diagrammatically by the shape of the binding site that binds to epitope. Each species of antibody is the product of one clone of B lymphocytes that can only make antibody with that shape, that is V-region sequence.

Under certain circumstances a monoclonal antibody response is generated. This may happen when the stimulating antigen is limited in its presenting epitopes or when it is present in extremely low amounts, thus selecting out only cells with the receptor with the highest binding avidity. Oligoclonal responses are also found in the cerebrospinal fluid in multiple sclerosis, possibly as a consequence of limiting the immune response to the few clones of cells that manage to cross the blood–brain barrier. More commonly, a monoclonal antibody *in vivo* is the product of abnormal proliferation of a single clone of B cells or plasma cells.

Kohler and Milstein, in 1975, devised a way of fusing normal (mouse) B lymphocytes to cultured plasmacytoma cells to generate immortal hybrid cell lines (hybridomas) that secrete the antibody of the B-cell parent. Because the donor of the spleen cells can be immunized at will, these monoclonal antibodies can be generated to any antigen. They have been used to explore the structure of human cells, particularly their surfaces, because unlike polyclonal antibodies made in another species, each monoclonal antibody reacts with a single component of the immunogen. They also have a multitude of practical applications in the study of growth factors, cell surface receptors, micro-organisms, and many other antigens. They have become routine tools for many diagnostic assays and are increasingly therapeutic applications are being developed, for instance the use of antitumour necrosis factor-a (anti-TNF-a) in the treatment of rheumatoid arthritis or the use of antibodies to respiratory syncitial virus to treat severe bronchiolitis in infants. For these clinical applications, it is possible to transplant the antigen binding sites of mouse antibodies into human immunoglobulins, retaining the antigen specificity. Antibodies that are 'humanized' in this way are less likely to provoke an immune response in recipients of the treatment.

Genetics of antibody production

The development of methods of DNA cloning, the use of the polymerase chain reaction, and sequencing have had a big impact on our understanding of immunoglobulin genes. The genes are arranged as shown in Fig. 5 on three chromosomes: 14 for heavy chain, 22 for _, and two for l. The antibody genes are arranged in exons, each coding for a single immunoglobulin domain, variable and constant region, with further exons for the hinge and transmembrane regions. The constant region exons are grouped according to antibody class. There are additional exons for the leader sequences which take the newly synthesized antibody chains across the membrane (and is then cleaved off). The transmembrane exon is only expressed on antibody that is attached to cell surfaces.

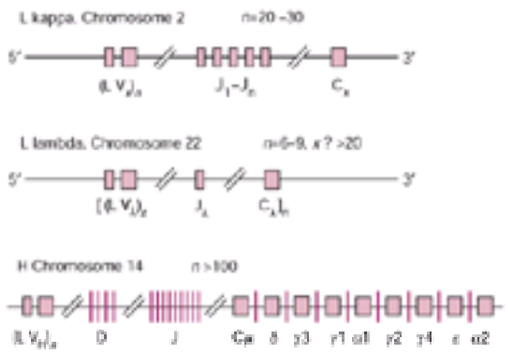

Fig. 5 Arrangement of the immunoglobulin genes. These are arranged on three chromosomes, chromosome 2 for *L*_, 22 for *L* l, and 14 for the heavy chain. The basic arrangement of the human genes are shown. *L*_ is arranged with a large number (*n*) of *V* genes, each preceded for a gene for the leader sequence *L*. Downstream are five *J* genes and further on the one *C* gene. *L*l is arranged in an unknown number (*n*) of sets, with a group of X (?*x* > 20) *L*–*V* pairs followed by one *J* and *C*. There may be six to nine such sets. *H* is arranged with a large number (>100) of *L*–*V* pairs followed by a set of *D* minigenes and a set of *J* genes. Downstream are the constant-region *C* genes, each split into separate exons for each domain, and an optional membrane segment, which are placed in the order shown.

The variable (V) genes are on the 5' side of the constant genes. (i.e. upstream, as DNA is read from 5' to 3'). There are many of these and it appears that any variable gene can combine with a constant gene on the same region of the chromosome. The antibody genes are therefore unusual and complex in their arrangement. Besides the multitude of variable genes there are also D (diversity) (for heavy chains but not light chains) and J (joining) genes which are short coding sequences (exons) found between V and C. The arrangement of the genes in B lymphocytes and plasma cells is different from that in all other cells. Early in B-cell development, a single heavy chain variable gene joins to a D and J gene to make a VDJ rearrangement. Similarly, in one light chain gene region a VJ rearrangement is made. Coupling of VDJ or VJ to the C gene occurs after transcription to nuclear RNA which is then processed to make messenger RNA, where, for both heavy and light chain transcipts, J is connected to C, and this is translated. The D segment, which is one to three amino acids long, is in the third hypervariable and the very many combinations of VD and J that are possible contribute substantially to antibody diversity. In addition to this, breaks in this region may occur in early B cells and be repaired in a random fashion by an enzyme called terminal deoxynuceotide transferase, which again adds further diversity.

Further variation in both heavy and light chain variable regions occurs by somatic mutation as B lymphocytes proliferate in large numbers in the germinal centres of lymphoid organs. This involves selection by antigen and a mechanism that locates the mutations in particular sites in the antigen binding site. As the concentration of antigen declines, only high avidity B cell clones will be stimulated to divide and this exerts selective pressure on mutations in the hypervariable regions. It is now known that developing B lymphocytes divide rapidly in the germinal centres and that a large proportion die by apoptosis (programmed cell death), a process not unlike that occurring in the thymus as T cells develop.

The process of gene rearrangement described above occurs on only one of the chromosomes encoding the heavy chain, and a similar process occurs on one of the four chromosomes encoding a light chain (allelic exclusion). A B cell is therefore committed to making one antibody, one heavy chain VDJC and one VJC by the time it is immunocompetent. It is not clear why this only happens on one chromosome for each chain. It is possible that it is such a complex process that the chances of a single cell making two rearrangements successfully is extremely remote. Alternatively, there may be some suppressive signal generated once a successful VDJ arrangement has occurred. This property provides a useful way of determining whether proliferating or infiltrating lymphocytes (for example in a tissue section) are polyclonal or monoclonal. The latter will all express either a _ or l chain; the former will include both light-chain types in roughly equal numbers.

The heavy chain VDJ sequence is attached to the C genes in an orderly progression during B cell development. The gene order is Cμ, C†, Cg3, Ca1, Cg 1, Cg 2, Cg 4, Ce, and Ca 2. All the B cells appear to go through a Cμ, stage, most go through C† and Cg, but may end up at one of the g subtypes, or a or e, probably jumping segments in the process. This progression involves deletion of DNA coding the no-longer-used C genes as the B cell develops. It is therefore a one-way process. Switching of B cells from production of IgM to IgG is a striking and normal feature of a simple antibody response. The process is, in part, regulated by external factors, particularly the cytokines IL4 and IL5. IL4 drive switching to IgE and IL4-secreting T cells (Th2 cells) probably play a key role in the development of allergic responses. It is also of practical importance that fetal and cord B lymphocytes do not switch from IgM to IgG production.

The T-cell receptor

Although the T-cell receptor was elusive for many years it is now well understood and some crystal structures have been determined. Early studies with monoclonal antibodies revealed a two-chain glycoprotein of 85 000 molecular weight, reducing to two components of 40 000 and 45 000 daltons. When its DNA was cloned it was found to rearrange in ways very similar to that described above for B-cell immunoglobulin receptors. Unexpectedly, two families of T cell receptors were found, the a–b receptor present of all conventional T cells and the g–† receptor present on a subset of T cells whose function is still less clear.

Both chains of ab T-cell receptors have been sequenced from multiple T-cell clones of known antigen specificity. Both chains are similar to immunoglobulin light chains with two external domains, each of about 100 amino acids. The N terminal domains of both a and b chains are variable. They include V and J segments, with a D segment for the b chain. Several families of Vb, Jb, Va, and Ja have been identified. The genes for these rearrange as T cells develop, whilst the cells are in the thymus. There are two constant region classes for the b chain, Cb1 and Cb2, which are very similar in structure. The number of possible T-cell receptors has been estimated to be a staggering 10^{14}, generated by the multiple combinations of the gene segments on the two chains. A substantial part of this diversity comes from the activity of the terminal deoxynucleotide transferase creating much variability at the V–(D)–J junction.

The crystal structure of the T-cell receptor shows that the three hypervariable regions (complementarity determining regions, CDR) form the MHC–peptide antigen binding site. This structure places the CDR-3 region, made up by the most hypervariable part of the T-cell receptor where the V–(D)–J join occurs, in a critical site to interact with the peptide part of the complex. The rules for this engagement are now being worked out. The T-cell receptor lies diagonally across the peptide binding groove of a class I MHC molecule and more at a right angle to the peptide in a class II MHC molecule. These orientations put the most variable parts of the receptor over the peptide and more conserved, but still variable, parts of the receptor over the MHC molecule.

Why do the T cells not simply use the antibodies as their receptor? The advantage of using MHC molecules as the antigen presenter is that it means that T cells do not see native antigen and thus cannot be inactivated by, for instance, free virus. In addition, by responding only to cell surface antigens the response can be controlled by signals derived from the presenting cell. Thus T cells that react with self-antigens in the thymus may be eliminated while those that react with foreign antigens in the periphery are stimulated.

The function of the T cells that carry the gd T-cell receptor remains enigmatic. In mice they are abundant in the intestinal mucosa. In humans they have been found at sites of chronic inflammation, particularly mycobacterial infections. Some bind to non-classical MHC molecules including CD1 and MIC-1, but why is less clear. Some are probably important in antibacterial immunity. One particular subset of T cells that carry some natural killer cell markers express a particular receptor and interact with CD1d; these T cells are thought to play a role in regulating Th1 and Th2 responses (see below).

Lymphocytes

Lymphocytes mediate immune reactions and can be divided into two groups: B and T cells.

B lymphocytes

B lymphocytes are the precursors of antibody-secreting plasma cells. They express immunoglobulin on their surface, which acts as antigen receptor. The B cell expresses only one pair of immunoglobulin VH and VL gene products and thus antigen receptors of only one molecular type and sequence. The progeny, or clone, of this cell retains the same commitment and the antibody secreted uses the same variable genes. Thus, antigen on first immune challenge selects B cells that already express appropriate receptors. These divide and some mature to antibody-producing cells while others develop into memory cells. The latter greatly exceed the original population in number and as they can in turn be activated by antigen to generate antibody-producing cells this provides a basis for the memory phenomenon.

Immature B cells express IgM or IgM plus IgD antibody as their receptor. As the B cells differentiate they switch their heavy chain VDJ gene product to associate with a g, a, or e chain and thus switch secretion from IgM to IgA or IgE. Memory cells have g, a, or e receptors and secrete this class without an intermediate phase.

A number of B-cell differentiation antigens have been found using murine monoclonal antibodies raised against human lymphocytes. The best characterized of them are shown in Table 4. As has been the case with the T cell antigens described below, it is gradually emerging that these have important functions. Thus, antibodies to CD20 trigger B cells to divide, CD22 is involved in B-cell signalling, CD19 is part of the B cell antibody receptor complex, CD21 is the complement C3b receptor and is also the receptor for Epstein–Barr virus (EBV) which readily transforms B lymphocytes *in vitro* and probably *in vivo*. Another molecule that is crucial in B cell signalling is CD40; its ligand, CD40L, is expressed on T lymphocytes. In the hyper-IgM syndrome, where there is a failure of B cells to switch from IgM to IgG production, DC4L is mutated, implying a role for CD40 in immunoglobulin isotype switching. CD40 is also expressed on dendritic cells and is important for receiving signals from CD40-ligand bearing T-helper cells to make them efficient at stimulating primary CD8+ T-cell responses by releasing the Th1-inducing cytokine IL-12.

Activation of B lymphocytes requires antigen and a signal from helper T (Th) lymphocytes which are themselves responding to the same antigen. The T cells, of the Th2 subset (see below) release cytokines including IL-4 and IL-5 as well as initiating signals through CD40; these activate B lymphocytes in the presence of antigen to divide and differentiate. Note that two kinds of signal are needed, an antigen specific trigger through the antigen receptor and a second type mediated in a non-antigen specific fashion. Inappropriate signalling, such as an antigen signal in the absence of the second type, can lead to inactivation of the B cells.

Besides secreting antibody, B cells have a role in antigen presentation that is increasingly recognized as important. B cells can bind foreign antigen directly through their immunoglobulin receptor or as an immune complex through the Fc or complement (immune complexes bind complement—see Chapter 5.4) receptors. Such antigen can be internalized and digested in endosomes to generate peptides that bind to class II MHC. In this way, small amounts of circulating antibody can enhance primary T-cell responses by facilitating processing of antigen and, in the early immune response, can act as a positive feedback.

B cells have a complex life-cycle that includes a selection process in the germinal centres of lymphoid organs. Here, many cells die by apoptosis and there is selection by antigen in an environment that favours somatic mutation. The ontogeny of B lymphocytes is of some clinical relevance because various leukaemia and lymphomas express surface antigens characteristic of B cells at various stages of development. Figure 6 gives the scheme for B-cell differentiation indicating the corresponding leukaemias and lymphomas. Studies on the immunoglobulin light chains expressed indicate that these malignancies are monoclonal diseases.

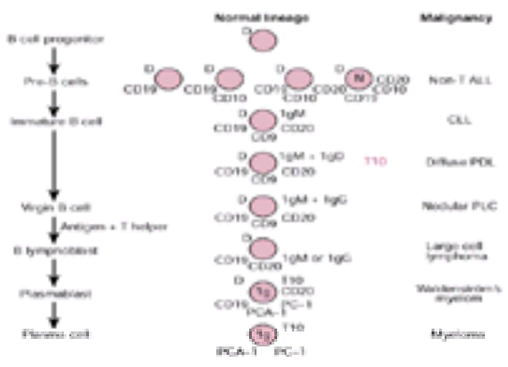

Fig. 6 Expression of B-lymphocyte differentiation antigens on the surface of differentiating B cells. The circles represent developing B cells. The CD antigens are listed in Table 4. In addition, D is HLA class II, μ is an intracellular immunoglobulin μ-chain. IgM, IgD, and IgG are surface immunoglobulins. Plasmablasts and plasma cells are shown with intracellular immunoglobulin (Ig). On the right are the B-cell malignancies that are thought to arise at the levels shown. They express the surface antigens indicated for their level. The B cell lymphomas and their abbreviations are described in Chapter 22.4.3.

Burkitt's lymphoma is a B-cell malignancy which is caused by Epstein–Barr virus (EBV). In addition to the presence of EBV DNA and protein in the malignant cells, there are some chromosomal rearrangements. The c-*myc* oncogene on chromosome 8 is translocated to chromosome 2, 14, or 22. There, it comes into close proximity with one of the three sets of immunoglobulin genes. It is likely that the tissue-specific enhancer that is present between the J and C exons activates the oncogene.

T lymphocytes

T lymphocytes require the thymus for their development and show a set of characteristic surface glycoproteins and their own form of receptor, as described above. They can be divided into types: cytotoxic T lymphocytes (CTL) that carry the CD8 marker and helper T cells that carry CD4. The latter can be divided according to the cytokines they release on antigen contact into Th1 (IL-2, IL-15, and interferon-g) and Th2 (IL-4, IL-5, IL-10, and IL-13). There are also intermediate T cells, Th0 cells, and some claim for more immunosuppressive T cells in the gut which secrete transforming growth factor (TGF-b). T cells may also be divided into those in an inactive state (virgin T cells) and preactive state (memory T cells) by the CD45 isotype on the cell surface. The short version of the molecule CD45RO marks cells that have recently seen antigen; however, fully differentiated CD8+ T cells can revert to CD45RA expression. Another marker that characterizes a subset of memory T cells is the chemokine receptor CCR7. This is involved in the trafficking of T cells to lymph nodes and is present on the surface of long-term memory T cells but is lost as these are stimulated to become effector T cells, functional outside the lymphoid organs.

T-cell differentiation antigens

Hybridoma-generated monoclonal antibodies have been used to explore the surface of T lymphocytes and these have revealed a series of molecules that play essential, accessory roles in antigen recognition by T cells (Table 5). Monoclonal antibodies to these structures are now often used to define T-cell subpopulations or leukaemias and are being used therapeutically. Their expression on T cells as they develop is described in Fig. 7.

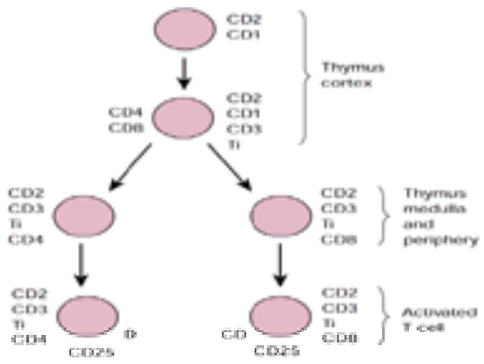

Fig. 7 Expression of T-lymphocyte differentiation antigens on differentiating T cells. The arrows indicate the probable pathway of T-cell development in the thymus and periphery. The CD antigens are described in Table 4 and in the text. Ti is the T-cell receptor. D is HLA class II. Negative selection (deletion of self-reactive T cells) occurs at the double positive (CD4+CD8+) stage and is followed by positive selection as either CD4 or CD8 is selected.

The T-cell receptor and CD3

The CD3 antigen is present on T-cell surfaces in association with the T-cell receptor. Antibodies to one will precipitate the other from detergent-solubilized cell membranes. The antigen is made up of three chains, which are closely associated with the T-cell receptor and form a complex on the inside of the T cell. When T-cell

receptor binds antigen the receptors cluster on the cell surface in lipid rafts, bringing the coreceptors CD4 or CD8 (see below) with them. This activates a cascade of kinases within the cell, involving kinases such as Lck and Zap 70. Through a complex series of interactions between enzymes and a parallel flux of calcium into the cytosol, several genes are activated including IL-2 and interferon-g. This causes a cytokine response within 6 h in memory T cells. Virgin T cells undergoing a primary T-cell response require additional activation through the cell surface glycoprotein CD28. This is activated by binding to its ligand CD80, which is expressed on dendritic cells, specialist antigen presenters. CD28 also sets up a kinase cascade important for T-cell activation and survival.

CD4

Recognition of processed antigen on antigen-presenting cells by helper T cells involves a specific binding interaction between CD4 and HLA class II molecules. Helper T cells carry the CD4 antigen. CD4 is also expressed at low levels on macrophages and some dendritic cells. The surface glycoprotein gp120 of human immunodeficiency virus (HIV) binds to CD4, giving the virus specificity for the cells that carry CD4, helper T cells, dendritic cells, and macrophages. The virus needs a second receptor to enter cells, either the chemokine receptor CCR5 or the chemokine receptor CXCR4. After high affinity binding to CD4, the gp120 undergoes a conformational change to expose the chemokine receptor binding site and then virus entry occurs. The cells targeted, with devastating consequences, by HIV are defined by the presence of these receptors, particularly CD4 which is restricted in its distribution to vital cells of the immune response.

CD8

This antigen is a glycoprotein of molecular weight 33 000. It is heavily glycosylated on a long stalk that holds an immunoglobulin domain away from the T-cell membrane. CD8 binds to the a-3 domain of HLA class I molecules and through its cytoplasmic domain recruits the tyrosine kinase Lck. It is the counterpart of CD4. In T-cell development in the thymus, immature T cells express both CD4 and CD8; if their receptor interacts strongly with self HLA antigens those T cells are deleted, if they react less strongly, but receive enhancing signals though CD4 or CD8, they are positively selected. In this process they lose expression of the inappropriate accessory molecule, CD4 or CD8, and become either CD4+ or CD8+ mature T cells.

Other important molecules on the surface of T lymphocytes are the chemokine receptors CCR5, CXCR4, and CCR7 which help to determine the trafficking of the T cells. The adhesion molecule LFA-1 (CD11a–CD18) is a two chain glycoprotein important for T and B cells to stick to endothelium and target cells. CD2 and CD44 have similar functions for different ligands. CD45 is an abundant glycoprotein that has several different isoforms and is expressed differently on lymphocytes at particular stages of differentiation; its cytoplasmic tail is a phosphatase that appears to control the state of activation of kinases such as Lck involved in T-cell activation.

T-cell subpopulations

Functionally, T lymphocytes can be divided into two major subtypes helper T cells (Th) which carry the CD4 glycoprotein and recognize antigens presented by class II HLA, and CTL which carry CD8 and respond to peptides presented by HLA class I. Th cells are divisible into two further major subtypes with different functions, Th1 and Th2. They differ in the cytokines they release on antigen activation. Th1 T cells release interferon-g, IL-2, and IL-15. These have direct and indirect antiviral effects and some inflammatory activity. They are potent in successful T-cell responses to infectious agents including mycobacteria, most viruses, and a range of parasitic infections. In contrast, Th2 cells release IL-4, IL-10- and IL-13. IL-10 has some immunosuppressive properties, IL-4 and IL-13 favour B-cell responses, facilitating the IgG immunnoglobulin switching. The extreme of a Th2 response is the IL-4 mediated switching to IgE production, resulting in allergic reactions. Th2 cells also produce IL-5 which stimulates eosinophils. Th2 immune responses are in combating parasitic worm infestations.

The balance between Th1 and Th2 is of considerable pathological interest. The two extreme forms of leprosy exemplify this beautifully. In tuberculoid leprosy, there is a Th1 response, with a strong inflammatory response of the delayed hypersensitivity type. In lepromatous leprosy, there is a Th2 response, the infection is poorly controlled with abundant organisms despite a good antibody response. Similar polarization can be found in tuberculosis (minimal disease (Th1) versus miliary (Th2)) and leishmania infection (minimal disease where there is a Th1 response and kala azar with a Th2 response). Whilst Th2 responses appear bad in these contexts, there are other situations where Th1 responses can be harmful, particularly in autoimmune diseases such as juvenile onset diabetes and rheumatoid arthritis. The polarization is not always complete and a variety of intermediate CD4+ T cells (Th0) have been described. Also, a Th3 type associated with the intestinal tract has been claimed, predominantly secreting TGF-b and protecting against immunization against food proteins.

For many years there were claims that there were a distinct population of specialist suppresser T cells that carried the CD8 marker. These do not exist as such but there are clearly suppressive phenomena mediated by subsets of CD4 or CD8 T cells through their cytokines or cytolytic effects. The term 'suppressor T cell' should be rested for the time being.

Cytotoxic T lymphocytes (CTL)

The effector T cells that mediate cellular immune responses are the CTL and Th1 cells that secreted cytokines such as interferon-g and tumour necrosis factor (TNF). Cytotoxic T cells recognize antigen plus class I HLA antigen on presenting cells. The antigen is peptide-derived, from intracellular proteins such as virus proteins. In fact, any cellular protein can enter the pathway that puts peptides into HLA molecules. The proteins are degraded by intracellular proteases, most important of which is the proteasome complex. The short peptides generated are transported by the transporter associated with antigen processing (TAP) into the endoplasmic reticulum where most are further degraded, but some that have the right sequence characteristics to bind to HLA class I molecules, and are then presented on the cell surface. CTL monitor the surface of cells for abnormalities and react when their receptors bind. In the case of an acute virus infection, the magnitude of the CTL response is extraordinary. Before infection, T cells with specificity for any single epitope (antigenic region) on a virus are extremely rare, less than 1 in a million lymphocytes. In several acute virus infections they have now been recorded at between 2 and 20 per cent of all lymphocytes, a massive expansion. These T cells are functional, able to kill virus-infected cells, and release cytokines such as interferon-g and TNF-a. The massive expansion is controlled by programmed cell death of the T cells and, as the virus antigen is removed, the number of antigen-specific T cells declines rapidly, leaving a memory T-cell response for rapid re-expansion should the virus attempt to reinfect.

There is considerable evidence that these T cells are crucial in clearing acute virus infections (such as measles, influenza) and controlling persistent infections, such as Epstein–Barr virus (EBV) or cytomegalovirus (CMV). Where CTL responses are impaired (e.g. by deliberate immunosuppression for transplantation) these viruses may escape control and cause disease, for example EBV-associated lymphomas. The CTL response is normally accompanied by a Th1 response that is important for initiating the CTL response and maintaining its functional activity and memory.

The CTL and Th1 responses, together often known as the 'cellular immune response' is central to the control of infections with intracellular pathogens that include not only viruses but some bacteria (e.g. *Listeria*, *Mycobacteria*) and protozoal infections (e.g. malaria liver stage). For some microbes, cytotoxicity is the important mediator of protection, for others interferon-g release or chemokine release is crucial. The CTL response could well be important in the control of some cancers. For those caused by viruses (EBV lymphomas, HBV-associated liver cancers, HPV-associated cervical cancer) this is already clear. There is increasing evidence that CTL responses are generated to some solid tumours, melanomas being the best example. For tumours and also many viruses, particularly HIV, CMV, EBV and HCV, selection of escape pathways arises. Many tumours and several viruses can decrease expression of HLA class I molecules on cell surfaces, making them invisible to CTL. Some viruses and many tumours mutate the epitopes recognized by CTL. Viruses and tumours can also increase expression of Fas-ligand on the cell surface, triggering apoptosis in the attacking T cells that express the ligand Fas. The presence of such mechanisms implies that the T cells are worth escaping from.

Graft rejection is a classical cellular immune response that has a long history in immunology. Both CTL and Th1 cells are involved and infiltrate the graft. HLA class II is essential to induce T helper cells and thus to activate T cells, the CTL recognize the foreign HLA class I molecules.

The role of thymus in T-cell function

T lymphocytes by definition are thymus derived. Thymectomized or congenitally athymic animals lack mature T cells and T-cell-mediated functions. Athymic (nude) mice and human infants with thymic hypoplasia (Di George syndrome) show no cellular immune responses and impaired antibody responses. B cells, however, can respond by secreting IgM to some polysaccharide antigens in the absence of T cells. Normal thymocytes carry the T-cell differentiation antigens described above and also CD1, which has some similarities to an HLA class I molecule but is not MHC encoded and has an unknown function in the thymus; the molecules are, however, also expressed on dendritic cells where they are involved in presentation of glycolipid antigens to T cells.

Immature lymphocytes enter the thymus from the bone marrow and first rearrange their T-cell receptor b genes, expressing first a primitive receptor associated with a

temporary second chain. Then the a chain genes rearrange and a functional receptor is expressed. At this point these thymocytes express both CD4 and CD8. Then two selection processes occur. The first is first deletion of any T cell that is self reactive (negative selection); dendritic cells enter the thymus from the periphery bringing in peptides from self tissues bound to self HLA class I and class II molecules. Self-reacting T cells that carry both CD4 and CD8 die by apoptosis. The second selection step is positive selection; a repertoire of T cells that express either CD4 or CD8 and have receptors that can recognize non-self peptide bound to self HLA molecules is generated. It is thought that the receptors on these T cells react weakly with the self peptides on the self HLA molecules, enough to trigger a survival signal rather than the stronger apoptotic signal of negative selection. During this process either CD4 or CD8 is lost. The T cells that then populate the periphery have an affinity for self that is too low to trigger a signal but can respond to foreign peptides bound to the self HLA molecules. In addition to the active selection processes in the thymus, many T cells whose receptors confer neither negative nor positive selection, also die. Thus more than 90 per cent of thymocytes die.

Some self-reactive T cells may escape to the periphery. Many of these are probably deleted but some may instead be put into an inactive (anergic) state. Under some circumstances these cells may be activated, for instance by a cross-reactive microbial peptide antigen, and autoimmunity can result.

A third way of preventing autoimmunity is for the self cell to be immunologically inaccessible. This may occur at certain sites such as the eye. It can also occur on cells that fail to express the costimulatory molecule B7 (CD80) which is necessary to initiate immune responses.

Cytokines

A number of cytokines have already been referred to, particularly in the context of understanding the function of Th cells and immunoglobulin class switching. They are small polypeptides, released by immunocytes and other cells, with normally short-range functions on target cells that carry the appropriate receptor. Specificity is therefore conferred by the nature and state of activation of the cell that makes the cytokine and by the cell that bears the receptor. The actual effects of cytokines tend to be pleiomorphic—activating cells, triggering general differentiation, and activation of specific genes (e.g. co-ordinated expression of HLA class I and II genes plus antigen processing genes, TAP and components of the proteasome by interferon-g). Of particular interest is the control of immunoglobulin isotype switching by cytokines (see Table 6) as well as by the CD40–CD40L interaction. Some cytokines, such as IL-12, seem more effective at orchestrating the others (the Th1 set for IL-12). Cytokine activity in terms of T-cell function can be described by the Th1–Th2 division. Also, Th3 cells that secrete the inhibitory cytokine TGF-b have been described. Although this is clear in mice it is more complex in human T cells, possibly because the original activation of the T cells *in vivo* is not under experimental control and also because the source of T cells, peripheral blood lymphocytes in man and spleen cells in mice, is different. In humans there are intermediate phenotypes known as Th0 cells. Nevertheless, it is a useful paradigm, implying that the response of Th cells may be set at the time of original activation and with implications for understanding disease processes. The cytokines relevant to the immune response are listed in Table 6. Some of these are being tried for therapy, for example interferon and IL-2. Also antibodies to some are useful, particularly anti-TNF for treatment of rheumatoid arthritis.

Accessory cells in the immune response

Antigen-presenting cells

Besides T and B lymphocytes, certain accessory cells play crucial roles in immune responses. Antigen-presenting cells are clearly important. B cells and CTL can react with antigen directly in native form or on altered cells, respectively, but both require signals from Th cells which are dependent on specialized presenting cells. The latter are either B lymphocytes or monocyte/ dendritic cells which can internalize antigen, degrade it, and display derived peptides in HLA class II molecules. They also carry specialized accessory molecules such as CD80 (also known as B7, not to be confused with HLA-B7) which binds to CD28 on T cells, delivering a cosignal. Dendritic cells are found not only in the T-cell areas of lymph nodes (see below) but also widely distributed in many organs. Here they may be important in activating local immune responses, for example to localized virus infection. Dendritic cells have to be activated to initiate CTL responses; this is achieved through the CD40 molecule recognized by CD40L on Th cells, although some viruses such as influenza may be able to activate directly. Dendritic cells seem to be able to internalize particulate antigens and can put these into the class I antigen presenting pathway. They are also able to take up apoptozing cells which may be an important pathway for initiating immune responses to viruses; macrophages are important for taking up necrotic cells and are not very effective in stimulating CTL responses. The requirements for initiating a primary CTL response are much more stringent than a secondary response, where the T cells may be able to respond and divide on contact with non-specialist cells that present antigen.

In the B-cell area of lymph nodes, the secondary follicles, there is a network of follicular dendritic cells. Unlike the dendritic cells referred to above, they are HLA class II negative but display receptors for C3b (of complement) and immunoglobulin Fc. They can therefore capture immune complexes which are particularly good at initiating primary immune responses. They are probably able to capture small amounts of antigen percolating through the sinuses of lymphoid organs. They can hold antigen at their surface for long periods, possibly months or years.

Adjuvants are chemicals given with antigen that are able to localize antigens at the site of injection, giving a local inflammatory response, activating macrophages, and antigen-processing cells and thus initiating immune responses more effectively. An example that was used clinically for several decades was potassium alum added to diphtheria and tetanus toxoids. By triggering a non-specific inflammatory reaction at the site of injection, an adjuvant may direct the type of immune response, Th1 or Th2, as well as enhancing the level. Recently, a hypothesis has been proposed by Matzinger, that non-specific danger signals are crucial in initiating immune responses to invading pathogens because self antigens do not provoke non-specific inflammatory responses and do not therefore provoke autoimmune reactions. Whilst the concept of the danger signal is probably correct, it is unlikely that the whole of self–non-self discrimination can be explained this way.

B cells are particularly important in priming Th cells. Because they carry antibody receptors, they can bind the foreign protein and internalize it for degradation. This can also be achieved if the antigen is bound to serum antibody; internalization occurs through the Fc receptor. In addition, complement receptors can facilitate presentation of antigen that is in immune complex form.

Natural killer cells

Interferon is a potent activator of natural killer cells. These are large, granular lymphocytes, neither classical T nor B cells, which lyse cultured tumour cells and virus-infected cells *in vitro* very efficiently. Their role *in vivo* is uncertain but they have been implicated in rejection of histocompatible bone marrow grafts, tumour immunity, antivirus immunity, and autoimmunity. They may thus form a general surveillance system, eliminating tumour cells and virus-infected cells as they arise. Although these effects are non-specific, antigen-specific T cells, by releasing g-interferon, could activate them to give a vital enhancement of T-cell killing.

Recently, much has been discovered about the specificity of their function. It is clear that they are particularly effective at recognizing and killing cells that lack expression of classical HLA class I molecules. Two series of receptors have been identified that specifically bind HLA class I molecules and deliver inhibitory signals to NK cells. One series KIR (killer inhibitory receptors) interacts with particular HLA-C or B molecules—there are at least three series of these receptors and different isoforms with differing specificities in each series. Expression of these receptors is complex and seems to vary on different NK cells within one individual. In addition, there are receptors in a related series that deliver stimulatory signals to NK cells. The second type of receptor is the CD94/NKG2 series which recognize a non-classical HLA molecule, HLA-E, which is expressed on a cell surface only if it has bound a peptide derived from the signal peptide of classical HLA class I molecules. This means that HLA-E can signal to NK cells that the classical class I molecules are present and thereby inhibit NK cell attack. Although one of the CD94/NKG2 family is activating, the predominant effect is inhibition of NK cell activity. Thus NK cells express a variety of receptors with differing specificities for HLA class I molecules, most with inhibitory function but some activators. It would appear that these cells are controlled by a set of modulating receptors that signal the type of cell that is in contact with the NK cell.

Mast cells

In addition to antigen-presenting cells, there are other accessory cells at the other end of the immune response which might be termed enhancers. The best characterized of these is the mast cell which has a receptor for the Fc portion of the e chain of IgE. When this antibody, bound by its Fc region to mast cells, binds antigen the cross linking of neighbouring Fc receptors triggers the cell to degranulate. This results in the release of histamine, kinins, and leucotrienes, which give the anaphylactic of type 1 allergic reaction. Mast cells also have receptors for some of the peptides released during complement activation.

Macrophages

Macrophages are derived from monocytes and are long-lived, potent phagocytic cells. Differentiation to macrophages and their activation is a response to local events such as contact with foreign material, lectins, and complement fragment C5a, but is also under the control of immune cells, with immune complexes and interferon-g, which is released by antigen-specific T cells, being potent activators. Macrophages are larger than monocytes and differ in their surface glycoproteins with less HLA class II antigen and increased amounts of receptors for immunoglobulin Fc fragments and complement. Within the cells, lysosomes are increased in number.

The main function of macrophages, and also granulocytes, is phagocytosis. This is greatly enhanced (several thousand-fold) if the foreign material is coated with antibody and/or the complement fragment C3b. Ingested particles are taken into the cell in a phagosome which fuses to a lysosome. Similar processes in granulocytes and macrophages are associated with a respiratory burst; there is a sudden uptake of oxygen and generation of hydrogen peroxide and hydroxyl radicals which are toxic to micro-organisms. Nitric oxide production through activation of NO synthase is also of considerable importance. Activated macrophages also produce a variety of enzymes that are important in inflammatory processes, including proteases, elastase, collagenase, plasminogen activator, and procoagulants. The last may account for the deposition of fibrin, which is responsible for the characteristic induration of delayed-type hypersensitivity reactions.

Macrophages also release monokines and synthesize complement components. The former include interleukin-1 and tumour necrosis factor (Table 6). The latter may help to amplify the local inflammatory responses. Bioactive lipids, including prostaglandins and leucotrienes, are also made.

Macrophages are thus highly active cells which are crucially important in converting immune responses into inflammatory reactions. They feature prominently in granuloma formation where antigen persists or forms immune complexes. Mycobacteria are thought to inhibit fusion between phagosomes and lysosomes and thus evade the toxic mechanisms. Under these circumstances, the macrophages form epithelioid and giant cells in forming the granuloma.

Like natural killer cells, macrophages may be dangerous to the body and a number of inhibitory receptors have been identified. These include the 'immunoglubulin-like transcripts', ILT-2 and ILT-4, which bind HLA class I molecules, both classical and non-classical. Again normal cells deliver a 'hands off' signal whereas HLA-negative cells would be targets. A similar situation applies to the ligand for CD46, the latter is expressed on red cells and protects them from destruction by splenic macrophages in the white pulp.

Complement

The complement pathway is described in Chapter 5.4. This is an important, intrinsic pathway of immunity, activated directly by micro-organisms or by immune complexes. Complement can activate cells such as monocytes, macrophages, and neutraphils, contributing to inflammatory responses.

Organization of the immune system

The immunocytes are divided into those which are circulating in blood and lymph, and those localized in lymphoid organs: the thymus, bone marrow, fetal liver, spleen, lymph nodes, and the gut-associated immune system of tonsils, Peyers patches, and intraepithelial lymphocytes.

The circulating lymphocytes follow precise routes. From the efferent lymph nodes they travel to the thoracic duct and thence to the venous blood. From the blood they return to lymph nodes or spleen through high-walled capillary venules. Gut-associated lymphocytes also circulate and tend to home back to gut lymphoid tissue, or bronchial or mammary tissue, thus distributing antigen-sensitive cells widely to all possible sites of entry of organisms.

The structure of a lymph node is shown in diagrammatic form in Fig. 8 (see also Chapter 23.1). The B cells are congregated in follicles. Primary follicles contain mostly early B cells with IgD on their surface. Activation of B cells by an immune response in a germinal centre results in division and accumulation of B cells to generate secondary follicles which contain mostly IgG-bearing B cells. Scattered through the follicle are helper T cells and follicular dendritic cells. From the follicles, stimulated B cells mature to plasma cells in cords in the medulla where they secrete immunoglobulin.

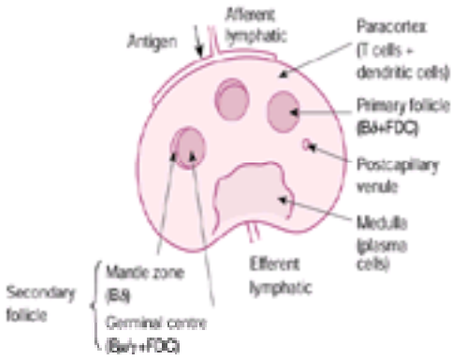

Fig. 8 Schematic representation of the structure of a lymph node. The drawing is not to scale but shows the main components. The cell types found in each region are indicated: B†, B cells expressing surface IgD; Bμ/g, B cells expressing surface IgM or surface IgG; FDC, follicular dendritic cells; T, T cells (a few T cells are also found in the germinal centres where B cells may present antigen).

The majority of T cells in the lymph nodes are in the paracortex surrounding the follicles. The T helper cells and Tc/Ts are found there. They are clearly associated with the HLA class II-positive dendritic cells. Antigen enters by the afferent lymphatics and percolates through the lymph nodes, activating immune cells via the antigen presenting cells.

The spleen is similarly organized in the white pulp, which surrounds the end arterioles, whence the cells and antigen enter. Circulating lymphocytes leave by venous sinuses (Fig. 9).

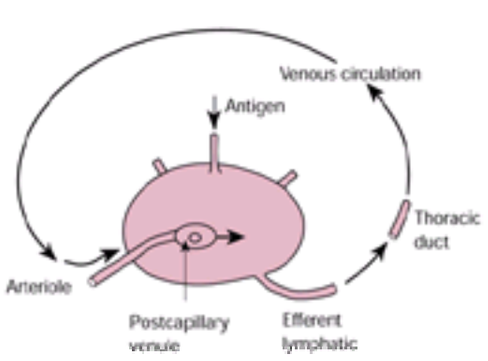

Fig. 9 Lymphocyte recirculation. Antigen enters the lymph node by the afferent lymphatics. Lymphocytes enter the lymph node through the walls of the postcapillary (high endothelial) venules. They leave by the efferent lymphatics, whence they go to the thoracic duct and the superior vena cava.

Conclusions

Immune responses are occurring in healthy individuals continuously. The immune system should be thought of as an essential part of the homeostatic mechanism, continually keeping out and destroying invaders and abnormal cells as they appear. At the same time it is regulating its own cells as they develop and circulate. Although the immune system has been described in terms of its individual components they do not react in isolation. Thus, an infecting virus, for instance, will evoke an antibody response, activate complement through the classical and alternative pathways, stimulate T-cell immunity involving both regulatory and effector T cells, stimulate lymphokine release, and activate natural killer cells. In a later chapter the consequences of abnormal immune responses are described, both where there is a deficiency in immune reactivity and where, for various reasons, the immune reaction itself is harmful.

5.2

Allergy

L. M. Lichtenstein

Introduction

Approximately 20 per cent of the population suffers from allergy. In allergy, exposure to common environmental substances induces the production of specific antibodies of the IgE class that arm mast cells and basophils to initiate a complex response which leads to the tissue inflammation. It is believed that the IgE response originally developed to combat parasitic diseases but this has never been proved.

Allergens are antigens which induce IgE antibody responses. They may be large molecules, usually proteins, or they may be small molecules, 'haptens', such as penicillin, which link to protein molecules to induce the immune response. Not all individuals who develop an IgE antibody response develop allergic symptoms, but after exposure to the allergen most will suffer rhinitis, asthma, or anaphylaxis. The synthesis of allergen-specific IgE by B lymphocytes is thought to be mediated by activated CD4+ T lymphocytes. The IgE occupies high-affinity receptors on mast cells and basophils and the response is triggered when these cells bind allergen. Murine CD4 T-cell populations have been defined as T_{H1} cells, which produce interleukin 2 (**IL-2**) and g-interferon, and T_{H2} cells, which produce IL-4 and IL-5. Both populations of cells secrete other cytokines. In humans, the distinctions between T_{H1} and T_{H2} cells are not so clear, but none the less help us to characterize allergic disease. Allergic individuals have much higher IgE levels than non-allergic individuals, which contribute to diagnosis. Allergen skin testing allows specific diagnosis.

Cytokines influence all phases of the allergic inflammatory response. IL-4 is required to initiate IgE synthesis, while ongoing synthesis is enhanced by IL-5. Other cytokines such as g-interferon downregulate IgE synthesis. Granulocyte–macrophage colony-stimulating factor (**GM-CSF**) and IL-3, -4, and -9 promote the differentiation and expansion of mast cells, whereas g-interferon interferes with their growth. Another group of recently discovered cytokines are the histamine-releasing factors, first identified in monocytes. Mast cells and, particularly, basophils, also synthesize cytokines which include IL-4 and IL-13. The stages of an allergic reaction are seen in Fig. 1, Fig. 2 and Fig. 3.

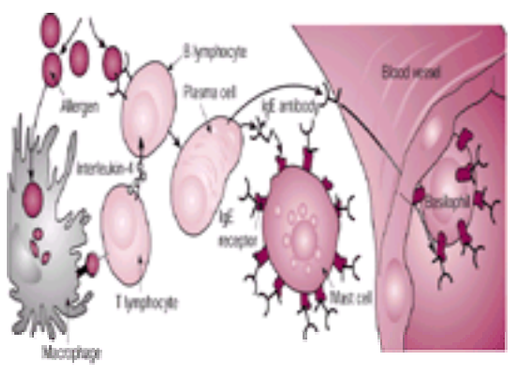

Fig. 1 Stages of an allergic reaction: sensitization. The initial meeting of an allergen and the immune system yields no symptoms; rather it may prepare the body to react promptly to future encounters with the substance. The sensitization process begins when macrophages degrade the allergen and display the resulting fragments to T lymphocytes (bottom left). The steps that follow are somewhat obscure, but in a process involving secretion of interleukin 4 by T cells, B lymphocytes mature into plasma cells able to secrete allergen-specific molecules known as immunoglobulin E (IgE) antibodies. These antibodies attach to receptors on mast cells in tissue and on basophils circulating in blood.

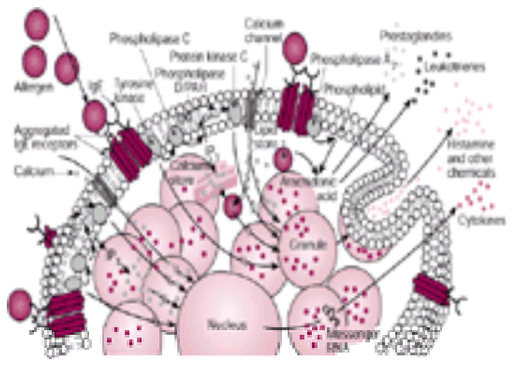

Fig. 2 Stages of an allergic reaction: activation of mast cells. In later encounters between the allergen and the body, allergen molecules promptly bind to IgE antibodies on mast cells (top left). When one such molecule connects with two IgE molecules on the cell surface, it draws together the attached IgE receptors, thereby directly or indirectly activating various enzymes (green spheres) in the cell membrane. Cascades involving tyrosine kinase enzymes, phospholipase C, protein kinase C, and an influx of calcium ions (black arrows) induce chemical-laden granules to release their contents. These cascades also appear to promote the synthesis and extrusion of chemicals known as cytokines (brown arrows). Other sequences of molecular interactions (green arrows) end in the secretion of such lipids as prostaglandins and leukotrienes. The various chemicals released by mast cells are responsible for many allergic symptoms. The reaction pathways shown are simplified and are only a few of those thought to occur; many are also only partly understood (broken arrows).

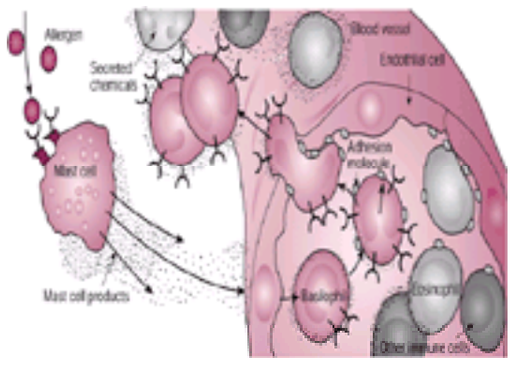

Fig. 3 Stages of an allergic reaction: prolonged immune activity. Chemicals emitted by activated mast cells (left) and their neighbours in tissue may induce basophils, eosinophils, and other cells flowing through blood vessels (right) to migrate into that tissue. The chemicals facilitate migration by promoting the expression and activity of adhesion molecules on the circulating cells and on vascular endothelial cells. The circulating cells then attach to the endothelial cells, roll along them, and eventually, cross between them into the surrounding matrix. These recruited cells secrete chemicals of their own (orange speckles), which can sustain immune activity and damage tissue.

Allergens

Modern techniques have facilitated characterization of important allergens, many of which have enzymatic activities that may favour penetration of mucosal surfaces. In the past, the allergen preparations used for diagnosis and therapy have not been standardized, resulting in unacceptable inconsistencies in diagnosis and treatment. The current trend is to insist upon standardization of such preparations, based on their major defined allergens. The mapping of T-cell epitopes has allowed development of peptide vaccines for immunotherapy; some of these have clinical efficacy and merit further therapeutic exploration.

Genetic basis of atopic disease

There is a genetic basis to the allergic diathesis. Allergic susceptibility is clearly polygenic. For example, certain ragweed allergens such as Amb a V and Amb a V1 are recognized in association with HLA DR2, the W2 and HLA DR11 haplotypes, respectively. Lineage studies of large families have suggested autosomal dominant or recessive patterns of inheritance. Rather than focusing on atopic individuals, early studies sought associations with one or more criterion: high serum IgE, positive skin tests, or clinical allergic disease. Linkage data suggested the presence of a gene for atopy on the long arm of chromosome 11. This finding implied that non-MHC linked genes may determine the overall predisposition to allergic disease, while MHC gene products control the specificity of the allergic response.

The cells involved in allergic disease

Mast cells and basophils

Tissue mast cells account for most acute allergic phenomena while the basophil, which infiltrates into the regions of an acute response, is responsible for chronic allergic manifestations. Both cell types originate in the bone marrow and have cytoplasmic granules. Tissue mast cells are found mostly in the lungs, skin, and gastrointestinal track, the location of most immediate hypersensitivity reactions. IL-3 and stem cell factor (**SCF**) are required for the growth, differentiation, and survival of basophils, while the added effects of SCF are critical for mast cell maturation and survival. The signal transduction events which are induced by cross-linking of cell-bound IgE by allergen have been studied with great interest, since interference with these signals would seem to be the best target for blocking the entire allergic response. Intracellular signals mediated by increased levels of intracellular calcium and activation of protein kinase C lead to phosphorylation of granule membrane proteins. These signals lead to the release of preformed mediators such as histamine and to the production of arachidonic acid metabolites including prostaglandin D and leukotriene C. This mode of activation is associated with cytokine generation.

Eosinophils

Circulating and tissue eosinophilia are cardinal manifestations of allergic diseases. Eosinophils are derived from the bone marrow aided principally by IL-5 but also by IL-3 and GM-CSF, and normally constitute less that 3 per cent of the circulating granulocytes. Tissue retention of eosinophils is determined by chemotactic factors which include chemokines (e.g. eotaxin), leukotrienes (e.g. LTC_4), and platelet-activating factor. Eosinophils have very few if any IgE receptors on their surface. Eosinophils contain highly cationic proteins including the so-called major basic protein. These are highly toxic products which have been implicated in the denudation of bronchial epithelium in asthma and in other types of cellular injury.

Monocytes, macrophages, and lymphocytes

Monocytes and macrophages may be activated by allergen binding to a low-affinity IgE receptor and contribute thereby to the non-specific inflammation of allergic diseases. Stimulated monocytes and macrophages produce many proinflammatory mediators and cytokines, including lysosomal enzymes, superoxide anions, lipid mediators, and diverse cytokines. Lymphocytes contribute critically to allergic disease.

The mediators of allergic disease

Histamine

This is the principal mediator of immediate hypersensitivity reactions; it is produced by basophils and mast cells and reacts with three specific histamine receptors. The first recognized, H_1, mediates hypersecretion of mucus, pruritus, contraction of non-vascular smooth muscle, and relaxation of vascular smooth muscle. There are now several non-sedating H_1 antihistamine drugs which are useful in controlling the manifestations of allergic disease. The H_2 receptor mediates enhanced gastric acid, mucus secretion, and bronchodilatation. There are also specific H_2 antihistamines. An H_3 receptor mediates the synthesis and release of histamine and neurotransmitters; anti-H_3 drugs are not available.

Eicosanoids

Eicosanoids are synthesized by mast cells, basophils, and eosinophils by the oxygenation of arachidonic acid metabolites via two pathways: the cyclo-oxygenase pathway forms prostaglandins and thromboxanes and the 5-lipoxygenase pathway generates leukotrienes. Prostaglandin D_2 and thomboxane A_2 are bronchoconstrictors. Leukotriene A is an unstable intermediate in the formation of leukotrienes B, C, D, and E. Leukotriene B is a chemotactic for leucocytes and leukotrienes C, D, and E increase systemic vascular permeability, smooth muscle contraction, and mucus secretions. The recent introduction of leukotriene antagonists has been a useful adjunct to the control of allergic diseases.

Platelet-activating factor

Platelet-activating factor is a proinflammatory molecule whose true function in allergic phenomena is not clearly understood. It is derived from the membrane phospholipids of mast cells and other cell types. Inhalational challenge with platelet-activating factor promotes bronchoconstriction and airways hyperreactivity in both asthmatic and non-asthmatic individuals and increases vascular permeability and mucus release. Platelet-activating factor is also a chemoattractant for eosinophils and neutrophils.

Kinins

Kinins are generated by kallikrein action on serum kininogens. Their biological activities are quite similar to histamine.

Allergic diseases

Anaphylaxis

Anaphylaxis results from the rapid degranulation of mast cells and basophils, usually, but not always, caused by the parental administration of drugs such as penicillin, or insect stings. Anaphylaxis is a medical emergency that can result in death either by cardiovascular collapse, laryngeal oedema, and/or bronchial smooth muscle constriction and anoxia. Anaphylaxis can also be induced by several food allergens such as cow's milk, shellfish, or peanuts. Anaphylactoid reactions, which do not act through IgE-related mechanisms, may follow ingestion of aspirin or other non-steroidal anti-inflammatory drugs or by the injection of radiocontrast media, metabisulphites, or opiates.

The clinical manifestations of anaphylaxis or anaphylactoid reactions are similar and may involve the skin (erythema, urticaria, angio-oedema), laryngeal oedema, bronchoconstriction, vascular shock, and gastrointestinal symptoms (abdominal pain, nausea, vomiting, or diarrhoea). These reactions cause tachycardia, arrhythmias, hypotension, and anoxia, leading to myocardial or cerebral damage. Treatment involves the removal of the inciting agent when possible with the immediate therapeutic use of adrenaline intravenously, if necessary. Antihistamines may be given but probably have little effect, and corticosteroids, while often recommended, are not useful in the acute phase. Attention to airway and cardiovascular support is crucial. After anaphylaxis, patients should be maintained under observation for a minimum of 24 h as the anaphylactic reaction may recur. Disseminated intravascular coagulation with widespread haemorrhage due to thrombocytopenia is a a severe late complication of anaphylaxis. Individuals allergic to insect venoms whose treatment is not complete, and patients who have food allergy should be advised to carry prepackaged adrenaline syringes.

Asthma (see also Section 17.4)

Extrinsic asthma is sometimes differentiated from intrinsic asthma. There is real doubt, however, as to whether intrinsic asthma exists or whether the causal allergen is simply not identified. Asthma affects 10 per cent of children and 3 to 5 per cent of adults and may range from a modest shortness of breath to a severe, life-threatening, obstructive ventilatory disease. By definition, asthma is characterized by widespread narrowing of the airways, which is reversible either spontaneously or as a result of treatment. However, chronic asthma may ultimately cause fixed airway obstruction. Asthma is usually associated with a personal family history of allergic disease and offending allergens may be known to precipitate attacks. However, a definitive clinical history and appropriate skin testing may be needed for diagnosis. Asthma may often be perennial, as a result of exposure to house dust mites or pet allergens.

Asthma is increasing all over the world, and this is especially true in inner-city African-American people. When wealth and environmental status are taken into account, the increase in African-American patients is still greater than that in Caucasian populations. The reasons for this are not known. Environmental pollution and cockroach allergy have been suggested to account for this, but evidence is lacking. The increase in asthma, for example, was shown to be greater in western Germany than in heavily polluted eastern Germany. The pathogenesis of asthma is exceedingly complex. When an atopic or asthmatic individual is challenged by bronochial allergens there is an early bronchocontraction, which is due to the release of mediators such as histamine and leukotrienes, followed by a recovery and a so-called late-phase response, which has been shown to be due to the infiltration of basophils, eosinophils, and other proinflammatory cells as well as the mediators of the acute phase. Asthmatic individuals have a heightened non-specific response to bronchoconstrictors such as histamine, methacholine, and especially, bradykinin.

The diagnosis and management of asthma are discussed in Section 17.4. However, a comment on a new therapy is appropriate here. A humanized anti-IgE antibody has been developed at Genentech and has been used in a variety of clinical trials. The use of this antibody in appropriate dosage intravenously decreases the serum IgE by more than 90 per cent. Moreover, as we predicted 20 years ago, based on the close correlation between serum IgE and mast cell and basophil IgE receptor number, it also decreases the IgE receptors on these cells. When this reduction is sufficient, there is a partial or complete inability to elicit basophil histamine release and the results of skin tests can be depressed or negative. The appropriate individuals for treatment with this regimen are just those who most need it: asthmatic patients with sensitivities to multiple allergens. In these individuals, the number of allergen-specific IgE antibodies can be reduced below the necessary level for initiating mediator release. In most individuals with asthma caused by a single or a few allergens, anti-IgE therapy will not be helpful. Clinical trials in a mixed population, including those who should and should not be receiving anti-IgE, showed a modest amelioration of asthma. It seems likely that if therapy were limited to appropriate individuals, the relief may be greater.

Allergic rhinitis

Allergic rhinitis affects about 10 per cent of the population and may be seasonal, in response to the pollens of weeds, trees, and grasses, or perennial, usually linked to house dust mite sensitivity or animal dander. The symptoms are sneezing, nasal congestion, rhinorrhoea, and often pharyngeal and conjunctival pruritus. Inspection of the nasal passages usually reveals a pale mucosa with swollen turbinates. The disease may be diagnosed by the timing of symptoms since grass, tree, or weed pollination occurs at predictable times, or symptoms may appear in association with pet exposure. In order to induce allergy, the particles of pollens or dust mite must be in the range of 10 to 100 μm in diameter. Nasal polyps may accompany the mucosal oedema, particularly in perennial rhinitis. Vasomotor or non-allergic rhinitis has many of the same symptoms but it is not due to IgE-mediated events. The diagnosis of allergic rhinitis is made by clinical history and evidence of specific IgE antibodies by skin testing or by the presence of serum specific IgE detected in the laboratory. The former diagnostic test is preferable.

Insect venom allergy (see also Chapter 8.2)

Insect venom hypersensitivity can be demonstrated in approximately 20 per cent of individuals in the United States, although only 3 to 5 per cent have a history of an anaphylactic reaction. While the number of deaths caused by this sensitivity is few (perhaps 50 per year in the United States), the social morbidity induced by insect sensitivity is very significant and this condition is one of the few where allergen immunotherapy is clearly indicated and effective. The history of the treatment of insect sensitivity shows how misleading uncontrolled studies can be. The disorder was formerly treated with 'extracts' derived by grinding-up the entire insect and injecting it. When controlled studies were initiated, it was found that treatment with placebo and whole-body extract were identical, while, as noted, venom immunotherapy was almost completely effective.

Insect reactions are characteristic of the order Hymenoptera including honey bees and vespids, such as wasps, white and yellow hornets, and yellow jackets, as well as polistes and fire ants. Another form of response to an insect sting is a large local reaction which occurs immediately contiguous to the sting and does not involve any life-threatening response of blood vessels or airways. These individuals rarely develop systemic reactions and usually do not require specific treatment, but in some these reactions are very large, crossing a joint space and causing marked discomfort. Immunotherapy should be considered in these individuals because it is effective. Diagnosis, as with other allergies, can be established by history, skin testing, or by the measurement of specific IgE antibodies. Rarely, an individual will have an anaphylactic episode despite being unaware of the sting, so this possibility must be considered in all cases of idiopathic anaphylaxis. While patients are unprotected, as in early stages of immunotherapy, they should carry emergency kits containing adrenaline.

Since immunotherapy is extremely effective, it should be used in all adult patients. Immunotherapy is usually continued for 4 or 5 years and may then be stopped, although there is some risk even after the several years of therapy. There is a difference between adults and children with respect to the manifestations of insect hypersensitivity. In adults, most reactions involve the airways or vascular system and are life-threatening. This occurs only rarely in children, with most manifestations being cutaneous. Children who have had such a cutaneous reaction usually do not have a further reaction on re-sting and need not be treated.

Urticaria (see also Section 23)

Urticaria is characterized by well-defined areas of transient pruritic dermal oedema, demarcated by a red border, which usually resolve spontaneously within a few hours, although episodes may continue for days. If the oedema spreads through the underlying epidermis, then it is called angio-oedema. The latter occurs mostly in the periorbital regions, the lips, the tongue, and the oropharynx and does not itch. In these instances, the possibility of pharyngeal obstruction may develop rapidly. Urticaria is probably due to mast cell degranulation, whether this is immunologically or non-immunologically mediated. Basophils may play a role in the longer episodes. Biopsies of acute urticarial lesions simply show oedema, but infiltration with neutrophils and eosinophils with perivascular monocytes may occur. Most

commonly, urticaria is 'idiopathic' as no offending allergen can be identified. However, certain foods such as eggs, shellfish, and peanuts, or drugs are implicated occasionally. There is also a syndrome caused by aspirin and other non-steroid anti-inflammatory agents. Underlying atopy is not usually associated with urticaria.

Acute urticaria usually resolves within hours or days. In urticaria which is protracted or recurrent, the causal agents are usually undiscovered. However, increasingly, antihypertensive drugs, antirheumatoid arthritis drugs, and hormone-based medications such oral contraceptives are identified as triggering agents. There are forms of urticaria that have physical triggers: dermatographism is the condition where individuals suffer from urticaria on scratching or pressure. Cholinergic urticaria is associated with a tendency to show symptoms due to perspiration. Urticaria may also be evoked by cold, heat, pressure, or sunlight. There is a rare condition called hereditary angio-oedema, which is an autosomal dominant disorder characterized by severe episodic attacks of intractable bowel, laryngeal, and cutaneous angio-oedema. A quantitative or qualitative defect of the C1 esterase inhibitor is associated with an uncontrolled activation of complement components, C4 and C2.

If attacks of urticaria are recurrent and without obvious precipitating factors, patients should keep a diary to document food, beverage, and drug intake. In this way, triggers may be identified. It should also be remembered that urticaria sometimes is associated with systemic diseases such as lymphoma or systemic lupus erythematosis.

Treatment at first is with antihistamines, and since they may have to be used quite vigorously, the non-sedating antihistamines are probably preferable. These may be ineffective and, if so, some of the other sedating H_1-antihistamines such as cyproheptadine or cetirizine should be used. Systemic corticosteroids may be required in very severe cases that do not respond to other treatments.

Food allergy

True IgE-mediated food allergy is far more rare in adults than is generally believed. As noted, this usually occurs with the ingestion of specific allergens such as eggs, nuts, or shellfish. Food allergy is far more common in children. Skin tests are rather ineffective and double-blind, controlled, oral challenge is usually necessary for diagnosis.

The diagnosis of allergic disease

Skin testing

Skin testing was first described in the 1860s by Charles Blackley. It may be performed at any site, but is usually on the lower aspect of the forearm. Allergen testing must be accompanied by saline as a negative control and histamine as a positive control. Methods differ with intradermal skin testing being most common in the United States while prick testing, a lancet through a drop of allergen extract, is in frequent use in the United Kingdom. Results are read at 15 to 20 min and are interpreted by several techniques which measure the magnitude of the weal and flare response. Large numbers of skin tests are not usually indicated; skin testing with 5 to 10 different allergens, based on history, is the proper clinical procedure. The identification of food allergies is less useful, since there are many false positives requiring appropriate double-blind ingestion of suspected foods.

In vitro tests for specific IgE antibodies

Such testing is necessary in certain conditions such as in dermatographism and in young children. Allergen extracts are immobilized on an insoluble particle and then are allowed to react with a patient's serum. After appropriate washing, antihuman IgE is added, either radiolabelled or conjugated to an enzyme.

The treatment of allergic disease

The most effective measure is allergen avoidance, and this should be rigorously attempted by scrupulous house-cleaning, impenetrable mattress and pillow covers, and the use of air conditioning and filters. The first line of medical treatment is with long-acting antihistamines. The standard antihistamines should be tried first as they are much cheaper than the non-sedating antihistamines and only a small percentage of the population are sedated by them. The next line in therapy is a topical corticosteroid spray. Used properly, these have no systemic side-effects and are very effective. Topical vasoconstrictors are not recommended as they cause a rebound chemical rhinitis.

For rhinitis unresponsive to these measures, immunotherapy involving weekly injections of gradually increasing doses of the allergens to which the patients are sensitive is effective, as shown by double-blind trials in the United Kingdom and the United States. The new standardized allergen extracts should be administered by an experienced physician. Immunotherapy is not effective for asthma in children and has marginal utility in adults.

The underlying immunological mechanisms of successful immunotherapy have not been fully determined. There is an increase in specific IgGantibody to the allergen that is associated with successful immunotherapy, but this association is not felt to be causal. Other types of immunotherapy are being evaluated: in one, the relevant allergen peptides are determined by reaction with T lymphocytes. This has been shown to lead to significant clinical improvement unassociated with any changes in allergen-specific IgG or IgE. The method has been largely abandoned because it was shown to be less clinically effective than standard immunotherapy; however, only a single regimen was examined. The therapy has considerable potential as the peptides are completely unreactive with mast cells or basophils and is thus extremely safe. Another new therapy uses allergens linked to bacterial DNA, which leads to a complete switch of the established T_{H2} response to a T_{H1} response in mice. Recent experiments in primates shows a similar type of immune response to these materials and the results of clinical trials are eagerly awaited.

5.3 Autoimmunity

Antony Rosen

Introduction

The effector mechanisms that the immune system utilizes to destroy extracellular pathogens, or host cells that harbour intracellular foreign bodies (such as mycobacteria or viruses) must be appropriately targeted if indiscriminate damage to normal host tissue is to be avoided. Under most inflammatory circumstances, some bystander tissue damage is unavoidable. In most circumstances, this damage is self-limited, due to efficient clearance of the exogenous antigen source and appropriate down-modulation of the immune response. Tissue damage in autoimmune diseases differs fundamentally from bystander damage in that the host immune system is specifically activated and driven by self-components, focusing damaging immune effector pathways on host tissues expressing those components, in an autoamplifying and self-sustaining way. The danger inherent in initiating a self-sustaining, specific immune response directed against components of self-tissues is intuitively apparent, since antigen clearance under these circumstances is necessarily associated with complete tissue destruction.

It is now clear that an autoimmune component is a feature of many human diseases. Indeed, there are some estimates that autoimmune diseases afflict more than 3 per cent of inhabitants of Western countries, and impose a significant personal and economic burden on individuals and nations. This chapter will illustrate many of the principles unifying various autoimmune states, and will present a conceptual framework within which to understand their aetiology, pathogenesis, and pathology. The rapid advances in knowledge being made in this group of disorders predict that disease mechanisms will soon be more clearly understood, and will greatly impact therapeutics.

Definitions

Autoimmune disease occurs when a sustained, specific, adaptive immune response is generated against self-components, and results in tissue damage or dysfunction. Although a single immune effector pathway may predominate in generating tissue dysfunction and damage in some autoimmune diseases, it is much more frequent for multiple effector pathways to participate in generating the final phenotype. Those pathways which generate tissue damage or dysfunction include autoantibody binding to target cells, immune complex-mediated activation of complement and Fc receptor pathways, cytokine pathways, and lymphocyte-mediated cytotoxicity of target cells. The nature and sites of the tissue damage are what determine the pathological and clinical features of the specific diseases.

Tissue-specific autoimmune diseases (Table 1)

These occur where immune-mediated damage is restricted to a particular tissue or organ that specifically expresses the targeted antigen. Pertinent examples include: (i) Graves' disease (where autoantibodies bind to and stimulate the thyroid-stimulating hormone receptor, resulting in thyrotoxicosis); (ii) myasthenia gravis (where autoantibodies target the acetylcholine receptor at the neuromuscular junction, resulting in muscular weakness and fatigue due to the inefficient transmission of the acetylcholine signal); and (iii) insulin-dependent diabetes mellitus (where a cytotoxic T-cell response to the b-cells of the pancreatic islets results in destruction of the insulin-producing cells).

Systemic autoimmune diseases (Table 2)

These are frequently characterized by simultaneous damage in multiple tissues (such as kidney, lung, skeletal muscle, nervous system, and skin). Unlike tissue-specific autoimmune diseases which target tissue-specific antigens, autoantibodies in systemic autoimmune diseases are frequently directed against molecules expressed ubiquitously in multiple tissues. Examples include the tRNA synthetases targeted in autoimmune myositis, the small nuclear ribonucleoproteins (snRNPs) targeted in systemic lupus erythematosus, and topoisomerase-1 targeted in scleroderma. Each of these molecules is expressed in all cells, where they play critical roles in essential cellular processes (such as protein translation, mRNA splicing, and DNA replication and remodelling, respectively). Recent studies have suggested that novel forms of these ubiquitously expressed antigens are generated when cells undergo some forms of apoptotic death, and that apoptotic cells may represent an important source of immunogens in this group of disorders. While tissue damage is frequently mediated by numerous mechanisms in systemic autoimmune diseases, deposition of immune complexes at sensitive sites (such as skin, joints, and kidney) represents a prominent mode of tissue damage (see below).

Non-sustained autoimmune diseases

These are characterized by organ or tissue damage and dysfunction, which tends to be self-limited and resolve after the first attack, and are very unlikely to recur (e.g. epidemic Guillain–Barré syndrome). These processes typically occur in the setting of infection, and are associated with cross-reactive antibody responses that recognize both components of the infecting organism as well as the target tissue.

Epidemiology

Autoimmune diseases may affect individuals at all stages of life. In general, diseases have a predilection for beginning after the second decade, with peak incidence in the third to sixth decades. In many instances, females predominate, with the magnitude of this sex difference varying among the different diseases. Thus, for the systemic autoimmune diseases (such as systemic lupus erythematosus, rheumatoid arthritis, Sjögren's syndrome, scleroderma, and autoimmune myositis) and autoimmune thyroid disease, the female:male (F:M) ratio is approximately 4:1 to 9:1, whilst for insulin-dependent diabetes mellitus, multiple sclerosis, and myasthenia gravis, the female predominance is much less prominent (F:M ratio less than 2:1). The exact mechanisms underlying this female predominance remain unknown, but this striking biological difference provides a major clue to pathways underlying susceptibility to autoimmunity.

Aetiology

A general theme in the autoimmune diseases is that the diagnostic phenotype appears subacutely over weeks to months, even though non-specific symptoms and signs frequently predate this. Examples include the fatigue and constitutional symptoms that predate diagnosis of systemic lupus erythematosus and rheumatoid arthritis. The well-developed phenotype represents a highly driven immune response directed against self-antigens, which is amplified between the moment of initial immunization and development of diagnostic disease features. It is therefore operationally useful to divide autoimmune diseases into separate kinetic phases: (i) susceptibility (pre-disease, in which inherited or acquired defects in pathways required to maintain tolerance to self-antigens render the individual susceptible to

disease initiation); (ii) initiation (the interface of susceptibility genes and unique environmental events, which initiate an immune response directed at and driven by self-antigens); and (iii) propagation (a self-amplifying phase in which the specific immune response to self-antigens causes damage of tissues, with the release of more antigens, which further drive the immune response). Although these phases are conceptually distinct, they probably overlap considerably *in vivo*. Diagnostic symptoms and signs represent the highly amplified form of the phenotype generated by the immune system, and generally are kinetically widely separated from the initiating event. This has greatly complicated the study of events underlying disease initiation, since this phase is frequently non-specific and difficult to classify clinically.

Both genetic and environmental factors play important roles in initiation and propagation of autoimmune diseases. They probably play their central roles by regulating the activation, function, and targets of the host immune system. There is also evidence that stochastic processes play an important role in disease initiation, greatly complicating studies to define the causes and mechanisms of autoimmune disease (see below).

Genetic factors

There is accumulating evidence that numerous genes interact to determine the susceptibility threshold for initiating and propagating a self-sustaining autoimmune process in a given individual. Relevant genes include genes that: (i) regulate the immune response; (ii) facilitate efficient, non-inflammatory clearance of apoptotic cells (such as C1q and C-reactive protein); or (iii) influence the target tissue. Recent genetic studies in mice by Wakeland and colleagues in systemic lupus erythematosus (see below), and by Todd and colleagues in human and mouse insulin-dependent diabetes mellitus, have underscored several important observations.

1. Multiple genes interact to generate the final phenotype. Some of these genes render an individual susceptible to initiating an autoimmune response; others affect the target tissue and contribute to the fine disease phenotype.
2. Background genes can have a profound effect on the ability to generate a self-sustaining phenotype. The presence or absence of suppressor genes appears to be particularly important.
3. Genes in the MHC region as well as non-MHC genes appear to play critical roles. While there is a particularly striking contribution from MHC alleles (particularly MHC class II) to disease susceptibility and protection, the mechanisms underlying this phenomenon are still incompletely defined.

MHC class II genes

The associations of MHC class II alleles with disease susceptibility and phenotype can be grouped into the two broad categories that follow.

Association with an increased frequency of the disease itself

Some MHC class II alleles are found at increased frequency in patients with different autoimmune diseases. For example, patients with rheumatoid arthritis have an increased frequency of HLA DR4. HLA DR4 (initially defined serologically) encompasses numerous different alleles that have been defined by sequencing. Interestingly, not all subtypes of HLA DR4 are associated with an increased frequency of rheumatoid arthritis, but those alleles that are associated with this disease share a short amino acid sequence (QKRAA) at positions 70 to 74 of the b-chain of the HLA DR molecule. This sequence, termed the 'shared epitope' is located along the peptide-binding groove of HLA DR4, which presents peptides to the antigen receptor of T cells. Interestingly, this same 'shared epitope' is present in many individuals with rheumatoid arthritis who are positive for HLA DR1.

A similar principle appears to hold for patients with insulin-dependent diabetes mellitus, where there is a strong association of disease with a specific DQb genotype. Whereas the DQb sequence from most normal individuals has an aspartic acid at position 57, most patients with diabetes from the same population group had valine, serine, or alanine at that position.

Since MHC class II molecules function as a scaffold for presentation of specific peptides to T cells (see below), it is possible that this MHC-encoded susceptibility to disease reflects the ability of these alleles to present unique self-peptides to autoreactive T cells. Presentation of these specific peptides may play a critical role in disease initiation and propagation. It is important to note that an added level of complexity appears to be present that has not yet been accounted for. The presence of significant linkage disequilibirum within the MHC region (i.e. large stretches of DNA do not undergo recombination, generating functional cassettes of associated genes) also creates the potential for the disease association of particular MHC alleles to be influenced by additional genes on the extended haplotype in affected individuals.

Determination of which autoantibodies are produced in patients with a particular disease

In some autoimmune diseases, certain MHC class II alleles are strongly associated with the ability to mount a particular autoantibody response in that disease. For example, glutamate at position 34 and leucine at position 26 of the DQa1 and DQb1 chains, respectively, have the strongest association with the ability to make antibodies to Ro and La (ribonucleoprotein antigens in systemic lupus erythematosus/Sjögren's syndrome). Similar observations have been made for numerous other autoantibody specificities, for example anti-DNA, antiphospholipid, and antiribonucleoprotein antibodies. This specificity may again reflect the ability of a particular MHC class II molecule to capture and present self-peptides to T cells. Where specific autoantibodies are associated with unique elements of disease phenotype (such as anti-DNA with renal disease, anti-Ro with photosensitive skin disease), MHC alleles may also be associated with specific disease phenotypes.

Non-MHC genes

Genes outside the MHC affect both susceptibility to, and the phenotypic expression of, autoimmune disease. For example, in studies performed by Wakeland and colleagues in lupus-prone mice, susceptibility and severity of lupus nephritis have been mapped to several different genetic intervals, including regions on chromosomes 1 (*sle1*), 4 (*sle2*), 7 (*sle3*), and 17 (*sle4*). While *sle1* mice exhibit loss of tolerance to chromatin and make autoantibodies to nucleosomes, they do not develop lupus nephritis. Similarly, mice having *sle3* exhibit low-grade polyclonal B- and T-cell activation, and only mild glomerulonephritis. Mice having both *sle1* and *sle3* and female gender show robust autoantibody response (targeting numerous antigens including nucleosomes), splenomegaly, and severe, fatal glomerulonephritis. The definition of the complex genetics underlying autoimmune diseases may delineate those critical pathways required for development of self-sustaining disease, which might be amenable to therapy (see Fig. 1).

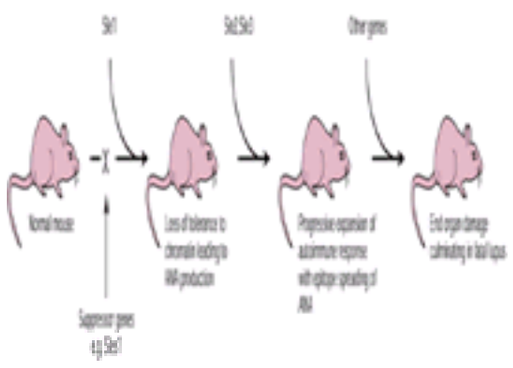

Fig. 1 Genetic susceptibility to autoimmune disease involves multiple interacting loci. Wakeland and colleagues have shown that numerous genes (*sle1*, *sle2*, *sle3*) interact to generate lupus-like autoimmunity in mice. By taking a non-autoimmune mouse (B6), and making a series of mouse strains carrying discrete disease susceptibility intervals, these investigators reproduce fully the phenotype in a lupus-susceptible host (NZM2410). In addition to genes that have a positive effect on generating the autoimmune phenotype, other 'suppressor' genes may counteract the effects of susceptibility genes. (Redrawn from Wakeland EK *et al*., 1999, *Immunity* **11**, 131–9).

Similar types of observations have been made in insulin-dependent diabetes mellitus, where multiple non-MHC genes are associated with development of disease. There has also been the recent description of a single non-MHC gene (AIRE—for autoimmune response—that appears to be a transcription factor) which is strongly

associated with the development of autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia (APECED) syndrome. The mechanisms whereby single or combinations of genes render individuals susceptible to development of autoimmune diseases are not yet clear, but major strides in this area are likely to be forthcoming within the next 5 to 10 years.

Environmental factors

That environmental insults and stochastic events influence the development of autoimmunity is clear from twin studies and in animal models, as individuals with an identical genotype may be variably affected by disease. For example, the concordance of systemic lupus erythematosus in identical twins is approximately 30 to 50 per cent, and for rheumatoid arthritis it is only about 15 per cent. Many potential environmental insults have been suggested to play a role in autoimmune diseases. These include infections, irradiation, and exposure to drugs and toxins. For example, exacerbations of systemic lupus erythematosus can follow sunlight exposure, and there are numerous reports that disease initiation may have a similar association with ultraviolet irradiation in rare patients. Numerous infections have been postulated to play a role in disease initiation across the spectrum of human autoimmune diseases (see below). In rare cases, the association between antecedent infection and subsequent development of disease is evident (for instance autoimmune myocarditis induced by Coxsackie virus infection, acute rheumatic fever following streptococcal infection, and Epstein–Barr virus infection with childhood systemic lupus erythematosus).

In the majority of autoimmune diseases an environmental connection has not been possible to confirm with any certainty. This does not imply that a causal connection does not exist in these instances, but rather reflects several features of the diseases that greatly complicate firm establishment of such a connection. These are (i) the kinetic complexity of the autoimmune diseases—since establishment of a recognizable disease phenotype often takes months, evidence of the initiating insult may have disappeared by the time the environmental component is sought for the first time; (ii) several different environmental insults may induce a similar response; and (iii) the environmental force may be extremely frequent in the population, and may only induce autoimmune disease in a unique subset of individuals with appropriate susceptibility genes.

How environmental forces influence initiation of autoimmune diseases is not yet known for most autoimmune diseases, but several plausible mechanisms have been advanced. These include: (i) the disruption of cell and tissue barriers, allowing previously sequestered antigens access to a previously ignorant immune system (see below); (ii) inducing novel pathways of antigen presentation; (iii) alteration of the structure of self-antigens; and (iv) molecular mimicry. Some of these mechanisms are dealt with in more detail below.

Pathogenesis

Although extraordinarily complex in detail, the adaptive immune response operates by a set of relatively simple principles: (1) the immune system has the capacity to discern molecular structure in extremely fine detail; (2) it has a uniquely adapted set of signalling systems that computes the amount of antigen; and (3) it responds in a binary way to contextual information, that is, seeing an antigen in the setting of a dangerous context (such as infection) initiates an immune response, while seeing the antigen in the absence of such costimulatory signals leads to tolerance. Numerous studies over the past two decades have underscored that the sustained autoimmune response is extremely similar to adaptive immune responses directed against foreign pathogens, except that the driving antigens in autoimmune disease are self-molecules. For example, autoantibodies in most autoimmune diseases display evidence of isotype switching (for example from IgM to IgG or IgA), and show features of having undergone affinity maturation through somatic hypermutation. These properties of autoantibodies require the activity of antigen-specific CD4+ T cells, and have therefore focused much attention on defining the mechanisms whereby self-reactive T cells are activated in autoimmunity. Since this is such a central issue in the understanding of autoimmunity, and since there are numerous mechanisms employed by the normal individual to prevent activation of autoreactive T cells, it is important to review briefly the mechanisms that the normal immune system uses to maintain tolerance against self-proteins.

Thymic and peripheral T-cell tolerance purges the T-cell repertoire of receptor specificities that recognize self-peptide/MHC complexes

In order to prevent the survival of lymphocytes that will probably encounter their cognate antigens in healthy self-tissues, with potential autoimmune destruction of tissues, the immune system spends significant energy on testing the specificity of all receptors generated during antigen-independent development of lymphocytes, initially in the thymus and subsequently in the periphery. When the T-cell receptor generated through somatic recombination recognizes a peptide/MHC complex in the thymus with high affinity/avidity, cells expressing this receptor are negatively selected (since they are probably self-reactive, and will recognize their cognate antigens at additional peripheral sites). These self-reactive cells undergo apoptosis in the thymus, and never make it into the periphery. In contrast, those T-cell receptors that have some affinity for the selecting MHC molecule, but not for the peptide ontained in the groove, are likely to recognize foreign peptides, and are positively selected. This process of establishing tolerance to self-proteins in the thymus is called 'central tolerance'.

T cells exiting the thymus therefore encompass cells which can recognize peptides within the scaffold of the MHC molecule used to select that T cell, but which have not encountered their specific peptide in the thymus. Since not all self-antigens are expressed in the thymus, there is still a chance that these T cells will encounter a self-peptide/MHC complex in the periphery for which they have high affinity. Since cells that have left the thymus no longer have the developmental context that is likely to denote a self-peptide (that is, recognition with high affinity of a peptide/MHC complex during development in the thymus), peripheral T cells utilize another binary system to define whether a high affinity interaction should lead to activation or inactivation. This binary system uses additional cell surface molecules (called costimulatory molecules) to denote context. Thus, when peripheral T cells recognize a peptide/MHC complex with high affinity in the absence of costimulation (through ligation of CD28 by surface B7.1 or B7.2 on the antigen-presenting cell), T cells are inactivated or tolerized. This is known as peripheral tolerance. In contrast, when peripheral T cells recognize a peptide/MHC complex with high affinity in the presence of costimulation, these T cells are activated.

In addition to T-cell tolerance, B-cell tolerance to self-components is also actively maintained. Thus, if B cells encounter either soluble or membrane-bound antigen during development in the bone marrow, these cells are either deleted (tolerance) or inactivated such that they become refractory to specific stimulation by their antigen (anergy).

Mechanisms which allow an immune response to be directed against self-antigens

Although tolerance to self-molecules is stringently maintained at the T- and B-cell levels, reactivity against self-molecules may still be possible for several reasons. These include the following.

Abnormal immunoregulation

There are numerous mechanisms used to establish and maintain T- and B-cell tolerance. There is accumulating evidence that defects in regulation of these pathways may result in the failure to eliminate autoreactive lymphocytes, or an altered activation threshold for lymphocytes. Examples include defects in the Fas/Fas–ligand system, a receptor–ligand pair which is required for removal of activated, self-reactive lymphocytes. Mice or humans with defects in this pathway manifest profound lymphadenopathy and a spectrum of autoimmunity. Similarly, defects in regulatory molecules which normally function to dampen the immune response (such as CTLA-4, the inhibitory T-cell receptor for the costimulatory molecules B7.1 and B7.2) may result in profound autoimmune responses. Mice lacking CTLA-4 develop fatal autoimmunity, with widespread T-cell infiltrates. Whether similar defects occur in human autoimmune diseases remains to be determined. It should be remembered that the immune system is a highly complex system, with interdependent regulation present at numerous levels. It is likely that many of the susceptibility genes in human autoimmunity impinge on these immunoregulatory pathways.

Existence of sites of immune privilege

Strict sequestration of tissue-specific antigens behind anatomical and immunological barriers prevents the development of tolerance to molecules expressed preferentially at these sites. Events (such as penetrating trauma) which breach this tight boundary may allow initiation of an immune response to these previously hidden self-molecules. Relevant examples include antigens within the eye, testis, and central nervous system. In the eye for instance, penetrating injury to one eye may be followed by development of inflammation in the contralateral eye (sympathetic ophthalmia) approximately 1 to 2 weeks after injury. Several mechanisms have been proposed to be responsible for maintaining the immune-privileged status of these tissues. One powerful mechanism appears to involve the constitutive expression of Fas–ligand in the relevant tissue (such as the eye). When this molecule binds to and activates its receptor on lymphocytes, these cells undergo apoptotic death, and are prevented from entering the tissue.

Cryptic determinants within self-molecules that are not normally revealed during antigen processing by default pathways, and allow the persistence of

potentially autoreactive lymphocytes

Not all regions of a molecule are equally immunogenic. Regions of the molecule that are captured well by class II MHC molecules during natural processing of self-antigens are able to tolerize T cells (these determinants have been termed 'immunodominant' by Sercarz and colleagues). In contrast, regions of self-molecules that are not generated in significant amount during natural antigen processing (so-called 'cryptic determinants') cannot effectively tolerize T cells, since they are never seen by these cells either in the thymus or peripherally. This immunodominance appears to be influenced by the intrinsic affinity of the peptide for MHC class II, as well as by neighbouring structural determinants on the antigen that may influence its binding to the peptide-binding groove. On self-molecules, two sets of determinants can therefore be defined (Fig. 2):

1. those that are easily processed and presented (comprising the dominant self), which readily tolerize developing T cells.
2. those that are not presented in appreciable amounts after natural processing (comprising the cryptic self), which do not tolerize.

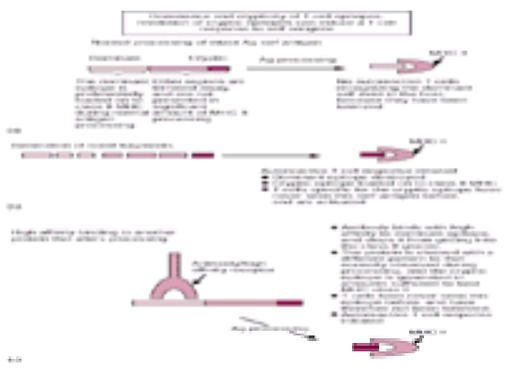

Fig. 2 Dominant and cryptic T-cell epitopes in autoimmune disease. (a) The default processing pathway for intact antigen results in the preferential and reproducible loading of the 'dominant' peptide determinant into the antigen-binding groove of MHC class II. During establishment of thymic and peripheral tolerance, T cells recognizing this dominant epitope are purged from the repertoire, but T cells recognizing cryptic epitopes do not encounter their antigens, and are not deleted or anergized. (b) and (c) When the processing of self-antigens is altered (for example by novel proteolysis or through high-affinity binding to another molecule), a different hierarchy of epitopes is loaded on to class II MHC. If cryptic epitopes are loaded in sufficient amounts, these peptides can stimulate autoreactive T-cell responses directed against the cryptic self, and drive the autoimmune process.

There are unusual circumstances in which natural processing of self-antigens is altered from the default pathway. Examples include novel proteolysis of autoantigen (which destroys the dominant epitope or generates a new dominant epitope) prior to entry into the processing pathway, as well as high-affinity binding to specific receptors or antibodies, which can hinder access of the dominant epitope to the antigen-binding groove of MHC class II molecules, or optimize the loading of a previously cryptic epitope. Since T cells recognizing these cryptic peptides have not previously been tolerized, such 'autoreactive' T cells can now be activated (Fig. 3).

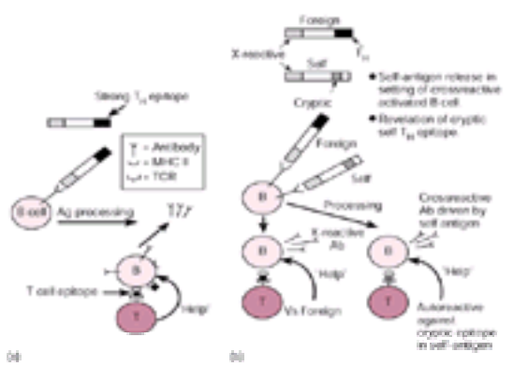

Fig. 3 Molecular mimicry. (a) Foreign antigens, which clearly differ from their homologous self-antigens in some areas, may nevertheless bear significant structural similarity to self-antigens in other regions. Initiation of an immune response to the foreign antigen may generate a cross-reactive antibody response that also recognizes the self-protein. When the self-antigen is a cell surface molecule, antibody-mediated effector pathways can lead to host tissue damage. Although the antibody response is cross-reactive with self-molecules, the T cells that drive this response are directed exclusively at the foreign antigen. (b) Under highly novel conditions, the simultaneous liberation of significant amounts of self-antigen in the setting of a cross-reactive antibody response may allow effective presentation of cryptic epitopes in the self-antigen to autoreactive T cells by activated cross-reactive B cells. These autoreactive T cells can now continue to drive an autoantibody response to the self-antigen. If continued release of self-antigen occurs as part of this process, a specific, adaptive immune response to self will be sustained.

There are several clear demonstrations that autoreactive T cells recognizing cryptic epitopes can be activated *in vivo* through altered processing of self-molecules to reveal these previously immunocryptic epitopes. For instance, high-affinity binding of the HIV surface protein gp120 to CD4 alters the processing of CD4, and activates T cells which recognize epitopes of CD4 not generated during normal antigen processing. This mechanism may account for the autoimmune response to CD4 seen during HIV infection. Similarly, although intact mouse cytochrome c is not immunogenic in mice, cleavage of the molecule into smaller peptides induces a robust T-cell response to cryptic areas of cytochrome c, which were never previously presented by the natural processing pathway, and therefore did not induce tolerance.

The revelation of cryptic epitopes in self-antigens is likely to be a highly relevant mechanism in many human autoimmune diseases, but the studies to demonstrate the importance of this mechanism have only recently begun in earnest. Since the structure of autoantigens influences the hierarchy of dominant and cryptic and determinants generated when the molecule is processed, unique processes which alter the structure of molecules may play critical roles in initiation of autoimmune diseases. These unique events are not likely to occur during normal homeostasis, but may occur preferentially during infectious or other pro-immune events at the host–environment interface. Relevant examples include the following.

1. Unique proteolytic pathways are activated that specifically alter the structure of autoantigens during immune effector pathways. It has recently been observed that the majority of autoantigens targeted across the spectrum of human autoimmune diseases are specifically cleaved by granzyme B during killing of infected target cells by cytotoxic lymphocytes. This cleavage generates unique molecular fragments never generated in the organism during development or homeostasis. Interestingly, this cleavage is a unique feature of autoantigens, and does not affect non-autoantigens. Although it has been proposed that these cleavage events allow the efficient presentation of previously cryptic epitopes, this remains to be formally demonstrated.
2. Additional post-translational modifications alter conformation of antigens and modify their subsequent processing. It is noteworthy that numerous post-translational modifications of autoantigens occur, and that in some cases the autoimmune response is strictly dependent on the occurrence of these modifications. Examples include phosphorylation, acetylation, deimination, and isoaspartyl formation, amongst others.
3. High-affinity complexes are formed between autoantigens and other viral or self-proteins.

In all these examples it should be remembered that the initiating event in autoimmunity requires that, on the background of appropriate susceptibility genes, several stringent criteria needed to initiate a primary immune response must be simultaneously satisfied. These include the generation of suprathreshold concentrations of self-molecules that have a structure not previously tolerized by the immune system, and the presentation of these unique molecular forms to T lymphocytes in the presence of costimulation (that is, in a pro-immune context).

Molecular mimicry

Foreign antigens, which clearly differ from their homologous self-antigens in some areas, may nevertheless bear significant structural similarity to self-antigens in other regions. Initiation of an immune response to the foreign antigen may generate a cross-reactive antibody response that also recognizes the self-protein (molecular mimicry). When the antigen is a cell surface molecule, antibody-mediated effector pathways can lead to host tissue damage. Although the antibody response is cross-reactive with self-molecules, the T cells that drive this response are directed at the foreign antigen (see below). Diseases involving this sort of 'antigen mimicry' therefore tend to be self-limited. It is important to realize that molecular mimicry alone cannot explain self-sustaining autoimmune diseases, which are driven by self-antigens and autoreactive T cells. In these cases, there is a requirement for overcoming T-cell tolerance to the self-protein. The simultaneous liberation of self-antigen in the presence of the cross-reactive antibody response is likely to play a critical role in this regard (see below).

Mechanistic insights into molecular mimicry: source of cross-reactive antibodies and potential role in overcoming T-cell tolerance to self-proteins

Although a number of microbial and viral antigens have regions of high homology with various human autoantigens, a causal link between exposure to these foreign antigens and the onset or exacerbation of autoimmune disease has been extremely difficult to establish. However, there are clear examples which suggest the existence of 'one-shot' autoimmune processes, in which cross-reactive antibodies directed against surface self-antigens are generated following infection, and result in tissue damage. This persists until infection is cleared, and the immune response wanes. Although the mechanistic details of this scheme are difficult to prove *in vivo*, several pertinent examples exist. One of these is a seasonal epidemic form of Guillan–Barré syndrome seen in northern China, which follows *Campylobacter jejuni* infection. Affected patients make antibodies recognizing gangliosides, and the disease has a self-limited course, which rarely recurs. The anti-ganglioside antibodies generated are probably responsible for the pathological findings of acute motor axonal neuropathy. Another plausible example of this mechanism (although with meager *in vivo* evidence) is immune thrombocytopenia in children. This process characteristically: (i) follows an infectious process; (ii) demonstrates antiplatelet antibodies, and (iii) frequently shows durable remissions. The mechanistic details of this process have been difficult to prove *in vivo*, and cross-reactive epitopes on potentially initiating pathogens have not yet been defined.

The single episodes of tissue damage in the setting of a cross-reactive immune response following infection must be contrasted to the sustained, autoamplifying disease frequently seen in other autoimmune syndromes. The central issues in this regard are: (i) how T-cell tolerance to self-antigens might initially be broken, and (ii) once this has occurred, why these antigens continue to drive the immune response to self. Examination of tolerance to cytochrome c, a ubiquitous protein that has regions of homology and divergence across different species, has been very useful in understanding molecular mimicry of cross-reactive epitopes. Mouse cytochrome c shares significant homology with human cytochrome c, although they are entirely different in other areas. When Mamula and colleagues used mouse cytochrome c to immunize mice, no T-cell or antibody response to the murine protein was observed. When human cytochrome c was similarly used to immunize mice, strong T-cell epitopes on the foreign cytochrome c were able to induce a strong antibody response to the foreign protein. The antibodies induced recognized both the murine and the human forms of cytochrome c, that is, cross-reactive antibodies that recognize the self-protein were produced. However, the T-cell response to cytochrome c was directed entirely against the foreign (human) form of the protein, and no T cells against the murine protein could be found. These cross-reactive antibodies disappear as the immune response to the foreign protein wanes.

Interestingly, when mouse cytochrome c was included with human cytochrome c during the immunization, a T-cell response to human cytochrome c, and a humoral response to the human protein that cross-reacts with the murine protein were induced. Within a few days, a strong helper T-cell response specific for murine cytochrome c was detected. This breaking of T-cell tolerance to murine cytochrome c was dependent on activated B cells specific for cytochrome c, which probably exert their effect through altering the processing of mouse cytochrome c, potentially uncovering previously cryptic epitopes in the self-protein (see Fig. 3). In the presence of continued release of self-antigen, this response may become self-sustaining—self-antigen driving autoreactive T cells, providing help to autoantibody-producing B cells (Fig. 3).

Molecular mimicry may therefore induce the production of cross-reactive antibodies, which in the absence of liberation of significant amounts of self-antigen, should disappear when the foreign pathogen is cleared. The form of epidemic motor axonopathy described above is probably representative of this scenario. Under highly novel conditions, the simultaneous liberation of significant amounts of self-antigen in the setting of a cross-reactive antibody response may allow effective presentation of cryptic epitopes in the self-antigen to autoreactive T cells by activated cross-reactive B cells. If continued release of self-antigen occurs, a specific, adaptive immune response to self will be sustained. Antigen release from tissues probably plays a critical role in driving this autoimmune process. Understanding the mechanisms of ongoing antigen release at sites of tissue damage in autoimmune disease (such as unique pathways of cell injury and death) is a high priority for future work, as it provides a novel target for therapy (see below).

It is clear from the above discussion that extraordinary complexity is operative in initiation of the human autoimmune diseases. The patient population is genetically heterogeneous, the human immune system is complex and extremely plastic, and it interacts with a plethora of environmental stimuli and stochastic events. The simultaneous confluence of susceptibility factors and initiation forces to set off the self-sustained and autoamplifying process is therefore an extremely rare occurrence. In contrast, once activation of autoreactive T cells has occurred, the ability of the immune system to respond vigorously to vanishingly low concentrations of antigen, to amplify the specific effector response to those antigens, and to spread the response to additional antigens in that tissue, greatly reduces the stringency that must be met to keep the process going (Fig. 4).

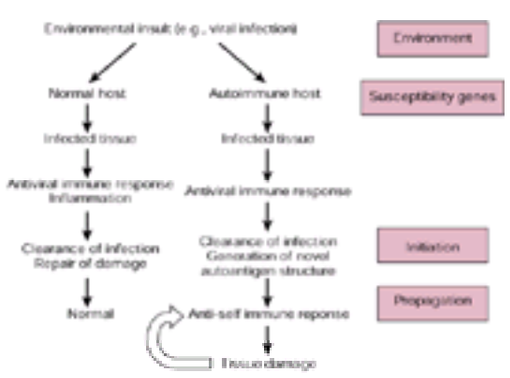

Fig. 4 Model of initiation and propagation of autoimmune disease. Autoimmune diseases are highly complex disorders which require the simultaneous co-operation of multiple factors for their development. Numerous susceptibility genes (some of which regulate the immune response) appear to determine the threshold for disease initiation. In many diseases, a discrete, pro-immune environmental trigger probably plays a role in disease initiation, but is infrequently recognized. A critical requirement for disease initiation is the generation of suprathreshold concentrations of self-antigen with novel structure. Development of a recognizable disease phenotype generally requires marked antigen-driven amplification of the autoimmune response, in which immune effector pathways play a role in generating the ongoing supply of antigen to sustain the process.

Effector mechanisms in autoimmune diseases

The initiation phase of autoimmunity requires co-operation between many different cell types, including antigen-presenting cells, T cells, and B cells, as well as numerous soluble mediators including antibodies, chemokines, and cytokines. The effector phase of autoimmunity uses the same immune and inflammatory effector mechanisms that the immune system has evolved for removing and destroying pathogens. These include activation of the complement cascade, which generates signals that effect inflammatory cell recruitment and activation. Similarly, ligation of activating Fc receptors on inflammatory cells by immune complexes activates macrophage and neutrophil effector function. Autoantibodies directed against cell surface antigens initiate antigen-dependent cellular cytotoxicity, probably mediated by macrophages and natural killer cells. Cytokines and chemokines play a central role in inflammatory cell recruitment and activation in the target tissue. Tissue damage can also be effected by cytolytic lymphocytes. The pathology characteristic of each autoimmune disease reflects the particular antigens targeted as well as the predominant effector mechanisms activated.

One principle of central importance in the effector phase of autoimmunity is autoamplification (Fig. 4), which appears to play a central role in the self-sustaining nature

of the autoimmune process. Thus, immune effector pathways cause damage to cells in the target tissue, liberating antigen which further stimulates the immune response and effector pathways, thus liberating more antigen. Although this is probably an oversimplification, the view that the immune system plays a role in generating an ongoing supply of autoantigen is useful therapeutically, since it focuses attention on controlling both the supply of antigen as well as immune effector pathways (see below).

Clinical features

The clinical features of the different autoimmune diseases are extremely diverse, and reflect the specific tissue dysfunction which results from activity of immune effector pathways. Almost all tissues may be affected, including prominent involvement of endocrine organs, nervous system, eye, bone marrow elements, kidney, muscle, skin, liver and gastrointestinal tract, blood vessels, lung, and joints. For tissue-specific autoimmune processes (such as insulin-dependent diabetes mellitus, immune thrombocytopenia, autoimmune haemolytic anaemia (AIHA)), symptoms may relate to tissue hypofunction resulting from: (i) target cell destruction (for insulin-dependent diabetes mellitus, destruction of the b-cells of the pancreatic islets; for immune thrombocytopenia and AIHA, destruction and phagocytosis of platelets and erythrocytes); or (ii) antibody-mediated interference with function or down-regulation of autoantigen expression (for example in myasthenia gravis, bullous pemphigus). In other cases, symptoms may arise from tissue hyperfunction (for example in Graves' disease) due to activating effects of antibody binding (where antibodies to the thyroid-stimulating hormone receptor induce non-physiological thyroid hormone secretion).

In the case of systemic autoimmune processes, symptoms frequently result from localized target tissue destruction (for example skeletal muscle in polymyositis, skin disease in systemic lupus erythematosus) as well as from the more general activities of inflammatory effector pathways. The latter result from: (i) immune complex deposition at multiple sensitive sites (such as joints, kidney, skin, and blood vessel walls) with activation of the complement cascade and recruitment and activation of myelomonocytic cells; and (ii) ongoing secretion of pro-inflammatory cytokines. In this regard, the profoundly positive effects of tumour necrosis factor inhibition recently observed on the inflammatory symptoms and joint destruction in rheumatoid arthritis underscore the central role of these general inflammatory mediators in generation and maintenance of the disease phenotype in systemic autoimmune diseases.

Prognosis

While the barriers that need to be overcome in terms of initiating an autoimmune disease are highly stringent, and are very difficult to satisfy even in the setting of appropriate susceptibility genes, the immune system is equipped with a powerful memory. The mechanisms of memory are still incompletely defined, but include the generation of a population of memory cells specific for the antigen that initiated the response, which respond vigorously (in terms of clonal expansion as well as effector function) to very low concentrations of antigen if they encounter it again. Since the autoimmune diseases are disorders driven by the ongoing release of self-antigen, this immunological memory constitutes a major barrier to complete cure. Autoimmune diseases therefore tend to be self-sustaining over long periods, and are often punctuated by clinical exacerbations (flares), which are probably due to re-exposure of the primed immune system to antigen (for example in systemic lupus erythematosus, autoimmune myositis, and rheumatoid arthritis). The possibility of disease recurring, even after long clinical remission, remains present in most of the autoimmune diseases. Tissue-specific autoimmune diseases may result in the complete destruction of the target tissue over time, with loss of function of that tissue accompanied by a waning immune response (for example in insulin-dependent diabetes mellitus). Interestingly, in cases where immune-mediated tissue pathology results from effector pathways being driven by a cross-reactive T-cell response to a foreign antigen (for example in epidemic Guillain–Barré syndrome), disease has a finite duration, and generally does not recur.

Therapy

It is not possible to discuss the therapy of this broad group of disorders in any detail in this chapter, but a few principles that underlie current approaches to therapy are discussed. Autoimmune diseases cause significant tissue dysfunction through: (i) inflammation, (ii) tissue destruction with loss of functional units, (iii) the consequences of healing, and (iv) functional disturbances (such as interference with acetylcholine signalling by autoantibody to the acetylcholine receptor and inducing receptor down-modulation in myasthenia gravis). Therapeutic interventions in autoimmune diseases are generally focused on controlling immune and inflammatory pathways, and at replacing or accommodating lost function.

Controlling the immune and inflammatory pathways responsible for ongoing damage

Since in the majority of instances, the critical autoantigens and effector pathways responsible for unique diseases have not been defined, this goal is frequently extremely challenging to accomplish. Thus, frequent use is made of anti-inflammatory and immunosuppressive therapies which broadly target many aspects of the immune response (such as steroids, azathioprine, cyclophosphamide, methotrexate, and mycophenolate). Since a robust immune response is required to protect the host from a myriad of infectious threats, this non-targeted suppression of the immune system can have deleterious consequences in terms of increased susceptibility to infection, with its attendant high morbidity and mortality. In this regard, therapeutic targeting of specific inflammatory pathways is extremely attractive, and there are recent examples in which this approach has been highly successful. In rheumatoid arthritis, the maintenance of chronic inflammatory joint pathology appears to be dependent on the activity of tumour necrosis factor. Specific inhibition of tumour necrosis factor through the use of either soluble tumor necrosis factor receptors or humanized monoclonal antibodies has led to an astonishing effect on disease activity in rheumatoid arthritis, with abolition of systemic symptoms, and a striking decrease in the rate of joint destruction. These positive effects were associated with only a minimal increase in susceptibility to infection, although this risk is certainly present. Inhibition or stimulation of specific inflammatory pathways as therapy for autoimmune diseases may well be more broadly applicable, and will certainly be tested in other autoimmune processes once critical roles of additional specific inflammatory pathways are defined.

Another example of specific targeting of pro-inflammatory pathways is that of intravenous immunoglobulin. This is prepared from pooled serum and its major component is immunoglobulin G. Intravenous immunoglobulin therapy has been used as a treatment for several autoimmune diseases, including immune thrombocytopenia, autoimmune myositis, and acute demyelinating polyneuropathy, but is only available at prohibitive cost. Recent data from mice have demonstrated that intravenous immunoglobulin induces surface expression of the inhibitory Fcg receptor (FcgRII $_{B}$) on macrophages, and shifts the balance of signalling through Fc receptors towards inhibition, down-regulating the pro-inflammatory response to immune complexes. It is likely that continued identification of additional agents that precisely modulate specific inflammatory pathways will have a major therapeutic impact on this group of diseases.

Interventions aimed at replacing or accommodating lost function

The majority of autoimmune diseases are associated with loss of function of organs and tissues, many of which perform essential physiological functions. Indeed, recognition of the autoimmune phenotype in many instances requires that tissue damage is sufficiently severe to have led to characteristic loss of function. For example, loss of insulin-secreting b-cells of the pancreatic islets results in insulin-dependent diabetes mellitus, and blockade and down-regulation of the nicotinic acetylcholine receptor causes striated muscle weakness and fatigue in myasthenia gravis. Similarly, chronic immune complex deposition in glomeruli causes renal inflammation and scarring in systemic lupus erythematosus. Where significant functional reserve is still present in a particular disease, a strong argument can be made for preventing further damage through specific or general immunosuppressive strategies described above. This is particularly relevant where the 'supply' of tissue that could be damaged is essentially inexhaustible (for example most instances of systemic autoimmune disease). Where functional impairment is already established, interventions aimed at replacing or accommodating lost function are indicated. For example, insulin replacement is required for insulin-dependent diabetes mellitus, and treatment for hyperthyroidism is indicated in Graves' disease.

Summary

Autoimmune disease results when the immune system becomes activated to recognize self-antigens. The response is antigen-driven and T cell-dependent, and is directed against highly specific autoantigens that are in many instances disease specific. The genetic contribution to autoimmunity is important, with MHC and non-MHC genes playing significant roles. MHC genes may confer susceptibility to disease in some cases, and determine the autoantibodies produced in others. The essence of sustained autoimmune disease is the breaking of T-cell tolerance to self-molecules, resulting in a sustained immune response to self, and consequent tissue damage. Although the mechanisms by which tolerance is broken remain unclear, it is likely that, in the genetically susceptible host, environmental influences play an important role in the initiation of an autoimmune response. Possible mechanisms include alteration of antigen structure, location, concentration, processing, presentation, and context. The pathology characteristic of each autoimmune disease reflects the particular antigens targeted as well as the immune effector mechanisms activated. Ongoing immune-mediated damage probably plays a central role in providing autoantigen to drive the continuing autoimmune response.

5.4 Complement

Mark J. Walport

Introduction

Jules Bordet first discovered complement as an activity in serum that complemented the activity of antibody in the killing of bacteria—hence its name. Complement comprises a group of more than 20 plasma and cell-bound proteins and is part of the innate immune system. The direct binding of particular complement proteins to potential pathogens activates a cascade of sequentially acting complement proteins.

Complement is a triggered enzyme cascade, initiated by the binding of any of three complement proteins, C1q, mannose-binding lectin, or C3, to acceptor molecules, especially on the surface of potential pathogens. The binding of these molecules may be direct or, in the case of C1q, to antibody bound to antigens (immune complexes). The binding of C1q to immune complexes represents an important bridge between the adaptive immune system and the innate immune system.

After initiation, the activation of complement is amplified by the sequential activation of a series of enzymes, which lead ultimately to the cleavage of C3 and C5. Thus a small initiating signal, for example from binding of a few mannose-binding lectin molecules to the surface of a bacterium, leads to cleavage of a large number of C3 and C5 molecules. These amplification steps in complement activation increase the effectiveness of complement as a host defence mechanism but also carry the risk to the host that inappropriate complement activation may cause bystander inflammatory injury to host tissues. To prevent this, there is a large array of regulatory mechanisms that prevent inappropriate complement activation and reduce the chance of complement injury to self tissues.

A detailed description of the biochemistry of complement is beyond the scope of this chapter; recent reviews that describe this are provided at the end of the chapter. This chapter will focus on the diseases associated with abnormalities of the complement system. We will first consider the different physiological activities of complement, which is necessary in order to understand the role of complement in disease. We will then review the diseases associated with hereditary disorders of complement, followed by diseases in which there are acquired complement abnormalities. The chapter will end with a consideration of when and how assays of the complement system should be performed in the assessment and management of disease.

Physiology of complement

The physiological activities of complement are summarized in Table 1. There are three overarching activities. The first is the role of complement in host defence against infectious disease. Complement provides mechanisms for the killing and clearance of micro-organisms; it does this by the covalent binding to their surface of C3 and C4 fragments that are ligands for receptors on phagocytic cells that ingest and kill the organism. The activation of complement also causes the generation of the anaphylatoxins, C5a and C3a, which have chemotactic activity and recruit leucocytes to sites of infection and inflammation. A further role of complement in host defence against infection is generation of the membrane attack complex. This may disrupt the cell membrane and kill the micro-organism.

The second activity of complement is as a bridge between the humoral adaptive immune system (antibody) and innate immunity. Activation of complement by immune complexes facilitates the clearance of antigen and thereby helps to prevent immune complexes from causing inflammatory damage to tissues, although, as we shall see, complement may contribute to inflammatory injury to tissues in circumstances when immune complexes persist. Activation of complement also augments antibody responses and thereby enhances host defence against pathogens. The binding of complement to antigens reduces the threshold of B lymphocytes for activation. It enhances antigen presentation and B cell memory by helping to localize antigen on antigen-presenting cells and on the follicular dendritic cells that are key to the maintenance of B cell memory for foreign antigens.

The third activity of complement is in the resolution of inflammatory responses. It is in this role that complement may prevent the development of systemic lupus erythematosus (SLE) by promoting the clearance of tissue debris.

Complement in disease

Hereditary disorders

Studies of the inherited abnormalities of the complement system have illuminated our understanding of the major roles of the complement system *in vivo*. There are three types of disease associated with hereditary complement deficiency. The first is immunodeficiency, which illustrates the role of complement in host defence against infection. The second is the association of systemic lupus erythematosus with deficiency of certain classical pathway proteins. This association has led to a greater understanding of the role of complement in the resolution of inflammation and in the waste disposal mechanisms of the body. The third category of disease is caused by deficiencies of proteins of the regulatory mechanisms of the complement system. This small group of diseases illustrate the effects of unrestrained activation of the complement system. We will consider each of these associations.

Complement deficiency and infection

Patients lacking C3 and the pathways leading to C3 activation show increased susceptibility to pyogenic infections with bacteria such as *Streptococci* and *Staphylococci*. There is a similar susceptibility to infections in patients lacking antibodies or normal phagocytic function (see Chapter 5.5 and Chapter 5.6). This shows that the normal pathway for host defence against such bacteria is binding of antibody, followed by complement, providing opsonins for uptake and bacterial killing by phagocytes. Disruption of any of the links in this chain causes increased susceptibility to infection by these pyogenic bacteria.

Neisserial infection and complement deficiency

Humans who lack one of the proteins of the membrane attack complex (C5, C6, C7, C8, or C9) display a unique susceptibility to neisserial infection, especially by *Neisseria meningitidis*, which is frequently recurrent (Fig. 1 and Plate 1). This pattern of infection shows that host defence against these bacteria, which are capable of intracellular survival, is mediated by their lysis by the membrane attack complex. Individuals lacking the earlier components of the complement system, which are the necessary precursors for the formation of the membrane attack complex, are also at increased risk of neisserial infection. Deficiency of properdin is also especially associated with neisserial infections. This protein stabilizes the alternative pathway C3 convertase enzyme and augments the cleavage of C3. It is encoded on the X chromosome and therefore properdin deficiency is found almost exclusively in males. Increased susceptibility to neisserial infections is also a feature of acquired complement deficiency, such as may be seen in patients with SLE or with C3 nephritic factor.

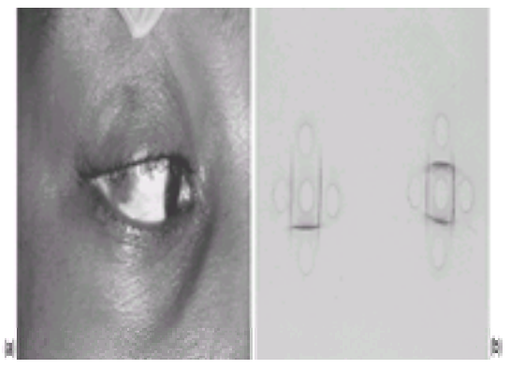

Fig. 1 Patient with hereditary deficiency of C6 who presented with meningococcal septicaemia. (a) a subconjunctival haemorrhage. (b) The deficiency of C6. Serum from the patient was placed in the central well of an agarose-coated plate. In each of the outer wells was placed antiserum to, respectively, C5, C6, C7, and C8. The antibody and antigen were allowed to diffuse in the gel and where the antibody encountered its antigen a precipitate formed, which was stained blue. No precipitate formed between the anti-C6 antibody and the patient's serum, indicating C6 deficiency. (See also Plate 1.)

When should complement deficiency be suspected in a patient with infectious disease? Immunodeficiency should be suspected in any individual who has recurrent or unexplained major infections. The type of infection provides a clue to the relevant investigations of the immune system. Recurrent pyogenic infections imply a need to assay the activity of antibodies, the complement system, and phagocytic function.

In the specific case of meningococcal sepsis, factors that point to complement deficiency are recurrent attacks, a family history of meningococcal infection (especially if disseminated in time), or infection by unusual strains of *N. meningitidis*. Individuals with complement deficiency remain susceptible to neisserial infection throughout life and may present at any age.

Mannose-binding lectin deficiency

Mannose-binding lectin is a protein homologous in structure to C1q that initiates complement activation by a pathway similar to the classical pathway. Mannose-binding lectin binds to terminal mannose groups in a spatial orientation that is present on many micro-organisms, including certain Gram-positive and Gram-negative bacteria, mycobacteria, yeasts, and parasites, but absent on mammalian cells. It is one of the 'pattern-recognition' molecules of the innate immune system that binds molecules present on potential pathogens but not on the cells of the host. The importance of its role in host defence was identified when it was discovered that a group of children with recurrent bacterial infections in early childhood were deficient in the ability of their serum to opsonize yeast with C3 *in vitro*. It turned out that this *in vitro* opsonic deficiency was caused by a subtotal deficiency in the expression of mannose-binding lectin. The most important causes of this common deficiency are mutations of residues in the collagen domain of mannose-binding lectin, which cause misassembly of the multimer and thereby have a dominant effect suppressing mannose-binding lectin levels.

The clinical effects of mannose-binding lectin deficiency are most apparent in young children from the ages of 2 to 5, when maternal passive immunity has waned and the antibody response has not yet matured. At this stage of life the innate immune system is of particular importance in host defence against infection.

Complement deficiency and autoimmune disease

A dramatically increased prevalence of SLE is found amongst patients with deficiencies of proteins of the classical pathway of complement. There is a hierarchy of susceptibility and severity of SLE according to the position of the missing protein in the pathway of classical pathway activation (Table 2).

These cases of SLE, associated with inherited complement deficiency are, *in toto*, extremely rare and only account for a tiny minority of the population of patients with SLE. However, they provide an important clue to the aetiology of the disease. They show that there is an important activity of the early classical pathway of complement that protects against the development of SLE. The source of the autoantigens that drive the autoimmune response in SLE is thought to be apoptotic cells. Complement has been found to play a role in the disposal of apoptotic cells and in the processing of immune complexes. Loss of these activities might lead to abnormal processing of effete cells, that, in the context of an inflammatory response, could initiate and drive an autoimmune response leading to the development of SLE.

Hypotheses such as this may be tested in animal models of disease. A series of mice have been developed lacking molecules that have been implicated in the 'waste-disposal' mechanisms of the body. These include mice lacking C1q, serum amyloid P component (which coats and may mask extracellular chromatin from the immune system), DNase 1 (which digests extracellular chromatin), and IgM (which may augment the clearance of effete cells and cellular debris). Each of these spontaneously develops SLE and supports the hypothesis that effective mechanisms of cellular waste disposal are essential to prevent the development of SLE.

Abnormalities of complement regulation

C1 inhibitor deficiency

The disease hereditary angioedema is caused by deficiency of C1 inhibitor. This is inherited as an autosomal dominant disorder with partial penetrance. The disease is dominantly inherited because the production of C1 inhibitor from a single, normal allele is insufficient to maintain normal homeostasis of the complement and kinin pathways. The mutations may have two effects on protein production. In type 1 hereditary angioedema, which accounts for approximately 85 per cent of cases of the disease, the mutant prevents any expression of protein from the mutant allele. This variety of disease is therefore associated with reduced levels of C1 inhibitor.

Type 2 hereditary angioedema is caused by a series of point mutations in the C1 inhibitor gene that alter one of the amino acids at the active centre of the protein and abolish its activity as a serine proteinase inhibitor. These mutations allow expression of normal amounts of protein, which is non-functional, or even abnormally high C1 inhibitor levels, because the mutant protein is not consumed by normal interaction with activated serine proteinases. It is easy to miss the diagnosis of this variant of hereditary angioedema, if it is not appreciated that levels of C1 inhibitor can be normal or high in patients with the disease.

The clinical manifestations of hereditary angioedema are caused by vascular leakage of fluid that cause angioedematous swellings. The swellings are caused by the action of small peptides, called kinins, in particular bradykinin, that cause increased vascular permeability by their actions on vascular endothelium and smooth muscle. These kinins are produced by the action of serine proteinases that are ineffectively regulated in the presence of reduced activity of C1 inhibitor.

Allergy is much commoner than hereditary angioedema as a cause of angioedema. In hereditary angioedema, the swelling is not itchy and is not accompanied by other features of allergy such as asthma and urticaria. The disease is potentially life-threatening if there is major pharyngeal or laryngeal swelling, causing airways obstruction. Swelling of the submucosa of the intestines may cause severe abdominal pain and temporary obstruction of the bowel.

Diagnosis of hereditary angioedema is made on the basis of the clinical findings described above, the presence of family history, and blood tests. A family history of angioedema makes diagnosis much easier but is not always present. This is because some cases of the disease are due to new mutations in the C1 inhibitor gene. In other families, other members with C1 inhibitor deficiency may have no clinical symptoms.

The abnormal blood tests associated with hereditary angioedema are reduced C1 inhibitor protein levels (usually below 30 per cent of normal levels) in patients with type 1 hereditary angioedema. However, in the 15 per cent of patients with type 2 disease, protein levels may be normal or high. In these patients functional assays of C1 inhibitor are necessary. These are based on the ability of C1 inhibitor to block cleavage of a chromogenic substrate by activated C1s. In addition to these abnormalities, levels of C2 and C4 are typically low. This is because the reduced C1 inhibitor activity allows C1s to cleave C4 and C2 in an unregulated fashion.

Treatment of the disease involves, firstly, the treatment of acute attacks and, secondly, prophylaxis to attempt to prevent their recurrence. Acute attacks of hereditary angioedema do not respond to epinephrine, though if there is any cause to suspect allergic rather than hereditary angioedema, then administration of epinephrine is

unlikely to cause any harm. If attacks involve the airways, then respiratory support is the first priority. Acute attacks of angioedema may be arrested by infusion of purified C1 inhibitor concentrate. If this is not available, fresh frozen plasma may be infused. This is less satisfactory, as plasma not only contains C1 inhibitor but also kallikrein, C1r, and C1s, which may generate further kinin production. In patients with repeated attacks of angioedema or infrequent but life-threatening attacks of disease, prophylactic treatment should be given. C1 inhibitor levels originating from the single normal allele increase in response to treatment with impeded androgens, such as danazol and stanozolol. This is a moderately effective treatment, although these compounds still retain some virilizing activity. An alternative, though probably less effective therapy (there are no randomized trials), is the proteinase inhibitor tranexamic acid, which may reduce the consumption of C1 inhibitor by blocking the activity of the serine proteinases that interact with C1 inhibitor.

Diseases associated with unregulated C3 activation

Factor I and Factor H deficiency

A key step in the regulation of complement activation is control of the fate of the C3 fragment, C3b. This acts as the nucleus for formation of further C3 convertase enzyme, unless it is catabolized by the serine esterase enzyme, Factor I, in conjunction with the cofactor protein, Factor H. Deficiency of either of these proteins allows the unregulated formation of C3 convertase enzyme and continuing cleavage of C3 (Fig. 2). Patients with deficiency of Factor I or H have a severe secondary deficiency of C3 and are susceptible to the pyogenic infections associated with this C3 deficiency. In addition, the enormous turnover of C3 associated with these deficiencies allows some C3 to deposit in glomerular basement membrane, which leads to the development of glomerulonephritis, which may proceed to renal failure. A number of families have been identified with inherited mesangiocapillary glomerulonephritis and some of these have mutations in just one Factor H allele, suggesting a dominant form of glomerulonephritis caused by partial Factor H deficiency. The mechanism of this form of nephritis is not understood.

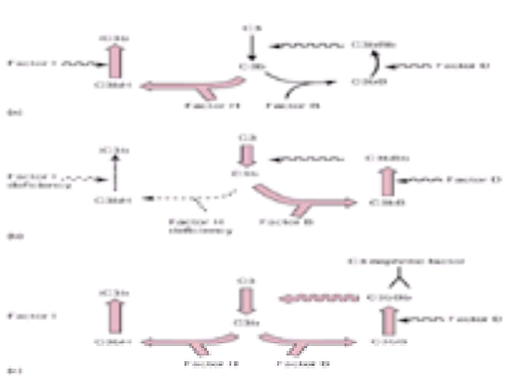

Fig. 2 Unregulated activation of C3 caused by Factor H or I deficiency, or by C3 nephritic factor. Panel A illustrates the normal control of C3 cleavage. In plasma and tissues any C3b that is formed by the normal low-grade turnover of C3 is bound by Factor H and catabolized by Factor I to inactive products. Panel B shows the effects of Factor H or Factor I deficiency. C3b can not be catabolized to inactive products. Instead there is increased formation of the alternative pathway C3bBb C3 convertase gene causing accelerated cleavage and depletion of C3. Panel C shows the effects of C3 nephritic factor. This antibody stabilizes the C3bBb C3 convertase enzyme. This results in accelerated cleavage and depletion of C3.

Acquired disorders of complement

Complement is activated *in vivo* by many stimuli, which include invading organisms, the formation of immune complexes, and tissue necrosis. When complement activation occurs on a substantial scale, this causes depletion of complement proteins, which may be measured as a reduction in their antigenic levels or as a reduction in the activity of the classical and/or alternative pathway. The measurement of complement activation may be useful in both the diagnosis and monitoring of some diseases.

In the case of sepsis associated with endotoxic shock, the large-scale systemic activation of the complement system may play an important part in the pathogenesis of this lethal condition. Activation of the classical and alternative pathways by bacterial endotoxin causes the generation of large amounts of the anaphylatoxins, C3a and C5a, and of membrane attack complex which activate neutrophils and endothelial cells causing vascular and pulmonary injury, leading to death. Diagnosis of this condition is sadly all too easy and the measurement of complement in such patients does not play an important role in assessment or management.

Tissue necrosis is also an important cause of complement activation. Therapeutic studies of experimental models of myocardial infarction, and of ischaemia–reperfusion injury in other organs, including the brain, have shown that inhibition of complement causes a significant reduction in tissue injury and final infarct size.

The diseases associated with acquired complement activation may be divided into two categories. The first category is the diseases associated with abnormal regulation of complement, which is most commonly caused by certain autoantibodies to complement. Paroxysmal nocturnal haemoglobinuria is a further example of an acquired disorder of regulation of the complement system. The second category is the diseases in which infection or autoimmunity cause clinically important activation of the complement system.

Diseases associated with abnormal complement regulation

We shall consider four diseases caused by acquired abnormalities of the regulation of complement. The first three of these are associated with the development of high-affinity autoantibodies to complement proteins, known as C3 nephritic factor, anti-C1q antibodies, and anti-C1 inhibitor antibodies. The fourth disease is paroxysmal nocturnal haemoglobinuria, in which a clone of haematopoietic cells loses expression of a family of cell surface molecules including regulatory proteins of the complement system.

Autoantibodies to complement proteins

C3 nephritic factor

C3 nephritic factor is an autoantibody that binds to and stabilizes the C3bBb C3 convertase enzyme. This increased stability of the C3 convertase enzyme disrupts the normal regulation of C3 activation and leads to chronic consumption of C3 (Fig. 2). Patients with C3 nephritic factor have very low C3 levels in serum, accompanied by normal C4 levels. When serum from a patient with C3 nephritic factor is mixed with normal serum, the C3 in the normal serum is activated and converted to C3b, which forms the basis of an assay for C3 nephritic factor.

The presence of C3 nephritic factor is associated with three clinical manifestations. The first of these is partial lipodystrophy, in which there is disfiguring loss of fat from the face and upper part of the body. Adipocytes, or fat cells, produce several complement proteins including C3 and factor D, which was independently discovered in fat cells and named adipsin. It is thought that C3 nephritic factor stabilizes the assembly of a C3 convertase enzyme on adipocytes causing the activation of complement on these cells leading to their destruction. The second clinical feature is of mesangiocapillary glomerulonephritis type II, in which electron-dense deposits of unknown composition, associated with C3 deposited at the margins of the electron-dense deposits, are found in the glomerular basement membrane. This form of nephritis may be severe, leading to renal failure. The third clinical feature is of recurrent infections, caused by the severe acquired deficiency of C3 associated with this condition.

The conventional approach to treatment of patients with type II mesangiocapillary glomerulonephritis is the use of corticosteroids, often in combination with immunosuppressive agents such as azathioprine or cyclophosphamide.

Anti-C1q antibodies

These autoantibodies react with a neoepitope, exposed in the collagenous region of C1q, which has dissociated from the other proteins of the C1 complex, C1r and C1s. Up to a third of patients with SLE develop anti-C1q autoantibodies. These are associated with activation of the classical pathway, causing very low C4 levels and, to a lesser extent, reduced C3 levels. The presence of anti-C1q autoantibodies is a marker for severe SLE, especially for the presence of lupus nephritis.

Anti-C1q antibodies are also found as the sole autoantibody in the uncommon disease hypocomplementaemic urticarial vasculitis (HUVS). In this condition, very high titres of anti-C1q antibodies are typically found, which may sometimes cause precipitation of C1q *in vitro*, hence they are known as C1q precipitins. The main clinical feature of HUVS is chronic urticaria, which is found on biopsy to be associated with a cutaneous vasculitis. Other clinical features of HUVS include glomerulonephritis, neuropathy, and chronic obstructive bronchitis. There is a considerable degree of overlap between the clinical manifestations of HUVS and SLE. This is analogous to the relationship between SLE and the primary antiphospholipid syndrome, discussed in Chapter 18.11.2.

Anti-C1 inhibitor antibodies

The third disease associated with an autoantibody to a complement protein is angioedema associated with autoantibodies to C1 inhibitor. The symptoms and signs of this are very similar to the disease of hereditary angioedema, though typically occur with a late onset. Measurements of complement proteins in the serum from patients with this disease show a similar abnormal profile to that seen in the blood of patients with hereditary angioedema, with low C1 inhibitor and low C4 levels. Additional abnormalities are low C1q levels and the presence of autoantibodies to C1 inhibitor. This serious condition is frequently associated with the presence of a B cell lymphoma.

Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) illustrates the role of membrane-bound complement regulatory proteins in protection against the activation of complement on normal cells. Haemolysis in this disease is caused by the loss of expression of a membrane protein named CD59. This prevents the formation and assembly of the membrane attack complex of complement in cell membranes and thereby inhibits the lysis by complement of autologous cells (see Chapter 22.3.12).

Complement in autoimmune disease

The measurement of complement is a useful diagnostic tool as part of the assessment of patients with vasculitis and glomerulonephritis (Table 3). Some of the causes of these conditions are associated with systemic activation of the complement system on a sufficient scale that plasma levels of classical pathway proteins and C3 are significantly reduced below normal. In these diseases, it is the formation of immune complexes, either in the circulation or *in situ* in tissues, that is responsible for the activation of the complement system.

SLE

The relationships between the complement system and SLE are complex. As we have discussed, inherited deficiency of classical pathway complement proteins causes SLE. However, the vast majority of patients with SLE do not have homozygous deficiencies of complement proteins. Indeed, in these patients, SLE is associated with large-scale activation of the classical pathway of complement. The deposition of complement proteins in tissues, associated with the presence of immune complexes, has been thought to play a role in causing inflammatory lesions in tissues in SLE. Deficiency of C1q protein is most strongly associated with the development of SLE, yet as we learnt above, approximately one-third of patients with SLE develop autoantibodies to C1q.

The explanation for these complex relationships between complement and SLE is partially understood. Studies in animal models of SLE show that the predominant manner in which immune complexes cause inflammation is by ligation of Fc receptors. Mice lacking Fc receptors were protected from glomerulonephritis caused by immune complexes, whereas mice lacking complement developed full-blown lupus glomerulonephritis. A key role of complement may be to protect against the development of tissue injury by immune complexes by promoting their clearance from tissues, rather than playing a major role in the causation of injury.

We have already discussed how C1q deficiency might cause the development of SLE. How might SLE cause the development of anti-C1q antibodies? The essential feature of SLE is the formation of autoantibodies to complexes of autoantigens, such as the spliceosome complex and chromatin. C1q binds to the cellular debris that is thought to be the source of the autoantigens that drive the autoimmune response in SLE. As part of the debris, C1q may become antigenic and evoke an autoimmune response. This is a situation analogous to the association in SLE, and the primary antiphospholipid syndrome, of the presence of anticardiolipin autoantibodies with anti-b2 glycoprotein I antibodies. b2-glycoprotein I is a plasma protein that binds to negatively charged phospholipids that are exposed on the cell membranes of apoptotic cells and may thereby become part of the cellular debris that drives the autoimmune response in SLE.

The measurement of complement and of anti-C1q antibodies in SLE is of clinical value in both the diagnosis and management of patients. Serum from patients with active disease typically shows evidence of classical pathway activation with reduced C4 and, to a lesser extent, reduced C3 levels. In patients with persistently very low C4 levels, there is a high likelihood that anti-C1q antibodies will be present and such patients are more likely to have, or to develop, glomerulonephritis. Patients with persistent, severe hypocomplementaemia are at increased risk of pyogenic infections and there are strong arguments for the use of prophylactic penicillin in such patients.

Haemolytic anaemia

There is sometimes sufficient systemic complement activation associated with the haemolytic anaemias caused by autoantibodies to erythrocyte surface antigens to cause reduction in the levels of complement proteins measured in serum. This is most prominent in cold agglutinin disease (see Section 22) in which IgM cold agglutinins, which bind to I antigen, cause the deposition of many thousands of C4 and C3 molecules per erythrocyte.

The accelerated clearance of erythrocytes in autoimmune haemolytic anaemias is mainly caused by ligation of cells bearing Fc receptors in the spleen, in the case of IgG autoantibodies. In the case of cold agglutinin disease, mediated by an IgM autoantibody which cannot bind to Fc receptors, there is typically low-grade intravascular haemolysis by complement.

Human red cells are well protected from complement-mediated lysis by complement regulatory proteins expressed on their cell membranes. As we have learnt, the activity of these proteins is illustrated dramatically by the disease PNH. Rarely, if there is extensive complement fixation, as in the case of a transfusion reaction caused by an ABO mismatch, then intravascular complement-mediated lysis of red cells may cause severe injury.

Infectious disease

We have already discussed the role of complement in the innate immune system and as an effector arm of humoral adaptive immunity by illustration of the infections that accompany hereditary or acquired complement deficiency. Complement is also involved in the pathogenesis of infections in other ways. For example several viral pathogens use the complement system in a subversive manner as part of their pathogenesis (Table 4). Several infections cause hypocomplementaemia through systemic activation of complement in a similar fashion to autoimmune disease and we shall consider some examples.

Complement activation is a feature of chronic bacterial sepsis, for example in subacute bacterial endocarditis or ventriculoatrial shunt infection. In both of these conditions there is chronic release of bacterial antigens in the presence of an antibacterial antibody response that cannot eliminate the infection because of its relative inaccessibility to the immune system. This causes the chronic production of immune complexes with complement activation by the classical pathway, associated with low C4 and C2 levels and glomerulonephritis and small vessel vasculitis.

Chronic viral infection by hepatitis C is a further important cause of acquired hypocomplementaemia. This infection stimulates the production of large amounts of rheumatoid factor, which in some patients may lead to cryoglobulin production, causing complement consumption and vasculitis. In one survey in Japan of hypocomplementaemia in blood donations, infection with hepatitis C was the major cause.

Another example of hypocomplementaemia associated with infection is the complement activation associated with poststreptococcal glomerulonephritis. In this disease, which is thought to be due to an immune response to a pathogen cross-reacting with host tissues, there is marked complement activation, which includes

activation of the alternative pathway, associated with low C3 levels.

Measurement of complement in clinical practice

Throughout this chapter examples have been given of diseases which are associated with abnormal levels of complement proteins in the blood. Complement levels and activity can be assayed in clinical practice. It is useful to consider the value of measuring complement proteins in two categories, firstly in diagnosis of disease and, secondly, measurement repeatedly to monitor the activity of particular diseases.

When to measure complement

Complement in the diagnosis of disease

There are four groups of diseases in which it is important to be able to measure complement activity in serum. The first is the immunodeficiencies—it is essential to measure complement in patients with recurrent pyogenic infections, particularly in the context of recurrent or familial meningococcal disease. In this group of diseases, simple antigenic measurement of C4 and C3 levels is insufficient—it is necessary to use tests that assay the activity of the whole complement system, preferably haemolytic assays of the classical and alternative pathways. If absent or severely reduced activity is detected, then the sample should be referred to a specialist laboratory to try to identify the precise nature of the deficient component. Treatment should comprise counselling, prophylactic penicillin, and vaccination against meningococci.

The second group of diseases is vasculitis and glomerulonephritis. We saw in Table 3 how a very useful diagnostic subdivision of these diseases can be made on the basis of whether or not there is evidence of systemic complement activation. It is in these diseases that it can also be helpful to use assays of complement to monitor disease activity.

The third group are the chronic infections, which may masquerade as primary systemic vasculitis and, in this context, there should be a high index of suspicion for the presence of bacterial endocarditis or hepatitis C.

The fourth group of diseases are those specifically associated with abnormalities of the complement system, including hereditary and acquired angioedema, the familial glomerulonephritis associated with factor H deficiency, and the syndrome of partial lipodystrophy with or without mesangiocapillary glomerulonephritis.

Complement in the monitoring of disease

There are very few diseases in which the repeated monitoring of complement levels is useful. In SLE, no single test acts as a reliable surrogate for the measurement of disease activity. However, there are some patients in whom fluctuation in complement levels correlates with the waxing and waning of disease activity and, in these individuals, it is useful to monitor regularly C4 and C3 levels. It can also be useful to measure complement levels regularly in patients with autoantibodies to complement proteins; in these individuals the complement levels are a useful surrogate marker for the continuing presence of the autoantibody.

How to measure complement

Complement can be measured in a several ways. The simplest is antigenic measurement of the concentration of individual proteins, and measurement of the levels of C3 and C4 are the most widespread assays in clinical use. The results of such assays need to be interpreted cautiously. The ranges of normality are wide, because there is substantial genetic variation in the levels of these proteins. Furthermore, protein levels are a product of both synthetic and catabolic rates and both of these may vary in health and disease. Both C3 and C4 are acute phase reactants and concentrations of these proteins may rise, in the case of C3 by as much as 0.5 g/l in response to acute phase stimuli.

Measurement of C4 and C3 levels act as very crude surrogate markers of classical and alternative pathway activation respectively. However, further measurements are needed if there is any suspicion of the possibility of inherited complement deficiency or of an abnormality elsewhere in the complement system. Functional assays of complement are fairly straightforward and have the advantage that they measure the activity of all of the proteins in the complement system between activation and the end point, which is the lysis of target erythrocytes. The classical pathway is usually measured by assessment of the lysis by serum of sheep erythrocytes coated with a rabbit polyclonal antisheep erythrocyte antibody. The alternative pathway is measured by assay of the lysis of guinea pig erythrocytes, which directly activate the alternative pathway of complement in the absence of antibody, in the presence of a buffer that prevents classical pathway complement activity. Results of these assays are normally expressed as CH50 or AP50 units, which are measurements of the haemolysis of 50 per cent of respective erythrocyte preparations.

Other approaches have been devised to assess the presence of complement activation *in vivo*. Many assays have been developed which identify the products of activation of the complement system. Although these assays are attractive in principle, the products of complement activation are only present in plasma very transiently and, in practice, assays of total C4 and C3 levels, together with measurement of CH50, have not been supplanted as the best 'rough and ready' estimates of complement activation in routine clinical practice.

5.5 Innate immune system

D. T. Fearon and M. Allison

Innate immunity is an ancient system of host defence found in invertebrates as well as vertebrates. There are similar mechanisms and parallels between aspects of the innate immune systems of the fruit fly, *Drosophila*, and man. The innate immune system can therefore be considered to have two general functions; first, as a mechanism of primary host defence and, secondly, as a means of priming the adaptive immune system. Innate immunity performs the first of these functions in both invertebrates and vertebrates, having evolved many systems that facilitate the recognition and elimination of pathogens. The second role of the innate immune system in vertebrates is the instruction of the adaptive immune system. The enhanced specificity of the adaptive response is guided by the uptake recognition mechanisms of the innate immune system with the consequent generation of immunological memory for components of infectious organisms.

A key concept in understanding why the innate immune system has evolved the way it has is that an essential requirement is fulfilled—recognition of the presence of foreign organisms and, in effect, the differentiation of infectious from non-infectious. During the evolution of the innate immune system certain properties of micro-organisms that differentiate them from the host have been identified and diverse ways of detecting pathogens have gradually developed. These recognition systems have evolved in association with a range of effector mechanisms, some innate themselves and others induced through the instigation of an antigen-specific, adaptive immune response. The innate recognition systems are described in this context.

Recognition systems, soluble and membrane-bound

The innate immune system has evolved several mechanisms for detecting the presence of 'infectious' substances as such, through the development of molecular species that recognize the lowest common structural denominators of invading micro-organisms. These receptors are both soluble proteins in blood and extracellular fluid and also membrane-bound species.

Complement

The complement system is an ancient system of host defence, found in invertebrates (e.g. sea-urchin) as well as mammals. The initial methods of activation and the specific members of the early component pathways differ between the classical pathway, the lectin pathway, and the alternative pathway. All, however, use as one of their effector arms the formation of the membrane attack complex, which forms a pore in the cell membrane, as the method of killing cells. The recognition reaction central to the tagging of surfaces of micro-organisms as infectious is the covalent attachment of activated C3 component to the microbial substance. This facilitates the elimination of the pathogen through recognition of the C3-coated surface by receptors which then phagocytose and kill the organism directly or indirectly, by formation *in situ* of the membrane attack complex and subsequent cytolysis (Fig. 1).

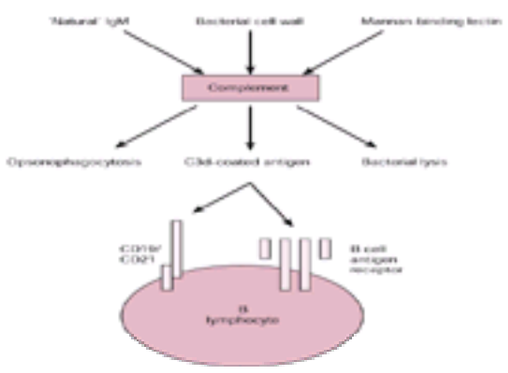

Fig. 1 The role of complement in the immune response.

The complement system is essential for protective immunity against certain bacterial infections with polysaccharide antigens to which natural IgM reacts. In models of acute peritonitis, activation of the classical pathway of complement is required for the generation of an inflammatory response and resolution of the infection. The ability of complement-coated antigen to augment the antigen-specific response has also been proven through co-ordinated ligation of complement receptor 2 on B cells with the surface immunoglobulin within the B-cell receptor complex.

The complement system is thus essential for protective immunity to polysaccharide antigens against which natural IgM is reactive, in the generation of an effective inflammatory response in models of acute septic peritonitis, and in facilitating the production of an antigen-specific antibody response.

Soluble recognition molecules

In addition to the complement proteins, there are other secreted proteins that have a significant role in the systemic or local immune response (Table 1). In respect of local defence systems, there is increasing recognition that antimicrobial peptides may have a important role, particularly at mucosal surfaces. These include the defensins, which are polypeptides of 29 to 40 amino acids that exert microbicidal activity, most commonly by disruption of bacterial membranes. These proteins are able to augment the immune response by the activity of the human b-defensins 1 and 2, which are chemotactic for immature dendritic cells and memory T cells.

Mannose-binding protein recognizes carbohydrate moieties and has selectivity for foreign, as opposed to self, cell surfaces or glycoproteins as a result of the spacing of its terminal carbohydrate-recognition domains. Mannose-binding protein exists as an oligomer in the circulation and therefore achieves high-affinity interaction with multivalent carbohydrate molecular species, such as those found on microbial surfaces. Several different mutant alleles of mannose-binding protein have been described and individuals who are homozygous or heterozygous for the mutant alleles seem to be more susceptible to a certain infections, and exhibit a defect in opsonophagocytosis. There is evidence that other proteins, such as C1q, may act similarly since mannose-binding protein is recognized by a C1q receptor recently

cloned from monocytes.

Mannose-binding protein is a member of the collection family of soluble proteins that also includes the surfactant proteins. These proteins possess collagenase domains and carbohydrate recognition domains. The latter mediate recognition of structures on the outer surface of micro-organisms. *In vitro*, surfactant protein-A and D bind carbohydrates on the surface of viruses, bacteria, and fungi and thereby may lead to the aggregation of the micro-organisms, thus encouraging phagocytosis by neutrophils and by alveolar macrophages. There is evidence that the surfactant proteins have a role in pulmonary defence; they bind to components of *Pneumocystis carinii* as well as *Cryptococcus neoformans*, which are important pathogens in immunocompromised individuals. Furthermore, patients with cystic fibrosis, who are susceptible to repeated pulmonary infections, have diminished levels of surfactant protein-A and D; the deficiency correlates with reduced effective killing of pathogen.

A further family of soluble proteins that have an emerging role in the innate immune response are the pentraxins. The members of this family, which includes C-reactive protein and serum amyloid protein, exist as a radial pentameric structure in solution and recognize a variety of ligands such as phosphate esters and polysaccharides. Their production is induced by inflammatory cytokines, such as IL-1 and IL-6, and, as a consequence of being multimeric, they are able to activate the classical pathway of complement by directly binding C1q. In animal models, C-reactive protein has been found to have a role in protection against endotoxin-induced mortality. Recently, mice deficient in C-reactive protein have been found to develop autoantibodies, suggesting that C-reactive protein may also participate in the maintenance of immunological tolerance to self proteins, possibly by mediating the clearance of apoptotic cells.

Membrane-bound recognition receptors

In addition to soluble recognition systems, there are several cell-associated receptors whose cellular distribution reflects the effector arms of the immune system to which they are linked (Table 2). There are two broad types of receptor; those that have primarily an endocytic capacity and those that have signalling capacity.

The mannose receptor is an example of an endocytic recognition system and is expressed on tissue macrophages, immature dendritic cells, and some endothelial cells. This receptor recognizes saccharide residues commonly expressed on microbial surfaces but not those frequently found exposed on self glycoproteins. Hence this receptor is able to differentiate infectious from non-infectious and binds a large number of different organisms including *Mycobacteria*, *Trypanosoma*, yeast, and both Gram-positive and Gram-negative bacteria. Significantly, this receptor, which constitutively recycles to the cell surface through endosomal compartments, is able to target bound antigen for presentation on MHC class II molecules, and, in the case of a component of mycobacteria, lipoarabinomannan, on the non-classical MHC class I molecule, CD1b**.**

Within the same lectin family, but containing carbohydrate-recognition domains with a different structure, is DEC-205. Initially used as marker of dendritic cells but now known to be expressed on a subset of dendritic cells, DEC-205 may also be able to enhance presentation of antigen in the context of MHC class II molecules.

A further family of cell-surface receptors that is increasingly being recognized as having an important role in recognition and clearance of invading pathogens are the scavenger receptors. This group of recognition molecules is characterized by their broad ligand specificity; it was first identified by Brown and Goldstein in 1979 as responsible for binding modified, but not native, low-density lipoprotein. As well as binding acetylated and oxidized low-density lipoprotein, members of the scavenger receptor family also can recognize Gram-positive and Gram-negative bacteria, lipotechoic acid and lipopolysaccharide, and aldehyde-modified proteins. There are considered to be five classes of scavenger receptors, differentiated by structure and binding characteristics as well as the cells on which they are expressed. The class A scavenger receptors, expressed on macrophages, have a role in clearance of micro-organisms from the circulation. Mice deficient in two allelic forms of the class A scavenger receptors have increased susceptibility to herpes simplex virus and *Listeria*, as well as to the lethal effects of endotoxin.

A further exciting aspect of the biology of scavenger receptors is that they recognize apoptotic cells. This is achieved, at least in part, through their ability to bind phosphatidylserine, which becomes exposed on the surface of apoptotic cells during the process of cell death—a mechanism which may represent a means of clearing apoptotic cells in a way that avoids an inflammatory response.

Recognition of cell-surface components of pathogens is an important warning mechanism, indicating to the host the presence of foreign micro-organisms. It has long been recognized that a major constituent of the walls of Gram-negative bacteria, polysaccharide, is a potent inducer of an inflammatory response; lipopolysaccharide can be lethal through the induction of shock. The recognition of lipopolysaccharide, and hence the generation of an inflammatory cytokines in response to this stimulus, occurs through the CD14 surface receptor which binds lipopolysaccharide once lipopolysaccharide is itself bound by lipopolysaccharide-binding protein, a constituent of serum. The means of signalling upon ligation of lipopolysaccharide–lipopolysaccharide-binding protein by CD14 was, until recently, unclear, because CD14 is a glycophosphatidylinositol-linked membrane protein, and therefore would have no intrinsic signalling capacity. However, in 1997, Medzhitov and Janeway demonstrated the presence in humans of a protein homologous to the *Drosophila* protein Toll; they further showed that this facilitated the production of inflammatory cytokines by monocytes. Subsequently, four further members of the same family have been discovered and mutations in the gene encoding one of these toll-like receptors (Tlr4) have been found in two different strains of mouse that are lipopolysaccharide-non-responsive. Different members of the Tlr family can differentiate between various classes of micro-organisms—Tlr4 responds to Gram-negative organisms while Tlr2 is activated by Gram-positive pathogens and yeasts. Downstream consequences of ligation of CD14 and Tlr4 by lipopolysaccharide–lipopolysaccharide-binding protein, which include generation of inflammatory cytokines, are mediated through activation of the transcription factor, NF_B.

Cellular components of the innate immune system

Just as B and T lymphocytes are clearly constituents of the acquired response, macrophages, dendritic cells, and polymorphonuclear cells must be considered as key members of the innate response. Recently, greater attention has been given to the roles of these cells and the way they orchestrate an immune response, not just in their own right but also in co-ordinating the involvement of different arms of the adaptive immune system.

Macrophages

The monocyte/macrophage is beautifully adapted for its role of ingestion and intracellular killing of pathogens. It has several receptors that are able to recognize organisms or components of organisms and it is extremely active phagocytically—thus it can internalize bound micro-organisms and kill them after formation of phagosomes. In addition to the well-established production and activity of reactive oxygen species macrophages also produce reactive nitrogen intermediates (RNIs), including nitric oxide, by inducible nitric oxide synthase (iNOS or NOS2). Studies in mice deficient in NOS2 have demonstrated that the production of reactive nitrogen intermediates plays a non-redundant role in protection against viruses and intracellular pathogens. There is also synergy between nitric oxide formation and reactive oxygen intermediates, through the generation of peroxynitrite ($ONOO^-$) which possesses additional microbicidal activity.

Dendritic cells

These cells are also bone-marrow derived (with the exception of a small subtype of dendritic cells). During maturation they pass through two functionally very different stages (Fig. 2). As immature dendritic cells, they populate various non-lymphoid tissues (e.g. Langerhans cells in the skin are immature dendritic cells) and actively sample their microenvironment through receptors, including the mannose receptor, DEC-205, and Fc receptors. Immature dendritic cells are thus well equipped to take up a large variety of antigens, and once activated by bacterial constituents, such as lipopolysaccharide and the CpG motifs within bacterial DNA, their surface phenotype changes and they are induced to migrate out of the tissues to draining lymphoid tissue. By the time they reach the draining lymph nodes they acquire a fully mature phenotype; such antigen-capturing receptors as the mannose receptor and Fc receptor are down-regulated, and surface expression of MHC class II, as well as costimulatory molecules, CD80 and CD86, and, vitally, CD40, are up-regulated. At the same time, there is increased activity of the antigen-processing machinery within these cells, rendering them powerful 'professional' antigen-presenting cells.

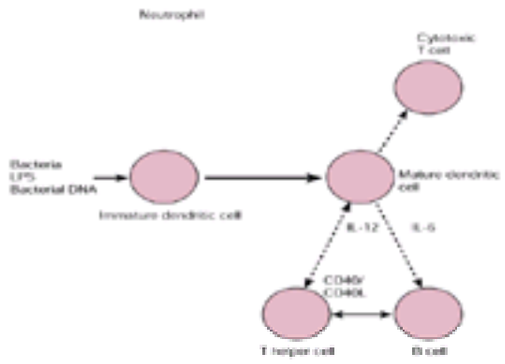

Fig. 2 The central role of the dendritic cell in the innate and acquired immune responses.

The efficiency of dendritic cells is utilized by the immune system in several settings, and it is increasingly clear that they participate critically in the development of immune responses to certain tumours and viruses, both of which are mediated through CD8+ T cells. For some viral infections, the production of virus-specific CD8+ T cells requires the presence of antigen-specific CD4+ T cells. In this setting, activated dendritic cells provide the link, as these cells are able to stimulate CD4+ T cells, that then reciprocate by upregulating CD40 ligand on their surface. CD40 ligand then binds to CD40 expressed on the dendritic cells, giving a signal to these cells that enable them to activate antigen-specific CD+ T cells. Dendritic cells are absolutely required for initiation of antigen-specific CD8+ T cell responses to certain viral infections and tumours through a process called 'cross priming'. Antigens derived from one cell are captured by a second cell and this cell processes and presents antigenic determinants from the first cell in the context of surface MHC class I to CD8+ T cells. These CD8+ T cells are activated and expand clonally; they are then able to exhibit cytolyic activity for the first cell type, be it a tumour cell expressing the antigen or a virally-infected cell.

Neutrophils

Polymorphonuclear phagocytes constitute one of the principal arms of the innate immune system. As one of the first immune cells to arrive at the site of an infectious challenge, their response is important not only in the initial control of infection, but also in guiding the migration of other components to the local environment. Neutrophils, like macrophages, are phagocytically active and express receptors for bacterial peptides, complement components, and the constant regions of specific immunoglobulin isotypes. Hence, specific phagocytosis of either immunoglobulin- or complement-opsonized bacteria can occur. Signalling though some of these receptors induces activation of the neutrophil, with immediate release of reactive oxygen species and phospholipid-derived inflammatory mediators which exhibit microbicidal activity. The importance of this function in neutrophils and macrophages is reflected in the phenotype of individuals with chronic granulomatous disease who have a defect in the generation of the reactive oxygen species and who suffer from recurrent, non-resolving infections that are usually caused by organisms that express catalase.

Natural killer cells

Natural killer cells, although clearly related to T and B lymphocytes, are distinct in not expressing rearranged receptors for antigen or peptides fragments of antigen. First discovered as responsible for tumour cytolytic activity in mice devoid of lymphocytes, these cells can develop both from the bone marrow and from fetal thymocytes.

Natural killer cells act as a means of non-adaptive cellular cytotoxicity against tumour cells and some virally infected cells. Although these cells do not have antigen-specific receptors, a surface molecule, MICA, up-regulated on tumour cells and stressed cells (e.g. when virally infected) is recognized by a natural killer cell receptor, with consequent activation of the cell-killing machinery. Protection against lysis of healthy host cells is provided through the recognition by receptors on natural killer cells of self MHC class I molecules. Ligation of these receptors negatively regulates the natural-killer-cell-mediated lysis. Natural killer cell activation can be induced through ligation of CD16, the low affinity Fc receptor for IgG, on the surface of the cell leading to antibody-dependent cellular cytotoxicity. Inflammatory cytokines, including IL-15, TNF-a, IL-12, and IL-18, also trigger natural killer cell activation, with the concomitant production of interferon-gamma (IFN-g).

Natural killer cells play an important and individual role in antiviral responses. For example adenovirus- and human cytomegalovirus-infected cells secrete proteins that inhibit surface MHC class I expression, which protect against antiviral cytotoxic T lymphocyte (CTL) activity, but these proteins also render the cells more susceptible to natural-killer-cell-mediated killing. A further protein, also produced by cytomegalovirus, however, is homologous to class I heavy chain and is able to bind to b_2-microglobulin. This protein facilitates transport of the complex to the cell surface and confers on the cell resistance to natural-killer-cell-mediated lysis.

Mast cells

Mast cells are most widely recognized for their role in allergic responses. They are bone marrow-derived cells whose proliferation and maturation are stimulated by a number of cytokines including, in particular, IL-3 and stem cell factor. The expression of FceRI, the high affinity Fc receptor for IgE, is characteristic of mast cells. Once multiple molecules of IgE have bound to an allergen, ligation and cross-linking of this receptor can occur, which causes mast cell degranulation. The degranulating mast cell releases histamine, neutral proteases (for example tryptase), proteoglycans, and lipid mediators with diverse effects, including vasodilatation and increased vascular permeability, bronchoconstriction, and intestinal smooth muscle constriction.

Mast cells also aid the immune response to micro-organisms. They can phagocytose and, *in vitro* at least, present antigen in the context of MHC class I and class II molecules—although the functional importance of this in the host has not been demonstrated. These cells do, however, have a prominent role in the development of a protective response in animal models of acute septic peritonitis, in which they promote the clearance of organisms, in part by the production of TNF-a and the subsequent recruitment of neutrophils. In this setting, it is thought that mast cells are activated by complement products, and the generation of C5a anaphylatoxin induces mast cell degranulation as a result.

g† T cells

These cells show features of both the innate and the adaptive immune systems. They have a limited ability to rearrange their T cell receptor genes, and *in vivo* are composed of prominent clones of g† receptor combinations that respond to alkylamine components of micro-organisms.

The cytokines of the innate immune system

Interferons

The interferons (IFNs) were originally considered to have mainly antiviral activity. There are two groups—the type I interferons, IFN-a and IFN-b, and the type II, IFN-g. While the type I IFNs are produced by virally-infected cells, IFN-g is secreted by T lymphocytes and natural killer cells. The IFNs exert their antiviral activity through several mechanisms, that may be specific to the infected cell or involve the induction of broader host responses. The two groups of IFN inhibit cellular protein synthesis and induce activation of cellular RNAses, thereby destroying viral double-stranded RNA.

The broader actions of the IFNs affect innate as well as adaptive responses in host immunity. IFN-g is produced by natural killer cells, once these are activated by IL-12. The IFN-g itself activates the natural killer cell cytolytic machinery and also simulates macrophage microbicidal activity by inducing transcription of the *NOS2* gene and activating NADPH oxidase. Both classes of IFN, but particularly IFN-g, can encourage the generation of the adaptive immune response, by inducing transcription of several genes that encode proteins involved in antigen processing and presentation. In these ways, interferons enhance humoral immune responses as well as antiviral T cell responses.

The inflammatory cytokines—TNF, IL-1, and IL-6

Tumour necrosis factor-alpha (TNF-a) plays a central role in the host response to bacterial infection, and while its production is essential for protection, excess TNF-a can also be lethal to the host. TNF-a is produced by macrophages when stimulated by bacterial products (including lipopolysaccharide) from Gram-negative bacteria, but can also derive from many other cell types from diverse tissues in response to inflammatory stimuli. TNF-a propagates the inflammatory response; it induces the microbicidal activity of macrophages, stimulates production of macrophage IL-1, IL-6, IL-8, as well as TNF-a, and augments the cytotoxic activity of natural killer cells. An additional feature of TNF-a is that it can induce the maturation of immature dendritic cells, that then leave the local environment where they have encountered micro-organisms and migrate to local lymphoid tissue to initiate an adaptive immune response. TNF-a can be considered as a double-edged sword because it also plays a role in the syndrome of septic shock, characterized by hypotension, capillary leak, and multiorgan failure.

IL-1 has many proinflammatory activities, most of which overlap with TNF-a. As well as influencing almost all cells of the immune system, it exerts activity in neuronal tissue, the liver, adipose tissue, and the endothelium. IL-1 results in the increased expression of adhesion molecules, accumulation of neutrophils at a site of inflammation, the hepatic acute phase response—and is involved, with IL-6 and $PGE_{2,}$ in the generation of fever. Clearly, regulation of the activity of IL-1 is important; of the two types of IL-1 receptor, one (the type II IL-1 receptor) acts merely as an inactive ligand or decoy for IL-1, thereby preventing it binding to the type I IL-1 receptor. Furthermore, there is also an inactive analogue of IL-1 called IL-1 receptor antagonist (IL-1Ra) that binds to the type I IL-1 receptor but does not induce an activating signal.

IL-6 is produced by a large number of cell types, and its expression is increased in almost all tissues in response to infection. Inflammatory stimuli such as lipopolysaccharide, TNF-a, and IL-1 are responsible for the induction of IL-6 in infections. IL-6 is partly responsible for the hepatic acute phase response exemplified by enhanced transcription of the pentraxin C-reactive protein discussed earlier. IL-6 also induces B-lymphocyte differentiation and can induce activation of T cells.

IL-12 and IL-18

Both macrophages and dendritic cells possess further means by which they can stimulate their antimicrobial activity and that of other cells. IL-12 is a cytokine which is produced by macrophages and dendritic cells, either upon direct stimulation by certain microbial products, for example lipopolysaccharide or CpG motif-bearing DNA, or more commonly by stimulation of these antigen-presenting cells by CD4+ T cells, themselves activated by the antigen-presenting cells. The cognate interaction-mediating IL-12 generation by these cells is mediated by CD40 on the antigen-presenting cells, the stimulation of IL-12 production having a number of effects. IL-12 stimulates IFN-g secretion by natural killer cells, which can then both stimulate CD8+ T cells and Th1-type CD4+ T cells. IL-12 also directly activates the microbicidal activity of macrophages by inducing the transcription of NOS2, with the consequent generation of reactive nitrogen intermediates as discussed earlier.

Another cytokine whose full role in the immune response to micro-organisms is still being elucidated, is IL-18. Initially described as a product of activated Kupffer cells and called IFN-g-inducing factor (IGIF), IL-18 is now known to be produced by macrophages. IL-18 is synergistic with IL-12 in the induction of IFN-g and, independently of IL-12, it also enhances natural killer cell activity.

Conclusions

The innate immune system, through various receptor species, is able to detect motifs common to pathogen subtypes, thus keeping the requirement for such receptors to a minimum. The receptors are linked to diverse effector mechanisms that facilitate inactivation or death of the micro-organism. An emerging pattern is that while the adaptive immune system recognizes protein structures, it is carbohydrate moieties that are the determinants for innate immune ligands.

Within the innate immune system, new components continue to be uncovered, and, at the same time, additional functions are being ascribed to previously characterized molecules. Thus, the field of innate immunity and especially its role in directing the subsequent adaptive response is one of the most active and exciting areas in contemporary immunology.

Introduction

The primary immunodeficiencies have provided a valuable insight into the critical components of the immune system for protection against infection. Although 10 years ago only two of these conditions were understood at a molecular level, over 80 defective genes causing a variety of clinical phenotypes have now been identified. This section focuses on lymphocyte disorders causing susceptibility to infection; defects in phagocytes and the complement pathways, which are important components of the innate immune system, are described in Chapter 5.4.

In the United Kingdom, there is still an unacceptable delay of 5 years on average for the diagnosis of some types of immunodeficiency, emphasizing a need for clinicians to be more aware of these disorders.

Classification

The primary immunodeficiencies (**PIDs**) are mostly inherited single-gene disorders presenting in infancy and early childhood. However, the one important exception is common variable immunodeficiency (**CVID**) that is still not precisely defined, most patients having a complex polygenic disorder of immune regulation which frequently presents in adults. PID includes a wide variety of cellular disorders of both the adaptive and innate immune systems, some causing autoimmunity rather than susceptibility to infection. The International Union of Immunological Societies (**IUIS**) supports a committee to meet every 5 years to review these classifications.

Secondary immunodeficiency occurs in a wide range of diseases, the immunodeficiency often being caused or exacerbated by therapy with immunosuppressive drugs.

History and examination

The family history is important, particularly since it may suggest X-linked or autosomal inheritance. There are few characteristic physical features, but the total absence of tonsils in infants and children is a feature of X-linked agammaglobulinaemia and severe combined immunodeficiency, the latter also being associated with failure to thrive and an absent thymic shadow on a chest radiograph. Signs of chronic otitis media, sinusitis, conjunctivitis, bronchitis, and bronchiectasis are typical, and splenomegaly is common in some types. Growth retardation, dysmorphic features, and severe skin disease (e.g. eczema, erythroderma) occur individually or in combinations in some of the PID syndromes. Chronic infection with atypical mycobacteria in young children suggests a defect in the g-interferon and interleukin-12 signalling circuit. Massive lymphadenopathy and splenomegaly with autoimmune disease is a feature of lymphocyte apoptotic defects.

Primary immunodeficiency

Antibody-deficiency syndromes

Prevalence

The lifetime prevalence of the severe antibody-deficiency syndromes is about 16 per million of the Caucasian population in Western countries, but there is no reliable information on prevalence in developing countries; there are currently about 1000 diagnosed patients in the United Kingdom. However, selective IgA deficiency is common, occurring in about 1 in 700 of Caucasians, most of whom are healthy.

Aetiology

Most of the disorders are caused by single-gene defects leading to blocks at various stages of the maturation and differentiation of B lymphocytes (Fig. 1). However, common variable immunodeficiency, the most common of all the PIDs, appears to be a complex polygenic disorder of immune dysregulation.

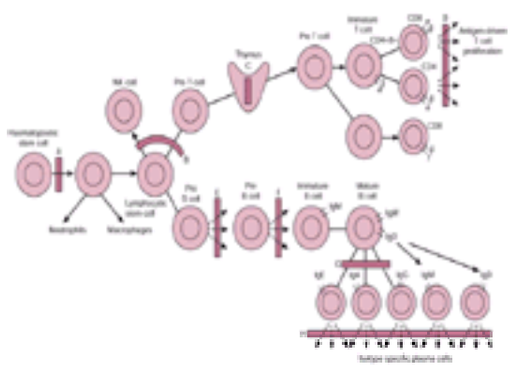

Fig. 1 Various blocks (hatched bars) in the maturation and differentiation of lymphocytes in the primary immunodeficiencies. (a) Reticular dysgenesis; B: X-linked severe combined immunodeficiency (**SCID**) (gc defect), JAK3 deficiency, adenosine deaminase (ADA) defects; C: purine nucleoside phosphorylase, *RAG1* and *-2*, *Artemis*, ZAP-70, CD45, IL-7Ra, and lymphocyte HLA class II defects; D: common variable immunodeficiency (CVID), $p56^{lck}$ defects. (b) E: defects in surface µ

heavy-chain expression, Blnk, Iga, and l5 surrogate light chain, RAG1 and -2, Artemis, ADA; F: XLA (Btk deficiency); G: X-HIM (CD40-ligand deficiency, CD40) and activation-induced cytidine deaminase deficiencies; H: CVID. Note that all defects causing SCID, other than those affecting B-cell development, will compromise antibody production through the lack of T-cell interactions in the lymphoid apparatus at stage G.

Nomenclature (Table 1)

These follow IUIS guidelines, the individual types usually being referred to as a clinical description (e.g. X-linked agammaglobulinaemia), or alternatively by the molecular defect (e.g. CD40-ligand deficiency). The common use of acronyms by immunologists can be confusing for those outside the field.

Major types of antibody deficiency

Common variable immunodeficiency (CVID)

This is the most common of all the primary immunodeficiencies, affecting about 1 in 30 000 Caucasians. It is likely that the majority of patients labelled as CVID have a consistent combination of molecular abnormalities, the remaining few having as yet unidentified single-gene defects. Patients become symptomatic at any age, but usually in early childhood or late adolescence. Serum immunoglobulin levels are variable, but typically the serum IgA is below 0.1 g/l, the IgG below 2 g/l, and the IgM below 0.2 g/l. However, some patients have near-normal IgM levels and can occasionally make IgM antibodies. At least 20 per cent of patients with CVID can be shown to have a polygenic inherited disorder which is genetically linked to selective IgA deficiency. The pedigrees of affected families show a variable phenotype, even in affected siblings, ranging from IgG subclass defects, IgA deficiency, to CVID. Mothers with IgA deficiency and circulating antibodies to IgA are more likely to have affected offspring. The major predisposing genetic locus is located in the MHC region on chromosome 6, covering part of the class III and adjacent class II region. None of the genes has yet been identified, and there are at least three minor susceptibility genetic loci on other chromosomes.

A third of patients are lymphopenic, with circulating CD4+ T-cell counts between 0.15 and 0.4 × 10^{9}/l, often with a relative increase in CD8 T cells. Splenomegaly occurs in about 30 per cent of patients, and splenectomy may be necessary for those who develop hypersplenism. The spleen usually contains numerous non-caseating granulomas, with excessive numbers of activated macrophages in the surrounding tissue. A smaller number of patients develop granulomatous disease, requiring steroid therapy, in the lungs and liver; other organs such as the skin, brain, and kidneys are less commonly involved. Scandinavian patients are much less prone to granulomatous complications, suggesting an environmental factor is involved.

Chronic or recurrent diarrhoea, not related to known pathogens, occurs in at least 20 per cent of patients. This is often associated with a mild colitis and an excess of intraepithelial T lymphocytes. A minority have a Crohn's-like condition with a florid ileitis, and occasionally strictures. A few patients have upper intestinal villous atrophy with a florid inflammatory infiltrate; a minority of these will respond to a gluten-free diet, while the others need steroids to induce remission. About 10 per cent of patients have a pan-gastritis, sometimes with anaemia due to a lack of intrinsic factor and poor vitamin B12 absorption. Submucosal lymphoid nodules are common in the small bowel, but can occur elsewhere in the gut; this nodular lymphoid hyperplasia probably represents an aborted attempt at a local immune reaction to antigens in the gut.

The mechanism of CVID is complex and not well understood, but the evidence suggests that the fundamental abnormality is a failure to generate the ppropriate microenvironment in the lymphoid apparatus for B-cell differentiation and antibody production. There is evidence of an excessive production of g-interferon and interleukin-12 by lymphocytes and monocytes, respectively; this cytokine dysregulation is likely to cause a marked skewing towards a TH1-type response and increased susceptibility to chronic inflammatory disease. The antibody deficiency has recovered after HIV (human immunodeficiency virus) infection in five reported cases, probably by altering these abnormal cytokine patterns.

The differential diagnosis of CVID depends on excluding the other rarer single-gene PIDs and secondary immunodeficiency (see below).

Thymoma and hypogammaglobulinaemia

This has some distinctive features but many clinical and laboratory similarities with CVID. The thymoma, usually benign and well encapsulated, occurs in patients over 40 years of age, the hypogammaglobulinaemia being of varying severity. There may be autoimmune phenomena such as neutropenia, haemolytic anaemia, and red-cell aplasia. The disease has a poor prognosis, with most patients dying within 15 years from opportunistic viral or fungal infections due to deteriorating cellular immunity. Surgical removal of the thymoma has no effect on the immunodeficiency or the prognosis, but is usually necessary to exclude malignancy and/or involvement of neighbouring structures. The mechanism of the association with hypogammaglobulinaemia is not understood.

X-linked (Bruton's) agammaglobulinaemia (XLA)

Affected males usually develop recurrent infections in the first 2 years of life, often at about 6 months when maternal IgG is exhausted. Most patients have some residual IgG production (less than 50 mg/100 ml), but make no IgA and IgM. T-lymphocyte function is normal, but there are very few circulating B cells due to a block in the differentiation at the pre-B-cell stage in the bone marrow. The relevant gene on the X-chromosome codes for **Btk** (Bruton's tyrosine kinase), an intracellular signalling molecule involved in pre-B-cell development. A similar phenotype occurs in males and females with rare, autosomal recessive defects in critical molecules for B-cell differentiation upstream of Btk (see Table 1). Provided serious infection can be prevented, the patients have an excellent prognosis, and suffer from none of the chronic inflammatory/granulomatous complications seen in CVID. This may be partly explained by Btk having a role in the signalling cascade for macrophage activation, causing XLA patients to have a downregulated inflammatory response.

Hyper-IgM syndrome (HIM)

There are three known rare molecular defects causing a failure of immunoglobulin class switching from IgM to IgG, and then to IgA and IgE. Two involve either the CD40 ligand (CD154), an activation-induced surface protein on CD4+ T lymphocytes, or its ligand CD40 on B cells. The CD154 gene is on the X chromosome, affecting males who have a poor prognosis due to an unexplained susceptibility to sclerosing cholangitis, cirrhosis, and liver cancer. X-HIM patients are also prone to opportunistic infections with, for example, *Pneumocystis carinii* and *Cryptosporidium parvum*, suggesting that the failure to express CD40 ligand has wider implications for T-cell immunity. Sometimes female carriers of the genetic mutation can present with mild antibody deficiency due to incomplete Lyonization.

A rarer cause of HIM is caused by deficiency of a lymphocyte-specific cytidine deaminase, an enzyme involved in RNA editing in activated B cells. This autosomal recessive condition has a milder phenotype than X-HIM, resembling CVID and not being associated with opportunistic infections and liver disease.

X-linked lymphoproliferative syndrome (XLPS)

Affected males have a defect in the control of T-lymphocyte immunity to the Epstein–Barr virus (**EBV**), either dying during acute infectious mononucleosis or developing Burkitt's-like B-cell lymphomas and/or hypogammaglobulinaemia. XLPS is caused by mutations in the gene coding for **SAP** (surface lymphocyte activation molecule (SLAM) associated protein), a cytoplasmic protein that regulates the activation of cytotoxic CD8+ lymphocytes; those dying in the acute phase have a massive multiorgan infiltration by these cells. There appears to be a defect in the control of EBV reactivation leading to lymphoma in some survivors of acute infection. The mechanism of the immunodeficiency is not known, with some patients being misdiagnosed as having CVID.

Transient hypogammaglobulinaemia in infancy and childhood

Maternal IgG crosses the placenta in the last trimester of pregnancy and helps to protect the infant against infection for the first few months of life. Between 4 and 6 months of age the normal infant will develop an increasing repertoire of IgG antibodies, mainly of the IgG1 subclass. The capacity to make IgG2 and IgA is not fully developed until adolescence. This sequence may be retarded in some infants, who present in early childhood with infections and hypogammaglobulinaemia. There is no consensus on the precise definition of this disorder except that recovery should have occurred by 5 years of age. There is evidence that the mechanism has

similarities with CVID.

Infections associated with hypogammaglobulinaemia

Patients are prone to bacterial septicaemia and respiratory infections, with a minority being also susceptible to mycoplasma and enteroviral infection (Fig. 2). There is usually uneventful recovery from most common childhood viral infections (e.g. measles, varicella, and mumps).

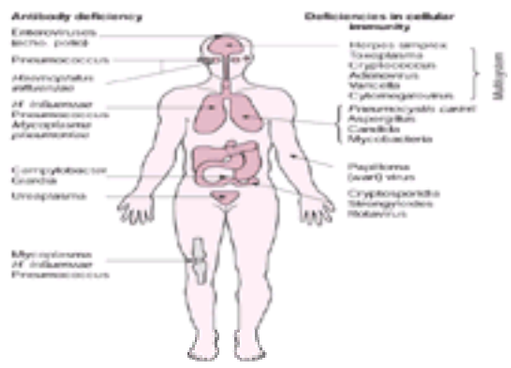

Fig. 2 Pattern of infections associated with severe defects in antibody production or cellular immunity. Patients with severe combined immunodeficiency (**SCID**) disease suffer from all the infections listed, while those with the acquired immunodeficiency syndrome (**AIDS**) are prone mainly to infections shown in the right-hand column.

Bacteria

Patients may present with pneumococcal, *Haemophilus influenzae* (capsulated), or meningococcal septicaemia, but more often there is a history of recurrent respiratory infection, the main organism involved being non-encapsulated *Haemophilus influenzae.* This semi-commensal organism colonizes the upper respiratory tract of many normal individuals, spreading to involve the bronchi following common viral infections. Patients with antibody deficiency suffer from chronic infection in the ears, sinuses, and bronchi, often leading to bronchiectasis and deafness. *Pneumococcus* spp. and *Moraxella catarrhalis* are other common respiratory pathogens in these patients. Staphylococcal skin infection is common in children.

Mycoplasmas

Antibodies inhibit the growth of mycoplasmas on mucosal surfaces. About 10 per cent of XLA or CVID patients develop chronic mycoplasma arthritis with destruction of joints. Overgrowth of these organisms on mucosal surfaces (usually in the respiratory or genitourinary tracts) apparently leads to the uptake of viable organisms by phagocytes, which then transport them to joints where the microenvironment supports growth. A variety of mycoplasma species have been implicated (e.g. *M. hominis* and *Ureaplasma urealyticum* from the urogenital tract, *M. pneumoniae* from the lungs). Rarely, infection can be acquired from animals as a zoonotic infection. Local infection can lead to chronic cystitis or urethritis, and there is the possibility that some species cause chronic bronchitis. Although methods based on the polymerase chain reaction (**PCR**) are being developed for rapid molecular diagnosis, very few laboratories can culture these organisms and provide antibiotic sensitivities. A working diagnosis of mycoplasma infection should be made in hypogammaglobulinaemic patients with arthritis, cystitis, or urethritis when samples taken for routine microbiological testing are negative; doxycycline should be given in the first instance, and specialist advice sought to confirm the diagnosis and provide antibiotic sensitivities in case the organism is resistant.

Viruses

Enteroviruses

These include polio-, coxsackie-, and echoviruses. Coxsackie- and echoviruses, of which there are many different strains, are a common cause of self-limiting mild enteritis and/or meningitis in normal individuals, but cause chronic meningoencephalitis and myositis in patients with severe hypogammaglobulinaemia. Echoviruses are usually involved, the classical features being convulsions, VIIIth nerve deafness, headache, and myositis, the last leading to fibrosis of the limb muscles with contractures. The diagnosis is usually made by culturing enteroviruses from the cerebrospinal fluid, or by a positive PCR for viral RNA. There is usually a gradual deterioration in the central nervous system features and death within 5 years; however, in a few people the disease can be modified or even cured by giving pooled immunoglobulin containing specific antibodies to the virus intravenously and into the cerebrospinal fluid on a regular basis. Standard prophylactic immunoglobulin therapy (see below) probably reduces the risk of enteroviral infection, but is not fully protective and often obscures the diagnosis by preventing culture of the virus from cerebrospinal fluid; patients in this situation may present with insidious mild symptoms of cerebral involvement such as altered personality and decreased mental ability. It is important to make the diagnosis because there is a new antienteroviral drug, pleconaril, which has cured most of treated patients.

There is a risk of paralytic poliomyelitis after live oral polio vaccination which is contraindicated in these patients. Fortunately, regular immunoglobulin therapy appears to prevent poliovirus infection from recently immunized family members, probably because enough neutralizing IgG leaks into the saliva and prevents faecal/oral transmission. However, rarely, a patient may become a chronic excreter of a virulent polio (vaccine related) strain. The World Health Organization, who are planning to discontinue routine polio immunization, are concerned about such patients who could start a new polio epidemic if immunity waned in the general population.

Other viruses

Patients with CVID are prone to recurrent *Varicella zoster* skin infection (shingles) but this rarely recurs after treatment with immunoglobulin. Reactivation of *Herpes simplex* (cold sores) or vaginal herpes is uncommon. The role of persistent picornavirus (e.g. rhinovirus, enterovirus) infection in the respiratory tract is unclear, but these viruses may have a role in the susceptibility to recurrent sinusitis and bronchitis.

Gastrointestinal infections/complications

Infections

Giardia lamblia

This is the only protozoal parasite to often cause symptoms in these patients. Mild to severe malabsorption may follow, with some patients complaining of abdominal distension, colicky pain, and flatulence. A secondary lactose intolerance may occur. The parasite may be difficult to eradicate with a standard course of metronidazole (2 g daily for 3 days), and tinidazole may be needed. It may be useful to give high-dose intravenous immunoglobulin therapy (2 g/kg body weight every 2 weeks) in resistant cases. Giardiasis is an uncommon complication nowadays in the Western world, probably because of higher dose immunoglobulin prophylaxis and improved cleanliness in the preparation of food.

Campylobacter

Campylobacter jejuni is the most frequent cause of bacteria-associated diarrhoea, usually responding to a course of a erythromycin (in adults, 500 mg four times a day for 10 days). Infection is currently uncommon in the United Kingdom, presumably because of improved hygiene. Stool culture will differentiate between shigella and salmonella infection, which occur no more frequently in these patients than in the general population.

Liver disease

The dependence on blood products led to a number of outbreaks of hepatitis C virus (**HCV**) infection before the early 1990s, with most infected patients dying from cirrhosis within 15 years. Hepatitis B virus (**HBV**) contamination of immunoglobulin products has not been a problem since the routine screening of blood donors started in the 1970s. No specific infection has yet been linked to the granulomatous hepatitis that occurs in at least 10 per cent of patients with CVID, the presinusoidal inflammatory reaction causing portal hypertension and oesophageal varices. The fact that about 30 per cent of patients with CVID in the United Kingdom have raised liver alkaline phosphatase serum levels is of concern as this is a good marker of liver involvement. This will lead to cirrhosis in some patients who should be considered for liver transplantation as their post-transplant survival is no worse than that for immunocompetent patients.

Sclerosing cholangitis is an important complication of X-HIM, and patients should be screened for abnormalities in liver function tests every 4 months, followed by cholangiography in those with persistently elevated liver enzymes. The cause is unknown, although cryptosporidial infection in the bile ducts may be the trigger in some cases. Affected patients should be considered for bone marrow transplantation, as well as liver transplantation for those with cirrhosis.

Malignancy

Apart from liver cancer and EBV-associated lymphoma in X-HIM and XLPS, respectively, malignancy is not a major complication of patients with hypogammaglobulinaemia. There is a small increase in lymphoma in XLA patients, with this being more impressive in patients with CVID (threefold increase over general population). However, a very high incidence of gastric carcinoma in patients with CVID was reported in the 1980s (50-fold increase over general population); this is now rare in the United Kingdom, possibly due to the wider use of prophylactic antibiotics for respiratory infection, which may have incidentally reduced the incidence of gastric infection with the cancer-promoting bacterium, *Helicobacter pylori.*

Prognosis

Recent surveys show that about 80 per cent of patients with CVID survive for 30 years, but morbidity and mortality depend on early diagnosis and management in an expert centre. The prognosis for X-linked agammaglobulinaemia is even better and is improving as patients are diagnosed earlier. Pneumonia and bronchiectasis remain the most common causes of death, liver and lung fibrosis being an additional complication in CVID. The overall prognosis for X-HIM and XLPS is poor, with most patients dying within 20 years of diagnosis.

Diagnosis

Diagnosing severe antibody deficiency is simple when the levels of serum IgG, IgA, and IgM are all very low or unrecordable. Death in childhood resulting from infection in a family member suggests one of the rare single-gene causes of immunodeficiency. For males presenting in childhood, blood should be sent to an expert laboratory to screen for Btk (XLA) and SAP protein (XLPS) in lymphocytes by Western blotting, and for expression of CD40 ligand on activated lymphocytes (X-HIM); XLA is likely if there is an absence of circulating B lymphocytes. Other rare syndromes should be considered in those presenting in childhood (see Fig. 3(a)). The interpretation of low immunoglobulin levels in children under 1 year of age is difficult, and further follow up is always needed to confirm the presence of a significant antibody deficiency. In affected families with single-gene immunodeficiencies, a molecular diagnosis can be made at birth and the infant started on treatment. Similarly, fetal diagnosis can be offered at about 14 weeks' gestation by screening DNA from fetal blood, or amniotic or chorionic villous cells.

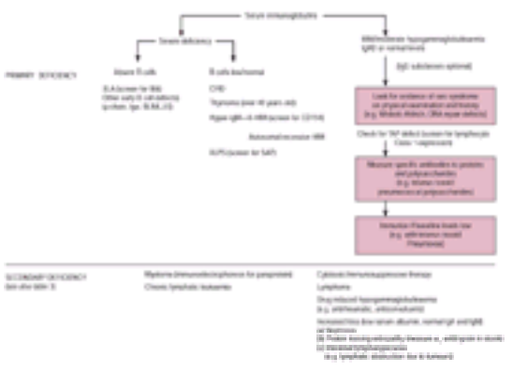

Fig. 3 A scheme for the diagnosis of primary and secondary immunoglobulin (antibody) deficiency.

Diagnosis of mild/partial antibody deficiencies

Selective IgA deficiency (IgAD)

The class switch to IgA requires a co-ordinated sequence of events within the germinal centre, involving continuing B-lymphocyte proliferation and T/B-cell interactions. It is therefore not surprising that IgA deficiency is associated with a variety of defects in lymphocyte function. IgA deficiency, defined as a serum IgA level below 0.1 g/l, is the most common of the primary immunodeficiencies, and is often genetically linked to CVID with which it shares a major susceptibility genetic locus in the MHC region. It occurs mainly in Caucasians, with about 1 in 700 of the population affected in northern Europe; it is rare in Africans (~1:6000) and very rare in Japanese (1:18 000). IgA deficiency is also associated with inherited single-gene defects in DNA repair (for example, ataxia telangiectasia) and major cytogenetic defects in chromosome 18. Various antirheumatic and anticonvulsant drugs can induce IgA deficiency. Most patients with IgA deficiency are healthy, and the defect is discovered either by chance or during surveys of families with CVID. A small percentage are discovered during investigation for recurrent infections, but these patients usually have additional defects in IgG antibody production, and therefore have a mixed partial deficiency.

Some IgA-deficient individuals have high levels of serum anti-IgA antibodies, which may cause anaphylactic reactions during blood or blood product infusion. There is a slightly raised incidence of IgA deficiency in patients with coeliac disease, probably because of shared susceptibility genes in the MHC region.

Other selective class deficiencies

Complete selective IgM deficiency, the mechanism not being understood, is rare and usually discovered by chance in patients not susceptible to infection. Low IgM levels occur in Bloom's and the Wiskott–Aldrich syndrome (see below). Selective IgE deficiency has been described but is not clinically important.

IgG subclass deficiencies

The clinical significance of IgG subclass deficiency is controversial. As in IgA deficiency, the complete absence of a major IgG subclass is compatible with normal health in the Western world. There are four IgG subclasses: IgG1 having the highest serum level; and IgG2, IgG3, and IgG4 having sequentially lower levels. Many healthy individuals have IgG4 levels close to the limit of detection, and most immunologists in the United Kingdom no longer measure this subclass. Apart from rare individuals with inherited genetic defects in the constant-region genes for IgG1, 2, and 4, the mechanism of subclass deficiency is unknown, although some susceptibility genes are probably shared with CVID and IgA deficiency because all three types of defect can occur in the same family. IgG2 deficiency and IgA deficiency can occur together, particularly in patients with ataxia telangiectasia.

The four subclasses have different functional capacities in relation to activating the first component of complement (IgG2 being weak) and Fc-g receptors on phagocytes. Specific IgG antibodies to bacterial components are also skewed towards certain subclasses, with those to polysaccharides being predominantly IgG2 in adults, and those to viral proteins being mainly IgG3. However, attempts to link subclass deficiencies with a predisposition to particular infections has been

unsuccessful, probably because of the flexibility and redundancy in the immune system.

IgG subclasses can be measured in most routine immunopathology laboratories, but it is difficult to show that the results influence clinical management. Moreover, there is no official International Standard serum for the subclasses, making it difficult to compare results from different laboratories. Experience has shown that it is not worth measuring subclass levels in patients with total IgG levels above 8 g/l; furthermore, measuring them in children under 5 years is of little use because of the wide range of levels in healthy children in this age group. The current consensus is moving towards measuring the levels of functional IgG antibodies as a better indicator of immune status in those with recurrent infections.

Functional immunoglobulin deficiencies

Functional deficiency is defined as a complete or partial failure to produce antibodies to specific proteins or polysaccharides, in the presence of normal total serum immunoglobulin levels. The mechanism is not understood and its prevalence in the general population is not known. In practice, only functional IgG antibody deficiency is considered clinically important for protection against infection. The standard practice is to measure baseline levels of antibodies to proteins such as tetanus toxoid, and polysaccharides such as those purified from the capsules of pneumococci; if these are low then the response after immunization is measured. Antibodies to other antigens such as diphtheria toxin, measles and polio viruses can also be measured to provide a broader range of responses. There are workable normal values for baseline levels of antibodies to tetanus and diphtheria toxins, and for pneumococcal and *Haemophilus influenzae* B polysaccharides, but the interpretation of responses after vaccination is difficult because of the paucity of data from healthy age-matched individuals. Nevertheless, complete failure to respond following a second vaccination is evidence of an abnormality that may influence the clinical management.

Treatment

Immunoglobulin replacement therapy

Immunoglobulins for therapeutic use are manufactured from large pools of donor blood (about 20 000 donations). Those used for intramuscular (**IMIG**) or subcutaneous (**SCIG**) injection are approximately 16 per cent solutions, while those for intravenous use (**IVIG**) are less concentrated (6–12 per cent solutions). The manufacturing process involves alcohol precipitation of plasma to produce an IgG concentrate with very little IgA or IgM remaining. All preparations should be subjected to rigorous safety measures, which include screening donors for HIV, HBV, and HCV infection, and manufacturing procedures which inactivate a wide range of viruses. Fortunately, HIV is inactivated by alcohol, but there were outbreaks of HCV hepatitis caused by contaminated batches prior to the introduction of improved safety measures in the early 1990s.

Immunoglobulin prophylaxis protects against pneumococcal and *H. influenzae* septicaemia, parvovirus, and probably reduces the susceptibility to infection from *Giardia* and *Campylobacter* spp. However, it is much less effective in preventing infection with mycoplasmas and enteroviruses. It reduces the frequency of acute bronchitis in antibody-deficient patients, probably by preventing common respiratory viral infections. However, there is poor penetration into the respiratory mucosa with little effect on the growth of *H. influenzae* in the respiratory tract.

Indications and dose

Most patients with severe hypogammaglobulinaemia and a history of recurrent infections should be offered immunoglobulin replacement therapy. IVIG at a dose of 400 mg/kg every 4 weeks is usually given in the United Kingdom and the United States, but an alternative regime is to give SCIG at an equivalent total dose every week; this route is popular in Scandinavia. Intramuscular therapy is now rarely used because it is painful. With adequate training, many patients infuse at home, with a nurse or partner inserting the intravenous lines for IVIG, or using infusion pumps for SCIG. The aim is to maintain the preinfusion (trough) IgG level towards the lower limit of the normal range (~8 g/l). Failure to maintain this level on standard doses suggests an increased loss or hypercatabolism of IgG, the latter being a useful marker of chronic infection and/or inflammation. The majority of patients tolerate IVIG and SCIG well. About 10 per cent of patients experience mild 'reactions' during IVIG infusions (for example, headaches, mild fever, backache), but these can usually be controlled by reducing the infusion rate and/or giving an antihistamine; reactions needing adrenaline (epinephrine) and steroid therapy are rare. Changing the immunoglobulin product may be helpful in those with recurrent reactions. Some reactions are caused by high plasma levels of anti-IgA antibodies, although there is poor correlation between the level of these antibodies and susceptibility to reactions. Nevertheless, anti-IgA antibodies are usually measured routinely in patients with a serum IgA level below 0.1 g/l, and an immunoglobulin preparation chosen with minimal contaminating IgA for those with very high levels of anti-IgA. In practice, patients benefit from being referred to specialist centres for immunoglobulin therapy where the response to infusions can be assessed by experienced staff.

Reaching a decision on the treatment of patients with mild or moderate antibody deficiency is more difficult. It may be best to use prophylactic or intermittent courses of antibiotics, particularly in children. Objectively assessing the efficacy of immunoglobulin prophylaxis is not straightforward, particularly since there is likely to be a significant placebo effect.

General management

Patients should be encouraged to take antibiotics early to treat bronchitis, and those with structural lung damage may require long-term prophylaxis. The quinolones (for example, ciprofloxacin) are particularly effective because they are concentrated in the mucous layer lining of the respiratory tract and have a very low minimal inhibitory concentration for non-typable *H. influenzae*. Amoxicillin, alone or in combination with clavulanic acid, or cotrimoxazole, is a useful alternative. Postural drainage and regular exercise are useful in promoting the removal of secretions from the lungs. Patients should be encouraged to join support groups which provide educational literature in lay language and assistance for social problems.

Major defects in cellular (T cell) immunity

Thymic aplasia (Di George syndrome)

This rare condition (about 1 in 3500 live births) is caused by fetal malformation of the third and fourth branchial arches at about 7 weeks of gestation, apparently due to abnormal cephalic migration of neural crest cells into these regions. These cells contribute to the development of the skull, palate, thymus, and parathyroid glands, explaining why the syndrome is associated with dysmorphic facies, palatal abnormalities, and hypoparathyroidism—affected infants sometimes presenting with tetany and convulsions due to hypocalcaemia. Although originally thought to be caused by teratogens or maternal disease, the majority of cases are now known to be associated with a chromosomal deletion at 22q11. The condition overlaps with other genetic disorders such as the velocardiofacial syndrome and conotruncal anomaly face syndrome, the phenotype broadening into endocrine, cognitive, and neurological defects. The cardiac defects may require major cardiac surgery in infancy.

Most affected infants retain nests of thymic tissue in the neck and have only a moderate T-cell lymphopenia, mainly affecting CD8 T cells, which improves over the first few years of life. Antibody production is usually adequate, and there is an increased incidence of autoimmune disease such as thyroiditis and haemolytic anaemia. A minority of infants have a more severe T-cell defect and are prone to severe infections.

Treatment

Apart from treating the associated abnormalities (for example, hypocalcaemia), infants with circulating T-lymphocyte counts above 500/µl usually need no specific immunological intervention, but should be followed up regularly to confirm recovery of T-cell immunity. Those with a more profound T-cell lymphopenia may need either a bone marrow or thymic graft. Transplantation of partially HLA-matched postnatal thymic tissue has been successful, with the appearance of mature functional 'educated' host T cells in the blood a few months later. As for other patients with severe T-cell defects, live vaccines should be avoided and blood for transfusion irradiated to avoid graft-versus-host disease (**GvHD**). Infants with major cardiac defects should be screened for the condition before cardiac surgery.

Severe combined immunodeficiency disease (SCID)

These rare immunodeficiencies (about 1:30 000 live births) are caused by inherited mutations of genes that influence the maturation of lymphocytes, particularly T cells (Fig. 1). Those affected, who are usually infants or children, are susceptible to life-threatening infection with a wide range of pathogens and opportunistic microbes. The emphasis is on early diagnosis and transfer to a specialist centre for bone marrow transplantation. Most of the rare adult patients who present with

severe infection associated with 'idiopathic CD4+ lymphopenia' have a 'leaky phenotype' of one of the known types of SCID.

Clinical features

Symptoms usually start before 7 months of age with failure to thrive, diarrhoea due to parasitic or viral infection (rotavirus, enteroviruses), *Pneumocystis carinii* pneumonia, and oral candidiasis. Other common viruses causing serious disease are adenoviruses, cytomegalovirus, human herpesvirus-6, and respiratory syncytial virus; systemic aspergillus or candida infections are less common but usually fatal. Routine immunization with live vaccines, particularly **BCG** (bacille Calmette–Guérin), may cause severe infection in patients with SCID. Most patients die within 2 years without a successful bone marrow graft. There are no specific features for any of the different types of SCID. The tonsils are usually absent and the thymic 'shadow' absent on a chest radiograph. Skin rashes due to a GvHD reaction, and more rarely lymphadenopathy and hepatosplenomegaly (Omenn syndrome), may confuse the diagnosis (see below).

Immunology

Most affected infants and children are lymphopenic, a characteristic finding which is often overlooked on the routine blood count. Table 2 outlines the differential diagnosis of lymphopenia in this age group. SCID can be classified into subgroups depending on the presence of T, B, and natural killer (**NK**) cells (Fig. 4), those with no NK cells being more likely to engraft following bone marrow transplantation. The levels of serum immunoglobulins are of little diagnostic use during the first year of life. The proliferation of T lymphocytes in culture in response to mitogenic and antigenic stimulation is nearly always very depressed. The diagnosis may be obscured when there are normal numbers of circulating T lymphocytes, for example in the Omenn syndrome, or following engraftment by maternal cells *in utero* or cells from an unirradiated blood transfusion.

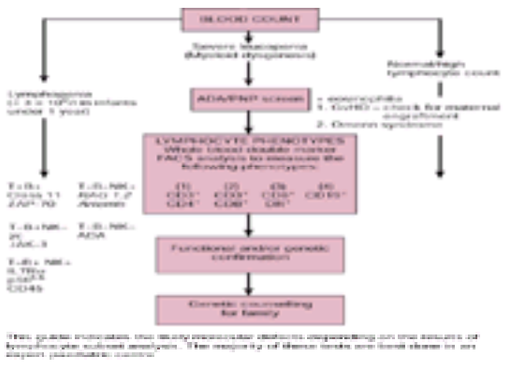

Fig. 4 Guide to the diagnosis of severe combined immunodeficiency (SCID) in infants and young children.

Molecular causes of SCID

There follows a brief description of the most frequent types of SCID, highlighting the contribution the discovery of the molecular defect has made to our understanding of the human immune system.

Defects of lymphocyte signalling

It was surprising when mutations in the g chain of the interleukin (**IL-2**) receptor were associated with X-linked SCID because the IL-2 'knock out' mouse had only a mild immunodeficiency. This led to a search for a wider role for the g chain, now known to be the signalling chain for the IL-2, IL-15, IL-4, IL-9, and IL-7 receptors, the latter being critical in the early development of T lymphocytes. This common g chain (gc) contains the appropriate tyrosine motifs on its cytoplasmic tail to facilitate the phosphorylation of Janus kinase-3 (JAK-3) which activates the signal cascade. Inherited defects in the IL-2-receptor a chain cause a multi-organ autoimmune disease, whereas defects in the IL-7-receptor a chain cause severe SCID. Failure to express HLA class II molecules on lymphocytes leads to severe SCID; research into the various molecular defects involved has improved our understanding of the factors that regulate class II gene transcription. Defects in the g and e chains of the CD3 complex are not always associated with severe immunodeficiency, suggesting some redundancy in the complex; inherited defects in ZAP (zeta chain-associated protein)-70 kinase, which interacts with the z chain, cause a predominantly CD8 lymphopenia. A defect in the p56 ^{lck} cytoplasmic kinase, which is important for signalling through the T-cell receptor, and complete absence of the surface protein tyrosine phosphatase receptor, CD45, are very rare causes of SCID.

*Defects in **VDJ** (variable, diversity, joining) recombination*

Molecular defects in the recombinase activating genes (*RAG1* or *RAG2*) lead to a variable phenotype depending on the amount of residual RAG protein produced. In cases of complete RAG1 or -2 deficiency there is failure to express a functional T- and B-cell receptor, the result being severe SCID. Partial RAG expression is one cause of Omenn syndrome, characterized by severe skin rash, lymphadenopathy, hepatosplenomegaly, eosinophilia, and autoimmune disease. Recently, mutations in another gene (Artemis), which appears to be involved in VDJ recombination and DNA repair, has been found in SCID infants who have a generalized sensitivity to ionizing radiation.

Defects in purine metabolism

Lymphocytes need efficient salvage and interconversion pathways for purines and pyrimidines during rapid bursts of proliferation, particularly in the lymphoid germinal centres and fetal thymus. Adenosine deaminase (**ADA**) deficiency was the first established cause of SCID: the condition also being the first example of enzyme replacement therapy (initially using red cell transfusions which contain ADA) in clinical medicine, and later being the first disease to be treated by gene therapy, although with only partial success. ADA has an important role in the intermediate pathways of purine metabolism. Purine-nucleoside phosphorylase (**PNP**) is also active in this pathway, but is a much rarer cause of SCID. It is interesting that deficiencies in both these enzymes predominantly affect lymphocytes, despite their presence in most other cells of the body.

Diagnosis and early management

In most cases the clinical diagnosis is obvious, the infant failing to thrive with a severe infection and profound lymphopenia. Congenital HIV has to be considered in the differential diagnosis, but is easily excluded by PCR tests for the virus. A detailed family history is important, asking whether the parents are related and whether there have been early deaths from infection in family members. Lymphoreticular malignancy may need to be considered in patients with lymphadenopathy and hepatosplenomegaly; biopsies from bone marrow, skin, liver, and lymph nodes should be reviewed by a histopathologist with experience of SCID and GvHD; it may be necessary to confirm T-cell engraftment (maternal or otherwise) using chromosome markers.

Affected infants often present in respiratory distress due to a viral or fungal pneumonia; co-trimoxazole should be given immediately for possible *Pneumocystis carinii* infection and the patient transferred urgently to an expert paediatric centre where the diagnosis can be confirmed and specific treatment arranged; time should not be lost trying to diagnose and treat infection before transfer.

Subsequent management

Having identified and treated any current infection, the next priority is to confirm the diagnosis of SCID and then counsel the parents on the practicalities and risks of bone marrow transplantation (**BMT**), regardless of whether the molecular defect is identified. Screening tests for some SCIDs can be completed within a few days (ADA, PNP, HLA class-II defects) but others may take some weeks/months unless the molecular defect is already known in the affected family. BMT from an HLA-identical sibling is the ideal treatment and has close to 100 per cent success, but haploidentical sibling or HLA-matched unrelated marrow has about an 80 per cent success. Transplantation of stem cells from HLA-matched cord blood is an alternative. Unlike BMT in non-immunodeficient patients (e.g. for leukaemia), no

preconditioning of the recipient is required to provide space within the marrow, but T-cell depletion of the donor marrow is necessary to minimize GvHD. The long-term outlook is good; there are now about 15 patients in the United Kingdom who have survived for between 12 and 20 years following BMT; the majority are healthy, although 20 per cent require regular immunoglobulin infusions because of failure to engraft donor B cells. For those rare adult patients who are diagnosed with SCID, bone marrow transplantation has previously been considered too risky; however, this view is changing since they rarely survive beyond a few years after presenting with severe infection. Some patients with ADA deficiency can be maintained on regular injections of bovine ADA, but this is very expensive and often does not completely correct the immune defect.

SCID is an ideal condition for gene therapy, but there have been problems in transfecting enough copies of the relevant gene into host bone marrow stem cells. However, this has been successfully achieved in at least four infants with X-linked (gc-deficient) SCID, possibly due to a selective advantage for the transfected stem cells; these patients now have normal immunity at up to 1 year of follow up.

Defects in the interferon-g/IL-12 pathway and susceptibility to mycobacteria

The study of rare children with a familial susceptibility to fatal mycobacterial infection has confirmed animal studies showing the critical importance of interferon-g (IFN-g) in stimulating macrophages to kill mycobacteria. Affected children have mutations in components of the circuit involved in delivering the signal to macrophages: which are the IL-12 p40 subunit, the IL-12 receptor b1 subunit, both chains of the IFN-g receptor (**IFN-gR**), and STAT1 (STAT, signal transducer and activator of transcription; a signalling component downstream of the IFN-gR). These are all autosomal inherited conditions in which the heterozygote carriers might be expected to be healthy; however, some families with heterozygotes for IFN-gR defects show a dominant inheritance pattern due to disruption of the receptor complex by non-functional chains. A similar dominant-negative effect has been described in a patient with a STAT1 defect because two functional molecules must be recruited to the cytoplasmic domain of the IFN-gR to provide a signal. Regular IFN-g therapy is useful for those with normal IFN-gR function and downstream signalling, while the others require bone marrow transplantation. It is extraordinary that affected patients are so selectively susceptible to mycobacterial disease, particularly BCG and atypical strains such as *M. avium* and *M. fortuitum*. This suggests that this lymphocyte/macrophage interactive circuit has been selected by humans to specifically cope with mycobacterial infection (Fig. 5).

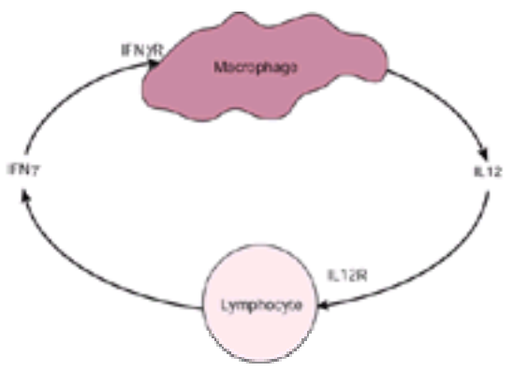

Fig. 5 This circuit is crucial for the effective killing of mycobacteria. Macrophages secrete IL-12 following uptake of bacteria, which amplifies the production of interferon-g by sensitized T lymphocytes, which in turn stimulates the macrophage to kill the organism.

Inherited syndromes associated with immunodeficiency

Defects in DNA repair

Efficient repair of DNA damage is fundamental to cell survival. Our knowledge of the cascade involved in the excision of damaged nucleotides, insertion of new nucleotides, and rejoining (ligation) of the DNA strands is rapidly expanding, helped by the study of rare syndromes caused by genetic defects in this pathway. Ataxia telangiectasia (**A-T**) is an autosomal recessive disease characterized by progressive cerebellar ataxia, chromosomal instability, telangiectasia on exposed areas of skin, early death from cancer, and immunodeficiency of variable severity. About 80 per cent of patients have IgA deficiency, with a third having complete absence of IgA; a minority have additional defects in IgG production, often IgG2 deficiency, while a few have severe panhypoimmunoglobulinaemia. T-lymphocyte function is often depressed. The relevant gene codes for a protein involved in the regulation of the cell cycle, probably having a role in the suspension of DNA replication after damage from ionizing radiation to allow time for repair. The defective gene in A-T leads to chromosomal instability and susceptibility to cancer, particularly lymphoma associated with translocations between chromosomes 4 and 7 involving the genes that code for immunoglobulin heavy chains and T-cell receptor a, b, g chains. Most patients with A-T die before their third decade from either tumours or respiratory infection, the latter usually caused by a combination of immunodeficiency and progressive neurological deterioration. About 1 in 200 of the general population is heterozygous for the genetic defect, and there is some evidence that they are at an increased risk of malignancy. Furthermore, the gene is mutated in some types of leukaemia cells (e.g. T-prolymphocytic leukaemia), suggesting its product acts as a tumour suppressor.

The Nijmegen breakage syndrome (**NBS**) has a similar phenotype with additional craniofacial abnormalities, including progressive microcephaly. The normal physiological function of the *NBS* gene is not known, but like *ATM* leads to chromosomal instability following exposure to DNA-damaging agents. Other recessive chromosomal instability syndromes predisposing to cancer are caused by mutations in the DNA ligase-1 gene (with severe immunodeficiency and dwarfism), and the helicase mutated in Bloom's syndrome which is associated with moderately low immunoglobulin levels.

Wiskott–Aldrich syndrome

This X-linked disease is characterized by thrombocytopenia, moderate immunodeficiency, eczema, autoimmune disease (including vasculitis), and susceptibility to EBV-induced B-cell lymphomas. Patients have a dysregulated humoral response with depression of IgM antibody production to polysaccharides, and often a raised serum IgE. There is a milder variant resulting in only thrombocytopenia. The defective gene codes for a cytoplasmic protein (**WASP**, Wiskott–Aldrich syndrome protein) which is involved in cytoskeletal reorganization following the activation of platelets and T lymphocytes. The diagnosis is based on the presence of small platelets and on demonstrating the absence of WASP in white cells by Western blotting. Splenectomy may be needed to reduce the thrombocytopenia, and bone marrow transplantation is recommended for most patients because of the poor prognosis.

TAP deficiency

The transporter associated with antigen processing (**TAP**) is composed of two subunits (TAP-1 and -2) and facilitates the transport of HLA class I molecules from the endoplasmic reticulum to the *cis*-Golgi compartment. Inherited defects in TAP (so far only confirmed for TAP-2) lead to the failure to express class I molecules on the lymphocyte surface, preventing cytotoxic T and NK cells from recognizing antigen in the context of 'self' class I molecules. However, adequate cytotoxic function against virus-infected cells is retained using mechanisms that are not completely understood. Affected patients are prone to progressive bronchiectasis that is not entirely explained by infection. Some patients have developed nose and mid-face destruction, similar to midline granuloma, probably caused by a failure to inhibit NK-cell self-destruction via class I mediated inhibitory signals.

Other rare syndromes associated with severe infection

Chronic mucocutaneous candidiasis is a very rare sporadic disease of unknown cause, which in some patients is associated with multiple endocrine abnormalities. Patients have subtle defects in humoral and cellular immunity that do not explain the severity of the candida infection. Most patients can be managed satisfactorily with long-term antifungal therapy (fluconazole or itraconazole). The hyper-IgE (Job's) syndrome is another poorly defined disorder characterized by eczema, deep staphylococcal abscesses, and serum IgE levels usually in excess of 10 000 kU/l. Many patients have consistent facial features, delayed shedding of primary teeth, and hyperextensible joints suggesting they share the same underlying genetic defect. The Chediak–Higashi and Griscelli syndromes are autosomal-recessive diseases characterized by the presence of giant lysosomes in all granulated cells that compromises the function of neutrophils and NK cells. The relevant genes have been identified but their precise function is still unknown. Patients often die from infection or bleeding due to thrombocytopenia during an 'accelerated phase', which is

similar to the virus-associated haemophagocytic syndrome. Bone marrow transplantation will correct the haematological abnormalities but not the other features, which include albinism and various neurological abnormalities.

Immunodeficiency associated with other congenital or inherited disorders

There are many rare disorders causing major multisystem disease in infants and young children that are associated with variable immunodeficiency states. Examples are inherited metabolic defects such as transcobalamin-2 deficiency (causing immunoglobulin deficiency secondary to severe vitamin B12 deficiency) and biotin-dependent carboxylase deficiency (causing a severe T-cell defect). A variety of skeletal (e.g. cartilage–hair hypoplasia), growth disorders (e.g. Schimke immuno-osseous dysplasia), and major dermatological abnormalities (e.g. ectrodactyly ectodermal dysplasia) are associated with T-cell defects and early death from infection. (For a comprehensive list of these disorders see reference to the IUIS Report, 1999.)

Secondary immunodeficiencies (Table 3)

Lymphoid malignancies, immunosuppressive agents, and AIDS are common causes of severe immunodeficiency, while nutritional deficiencies, metabolic disturbances (for example, uraemia), and trauma have a less severe effect on the immune system. In many of these situations the primary disease usually overshadows the immunodeficiency, although attention to the latter can improve the patient's quality of life.

Recurrent pneumonia and bronchitis suggest antibody deficiency, whereas varicella-zoster and herpes-simplex reactivation, oral candida, and rapid growth of skin warts are often early indications of a defect in cellular immunity. The presence of lymphopenia, often overlooked, indicates that the immune system is compromised but is a poor guide to the clinical significance of the defect. In practice, measuring the numbers of circulating CD4+ T cells and serum immunoglobulins are useful simple tests for monitoring the severity of the immunodeficiency.

Lymphoid malignancy

Various types of lymphoreticular malignancy are associated with both humoral and cellular immunodeficiency, exacerbated by the use of cytotoxic drugs. There is no consistent pattern of immunodeficiency for any particular lymphoid malignancy, presumably the severity depending on the genetic background of the patient and immunomodulating factors released from the malignant cells. However, an important exception is chronic lymphatic leukaemia (**CLL**) in which the majority of patients develop hypogammaglobulinaemia during the course of their disease. Although the immunoglobulin deficiency in most patients is mild, a few have severe hypogammaglobulinaemia and suffer from recurrent infections, particularly of the upper and lower respiratory tract; these patients will benefit from regular immunoglobulin replacement therapy, while others can be managed with prophylactic or intermittent courses of antibiotics. The cause of the antibody deficiency is complex and seems to be due to a combination of inhibitory factors released by the malignant clone and interference with the normal traffic of T and B lymphocytes through the lymphoid apparatus by proliferating CLL cells.

Patients with myeloma often have antibody deficiency, which explains their predisposition to pneumococcal pneumonia and septicaemia. In the past, few haematologists paid attention to the immunodeficiency because of the very poor prognosis of the underlying condition. However, modern cytotoxic therapy can now induce prolonged remissions, during which the immunodeficiency recovers, so it may be worth treating the more severely immunocompromised patients with immunoglobulin during the induction period. There is evidence that the malignant plasma cells produce factors that inhibit normal antibody production.

The increasing use of bone marrow transplantation to treat leukaemia carries a legacy of persistent antibody deficiency in a minority of patients due to inadequate B-cell engraftment and/or the drugs used to prevent rejection. Follow-up protocols should include appropriate screening to identify those patients who may require immunoglobulin replacement.

Drugs

The extensive literature on the immunological effects of cytotoxic agents and steroids will not be reviewed here. Many of these drugs have a profound effect on cellular immunity, as shown by the severity of varicella infection in patients treated with corticosteroids, and the risk of cytomegalovirus and EBV reactivation in those on immunosuppression therapy to prevent graft rejection. Some of these drugs, particularly cyclophosphamide and azathioprine, may compromise antibody production after prolonged use. A variety of antirheumatic and anticonvulsant drugs induce a partial (often IgA) deficiency, and occasionally a severe antibody deficiency in a small minority of treated patients, probably due to their genetic susceptibility to the metabolic effects of the drug on B-cell differentiation and/or antigen presentation. The effects are reversible, but it may take up to 2 years for antibody production to recover after stopping the drug.

Viruses

HIV is the most common and important immunosuppressive virus, and is described in Chapter 7.10.21. Many other viruses cause moderate immunosuppression during active infection, particularly measles which depresses cellular immunity. Fetal infection with the rubella virus may, rarely, lead to prolonged depression of IgG and IgA antibody production after birth, sometimes with a high serum IgM level. Fetal cytomegalovirus infection can have a similar effect. There is evidence of prolonged alteration in the type of immune response after common childhood virus infections, some researchers suggesting that these events 'programme' the system towards a TH1 response and reduce the risk of allergy; the marked reduction in measles and other severe childhood infections due to vaccination has been suggested as one reason for the increase in childhood allergy, including asthma.

Immunodeficiency secondary to metabolic and nutritional defects

This is probably the most common cause of immunodeficiency worldwide and contributes to the high infant death rate in the Third World. Protein-calorie malnutrition and deficiency of vitamins and trace elements, particularly vitamin A, zinc, and probably selenium, can lead to significant depression of T-lymphocyte function and reduced antibody production. Poor nutrition in the very elderly in Western countries probably contributes to their poor antibody responses and an increased risk of pneumococcal pneumonia. Vitamin A supplementation has been shown to reduce childhood mortality from infection in New Guinea.

Prolonged metabolic disturbances associated with liver and renal failure will compromise immunity; this persists in about 10 per cent of patients on ambulatory peritoneal dialysis who have low IgG levels and are susceptible to infection, and may be due to a combination of persistent uraemia and hypercatabolism of IgG by activated peritoneal macrophages.

Severe trauma and major surgery often compromises both T- and B-lymphocyte function, but is usually clinically masked by the routine use of broad-spectrum prophylactic antibiotics and immunoglobulin provided in blood transfusions. Even full-thickness burns involving less than 10 per cent of surface area in young children appear to suppress IgG2 and IgG3 subclass production for at least a week. This observation provided an explanation for the high incidence of deaths from the toxic-shock syndrome in one centre and prompted the routine use of prophylactic antibiotics on admission. In major surgery, particularly when hypothermic cardiopulmonary bypass is used in elderly patients, attempts are being made to reduce the risk of postoperative infection by 'boosting' the nutritional requirements of the immune system with supplements such as L-arginine and nucleotides.

Increased catabolism/loss of immunoglobulin

Loss of immunoglobulin from the kidney or bowel is an important cause of mild/moderate hypogammaglobulinaemia, but is rarely of clinical significance. Serum IgM, being a larger molecule, is usually normal, with low IgA and IgG levels. The nephrotic syndrome and protein-losing enteropathy are the most common causes, the latter being difficult to diagnose when the serum albumin level is normal. Leakage of protein and lymphocytes occurs in primary or secondary intestinal lymphangiectasia—the combination of hypogammaglobulinaemia, low serum albumin level, and lymphopenia being a useful clue to this diagnosis. An increase in the catabolism of many proteins occurs in chronic infection/inflammation, but this is never severe enough to cause severe hypogammaglobulinaemia unless there is an associated primary defect in immunoglobulin synthesis. A selective increase in the catabolism of IgG occurs in dystrophia myotonica, but the mechanism is unknown.

5.7 Principles of transplantation immunology

Kathryn J. Wood

Introduction

Transplantation of an organ, tissue, or cells between genetically disparate individuals within the same species, allografts, or between species, xenografts (Table 1), almost inevitably results in rejection of the graft if active steps are not taken to control the destructive immune response that is triggered immediately after transplantation.

Studies on the behaviour of tumour grafts in the early part of the twentieth century led Peter Gorer to formulate the concept of graft rejection in 1938. Gorer's description of what triggers rejection still holds today, even if the language he used does not fit with current immunological jargon: 'isoantigenic factors present in the graft tissue and absent in the host are capable of eliciting a response which results in the destruction of the graft'. The recognition that the immune system was involved came nearly 10 years later when Gibson and Medawar clearly identified specificity and memory as hallmark features of the rejection response.

The rejection process is complex. Many factors, including the nature of the tissue transplanted and the genetic disparity between the donor and recipient, the site of transplantation, as well as the immune status of the recipient, all contribute to determining the character of the rejection response (Table 2).

The events that lead to allograft rejection are summarized in Fig. 1. In brief, inflammation as a result of the removal of the graft from the donor and implantation into the recipient is always triggered as a result of the transplantation procedure itself, irrespective of whether the tissue is allogeneic or xenogeneic in origin. These 'danger' signals are responsible for activating both the innate and adaptive immune systems that act in concert to destroy the graft. For acute allograft rejection, activation of the adaptive immune system requires recognition of molecules that are mismatched or polymorphic between the donor and the recipient. Antigen recognition in combination with additional signals, termed costimulation, leads to the activation of donor reactive lymphocytes, both T cells and B cells. Clonal expansion, meaning proliferation of donor reactive lymphocytes, is triggered such that many more daughter cells with donor antigen specificity are produced rapidly. The environment created by such lymphocyte activation results in the differentiation of the activated donor reactive lymphocytes into effector cells, including cytotoxic T cells and mature B cells or plasma cells that secrete anti-donor antibodies. These antigen-specific effector cells in combination with activated components of the innate response, such as activated macrophages and natural killer cells, orchestrate the destruction of the graft (Fig. 1).

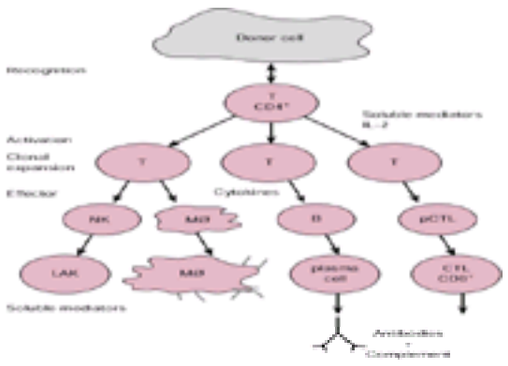

Fig. 1 Overview of allograft rejection. There are three phases to the responses—recognition (direct pathway allorecognition is illustrated), activation, and the generation of effector mechanisms. Each step involves the orchestrated interaction of cells and molecules to ensure that the response is driven towards an aggressive phenotype that will result in the destruction of the transplant. Immunosuppressive drug therapy is designed to interfere at different stages in the response to ensure effective inhibition of rejection.

If immunosuppressive drugs such as cyclosporin, tacrolimus, mycophenolate mofetil, or azathioprine are administered at the time of transplantation, many of the events that lead to acute allograft rejection can be inhibited. As a result of the effective use of these drugs in clinical transplantation the short-term, 1-year, graft survival rates for all solid organ grafts have increased dramatically in the last 20 years (up-to-date summaries of graft survival data can be obtained from the websites listed at the end of this chapter). Unfortunately, this short-term success has not translated into significantly improved long-term, more than 10-year, graft survival outcome. Following the first year after transplantation there is still a steady attrition of grafts; this delayed or late graft loss occurs due to a variety of different processes and factors, only some of which are immunological. Late graft loss is often referred to as chronic allograft rejection (Table 2). Unfortunately, the drugs in use in clinical transplantation at present are relatively ineffective at preventing chronic stimulation of the immune system by the graft in the longer term after transplantation.

When tissues are transplanted between species (xenotransplantation) where the recipient species has preformed natural antibodies against the donor (so-called discordant species that include pig to human), additional immunological events contribute to the destruction of the graft, resulting in the very rapid elimination of the graft through a process known as hyperacute rejection (Table 2). In the pig to human species combination, preformed natural antipig antibodies bind to carbohydrate determinants present on pig cells. As a result the endothelial cell surface develops procoagulant activity causing leucocytes to accumulate in the vessels, complement is activated, and the tissue is rejected very rapidly. If hyperacute rejection can be inhibited, for example by removal of the preformed antibody before transplantation or by controlling complement-mediated damage to the graft, the downstream events involving the adaptive immune system will be triggered resulting in acute vascular or delayed xenograft rejection.

Hyperacute rejection can also occur when an allograft is transplanted into a recipient who has already been sensitized to the histocompatibility antigens of the organ donor (Table 2). In allotransplantation, anti-donor antibody formation can occur as a result of the rejection of a first graft, pregnancy, or blood transfusion. Rigorous screening processes, whereby sera from the recipient are cross-matched against tissue from the donor, ensure that the recipient does not have preformed antidonor antibodies and that hyperacute rejection of allografts hardly ever occurs in current clinical practice.

This chapter will outline the key cellular and molecular events that lead to the destruction of a graft by the immune system of a naïve recipient. The events that lead to allograft rejection will be dealt with in most detail alongside a summary of the sequelae that also need to be considered when xenogeneic tissue is transplanted.

Transplantation sends danger signals to the host

The removal of tissue for transplantation from the donor and its implantation into the recipient will result in a series of changes in gene expression within the donor tissue that will markedly influence the way the recipient's immune system responds. When the organ or tissue to be transplanted is harvested from a cadaver donor some of these changes are a direct consequence of brain death. In addition, the trauma associated with the surgical procedures required to remove and transplant the tissue contributes to the very early events that initiate rejection. These factors are often referred to collectively as the events associated with ischaemia and reperfusion injury. Indeed, it has been suggested that there is a link between the ischaemia time and increasing immunogenicity of the graft.

The consequences of these events include the release of preformed P-selectin (CD62P) from the Weibel–Palade bodies contained within endothelial cells. This is an adhesion molecule responsible for the earliest step in leucocyte migration into the tissue. There is also *de novo* expression of a variety of genes, including those encoding chemokines (chemoattractant cytokines) and other adhesion molecules by the transplanted tissue. Expression of these molecules by the graft creates a proinflammatory environment and results in changes in endothelial cell function and the recruitment of inflammatory leucocytes into the graft, as well as the exodus of donor-derived passenger leucocytes from the graft and their migration to recipient lymphoid tissue. Thus the graft itself initiates a vicious circle of events that contribute to its own destruction.

It is important to note that some of these initial changes will occur even when there are no antigenic differences between the donor and recipient, as is the case when a graft is transplanted between genetically identical individuals—a syngeneic graft. These events are associated exclusively with organ retrieval and the transplantation procedure itself. Of themselves, they are not sufficient to lead to the destruction of the graft, as evidenced by the lack of rejection of autografts and isografts (Table 1). However, they can have a marked influence on early graft function and they will have a significant effect on the way in which the innate and adaptive immune responses to the graft are both triggered and evolve when an antigenic disparity does exist. Moreover, it has been suggested that these early events can predispose the graft to late dysfunction or chronic rejection, the distinctive feature of which is transplant vasculopathy (Fig. 2).

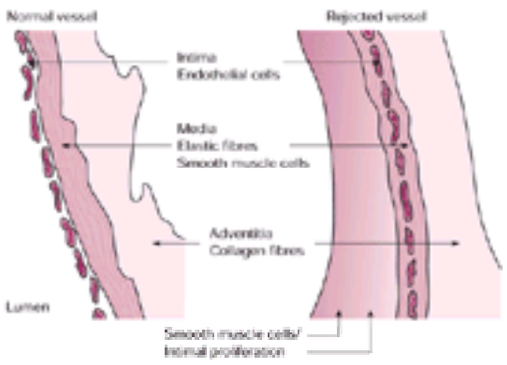

Fig. 2 Histological features of vascular rejection—the hallmark of chronic graft rejection. A normal and rejected vessel are shown in the cartoon. The rejected vessel (right) exhibits severe intimal proliferation compared with the normal vessel (left) as a result of the proliferation of smooth muscle cells.

One way of thinking about the changes that arise as a direct result of the removal and transplantation of tissue is in terms of the trauma of these events initiating a series of 'danger signals'. Receipt and integration of these signals by the host immune system, along with information about the genetic disparity of the tissue transplanted with the recipient, will determine whether and how the recipient immune system is triggered.

Role of the innate immune system

The innate immune system is used by the host as the first line of defence against any adverse event, including transplantation. It comprises a series of cells and molecules that are poised for action as soon as the normal resting situation in the body is perturbed. Elements of the innate immune system will be triggered by the danger signals arising from the trauma associated with the transplantation procedure. The nature of the components of the innate immune system involved in this phase of the rejection response are relatively poorly characterized but are likely to include the components of the complement system, particularly C3, and phagocytic cells such as macrophages.

The complement system is a cascade of proteolytic enzymes whose activation leads to opsonization of targeted cells as well as the generation of a membrane attack complex that can initiate cell lysis. Complement can be activated in a variety of ways, including by some of the proteolytic enzymes produced by the clotting cascade, as well as by contact with damaged or altered endothelial cells. Once activated the enzymes of the complement cascade release soluble mediators, such as C3a and C5a, that will attract leucocytes to the site of the graft, and also produce molecules that can bind covalently to the cells within the graft forming a focus for the damaging events that follow.

Macrophages express a series of pattern recognition receptors, including those that recognize carbohydrate structures, reactive oxygen species, and activated complement components. When these receptors engage their ligands the macrophage is triggered to release a battery of inflammatory cytokines—including tumour necrosis factor (**TNF**), interleukin-1 (**IL-1**), and IL-6 amongst others—that further augment the proinflammatory environment and promote the activation of the adaptive response.

Role of the adaptive immune system

Antigens that stimulate allograft rejection

The degree of histocompatibility (tissue compatibility) between the donor and recipient determines whether a graft is rejected or accepted when transplanted between two members of the same species. In molecular terms this arises from a series of molecules, both cell surface and intracellular, that are polymorphic or variant between different members of the species—so-called histocompatibility antigens. These were originally classified as either major or minor depending on the location of the gene encoding the polymorphic molecule in the genome.

A series of cell surface molecules encoded by genes present within one region of the genome, the major histocompatibility complex (**MHC**), are known as the major histocompatibility antigens or MHC antigens. Many of these molecules are well characterized. Any other polymorphic molecules that trigger rejection are called minor histocompatiblity (**miH**) antigens. The genes for miH antigens are scattered throughout the genome.

Incompatibility or mismatching for either MHC or miH antigens can trigger graft rejection. In general, in naïve recipients the greater the number of incompatibilities for MHC and miH antigens, the more vigorous the rejection response. However, the type of tissue transplanted as well as the site of transplantation will have a marked influence on graft outcome, even when the matching for MHC and miH antigens between the donor and the recipient is identical. For solid organ grafts such as the kidney, matching for MHC antigens between the donor and the recipient improves graft outcome in immunosuppressed recipients. However, in bone marrow transplantation even grafts transplanted between individuals who are identical for MHC antigens can still trigger an immune response, either rejection or graft-versus-host disease, as a result of mismatching for miH antigens.

MHC class I and class II molecules

The MHC encodes a series of polymorphic genes in every species of vertebrate (Fig. 3). Within any one species a large number of variant forms of each of these genes exists within the population as a whole. Of the genes present in the MHC there are two families that code for cell surface molecules known as the MHC class I and MHC class II molecules (Fig. 3). Some of the loci that form part of the class I and class II families have been well characterized and in humans these are called HLA A, HLA B, and HLA C, and HLA DR, HLA DQ, and HLA DP, respectively. Additional class I and class II genes are present in the MHC, but they are less well

characterized than those mentioned above and polymorphisms in these molecules are not considered routinely before either organ or bone marrow transplantation at present and they will not be discussed further here.

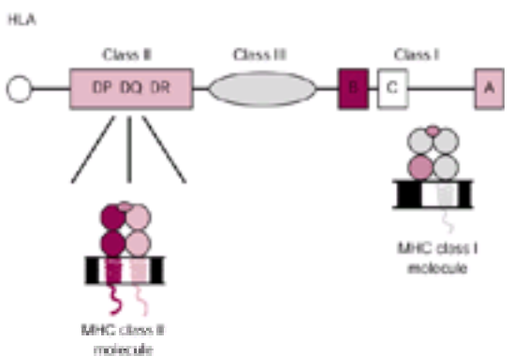

Fig. 3 Outline map of the major histocompatiblity complex (MHC) in man. The HLA gene complex maps to the short arm of chromosome 6. It is divided into regions and subregions that in simple terms each contain a family of genes. Only the well characterized loci are shown in this representation: HLA A, HLA B, and HLA C class I a-chain genes, and HLA DR, HLA DQ, and HLA DP class II A and B genes. Additional class I and class II genes have been described. A full map for the HLA region is available at the website attached to *Nature* (1999) **401**, 921–3.

MHC class I moleucles are cell surface glycoproteins comprising two polypeptide chains; the polymorphic a chain (molecular mass, **MM**, 45 kDa), which is anchored in the plasma membrane and encoded by a gene in the MHC, and b_2-microglobulin (MM: 12 kDa), which is not anchored in the membrane and is encoded by a gene on another chromosome (Fig. 3). MHC class I molecules are expressed on virtually all somatic nucleated cells, albeit at different levels in the resting state. Their expression is rapidly upregulated in response to cytokines such as interferon-g (IFN- g) and tumour necrosis factor- a (TNF-a) that are produced during an immune response. After transplantation, mismatched intact donor MHC class I molecules expressed by donor cells can be recognized and trigger the activation of recipient CD8+ T cells.

Class II molecules are also cell surface glycoproteins built up of two polypeptide chains. However, in contrast to class I, both chains—a and b (MM: 35 and 28 kDa, respectively)—are anchored in the plasma membrane. The two chains are encoded by genes found in the MHC; class II A and B genes for the a and b chains, respectively. Both genes can be polymorphic. MHC class II molecules are not expressed by all cells in the body, their tissue distribution is therefore much more restricted than for class I molecules and expression is only found constitutively on some cells, including dendritic cells, B lymphocytes, macrophages, and some endothelial cells. Importantly, expression of MHC class II molecules can not only be increased on the cells that already express class II molecules but can be induced on other cell types during an immune response. After transplantation, mismatched MHC class II molecules expressed by donor cells can be recognized and trigger the activation of recipient CD4+ T cells.

During the biosynthesis and transport of MHC molecules to the cell surface they become associated with short peptides derived from both intracellular and extracellular proteins. This process is known as antigen processing and presentation. As a result of these antigen processing pathways, MHC class I and class II molecules expressed at the cell surface report the status of the internal and external environment of a cell to the immune system. When the cell is functioning normally the peptides associated with MHC molecules are derived from self proteins, that is, the proteins belonging to the tissue itself, and including peptides derived from the MHC molecules themselves. However, when there is an adverse event such as a pathogen invading either the cell itself or its local environment, the MHC molecules will become loaded with peptides derived from the invader. It is this peptide–MHC complex that is recognized by T cells.

In the context of transplantation the situation is slightly more complex. Before transplantation, donor MHC molecules expressed by the transplanted tissue will contain peptides of donor origin. After transplantation, these donor-derived MHC–peptide complexes can be recognized by recipient T cells via the so-called direct pathway of allorecognition (Fig. 4). However, recipient antigen-presenting cells also come into contact with donor cells and molecules (see below) and through the normal pathways of antigen processing and presentation peptides of donor origin become associated with recipient MHC molecules in just the same way as any other foreign antigen. Recipient MHC–donor peptide complexes can then be recognized by recipient T cells via the so-called indirect pathway of allorecognition (Fig. 4), and this pathway is also used for recognition of mismatched miH antigens. Thus, after transplantation there are two routes of presentation of donor MHC molecules to the recipient immune system, the direct and the indirect pathways of allorecognition.

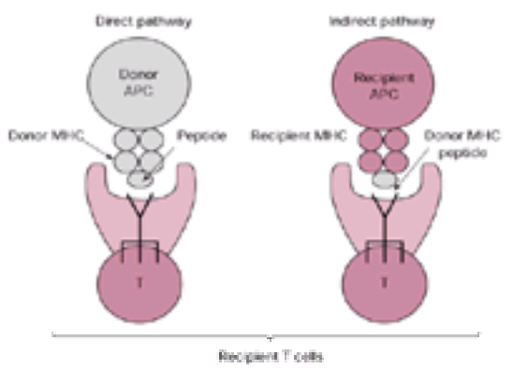

Fig. 4 Direct and indirect pathways of allorecognition. (1) Direct pathway: Donor MHC–peptide complexes are presented to recipient T cells by donor-derived antigen-presenting cells. Two hypotheses have been proposed to explain the high frequency of T cells, between 1 and 10 per cent of the repertoire, that can respond to alloantigens presented in this way. (i) High determinant density: the similarity in structure between MHC molecules results in T-cell receptors exhibiting cross-reactivity for donor MHC molecules irrespective of the peptide that is bound to each molecule. When donor molecules are expressed at high levels, as is the case on donor-derived passenger leucocytes, a sufficient number of T-cell receptors will engage the molecule to trigger a response. (ii) Multiple binary complexes: each donor MHC–peptide complex can be recognized by a different clone of T cell in the recipient giving rise to a high overall frequency of responding cells. (2) Indirect pathway: Donor MHC and miH antigens are processed by recipient antigen-presenting cells and presented as peptides by recipient MHC molecules. Each recipient MHC–donor peptide complex can be recognized by T cells in the recipient. The frequency of responding cells is of the same order of magnitude to T cells responding to other nominal antigens, such as viral antigens.

Two pathways for presentation of donor antigens to recipient T cells

Bone marrow-derived passenger leucocytes are present in non-lymphoid tissues throughout the body and have the characteristics of immature dendritic cells. After transplantation, in response to inflammatory cytokines and other danger signals, the donor-derived passenger leucocytes migrate out of the graft very rapidly and end up in the recipient lymphoid tissue. The migration process results in the passenger cells acquiring the phenotype and function of mature dendritic cells. Mature dendritic cells are often referred to as professional or immunostimulatory antigen-presenting cells as they express high levels of MHC class I and class II molecules as well as other cell surface and soluble molecules that enable them to stimulate naïve CD4+ and CD8+ T cells to respond (Fig. 5). The additional molecules required for an antigen-presenting cell to stimulate the activation of naïve T cells include costimulatory molecules such as members of the B7 family, in particular CD86, CD40, and adhesion molecules. Thus the donor passenger leucocytes that end up in the recipient lymphoid tissue have all of the attributes required for them to present any donor MHC molecules that were mismatched between the donor and the recipient to recipient T cells via the direct pathway of allorecognition.

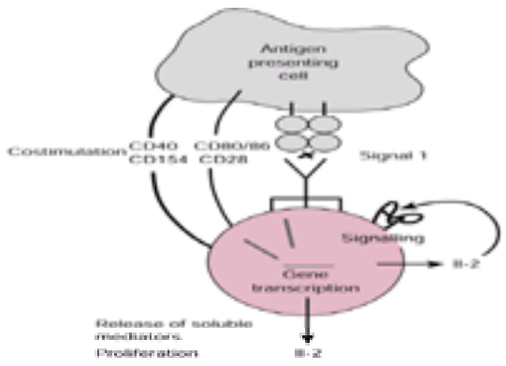

Fig. 5 Antigen presentation to naïve T cells. In conjunction with antigen recognition, additional signals or costimulation are required to trigger T-cell activation. Some of the molecules involved are illustrated, including on the T-cell side CD28 and CD154 (CD40L) and on the antigen-presenting cell side CD86 and CD40.

Evidence that the donor-derived passenger leucocytes play an important role in initiating rejection comes from studies showing that in certain situations removal of the passenger cells from grafts before transplantation can result in prolonged graft survival. However, this is not the case in every situation and the second route of antigen presentation—the indirect pathway—has also been shown to contribute to acute rejection as well as playing a significant role in the evolution of chronic rejection.

At the same time that donor antigen-presenting cells are migrating from the graft, recipient leucocytes are being attracted to the graft in response to chemokines (along with other mediators) released by the transplanted tissue. Amongst the cells recruited into the graft are circulating antigen-presenting cells. These take up debris arising from the tissue damage caused by the transplantation procedure itself, and then migrate to the draining lymphoid tissue. In addition, soluble antigens released as a result of damage to the tissue at the time of transplantation are also transported to the draining lymphoid tissue where they can be picked up by resident antigen-presenting cells. The captured antigens are then processed and presented as peptides with recipient MHC molecules to T cells in the T-cell areas of the recipient lymphoid tissue. In the context of transplantation this route of presentation is known as the indirect pathway of allorecognition (Fig. 4). It is clearly the more physiological of the two pathways that are used to trigger the activation of the response after allotransplantation. Moreover, indirect presentation of donor antigens is likely to continue in the long term after transplantation. Once all of the donor-derived passenger leucocytes have migrated from the graft they are obviously not replaced and therefore only so-called 'non-' or less-professional antigen-presenting cells, such as endothelial cells of donor origin, are available for the continued stimulation of direct pathway T cells.

It has been shown recently that migrating antigen-presenting cells are drawn to the correct area within the lymphoid tissue by chemokines, thereby ensuring that they come into contact with naïve T cells maximizing the chances of antigen presentation. Similarly, once a T cell has been triggered it migrates to other areas of the lymphoid organ, notably the B-cell area, in order to propogate the response and initiate the development of effector cells (Fig. 1).

Activation of recipient T cells

Recipients deprived of T cells either through manipulation of the immune system or through genetic mutations are unable to reject allografts. T cells are therefore a key element of the rejection response. The relative roles of CD4+ and CD8+ T cells in the initiation of the response will depend on the donor–recipient combination and the context in which the activation takes place.

As has become clear in the preceding sections, for T cells to become activated they need to recognize antigen. Every T cells bears a recognition structure, the T-cell receptor (**TCR**). The majority of T cells in the peripheral lymphoid organs and peripheral blood express a TCR comprising an a and b chain—the recognition structure—that is associated with a complex of polypeptides which form the signalling moiety known as CD3 (Fig. 5). abTCRs can recognize MHC–peptide complexes with exquisite specificity, each being specific for one MHC–peptide complex. Once recognition has taken place, signals are delivered to the intracellular machinery by CD3.

At this stage in the process the cell membrane in the vicinity of the TCR–CD3 complex becomes very active and reorganization of the molecules in the membrane occurs to form an immunological synapse. This results in all of the elements required for productive T-cell activation being brought into close proximity with the TCR, including the accessory molecules, CD4 or CD8, and molecules required for the delivery of costimulation or second signals to the T cell, CD28 and CD154. Other structures that are important for adhesion of the antigen-presenting cell and the T cell localize to the edges of the synapse, thus ensuring that the two remain in close contact with one another for long enough for information to be transmitted in both directions.

The localization of CD4 or CD8 in the immunological synapse brings them into close proximity with the TCR–MHC–peptide complex. CD4 is expressed by T cells that recognize MHC class II–peptide complexes (class II-restricted T cells) and CD8 by T cells that recognize MHC class I–peptide complexes (class I-restricted T cells). Each of these molecules can interact with conserved elements of the class II or class I structure, respectively, and they fulfil both an adhesion and signalling function when antigen recognition occurs.

In addition to signals coming through the TCR–CD3 complex and accessory molecules—also known as signal 1—additional signals arising from other cell surface receptors are required to ensure that the responding T cell is activated. These additional signals are often referred to as signal 2 or costimulation. In the presence of signal 1 but the absence of signal 2, T cells become unresponsive or anergic and fail to proliferate in response to further signals from antigen-presenting cells. Thus, during the initial phase of activation it is important that the antigen is presented by a professional antigen-presenting cell that can provide costimulation in addition to presenting donor antigen, either as the intact molecule or as recipient MHC–donor peptide complexes.

Costimulation is a complex process involving many cell surface structures. In strict terms costimulatory molecules can be defined as those that are essential for the initiation of a response from naïve T cells. The best characterized of these on the T-cell side is a molecule known as CD28 (Fig. 5). This is expressed by naïve T cells at rest, interacts with two cell surface ligands on antigen-presenting cells (CD80 and CD86), and is reported to have a preferential interaction with CD86 at the initiation of the response. CD86 is expressed at low levels by immature antigen-presenting cells, but upregulated rapidly during maturation of the antigen-presenting cell and following contact with T cells. By contrast, CD80 is expressed at lower levels than CD86 at the beginning of the response, but once expressed can also interact with CD28. The current interpretation of these data suggests that CD86 is more important for interaction with CD28 during the initiation of the response and that CD80 participates more actively in the downregulation of the response by preferentially interacting with another T-cell molecule, CD152 or CTLA4 (see below).

Signals delivered through CD28 result in increased cytokine synthesis by the responding T cell resulting from the stabilization of cytokine mRNA species. Signals through CD28 are independent of those delivered through the TCDR–CD3 complex and can be blocked independently by different immunosuppressive drugs. However, when the two signalling pathways occur in the same context the signals are integrated by the responding T cell, resulting in an augmented response. The complex series of phosphorylation and dephosphorylation events that take place results in the production of transcription factors, including nuclear factor of activated T cells (NF-AT), that translocate the nucleus of the T cells and switch on transcription of genes such as that for IL-2.

Regulation of immune responses is always critically important: dysregulated immune responses can have very dramatic and harmful consequences for the host. A pathway that counterbalances the positive signals coming through CD28 therefore exists to ensure that the process of T-cell activation does not continue indefinitely in an uncontrolled manner. Later during the course of T-cell activation a new molecule, CD152, is expressed by the activated T cells and acts as a negative regulator of the response. Evidence for this has been obtained by analysing mice that have a targeted disruption in the CD152 gene, so-called CD152 knockout mice. These mice have uncontrolled T-cell expansion when they are housed under normal environmental conditions where they are exposed continuously to a wide variety of antigenic stimuli. CD152 has been shown to have a higher binding affinity for CD86 and CD80 than CD28. Once it is expressed by the activated T cell it can therefore compete for binding with these molecules on the antigen-presenting cell. In addition, the interaction of CD152 with CD80 has been shown to deliver a negative signal to the T cell, shutting down further clonal expansion.

The construction of a fusion protein from the extracellular domains of CD152, CTLA4Ig or CTLA4Fc, and its use as a therapeutic agent has provided evidence that blocking costimulation through CD28 is sufficient to inhibit graft rejection, and confirming that T-cell costimulation through this pathway is a critical step in the

activation steps of the rejection response.

Following the initial stages of T-cell activation, CD4+ T cells also express another cell surface molecule, CD154 or CD40L, that can provide additional costimulatory signals for the responding cell. CD154 interacts with its ligand CD40, which is expressed by antigen-presenting cells, including dendritic cells, B cells, and monocytes (Fig. 5). Non-haematopoietic cells can also express CD40, including endothelial cells, fibroblasts, and epithelial cells. Interestingly, signalling through this pathway is a two-way event, not only leading to modification of the functional capabilities of the T cell but also those of the antigen-presenting cell. Thus, signalling through CD40 results in the augmented expression of CD86 and CD80 by antigen-presenting cells, potentially setting up an amplification loop for augmenting the response. For example, in the kidney, tubular epithelial cells have been shown to express CD40 and engagement by CD154 results in the increased production of chemokines, including IL-8 and Rantes.

CD40 and CD154 are members of the TNF and TNF receptor families, respectively. They utilize different signalling molecules to both the TCR–CD3 and CD28 pathways. Blockade of CD154 by a monoclonal antibody has been shown, either in combination with CTLA4Ig or at high doses alone, to prevent acute allograft rejection and lead to long-term rejection-free survival of vascularized as well as non-vascularized grafts. This pathway is therefore also critical for the early events in T-cell activation. Although CD4+ T cells are highly dependent on it for activation, evidence is emerging that activation of CD8+ T cells is much less dependent upon or independent of the CD154–CD40 pathway. Thus in some donor–recipient combinations rejection can still be initiated by CD8+ T cells even in the presence of high doses of anti-CD154.

Determining the character of the rejection response

The character of the downstream response is critically dependent on the context in which the initial activation and restimulation of donor antigen-specific T cells takes place. Once activated, T cells recruit other cells into the response and play a role in determining how these differentiate into effector cells. The antigen-presenting cells involved, the cytokine environment, and the immune status of the host will all have a marked influence on the downstream response. Following chronic antigen stimulation, such as will occur with time after transplantation, a marked divergence in cytokine production by the responding cells can take place. This was first noted following chronic stimulation of antigen-specific mouse T cells *in vitro*, but has subsequently been demonstrated to occur in humans as well.

T-cell activation in the presence of IL-12 has been shown to result in the differentiation of T cells that secrete IFN-g and IL-2. By contrast, if the initial contact between the T cell and antigen takes place in the presence of IL-4, then the cell will differentiate along a different pathway and secrete IL-4, IL-5, and IL-10, so-called signature cytokines (Fig. 6). The two types of T cell have been referred to as T_{H1} and T_{H2} or T_{C1} and T_{C2} depending on whether they express CD4 or CD8. T cells secreting IFN-g and IL-2 orchestrate cell-mediated immunity, resulting in the activation of cytotoxic T cells (T_C) and macrophages predominantly, whereas T cells secreting IL-4 and IL-10 trigger the differentiation of B cells into plasma cells producing certain isotypes of immunoglobulin (humoral immunity) and the activation of eosinophils. Both types of T-cell response have been shown to lead to rejection. Therefore the hypothesis that a T_{H1} response is aggressive and results in rejection whereas a T_{H2} response promotes tolerance—the T_{H1}–T_{H2} paradigm for transplantation—is not clear cut and the context in which the response evolves will have a marked influence on whether rejection occurs.

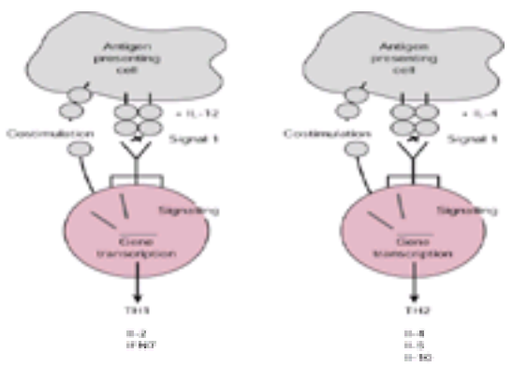

Fig. 6 T-cell differentiation. The microenvironment present when a T cell is activated will have a marked influence on the way in which it differentiates upon restimulation with antigen. T cells that are activated in the presence of IL-12 will differentiate into cells that secrete the signature cytokines IFN-g and IL-2, whereas T cells that encounter antigen in the presence of IL-4 will differentiate into cells producing IL-4, IL-5, and IL-10.

Migration of activated leucocytes into the graft

Once activated, the donor-specific leucocytes must migrate from the recipient lymphoid tissue back to the graft if they are going to be effective in destroying the transplanted tissue. To enter the graft the leucocytes have to cross the donor vascular endothelium. Leucocyte extravasation is a multistep process, controlled by the production of chemokines by the transplanted tissue and multiple interactions between cell surface molecules expressed by the endothelium and the migrating leucocytes. Chemokine receptors involved in the recruitment of leucocytes into tissues are only expressed at low levels on resting leucocytes, therefore activation of the different leucocyte populations that participate in either the innate or adaptive immune response to the graft is a key step in the recruitment process.

Characterization of the chemokines and chemokine receptors involved in recruiting leucocytes to the graft is currently in progress. Chemokines produced within the tissue can be tethered to endothelial cells by interaction with carbohydrate structures on the endothelial cell surface as well as secreted from the tissue. Thus leucocytes flowing in the blood through the vessel can become attracted to the endothelial cells as a result of chemotatic gradients being established from the vessel wall into the tissue. Cell–cell interactions between the leucocytes and the endothelial cells are initiated such that the leucocytes flowing past the tissue in the blood are taken out of the flow and begin to roll along the vessel endothelium. As the leucocytes roll they sample the environment of the endothelial cells. If there is nothing wrong with the endothelial cell surface, then the leucocytes detach and return to the blood flow. However, in the presence of 'danger' signals the leucocytes express new cell surface structures, including P-selectin. The rolling leucocytes then becomes tethered to the endothelial cell. As a result of interaction between additional families of cell surface molecules, both on the endothelial cell and the leucocytes, including integrins and immunoglobulin superfamily members, firm adhesion of the leucocytes to the endothelial cell surface occurs, allowing the cells to transmigrate between endothelial cell junctions into the tissue along the chemokine gradient.

Graft destruction

Unlike some immune responses, for example to certain viruses, where a single effector mechanism dominates the final stages of the process, for allograft rejection the immune system uses many strategies to destroy the graft (Fig. 1). Once the vascular endothelium of the graft has been damaged by one or more of the mechanisms outlined below, the blood supply to the graft will be lost and rapid necrosis of the transplanted tissue will occur. Later in the rejection process the parenchymal cells of the graft will also become targets for these destructive mechanisms.

Antibody

Alloantibodies have been shown to play a role in hyperacute, acute, and chronic rejection. As mentioned above, hyperacute rejection of allografts is very rarely seen in clinical transplantation as rigorous screening of recipients for antidonor reactive antibodies is carried out before transplantation to eliminate any patients who have preformed antibodies against the donor. Hyperacute rejection of xenografts is the first immunological barrier that needs to be overcome if xenotransplantation is to be successful in the future. Different approaches are being investigated with varying degrees of success. Understanding how antibodies can trigger the destruction of a graft is clearly one of the important pieces of information required to facilitate the design of effective strategies to prevent antibody-mediated damage.

Antibodies that react with the graft can trigger its destruction in two ways: by activating complement or through antibody-dependent cellular cytotoxicity via killer cells.

Complement is a cascade of proteases that are triggered sequentially following the initial activating event. The system can be activated when antidonor antibodies formed as a result of T-dependent B-cell activation (Fig. 1) bind to donor antigens. As a result, inflammatory mediators will be released, increasing the vascular

permeability of vessels in the graft and thereby facilitating the migration of leucocytes into the graft. The graft will become coated with antibody and activated complement components, targeting donor cells for opsonization by phagocytic cells which express receptors both for complement components and antibody. The membrane attack complex of the complement system is then formed, resulting in the lysis of donor cells. Many of the pathological changes that are associated with acute rejection, such as arteriosclerosis, interstitial haemorrhage, and fibrinoid necrosis of arteriolar cell walls, may result from the binding of antibodies and complement activation.

Antibody-dependent cellular cytotoxicity is cell dependent and occurs when the antibodies act as a bridge between the graft and killer cells, activating their lytic machinery. Killer cells are heterogeneous and many different types of leucocyte can participate in antibody-dependent cellular cytotoxicity when they are present in the correct microenvironment.

Although the appearance of antidonor antibodies can trigger rejection, their appearance does not necessarily mark the rejection of the graft. Indeed, the presence of antidonor antibodies may be perfectly compatible with continued graft survival. The specificity and the effector properties of the antibodies produced hold the key to whether particular antidonor antibodies are destructive.

Donor-specific cytotoxic T cells

Donor-specific cytotoxic T cells (**TC**) mature from precursor T_C (**pTC**) following activation of donor-specific T-helper cells (**TH**) (Fig. 1). T_C are activated either as a result of the formation of a three-cell cluster with the helper cell and the antigen-presenting cell, or as a result of the activated T_H cell 'licensing' the antigen-presenting cell to activate the pT_C. Once mature, effector T_C exhibit potent, antigen-specific cytotoxic activity. Their cytotoxic activity arises through a variety of mechanisms: these include the release of proteases called granzymes; the deposition of perforins, proteins that punch holes in the membrane of the target cell; the triggering of Fas-dependent cytotoxicity; and the release of soluble molecules such as tumour necrosis factor (TNF). The exact mechanism that is used *in vivo* may vary depending on the conditions that prevail within the graft.

There is considerable evidence to suggest that T_C can be involved in graft rejection. Most convincingly, when CD8+ cells are eliminated from the recipient before transplantation (most T_C recognize donor class I molecules and express CD8), graft rejection is often delayed or prevented. However, the presence of T_C is not mandatory for rejection as in some circumstances this has been shown to occur in the absence of demonstrable T_C activity. Moreover, the demonstration that donor-specific T_C activity can be detected *ex vivo* is not a guarantee that rejection is taking place. Again, the precise microenvironment in the graft markedly influences the ability of the effector cells to elicit graft destruction.

Natural killer cells

Natural killer (**NK**) cells form part of the innate immune response and are a potent source of cellular cytotoxicity. They are only triggered to kill when certain non-polymorphic MHC class I molecules, HLA E molecules, are missing from the target cells. In other words, NK cells are not used to destroy normal cells of the host unless they have been modified such that they no longer express HLA E molecules.

The receptors involved in NK-cell activation have been characterized and under normal circumstances these receive both positive and negative signals from both activating and inhibitory receptors when they engage their ligands on the target cell. Only when the inhibitory signals are missing do the cells exhibit cytotoxic activity. The role of NK cells in the rejection of solid organ allografts is still uncertain. NK cells with the ability to kill target cells *ex vivo* can be found in rejecting allografts, but to date there has been no direct demonstration that they play a role in rejection. By contrast, NK cells have been shown to be capable of rejecting bone marrow cells that express very low levels of MHC class I molecules and are thought to be very important in the rejection of xenografts where the graft will express no human class I.

Macrophages, eosinophils, and cytokine release

When T cells are activated they can elicit a non-specific effector mechanism referred to as a delayed-type hypersensitivity reaction (**DTH**). DTH reactions are characterized by the infiltration of leucocytes, including lymphocytes, macrophages, and eosinophils into the target site, in this case the graft. Damage to the graft occurs as a result of the production of non-specific mediators, such as nitric oxide, reactive oxygen species, IL-1, and TNF-a by the infiltrating cells. This activity is triggered in an antigen-specific manner by the T_H cell, but the effector mechanisms that lead to the destruction of the graft are non-specific. DTH reactions have been shown to be capable of playing a role in acute and chronic allograft rejection.

Conclusion

The immune response to a transplant is complex. The precise nature of the response will depend on many factors: the donor–recipient incompatibility, the type of graft, the site of transplantation, and not least the cocktail of immunosuppressive drugs that are used to try and prevent or control the response.

6.1 Epidemiology of cancer

R. Doll and R. Peto

Introduction

All cancers have certain pathological and clinical characteristics in common, but those arising in different organs often have very different causes. The epidemiology of cancer, by which is meant the study of the incidence of the disease in people under different conditions of life, is, therefore the epidemiology of specific types of cancer, usually, but not always, defined as cancers of specific organs. In this sense, the subject has a history dating back nearly 300 years to Ramazzini's observation that cancer of the breast occurred more often in nuns than in other women of similar age and to Pott's observation, 200 years ago, that scrotal cancer in young men occurred characteristically in chimney sweeps. The high risk in nuns (which largely reflected the protective effect of multiple pregnancies in the general population) helped the realization that hormonal factors can substantially affect the incidence of several types of cancer, while the latter led to the recognition that the combustion products of coal to which sweeps had been exposed could cause cancer on any part of the skin with which they came into repeated contact and to the isolation of the first specific chemical carcinogen. Many other similar observations were made over the next 150 years, mostly as a result of the acumen of individual doctors who were struck by the observation that clusters of cases of a particular type of cancer occurred in patients with a similar occupational or cultural background. Lip and tongue cancers were found in pipe smokers, bladder cancer in certain aniline dye workers, buccal cancer in those who habitually chewed mixtures of tobacco and betel in India, lung cancer in miners of particular ores (who, it was subsequently realized, were heavily exposed to radon and its daughter products), and skin cancer in the early radiologists and radiographers who were heavily exposed to X-rays and in farmers and seamen heavily exposed to sunlight. Gradually, however, clinical anecdotes were replaced by statistics as the epidemiological methods that are described below began to be applied to the study of cancer and other non-infectious disease. As a result, many other causes were identified with sufficient certainty to justify preventive action and data were obtained to suggest hypotheses that could be tested in the laboratory.

Preventability of cancer

Perhaps the most important result of such observations has been the realization that any type of cancer that is common in one population is rare in some other, and that the differences between populations are mostly not genetic. Hence, where they are common these cancers occur, in large part, as a result of the way people behave and the circumstances in which they live and they are, therefore, at least in principle, preventable. This does not mean that we can at present envisage a society in which any of the common cancers are completely eliminated (although this may prove to be possible when we understand more clearly the mechanisms by which they are produced). What it does mean is that we can envisage a society in which the age-specific risk of developing any type of cancer is low.

Differences in incidence between communities

Reliable evidence of variation in the incidence of particular types of cancer between different communities was slow to emerge because of differences in the standards of medical care, and hence in the extent to which any cancers are diagnosed, the absence of population-wide systems for the registration of any cases that were diagnosed, and differences in the reliability with which cases were reported when registration systems were established. Nowadays, however, the large differences that are reported between good cancer registries throughout the world are, for the most part, real, particularly if comparisons are restricted to the limited range of ages between 35 and 64 years. This excludes the youngest ages, at which cancer is rare, and the oldest ages, at which the records of the incidence of the disease are least reliable.

Table 1 shows, for selected types of cancer, the range of variation recorded by cancer registries that have produced data sufficiently reliable for the purpose of international comparison (International Agency for Research on Cancer, 1992) or, in a few instances, the range determined by special surveys. Types of cancer have been included if they are common enough somewhere to have a cumulative incidence among men or women of at least 1 per cent by 75 years of age. The ranges of variation shown are for incidence rates between 35 and 64 years (see above). The range of variation is never less than seven-fold and is sometimes more than a hundred-fold. Despite the selection of reasonably reliable registries, some of this tabulated variation may still be an artefact, due to different standards of medical service, case registration, and population enumeration; but in many cases the true ranges will be greater. First, there are still gaps in the cancer map of the world, so that some extreme figures may have been omitted because no accurate surveys have been practicable in the least developed areas and it is just these areas that are

likely to provide the biggest contrasts (both high and low) with Western society, as Chen *et al.* (1990) have shown in rural China. Secondly, the figures cited refer, with one exception, to cancers of whole organs and do not distinguish between different histological types or different locations within an organ and the more one learns about each type of cancer the more disadvantageous this is found to be. It is obvious in the case of skin cancer, which includes melanomas that have increased in incidence dramatically in the last 50 years, basal-cell carcinomas of the face, which affect more than half the fair-skinned population of Queensland by 75 years of age, scar epitheliomas of the leg, which develop on the site of old ulcers in some African populations and account for 10 to 20 per cent of all cancers seen in some hospitals in Malawi and Rwanda Burundi, '*dhoti*' cancers of the groin in India, and occupational cancers on the forearm due to exposure to tar and oil in industrialized countries. But it also applies, to a greater or lesser extent, to most of the cancers listed in Table 1.

The variation in incidence is not limited to the common cancers, but is also shown by many others. Burkitt's lymphoma, for example, never affects more than 1 in 1000 of the population, but it is at least 100 times as common among children in parts of Uganda as it is in Europe and North America; while Kaposi's sarcoma, which was extremely rare in most of the world until the advent of the acquired immunodeficiency syndrome (AIDS), was so common in children and young adults in parts of Central Africa, even before 1970, that it accounted for 10 per cent of all tumours seen in one of the African hospitals surveyed by Cook and Burkitt. Some few cancers occur with approximately the same frequency in all communities; but all of these are uncommon. Acute myeloid leukaemia at 15 to 25 years of age is an example; nephroblastoma is another, except that it appears to be only half as common in Japan as elsewhere.

The figures that have been cited so far all refer to the incidence of cancer in different communities defined by the area in which they live. Communities, can, however, be defined in other ways and no matter what method is used, including categorization by ethnic origin, religion, or socioeconomic status, substantial differences may be found. Jewesses, for example, have a low incidence of cervical cancer irrespective of the country in which they live, and the Mormons of Utah and the Seventh Day Adventists of California suffer fewer cancers of the respiratory, gastrointestinal, and genital systems than members of other religious groups living in the same American states.

Few of the large differences observed between communities can be explained by genetic factors, apart from some of the differences observed in the incidence of cancer of the skin, the risk of which is much greater for whites than blacks, and possibly also for some of those in the incidence of testis cancer, which rarely affects black populations, and in the incidence of chronic lymphocytic leukaemia, which rarely affects people of Chinese or Japanese descent. Genetic factors cannot explain the differences observed on migration or with the passage of time, which are discussed below, nor can they explain the correlations observed between the national rates for particular types of cancer and some measures of the lifestyle of the different countries.

Changes in incidence in migrant groups

That changes in the incidence of cancer occur on migration is certain. Many groups have been studied, including Indians who went to Fiji and South Africa, Britons who went to Fiji and Australia, and Central Europeans who went to North America. Among the most reliable data are those for the black Africans whose ancestors were taken to America and the Japanese who went to Hawaii. The former now experience incidence rates for internal cancers that are generally much more like those of white Americans than those of the black populations in West Africa from which most of their ancestors came, while the latter have experienced rates that are much more like those of the Caucasian residents in Hawaii than those of the Japanese still living in Japan (Table 2). The ancestors of black Americans and Hawaiian Japanese will have come from many different parts of West Africa and Japan, some of which are likely to have cancer rates somewhat different from those that have been cited in Table 2. Nevertheless, the contrasts are so great that there can be no serious doubt that new factors were introduced with migration.

Changes in incidence over time

Within one population there may be substantial changes in the incidence of a particular type of cancer over a period of a few decades that provide conclusive evidence of the existence of preventable factors. Changes in incidence over time may, however, be difficult to assess reliably, chiefly because it is difficult to compare the thoroughness of the selection and registration of particular types of cancer at different periods and partly because few incidence data have been collected for long enough, so we often have to fall back on changes in mortality rates even though these may be influenced by changes in treatment as well as by changes in incidence.

There are no simple rules for deciding which of the many changes in recorded cancer incidence and mortality rates are reliable indicators of real changes in incidence. Each set of data has to be assessed individually. It is relatively easy to be sure about changes in the incidence of cancer of the oesophagus, as the disease can be diagnosed without complex investigations and its occurrence is nearly always recorded, at least in middle age, because it is nearly always fatal. It is much more difficult to be sure about changes in the incidence of many other types. The common basal-cell carcinomas of the skin, for example, are also easy to diagnose, but they seldom cause death and can be treated effectively outside hospital, so they often escape registration. What appears to be a change in incidence may, therefore, be a change only in the completeness of registration. Cancers of the pancreas, liver, and brain, and myelomatosis, in contrast, usually cause death, but even when they do they may be misdiagnosed as another disease (for example brain tumours in old people could frequently in the past be misdiagnosed as other neurological conditions), so that an increased incidence or mortality rate may be wholly or partly due to improvements in diagnosis, in the availability of the medical services, or in the readiness of physicians to inform cancer registries of the cancers they find. Such changes are particularly likely to affect the rates recorded for people over 65 years of age, as many old people who were terminally ill used not to be intensively investigated.

Despite these difficulties, some of the decreases and increases in the recorded rates of particular types of cancer have been so gross that there must have been real changes in their incidence. Examples include the increase in oesophageal cancer in the black population of South Africa, the increase in lung cancer throughout most of the world (and its recent large decrease in men in the United Kingdom), the increase in mesothelioma of the pleura in men in industrialized countries, the decrease in cancer of the tongue in the United Kingdom, and the decrease in cancers of the cervix uteri and stomach throughout western Europe, North America, and Australasia. For a fuller account see *Trends in the incidence of cancer*, Doll *et al.*, 1994.

Identification of causes

Finally, it has been possible to obtain evidence of the preventability of cancer by defining agents or circumstances that are a cause of the disease and are capable of control. In general, reliable evidence of causality (and particularly of the magnitude of any risks) has to come from epidemiology and not from laboratory experiments, although the latter can often provide reinforcement of epidemiological findings and essential guidance or completely novel hypotheses for epidemiological study. Reliable epidemiological evidence does not require randomized trials within particular populations, but it does require the study of different individuals within populations and not just the comparison of incidence rates in different populations. Non-randomized epidemiological studies of individuals have often yielded proof of causation beyond reasonable doubt (like that required to convict in a court of law). Action based on such evidence has, moreover, often been followed by the desired result—for example a reduction in the incidence of bladder cancer in the chemical industry on stopping the manufacture and use of 2-naphthylamine and, on a national scale, the reduction in the incidence of lung cancer in men in the United Kingdom following the decrease in smoking over the previous half century. Cancer research workers have, therefore, accepted that the type of human evidence that has been obtained (often, but not invariably, combined with laboratory evidence that the suspected agents are carcinogenic in animals) is strong enough to conclude that a cause of human cancer has been identified and that, as a corollary, the disease can be prevented if this cause is controlled.

Biological factors

Speculations about the causes of cancer and the mechanisms that lead to its occurrence have been constrained by some of its biological characteristics. These include the relationships between incidence and genetic susceptibility, age, sex, and the delay (which is sometimes misleadingly called the 'latent period') that occurs between exposure to a causative agent and the appearance of clinical disease.

Genetic susceptibility

Genetic differences in susceptibility are discussed in Chapter 6.3. We note here only the role of epidemiology in (i) detecting familial clusters that are so marked that no statistical analysis is needed to show the reality of their existence, or (ii) demonstrating by large studies that if one member of a family develops a specific type of cancer, other members are somewhat more likely to develop that same type than would be expected in the population as a whole.

The first has shown that several rare genes have such a great effect on susceptibility that bearers of one such gene (if it is dominant) or two (if they are recessive) almost invariably develop a particular type of cancer. Examples include the dominant genes for polyposis coli and Gardner's syndrome that lead to cancer of the large bowel, and the recessive genes for retinoblastoma and xeroderma pigmentosum that lead (in the latter case) to squamous carcinoma and (less commonly) melanoma of the skin. Similar evidence has shown that other genetic syndromes frequently, but not invariably, lead to cancer, such as von Recklinghausen's neurofibromatosis

leading to fibrosarcoma, the Peutz–Jeghers syndrome leading to carcinoma of the small bowel, the Wiskott–Aldrich syndrome leading to non-Hodgkin's lymphoma, and ataxia telangiectasia, Bloom's syndrome, and Fanconi's anaemia leading to leukaemia. The recognition of these syndromes is important to the individual, as it may provide an opportunity for prophylactic surgery, or enable the diagnosis of malignancy to be made at an early stage when treatment is more likely to be effective, or (rarely) enable precautions to be taken to prevent exposure to the relevant carcinogens, as in the case of sufferers from xeroderma pigmentosum or albinism, who can be protected against sunlight. The proportion of all cancers that occur in people who are highly susceptible to cancer in this way is, however, very small.

The second sort of epidemiological evidence has shown that there is no material tendency for cancer as a whole to cluster in families and that there are no common genetic polymorphisms that substantially increase the risk of developing cancer in all organs (although mutations in the p53 gene may increase the risk in many). It has also shown, however, that several of the common types of cancer do tend to cluster in families to some extent. Differences of this sort do not necessarily imply that the familial clusters are genetic in origin; they could be due to familial similarities of behaviour. Nor, however, do they necessarily imply that any genetic difference in susceptibility is particularly small. Calculations show that they are compatible with 50- to a 100-fold differences in genetic susceptibility if the genes for high susceptibility have an appropriate prevalence in the population. That socially important genetic variants exist is demonstrated by the greatly increased risk of developing basal-cell and squamous carcinomas of the sun-exposed skin in fair-skinned populations compared with dark-skinned, and there may be other genes associated with localized populations, which, for example, diminish the risk of chronic lymphatic leukaemia and myelomatosis in Chinese, Japanese, and Indians. Other genes may have only a minor effect, such as the gene for blood group A, the possession of which increases the risk of gastric cancer by about 20 per cent over that of people belonging to blood groups O or B.

Discovery of genetic factors that affect particular types of cancer is unlikely to explain much of the social and geographical differences in the distribution of cancer other than skin cancer, but it should help to elucidate mechanisms and in extreme cases may help to focus health education and costly methods of early diagnosis on the sections of the populations that are most at risk.

Age

Some risk of cancer occurs at every age, but the risk of developing any particular type varies with age. The most common relationship with age is a progressive increase in incidence from near zero in childhood and adolescence to a high rate in old age. This type of relationship is shown by carcinomas of the skin, lung, and gastrointestinal and urinary tracts, and by myelomatosis and chronic lymphatic leukaemia. The rate of increase is rapid, being typically proportional to the fourth, fifth, or sixth power of age in years, so that the annual incidence may be 100 or 1000 times greater above age 75 than before age 25. With most of these cancers, the recorded incidence may stabilize, or even decrease, in the oldest age groups; but this is partly or wholly an artefact due to incomplete investigation of the terminal illnesses of old people. This pattern is observed for skin carcinoma due to exposure to ultraviolet light and for bronchial carcinoma, both in non-smokers and in men who regularly smoke a constant number of cigarettes a day, and can, under certain circumstances, be observed in the laboratory in skin-painting experiments on mice. It is probable that it reflects the cumulative effect of processes that operate steadily throughout life, starting at around the time of birth (or, for lung cancer among habitual smokers, in adolescence).

A less common pattern is a peak incidence early in life, which may be followed either by a decline virtually to zero or by a slow rise in middle and old age. Retinoblastomas and nephroblastomas occur only in childhood, with peak incidences (respectively) in the first and second years of life. Teratomas and seminomas of the testis have peak incidence rates at about 20 and 30 years of age, respectively, and later almost cease to occur, while osteogenic sarcomas have a peak incidence in adolescence and then show a slow increase with age from a lower rate in young adult life.

The remaining cancers show a variety of patterns. Carcinomas of the breast and cervix uteri of women, for example, begin to appear in adolescence and become rapidly more common up to the menopause. After the menopause the incidence of carcinoma of the breast may remain approximately constant, or may even become slightly reduced for a few years, before increasing again with age, though at a slower rate. Carcinoma of the cervix continues to increase fairly steeply for a few years after the menopause, before showing a stable or declining rate. Hodgkin's disease, on the other hand, appears in childhood and then continues to occur more or less evenly throughout life with only minor peaks in young adult life and in old age, while connective tissue sarcomas become progressively more common from childhood on, but with a much slower rate of increase than is shown by the common carcinomas.

Some of these relationships with age, like that for retinoblastoma in early childhood, seem to be invariant everywhere and, as far as is known, at all times. Others vary from community to community, or from time to time. In postmenopausal women, for example, cancer of the breast becomes progressively less common with increasing age in parts of Asia, but more common in Europe, while carcinoma of the lung used to show a peak incidence at about 60 years of age in the United Kingdom, which gradually moved to older ages, as a generation that had not smoked substantial numbers of cigarettes throughout adult life was replaced by one that had, and the same process is now being repeated in many developing countries.

These various patterns provide information, either about the period of activity of the stem cells from which the cancers derive, or about the period when the main exposure to causative agents occurs and the duration of that exposure. Some of this variation has already helped to explain some of the causes of cancer, as was the case with the shift in the peak incidence of bronchial carcinoma; but much of it still awaits elucidation.

Sex

Cancer used to be more common in women than in men in many countries due to the great frequency of carcinoma of the breast and of the cervix uteri and to the rarity of bronchial carcinoma, and this is still the case in populations for which similar conditions persist, as in parts of Latin America. Elsewhere, cancer is now more common in men, among whom lung cancer often predominates. This overall male preponderance hides, however, a wide range of sex ratios for cancer of different organs. If the sites of cancer that are peculiar (or almost peculiar) to one sex are ignored, the sex ratio varies (in Britain) from a male excess of about 6 to 1 for pleural mesothelioma and carcinoma of the larynx, through many types of cancer with only a small male preponderance, to carcinomas of the right side of the colon, thyroid, and gallbladder, which may be up to twice as common in women.

For many types of cancer the sex ratio is much the same in different countries and at different times. For some, however, and particularly for cancers of the mouth, oesophagus, larynx, and bronchus, the sex ratio is extremely variable—not only between countries and at different times, but sometimes also between different ages at the same time and in the same country. The most marked variation is shown by cancer of the oesophagus, which may affect both sexes equally or be 20 times more common in men than in women. As with the various patterns of incidence with age, these different sex ratios and their variation can provide useful clues to the causation of the particular type of cancer, not all of which have yet been successfully followed up.

Delay between cause and effect

One reason why it has been difficult to recognize causes of cancer in humans is the long delay that characteristically occurs between the start of exposure to a carcinogen and the appearance of the clinical disease. This 'latent period', as it is commonly, but rather misleadingly, called is often several decades, although it may be as short as 1 year or as long as 60. The exact relation between the date of exposure and the date of the appearance of different cancers is still uncertain, partly because the interval is subject to random factors, partly because few cancers are induced by a single, brief exposure, and partly because there are still very few sets of quantitative data with detailed information about the dates when exposure began and ended.

When cancer is induced by short but intensive exposure to ionizing radiation, as following the explosions of the atomic bombs in Hiroshima and Nagasaki or in patients treated by radiotherapy, the excess incidence of solid tumours rises for 15 to 20 years and then may continue to rise, level off, or decline. In the case of acute leukaemia, however, a peak incidence occurs much earlier (about 5 years after irradiation) and relatively few cases appear after more than 30 years.

Short, intensive exposure to a carcinogen is, however, exceptional. The more usual situation is for sporadic or continuous exposure to a carcinogen to be prolonged for years—a decade or two in the case of occupational exposure, several decades in the case of tobacco smoking, and a lifetime in the case of ultraviolet sunlight. In this situation the incidence of cancer increases progressively with the length of exposure. In the last two cases cited, the incidence appears to increase approximately in proportion to the fourth power of the duration of exposure so that the effect after (say) 40 years is more than 10 times as great as that after 20 years, and more than 100 times as great as that after 10 years. Whether the same holds for occupational exposure is not known; but it has been shown to hold in some experiments in which chemicals were repeatedly applied to the skin of genetically similar mice and it may prove to be a general biological rule for many types of carcinoma and many carcinogens.

There is still less quantitative information about what usually happens when exposure ceases; but in the case of cigarette smoking the rapidly rising annual risk

among those who continue to smoke stabilizes for one or two decades after smoking ceases before increasing again slowly. The exsmoker consequently avoids the enormous progressive increase in risk suffered by the continuing smoker.

These delayed effects accord with the idea that the appearance of clinical cancer is the end-result of a multistage process in which several mutations have to be produced in a single stem cell to turn it into the seed of a growing cancer. From the practical point of view, the important conclusions are that cancer may be very much more likely to occur after prolonged exposure to a carcinogen than after short exposure, that it is seldom likely to appear within a decade after first exposure (except in the case of leukaemia and the specific cancers of childhood), that it commonly occurs several decades after first exposure, and that some excess risk may continue to occur for decades after exposure has ceased. The exact relationship may, however, differ for different carcinogens and different types of tumour. Bladder tumours, for example, began to appear within 5 years of intensive exposure to 2-naphthylamine in the dye industry, while mesotheliomas of the pleura have seldom, if ever, appeared within 10 years of exposure to asbestos, but they continue to increase in incidence for up to 50 years after first exposure, even if the exposure was relatively brief.

Luck

There remains the influence of luck, which is commonly ignored; yet it is important for the individual as it is the reason why two animals of identical genetic constitution that have been treated in the same way do not, in general, develop cancer in the same place at precisely the same age. It reflects the element of chance that determines whether a particular series of events all occur in one particular stem cell out of the many thousands of stem cells that exist that don't give rise to a malignant clone. For any one individual the role of good or bad luck in determining the occurrence of cancer may be large (just as luck plays a substantial part in whether or not an individual driver has a traffic incident); but in a large population luck has little net effect on the incidence of cancer and only nature and nurture are important.

Avoidable factors

Tobacco

Tobacco is by far the most important single cause of cancer in developed countries. Chewed it can cause cancers of the mouth and oesophagus; smoked it is a major cause of cancers of the mouth, pharynx (other than nasopharynx), oesophagus, larynx, lung, pancreas, renal pelvis, and bladder. For these eight cancers, epidemiological evidence indicates that prolonged smoking of average numbers of cigarettes per day increases the risk 3 to 20 times. It is, however, now clear that cigarette smoking also causes a proportion of several other types of cancer, increasing the incidence up to twice that in non-smokers: namely, cancers of the lip, nose, nasopharynx, stomach, liver, and renal body and also myeloid leukaemia. Although the proportional increases are not large, the consistency of the findings in different countries, the evidence of dose–response relationships, the lower mortality in exsmokers than in continuing smokers, the lack of evidence for important confounding, and the presence in the smoke of many different carcinogens provide strong grounds for believing that most or all of these observed associations are causal.

In sum, smoking is estimated to have caused 30 per cent of all fatal cancers in the United Kingdom in 1995, down from 34 per cent 20 years earlier. The reduction was substantial in men (down from 52 per cent to 40 per cent) but it was largely counteracted by the increase in women (from 12 per cent to 20 per cent). Comparable figures from the United States and from some other developed countries are shown in Table 3. In men, there have been decreases in some developed countries, but increases in others, particularly in Central and Eastern Europe. In women, the proportion of cancer deaths attributed to smoking was generally low in 1975, but has subsequently increased in all developed countries and must be expected to increase further. It was, however, still small in countries such as France, where few middle-aged or elderly women had been smoking for long enough for any material effect to be produced.

In developing countries, the effects of smoking have only recently begun to be studied systematically and much remains unclear. In general, women in developing countries do not smoke (or if they do they smoke very little). In men, however, there has been a very large increase in cigarette consumption, the full effects of which have yet to materialize. China, with 20 per cent of the world's population, smokes 30 per cent of the world's cigarettes and by 1990 smoking was already responsible for about 20 per cent of male cancer deaths. In India, where many men have smoked 'bidis' (small home-manufactured cigarettes) for decades, the proportion may be even greater (chiefly because smoking can act as a cofactor for the production of cancers of the mouth, oesophagus, or stomach in those who habitually chew quids containing betel and tobacco). In some parts of South America, the male lung cancer rates from smoking are already as high as in developed countries. Overall, tobacco may be causing about as many cancer deaths in developing as in developed countries, in which case it would be responsible for about 20 per cent of cancer deaths throughout the world.

Alcohol

At least six types of cancer are caused in part by the consumption of alcohol. One, liver cancer, is produced only secondarily to the production of liver cirrhosis and is, consequently, caused only by heavy and prolonged consumption. Four are causally related to smoking as well as to alcohol: namely, cancers of the mouth, pharynx (other than nasopharynx), oesophagus, and larynx. The two agents act synergistically, increasing each other's effect, so that the risk from alcohol in non-smokers or long-term exsmokers is very small, while that in heavy smokers is disproportionately large. The remaining type, cancer of the breast, has been shown to be related to alcohol only within the last decade or so. Cohort studies show that the risk increases progressively with the amount drunk (at least up to moderately high levels) and laboratory studies that show that alcohol increases the level of oestrogen in the blood suggest a plausible mechanism.

Cancers of the large bowel have also been associated with alcohol in many studies, but the relationship is weak and its nature uncertain: it could be due to confounding with smoking and diet.

Ionizing radiations

Ionizing radiations, of whatever sort, share the characteristic of being able to penetrate animal tissues and damage DNA. It is not surprising, therefore, that they have been found to increase the incidence of cancer in practically every organ. It has not been possible to detect by direct observation the effect of the small amounts that adults receive as a result of exposure to (for example) radiological examination, atmospheric pollution, and normal levels of natural background; but it has been possible to make an estimate of their effect by extrapolating from the observed effects of the much larger doses received by the survivors of the atomic explosions at Hiroshima and Nagasaki, patients given radiotherapy or repeatedly screened radiologically, and people exposed occupationally to radium or to high concentrations of radon in mines or exceptionally in houses. Theoretical considerations and the dose–response relationship observed with these relatively large doses both indicate that there is unlikely to be any threshold below which no effect is produced. This conclusion is reinforced by the discovery that children who received doses of 10 to 20 mGy *in utero* (because their mothers were irradiated for diagnostic purposes whilst they were pregnant) were subject to an added risk of developing cancer in childhood of approximately 1 in 2000. At low doses (less than about 20 mGy) it seems probable that the carcinogenic effect is linearly proportional to the dose; at higher doses the same is true for most cancers other than leukaemia, for which the risk is approximately proportional to the square of the dose. It is unlikely, however, that we should be far out in our estimate if we accepted the conclusions of the International Committee on Radiological Protection (1991) and assumed that the lifetime risk of developing a fatal cancer is approximately 10 per cent per Gray (or per Sievert) to the whole body if the radiation dose is moderate and given acutely and about half that if the dose is low and spread out over time (that is 5 per 100 000 per mGy (or mSv)) with corresponding reductions if only part of the body is exposed.

People are exposed to different amounts of radiation in different countries, depending principally on the build up of radon in the air in domestic houses and the medical use of radiation for diagnosis and therapy. In the United Kingdom, the average annual dose is about 2.6 mSv, which, in a population of about 55 million, is estimated to cause about 7000 deaths a year from cancer, about 5 per cent of the total. In the United States, the average annual dose is about 50 per cent greater. The estimated hazard depends critically on the effects of chronic exposure to radon in houses, which, in the United Kingdom, contributes about half the total dose from all forms of radiation. In some parts of the country, however, most notably Devon and Cornwall, the average domestic radon dose is three or four times greater and in a few houses may be 10 or even 100 times greater. Its effect is discussed later under lung cancer. Nearly all the rest comes from other sources of natural radiation (35 per cent) and medical uses (14 per cent). The last, however, causes less cancer than would be deduced from the dose, as a large proportion is received by old or ill people who will not survive for long enough for a radiation-induced cancer to appear or because the doses given radiotherapeutically are so large that most of the cells that might have been made cancerous are destroyed. Less than 0.5 per cent of the average annual dose from all sources can be attributed to occupational exposure, fall-out from past bomb tests, and man-made products or radioactive waste.

Ultraviolet light

Photon energies in the ultraviolet (UV) range are sufficient to excite electrons in atoms to chemically active higher energy states permitting the formation of pyrimidine dimers between adjacent pyrimidine bases in DNA and these may, as a result of misrepair, be the origin of mutations. UV does not penetrate much below the skin, so that it is chiefly within the skin that it is directly carcinogenic. Within the skin, however, it is the principal cause of all types of cancer, other than Kaposi's carcinoma. Whether it has any indirect carcinogenic effect on other tissues (notably the lymphopoietic tissue) by (for example) destroying Langerhans cells and so modifying immune reactions, has yet to be proved.

Infection

Infection, principally viral, but also in some cases bacterial and parasitic, is a major cause of avoidable cancer.

Viral

Viruses that are known to cause human cancers, or suspected of doing so, are listed in Table 4, along with the types of cancer with which they are associated. Not all infected people develop the disease. In some cases the proportion doing so is quite small, unless other factors are also present. These include heavy malarial infection for Burkitt's lymphoma, the consumption of a type of salted fish for nasopharyngeal cancer, and the consumption of aflatoxin, a metabolic product of fungal infection with *Aspergillus flavus,* for liver cancer. What they are for the cancers produced by the human papilloma virus is not known.

Quantitatively, chronic infection with hepatitis B virus is one of the most important causes of cancer in many parts of the world. In China, for example, liver cancer accounts for about 20 per cent of all cancer deaths, the large majority of which are due to chronic lifelong infection with the virus. Infant vaccination against the virus is now being introduced and will protect the new generation, but will not provide retrospective protection for those born previously.

Bacterial

Only one bacterial infection has been closely linked with the development of cancer: namely, *Helicobacter pylori.* Persistent infection acquired early in life leads to chronic gastritis in the antrum of the stomach and increases the risk of gastric cancer two to three-fold. Non-specific chronic infection in the bladder may also increase the risk of bladder cancer by the local formation of carcinogenic nitrosamines.

Parasitic

In parts of Africa and Asia, parasitic infection is a major cause of cancer. Infestation with *Schistosoma haematobium*, which excretes its eggs through the bladder wall, causes a high incidence of bladder cancer in Egypt and East Africa while infestation with *Schistosoma japonicum*, which excretes its eggs through the wall of the large bowel, is responsible for a high incidence of intestinal cancer in parts of China. Liver flukes (*Clonorchis sinensis* and *Opisthorcis viverrini*) are similarly responsible for the high incidence of cholangiosarcoma of the bile ducts in parts of South East Asia. The parasites may not cause cancer directly but chronic infection may start a chain of events that leads to cancer in other ways, such as chronic bacterial infection and the local formation of nitrites and nitrosamines.

Medical drugs

Apart from ionizing radiations, some 20 agents have been used therapeutically that are known to cause cancer in humans. These are listed in Table 5. That so many carcinogenic agents should have been prescribed medically is not surprising when it is borne in mind that treatment often requires modification of cellular metabolism and is sometimes intended to interfere with DNA. The hazard of cancer, however, need not necessarily be a bar to the use of a drug if the risk to life due to iatrogenic cancer is materially less than the chance of saving life that is achieved by its use—as is commonly the case with antineoplastic agents, immunosuppressive drugs, and radiotherapy.

Some of the chemotherapeutic agents listed in Table 5 were soon abandoned, while others have continued to be used for the treatment of uncommon conditions, and the sum of the cancers that these now produce cannot amount to more than a 100 or so a year in the United Kingdom.

Three of the listed drugs are, however, used extensively: hormonal replacement therapy (HRT) for postmenopausal women, selected steroids for contraception, and tamoxifen for the treatment of hormone-sensitive breast cancer. The first two increase the risk of breast cancer and all three can increase the risk of endometrial cancer, but HRT does so substantially only when given in the form of oestrogen alone and steroid contraceptives do so only in the form (now abandoned) in which oestrogen and progestogen are given sequentially. The combined steroid contraceptives currently in use can also rarely cause liver cancer and they may possibly increase the risk of cervix cancer. In contrast to these effects, tamoxifen reduces the incidence of breast cancer, and combined steroid contraceptives reduce the incidence of endometrial cancer and halve the risk of ovarian cancer for many years after they have been used. HRT and the combined steroid contraceptive are, moreover, associated with a reduction of some 20 per cent in the risk of colorectal cancer, but whether this is causally related to their use remains to be proved.

Other drugs that may inhibit cancer rather than cause it are the non-steroidal analgesics, most notably aspirin, the prolonged use of which may somewhat reduce the risk of colorectal cancer.

Taken altogether it seems unlikely that medically prescribed drugs can be responsible for more than 1 per cent of all today's fatal cancers and may, in total, reduce the risk by somewhat more.

Occupation

In the years that followed Pott's observation that chimney sweeps tended to develop cancer of the scrotum, many other groups of workers were found to suffer from specific hazards of cancer and more substances that are known to be carcinogenic to humans have been unearthed by the search for occupational hazards than by any other means. These hazards, many of which are described in relation to individual types of cancer, are listed in Table 6. Many of the hazards that have been recognized caused large, or at least relatively large, risks, albeit for limited populations, and it may well be that other occupational hazards exist that have not yet been detected, either because the added risk is small in comparison with that due to other causes, or because only a few workers have been persistently exposed, or simply because the hazards have not been suspected and so not looked for. It must also be borne in mind that cancer in humans seldom develops until one or more decades after exposure to the carcinogen first occurs and it is, therefore, too soon to be sure whether agents that have been introduced into industry only during the last 20 years are carcinogenic or not.

Many groups of workers not listed in Table 6 have been suspected of having a special risk, but it has not been possible to decide whether the risk is real and attributable to their work. Many types of cancer have been examined in these groups and, in these circumstances, some differences that are conventionally 'statistically significant' are bound to have arisen by chance alone. Such differences can provide substantial evidence of a hazard only if highly significant ($p<0.001$), or if excess rates are confirmed in other studies, or if a risk of the specific type of cancer could be predicted from the nature of the agent to which they were exposed.

Other excess rates may be due to confounding; that is, they may be produced by social factors that are associated with the occupation in question rather than by the occupation itself. The potential importance of such confounding was illustrated by Fox and Adelstein's analysis of the occupational mortality statistics for England and Wales over the period 1970 to 72. They aggregated the occupations of men aged 15 to 64 years into 25 major categories and found that the lung cancer rates in these categories differed up to two-fold, a spread that was far too wide to be attributed to chance alone. However, data obtained from random samples of the general population showed that the proportions of men who smoked in each of these 25 large occupational categories varied from about 65 per cent of the national average to about 130 per cent, and that the differences in these proportions could account for most of the variation in the mortality from lung cancer.

Given sufficient details and the ability to repeat the observations, it is usually possible to obtain a fairly clear idea of whether or not an excess incidence in an occupational group does or does not reflect an occupational hazard by (for example) seeing whether the effect is related to the length of employment, the time after first exposure, and a specific type of work within the industry. Unfortunately these details are not always available and the reasons for many of the moderate excesses

of cancer that have been reported in certain industries are still uncertain.

At present it seems unlikely that occupational hazards account for more than 2 or 3 per cent of all fatal cancers in developed countries such as the United Kingdom; but the quantitative evidence is uncertain and this estimate could be out by a factor of two. The three principal causes are probably asbestos dust (lung and pleural cancer), the combustion products of fossil fuels (skin and lung cancer), and ionizing radiations (any cancer).

Pollution

The idea that pollution might be an important cause of cancer has been in the forefront of the minds of cancer research workers since it was realized that the incidence of lung cancer tended to be higher in towns than in the countryside and that the combustion products of coal, which used to produce a pall of smoke over all large cities in Britain, contained carcinogenic hydrocarbons. Subsequently, with the rapid expansion of the chemical industry and the discovery that some of its products are mutagenic *in vitro* and carcinogenic in laboratory animals, anxiety increased about the possible effects of distributing such products ubiquitously in the air we breathe, the water we drink, and the food we eat.

The effects of pollution of this sort are, however, peculiarly difficult to assess directly by epidemiological methods, as pollutants are likely to be present in most areas, the absolute risk from each is likely to be small, and there may be little difference in the extent to which individuals are exposed over a wide area. Reliance is, therefore, often placed on two indirect methods: extrapolation from the effects of chronic exposure to much larger amounts in an occupational setting, and prediction of the effects on humans from laboratory tests. Both, however, (but particularly the latter) involve substantial uncertainties.

So far as atmospheric pollution is concerned, the epidemiological picture is complicated by the personal pollution produced by tobacco smoke and the social distribution of smoking habits; but, despite this complication, the various methods that have been discussed under lung cancer all lead to the conclusion that the pollution of the past may have contributed to the production of a few per cent of all lung cancers; but that the levels over the last three decades (principally from the combustion of fossil fuels, but also from asbestos, dioxins, and various other materials) are unlikely to be responsible for more than a fraction of 1 per cent of future cancers—although there may be exceptions awaiting discovery in the neighbourhood of particular factories. The greater effect of the modern type of pollution with ultra fine particles and of the intense indoor pollution with smoke that occurs in parts of China is examined later under lung cancer.

The effect of polluted drinking water and food is more obscure. Until recently no serious consideration had been given to the possibility that either might be important, except for the possible effect of the contamination of food with smoke from urban air. Now, however, analytical techniques permit the detection of chemicals at concentrations of less than 1 p.p.b. in both food and water and, in consequence, many have been detected that might arguably be carcinogenic, including pesticide residues and a variety of halogenated organic materials produced by the chlorination of water supplies. Relationships have been reported between the concentrations of some of these compounds in water and the mortality from cancers of the bladder and, possibly, the large intestine, in different localities; but it is extremely difficult to know what these relationships mean as there are many potentially confounding factors.

Mortality rates from cancers of the gastrointestinal and urinary tracts are, for the most part, stable or decreasing in early middle age, when the effects of new agents might be expected to show themselves first, and, in the absence of more specific evidence, it seems unlikely that chemical pollution of water and food could have a greater effect than the small effect already estimated for pollution of the air. It is important, however, to monitor the situation and, in particular, to seek an explanation for any increase in incidence (as has occurred with testis cancer and with non-Hodgkin's lymphoma not attributable to AIDS) and for any irregularities in the geographical distribution of any type of the disease.

Diet

For many years there has been suggestive evidence that most of the cancers that are currently common could be made less so by modification of the diet; but, with few exceptions, there is still little reliable evidence as to the modifications that would be of major importance. If we define diet to include all materials that occur in natural foods, are produced during the processes of storage, cooking, and digestion, or are added as preservatives or to give food colour, flavour, and consistency, the ways in which diet could influence the development of cancer are legion.

Ingestion of preformed carcinogens

The most obvious is the ingestion of small amounts of powerful carcinogens or precarcinogens. Several have been identified in foodstuffs but only two have been related at all clearly to the production of cancer in humans: that is aflatoxin, a metabolic product of *Aspergillus flavus*, which contaminates stored or oily foods in many countries, and is a major cause of liver cancer in the tropics among those individuals who are also chronic carriers of the hepatitis B (or less commonly hepatitis C) virus. Likewise, the salted fish eaten extensively in South China, probably acts synergistically with EBV to cause nasopharyngeal cancer. A third possible source is bracken fern, an extract of which is carcinogenic in animals. It is eaten extensively in Japan and has been tentatively linked with the development of oesophageal cancer. The polycyclic hydrocarbons and other mutagens that are produced in food by grilling or smoking have often been suspected of playing a role, but intensive investigation has failed to detect one.

It seems, therefore, that if diet does affect the incidence of cancer in the Western world in any material way, it is likely to do so by more indirect means, such as those described in Table 7.

Overnutrition

That overnutrition could affect the incidence of cancer was first suggested by Tannenbaum's experiments on mice during the Second World War. These showed that the incidence of spontaneous tumours of the lung and breast and of a variety of tumours produced experimentally could be halved by moderately restricting the intake of food without modifying the proportions of the individual constituents. This protective effect has subsequently been demonstrated repeatedly, but has attracted little attention (perhaps because reports of such results emphasized the benefits of restriction rather than the harm of overeating). It is now clear, however, that what is considered normal nutrition in developed countries increases the risk of breast cancer (by bringing forward menarche and increasing body size) and possibly also that of testis cancer. With greater consumption obesity (that is a BMI greater than 25 kg/m ^{2}) has been estimated to be responsible for 5 per cent of all incident cases in Europe and 10 per cent of all cancer deaths in non-smokers in the United States (Peto, 2001): most notably cancer of the breast in women after the menopause and cancers of the endometrium, large bowel, pancreas, gallbladder, prostate, and kidney and myelomatosis. For some of these increases, the explanation is obvious: namely, those of the two female cancers, which in postmenopausal women are attributable to the formation of oestrogen from androstenedione in adipose tissue while the increased risk of gallbladder cancer may be due to a greater secretion of bile salts. For others, the explanation is obscure.

Meat and fat

Figures for food consumption and cancer incidence and mortality rates in different countries show fairly close correlations between the consumption of fat and, to a less extent, the consumption of meat and the incidence of several types of cancer. The correlations are closest for breast cancer and cancer of the large bowel and are less strong for cancers of the endometrium, pancreas, and prostate. When, however, attempts are made to associate the consumption of either type of food with the disease in individuals within a country the evidence is commonly conflicting. This could be because the international correlations are misleading, indicating only that the risks are correlated with something that is correlated with fat and meat consumption (for example some other aspect of a high gross national product), but it could be partly because of the inaccuracy of dietary histories and partly because people in developed countries, and particularly in North America, eat such similar diets. Overviews of the published data, however, do suggest that a high consumption of fat is associated with a high risk of colorectal cancer, but the claim that a high consumption of fat (or of particular types of fat) is associated with high risks of breast and endometrial cancer after the menopause, other than by providing a high calorie diet leading to obesity, is controversial.

Whether meat increases the risk of any type of cancer, apart from the contribution it makes through its calorie content, is also uncertain. The low incidence of several types of cancer that is commonly observed in vegetarian communities is not necessarily due to the absence of meat from the diet, as it can generally be explained by the increased consumption of protective foods (vegetables and fruits) and commonly by associated behavioural characteristics (below average use of tobacco and alcohol). Some studies that make allowance for these confounding factors have claimed that meat specifically increases the risk of large-bowel cancer, but the evidence is weak and the increase in risk, if any, is small.

Fibre

That fibre may play a part was suggested by Burkitt's observation that several intestinal diseases, including cancer of the colon, were common in countries in which cereals were processed to remove the fibre and rare in rural Africa and Asia where they were not. The idea was attractive, as 'fibre' passes through the small bowel unchanged and serves as pabulum for the colonic bacteria, thus increasing faecal bulk and possibly protecting against the development of cancer mechanically by diluting any carcinogens present and hastening their transit through the bowel. The idea was, however, too simple and has not been confirmed (using the original definition of fibre) by either epidemiological studies on individuals in developed countries or by experiments aimed at reducing the recurrence of colorectal adenomas. In fact, fibre is difficult to define and the term is better replaced by 'non-starch polysaccharides' as there are many that share the characteristics of passing through the small bowel unchanged and being, for the most part, partially or wholly degraded by bacteria in the large bowel. Some starch, moreover, known as 'resistant starch' and found in green bananas and cold potatoes, has similar physiological characteristics. Further studies that take these complexities into account are, therefore, needed before 'fibre' in any of its manifestations can be considered as having any place in protecting against the development of cancer.

Retinoids and carotenoids

Experiments on animals and on cell cultures *in vitro* have suggested that vitamin A (retinol) and its esters and analogues (retinoids) may, in appropriate circumstances, reduce the risk of cancer by reducing the probability that partially transformed cells become fully transformed and proliferate into clinically detectable tumours, although in other circumstances they appear to have opposite effects. Human studies, however, fail to support the idea that serum levels of retinol are related to the risk of any type of cancer, at least in countries in which clinical symptoms of vitamin A deficiency seldom or never occur. Such studies suggested that the risks were inversely related to the serum level of b-carotene, which acts as an antioxidant and is broken down to produce retinol. When, however, b-carotene was put to the test of clinical trials it provided no benefit and the inverse relationship commonly observed in epidemiological studies is presumably due to confounding with some other protective factors in vegetables.

Other components

Many other components of the diet, including lycopene in tomatoes, indoles in cabbages and sprouts, vitamins C, D, and E, and calcium and selenium have also been proposed as protective agents; while nitrates, nitrites, secondary amines, and the preservation of food by salting, have been thought to increase the risk of cancer. For some the evidence is strongly suggestive: notably for vitamin C as protective against gastric cancer and for salt-preserved foods predisposing to it. In general, however, the evidence of benefit or harm is too weak to justify any firm conclusion.

Conclusion

Some of the uncertainties about the effect of diet could be resolved only by means of controlled trials in which volunteers are allocated at random micronutrient supplements (such as vitamin C, lycopene, calcium, and selenium) or a dietary schedule that requires a substantial reduction in the consumption of fat. Several such studies are under way and if any such factors affect the later stages of cancer induction, clear answers may be obtained to some of the outstanding questions within a few years. Practicable modifications of the diet may well provide the means for reducing cancer deaths in developed countries by a third; but the range of uncertainty about this figure is large. Meanwhile the only dietary changes that can be recommended with confidence in developed countries are a general increase in the use of fresh fruit and vegetables and a sufficient limitation of calories to avoid obesity.

Reproduction and other factors affecting secretion of reproductive hormones

Epidemiological observations have shown clear relationships between a woman's reproductive history and the risk of cancers of the sex organs, which are generally thought to reflect changes in hormonal secretions; but which hormones are concerned and the mechanisms by which they act are, for the most part, still uncertain. An exception is endometrial cancer, the risk of which is directly related to the degree of exposure to oestrogen not followed after an appropriate interval by progestogen. Proof that oestrogenic stimulation of the mammary tissues is a cause of most cases of breast cancer in developed countries has been provided by randomized trials of tamoxifen, an antioestrogenic drug that blocks the oestrogen receptors in the cells of the normal breast. The effect is large and rapid: 5 years of tamoxifen approximately halves the incidence of breast cancer not only while the drug is being taken but also for some years afterwards. Exogenous oestrogen also increases the risk of breast cancer when given as hormonal replacement therapy and endogenous oestrogen accounts for the increased risk associated with adiposity after the menopause, as androstenedione, which continues to be produced by the adrenals, is converted to oestrogen in adipose tissue. It is presumably oestrogens, too, that cause a small increase in risk of breast cancer during and immediately after pregnancy and the oestrogen component of the steroid contraceptives that causes a similar small increase in risk during their use and for a few years after their use is stopped. It is, however, unclear which hormone-related processes are involved in reducing the long-term risk for the rest of a woman's life that occurs some years after the occurrence of each pregnancy and it is equally unclear why the use of oral contraception and the consequent suppression of ovulation reduces the long-term risk of ovarian cancer.

Hormones, it is thought, must also be involved in producing cancers of the testis and prostate in men, but the epidemiological evidence is, as yet, unhelpful. Randomized trials of the effects of physical or medical castration in men who already have prostate cancer have, however, shown that progression of the disease can be slowed substantially, presumably by the reduction of androgenic stimulation.

Physical inactivity

Physical inactivity contributes to the risk of cancer indirectly by increasing the risk of obesity but it may also contribute directly to the risks of cancers of the colon and breast. An association with colon cancer has been consistently reported, which may be due to a reduction in colonic mobility with corresponding prolonged exposure of the colonic mucosa to faecal carcinogens. An association with breast cancer may simply be due to confounding, but it may also reflect an effect on hormone secretion.

Interaction of agents

Attribution of the risk of cancer to different causes is complicated by the fact that some agents interact with others to produce effects that are much greater than the sum of the separate effects of each on its own. An example is provided by smoking and asbestos, which multiply each other's effects so that, compared with non-smokers in general, the incidence of cancer of the lung was increased six-fold among a group of asbestos insulation workers in the United States who did not smoke, but were heavily exposed to asbestos dust in the 1940s, 10- to 20-fold among cigarette smokers in general who did not work with asbestos, and nearly 90-fold among such asbestos insulation workers who also smoked cigarettes regularly. Other examples are provided by smoking and radon (which interact similarly, though somewhat less than multiplicatively, to produce cancer of the lung), by smoking and alcohol (which interact to produce cancers of the mouth, pharynx, larynx, and oesophagus), and by infection with the hepatitis B virus and aflatoxin (which interact to produce cancer of the liver).

Such interactions may come about through some analogue of the dual mechanism of initiation and promotion that was suggested 60 years ago by the experiments of Rous and Kidd and Berenblum and Shubik. They could, however, also be produced in many other ways, some of which have been discussed in the section on diet (see above). From a statistical point of view, they complicate the attribution of risk, as we may find ourselves appearing to claim that more cancer can be prevented than actually occurs by attributing, say, 80 per cent of lung cancers in men heavily exposed to asbestos to their occupational exposure and 90 per cent of the same cancers to cigarette smoking.

Conclusion

Estimates of the proportions of fatal cancers that can be attributed to environmental and behavioural factors are given in Table 8, along with the proportions that are now known to be avoidable in practicable ways. For this purpose, individual causes (such as the various carcinogenic drugs and occupational hazards) have been grouped into 12 main categories. The evidence on which these estimates are based is summarized in this chapter and for earlier periods in greater detail by Doll and Peto (1981) and the International Agency for Research on Cancer (1990).

The sum of the best estimates in Table 8 amounts to less than 100 per cent, despite the fact that some of the listed agents interact with one another to augment each other's effect and that some fatal cancers are consequently counted twice. The total would be somewhat more than 100 per cent, however, if the true proportions attributable to some of the categories turn out to be nearer the upper end of the acceptable estimates and it would be a great deal more than 100 per cent if it had

been possible to characterize the factors that have been classified as 'other and unknown'.

The estimates in columns two and three of Table 8 do not distinguish between factors (such as tobacco) that are sufficiently understood to enable specific action to be taken with a guarantee of success and those (such as diet) that are not. They should not, therefore, be taken as guides to the proportion of cancer deaths that can now be prevented by practicable means, without reference to the paragraphs in which they are individually discussed. This is illustrated by the fourth column in Table 8, which shows the proportions of United Kingdom cancer deaths in 1995 that are reliably known to be avoidable by practicable means. The only percentage that is both large and reliably known is that attributed to tobacco and that is more than twice the sum of the percentages reliably attributable to other specific factors for which practicable preventive measures are available: and tobacco causes about twice as many deaths from other diseases as it does from cancer. The position is different in countries such as China, where hepatitis B virus causes about as many cancer deaths as tobacco and the hazard for future generations can be avoided in a cost-effective way by infant vaccination.

Epidemiology of cancer by site of origin

In the following account of the epidemiology of cancers arising in specific organs, the description of each type is preceded by notes showing its importance in England and Wales. One figure gives the proportion of all cancers that arise in the site, as indicated by the national cancer register for England and Wales for 1994 (Office of National Statistics, 2000) and another gives the proportion of all cancer deaths allocated to the site in the national mortality statistics for 1998 (Office of National Statistics, 1999). A third gives the ratio of the age-standardized incidence rates for each sex. The way in which the incidence of the disease varies with age is shown for males and females in a series of graphs, using the data for England and Wales over a 5-year period (International Agency for Research on Cancer, 1992). Under 25 years the numbers of most types of cancer that occur in a 5-year age group, even in a 5-year calendar period, are small and the rates are consequently unreliable due to chance variation of small numbers. Trends in incidence and mortality for each type, along with the trends in possible causative factors, are given by Swerdlow *et al.* (2001). Major differences between Britain and other countries are commented on in the text and are described more fully in the report on *Cancer causes, occurrence and control* by the International Agency for Research on Cancer (1990).

Lip

- 0.1 per cent of all cancers and 0.02 per cent of cancer deaths.
- Sex ratio of rates 5.0 to 1. Age distribution like skin (non-melanoma).

Carcinoma of the lip was one of the first types of cancer to be related to an extrinsic cause when, more than 200 years ago, it was noted to occur characteristically in pipe smokers. Many years later it was realized that the disease could also be produced by smoking cigarettes, although much less readily, so that it must be produced by the chemicals in smoke rather than by the non-specific effect of local heat. It is also much more common in outdoor than in indoor workers and is induced by ultraviolet light in the same way as other cancers of the exposed skin. Ultraviolet light and tobacco account, between them, for the great majority of all cases in Britain, probably multiplying each other's effects. The disease is much less common than it used to be, because of the decrease in both pipe smoking and outdoor work.

Oral cavity and pharynx (excluding salivary glands and nasopharynx)

- 1.0 per cent of all cancers and 1.2 per cent of cancer deaths.
- Sex ratio of rates 2.3 to 1. Age distribution, see Fig. 1.

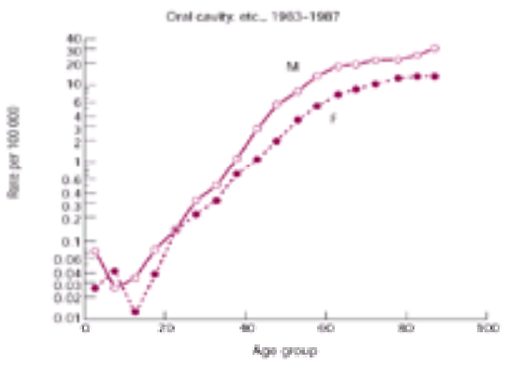

Fig. 1 Annual incidence of cancers of the oral cavity and pharynx by age and sex (excluding cancers of the salivary glands and nasopharynx).

Cancers of the tongue, mouth, and pharynx (other than nasopharynx) are all related to smoking (of pipes, cigars, and cigarettes) and to the consumption of alcohol. The two factors act synergistically and cancers in these sites are extremely rare in non-smokers who do not drink alcohol.

Cancer of the tongue is much less common in Britain than it was early this century, but the reason for the sharp decline in incidence is unknown. One explanation could be the decrease in syphilis, which was commonly believed to be a predisposing factor because of the clinical association with syphilitic leucoplakia. Recent increases in oral and pharangeal cancer in men are partly due to increased consumption of alcohol and possibly, in the case of pharyngeal cancer, to human papilloma virus infection.

Cancers that occur low in the hypopharynx are distinguished by a tendency to affect women who have suffered from iron-deficiency anaemia and dysphagia.

Cancers of the mouth and pharynx (excluding nasopharynx) are particularly common in South-East and Central Asia where tobacco smoking is largely replaced by chewing tobacco, betel nut or leaf, and lime (calcium hydroxide). A close association with such chewing habits has been established by studies that have shown that the cancers tend to originate in the part of the mouth in which the quid is usually held—a characteristic that varies both between individuals and between areas. The materials chewed differ in different places and, although the disease is commonly described as 'betel chewer's cancer', betel is not invariably a component of the quid and the most characteristic constituent seems to be a small amount of lime and, in most cases, some form of tobacco. In parts of Asia, the disease is so common that it accounts for 20 per cent of all cancers and in those populations the abandonment of chewing would be the single most effective means of reducing the total incidence of cancer—so long as the habit was not replaced by an increase in tobacco smoking. Among habitual quid chewers, the risks are particularly elevated in those who both chew and smoke—indeed, in parts of India the majority of deaths from 'betel chewer's cancer' could have been avoided if those affected had not also smoked. The incidence might also be reduced by improved nutrition, as the disease in Southern Asia tends to be associated with vitamin A deficiency.

In parts of India where women tend to smoke local cigars and cigarettes with the burning end inside the mouth to prevent them going out, the habit is associated with cancer of the palate.

Salivary glands

- 0.2 per cent of all cancers and 0.1 per cent of cancer deaths.
- Sex ratio of rates 1.3 to 1. Age distribution like non-Hodgkin's lymphoma.

The salivary glands are not common sites for cancer anywhere. They are, however, relatively more common in the Asiatic populations of Hawaii and in Canadian Indians than elsewhere. A small proportion of cases occurs specifically in families that also have a high incidence of breast cancer. No causative factors are known and no notable changes in incidence over time have been reported.

Nasopharynx

- 0.1 per cent of all cancers and of cancer deaths.

- Sex ratio of rates 2.0 to 1. Age distribution, see Fig. 2.

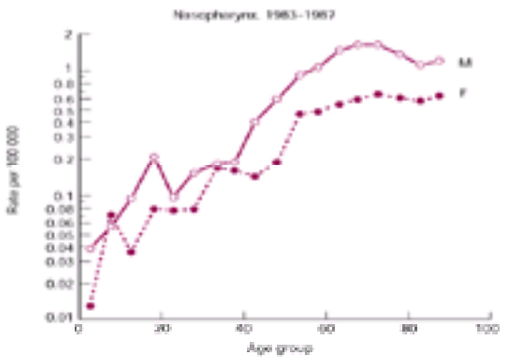

Fig. 2 Annual incidence of cancer of the nasopharynx by age and sex.

Cancers of the nasopharynx, unlike those in other parts of the pharynx, are not related to alcohol and are only weakly related to tobacco. They are rare in most populations but are common in those that originated from parts of Guangdong, in southern China, where the disease is the most common type of cancer. Moderately high rates have been observed in Alaskan Eskimos and American Indians, with intermediate rates in Malaysia, Kenya, and North Africa. A weakly significant relationship with HLA type has been reported from Singapore, but the existence of a specific genetic predisposition remains to be proved. Incidence rates appear to have been decreasing among Chinese Americans.

DNA characteristic of the Epstein–Barr virus (EBV) has been detected in the nuclei of nasopharyngeal cancer cells and patients with the disease tend to have unusually high antibodies against EBV-related antigens. Among adults, sudden increases in certain EBV antigens in the blood often precede by a few years the appearance of a pathological cancer. Infection with the EBV is, however, almost universal and can be only one of several agents that act in combination to produce the disease. One such agent in Southern China occurs in the 'salted fish' on which children are commonly weaned. This strongly flavoured delicacy bears little relation to the salted fish eaten elsewhere, and might better be described as decomposing fish: it contains various mutagens, and exposure to it in childhood when infection with EBV first occurs may alter the usual lifelong balance between host and virus in some hazardous way.

Oesophagus

- 2.3 per cent of all cancers and 4.4 per cent of cancer deaths.
- Sex ratio of rates 2.0 to 1. Age distribution like gastric cancer.

Cancer of the oesophagus, like other cancers of the upper respiratory and digestive tracts, is closely related to prolonged smoking and the consumption of alcohol. All types of smoking have comparable effects and, so it appears, do all alcoholic drinks, although spirits may be slightly more effective per gram of ethyl alcohol than other alcoholic drinks. Alcohol and tobacco act synergistically and, in the absence of either, the incidence of the disease in Britain would be greatly reduced. In France, where the consumption of alcohol is greater than in Britain, it would be reduced even more. A few cases originate from the scars produced by poisoning with corrosive substances and a very few in conjunction with a particular hereditary form of tylosis (presenting with keratoses of the palms and soles). The relatively small excess in men probably reflects the existence of other unknown causes in women, possibly nutritional in origin and similar to those responsible for cancers of the hypopharynx. Mortality (which, because of the high fatality rate, approaches incidence) fell progressively in the first half of the twentieth century in line with the fall in the consumption of alcohol, and rose again after 1950 when the trend in the consumption of alcohol reversed. Since pipe smoking affects oesophageal cancer risks at least as strongly as cigarette smoking, no large effects on male oesophageal cancer trends could be predicted from the male switch from pipes to cigarettes, although the switch by females from non-smoking to cigarettes should, other things being equal, produce a large upward trend. It appears, however, that other things were not equal and some other, possibly nutritional, cause of oesophageal cancer seems to have decreased, for any upward trends in oesophageal cancer are moderate. In men, in contrast, the rates have increased when they might have been expected to decrease. To some extent this can be accounted for by the increased consumption of alcohol and possibly by an increase in the nitrosamine content of tobacco smoke, which has resulted from changes in the method of curing tobacco and which could have a specific effect on the oesophagus. A small part of the increase is due to an increased risk of adenocarcinoma at the lower end of the oesophagus, which may be associated with a decreased prevalence of *Helicobacter pylori* and gastritis, and an increase in oesophageal reflux.

In Africa and Asia, the epidemiological features are quite different and present some of the most striking unsolved problems in the field of cancer epidemiology. In parts of China (particularly in North Henan but also elsewhere) and on the east coast of the Caspian Sea in Turkmenistan and Iran, oesophageal cancer is the most common type of cancer, with incidence rates in both sexes that are equal to the highest rates observed for lung cancer in men in European cities. Within China, the disease varies more than 10-fold from one county to another; alcohol and tobacco cannot account for these geographic differences, but when people within one particular Chinese county or city are compared with each other the disease is more common among those who smoke. In parts of Africa, particularly in the Transkei region of South Africa and on the east coast of Lake Victoria in Kenya, extremely high rates are also observed, sometimes equally in both sexes and sometimes only in men. In these and several other areas, as in Asia, the high incidence zones are strictly localized and the incidence falls off rapidly over distances of 200 or 300 miles.

When tobacco and alcohol are used, they increase the hazard, but they are not the principal agents in these high-incidence areas. Many causes have been proposed, including molybdenum deficiency in the soil (resulting in a deficiency of the plant enzyme nitrate reductase and a build-up of nitrosamines), contamination of food and pickled vegetables by fungi (particularly by species of *Fusaria*) with the production of carcinogenic metabolites, an agent associated with the production of beer from maize, and the residues left behind in pipes from smoking opium (which are commonly swallowed). None, however, is supported by any impressive epidemiological data. The high incidence area in Iran, which has been intensively investigated, is characterized by extreme poverty and a restricted diet consisting chiefly of home-made bread and tea, with some sheep's milk and milk products, and very little meat, vegetables, or fruit. In this area the disease has been common for centuries. In Southern Africa, however, it seems to have become common only since the First World War. In China, where cancer of the oesophagus was the second most important neoplastic cause of death in the 1970s, the high incidence has persisted.

Stomach

- 3.7 per cent of all cancers and 4.7 per cent of cancer deaths.
- Sex ratio of rates 2.5 to 1. Age distribution, see Fig. 3.

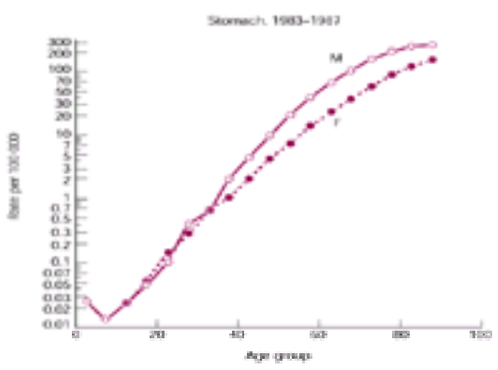

Fig. 3 Annual incidence of cancer of the stomach by age and sex.

Until about 1980, gastric cancer was responsible for more deaths from malignant disease world-wide than any other. Over the last 50 years, however, the incidence has declined in Western Europe, North America, and Australasia and recently it has begun to do so in South America and Japan. High rates are now confined to China, Japan, Russia and other countries of the old Soviet Union, and Central and South America, while the lowest rates are found equally in North America, Australasia, and some of the least developed parts of Africa. Irrespective of whether the incidence is high or low, the sex ratio is between 1.5 and 3 to 1.

Within Britain, cancer of the stomach is most common in North Wales and becomes progressively less common from north to south and from west to east. Over the last 70 years it has consistently been some five times more common in unskilled labourers than in members of the major professions, a gradient with socioeconomic status that has been one of the most marked for any disease. Relatively high rates have been observed in coal miners and in some chemical workers; but no specific occupational hazards have been identified and the excess in coal miners was paralleled by a similar excess in their wives. A hazard has been suspected from exposure to asbestos, but the apparent excess may be due to misdiagnosis of lung cancer and mesothelioma.

Four factors are known to predispose to the disease: blood group A constitution, gastritis associated with infection by *Helicobacter pylori* (sometimes leading to atrophic gastritis), a diet deficient in fruit and green and yellow vegetables, and a poor diet with large amounts of salt and salt-preserved food. Chronic infection with *H. pylori* is a major cause of peptic ulcer, a finding that is of considerable practical value in patients with ulcers, because the infection can generally be eliminated from the stomach by a short course of appropriate antibiotic therapy and this provides long-term protection against recurrence. Whether such treatments will have any material effect on the incidence of stomach cancer remains, however, to be shown. How these various factors influence the production of the disease is unclear. One possibility is that they encourage or discourage the formation of carcinogens *in vivo*, particularly perhaps the production of nitrosamines; but if they do, the intake of nitrates (which can be converted into nitrites by bacterial enzymes) is not a rate-limiting factor. Changes in the prevalence of the three environmental factors could have contributed to the decline in the incidence of the disease, but they could not have brought about such a large and widespread reduction in risk, and it seems probable that the better preservation of food, resulting from the extensive use of refrigeration, has played the major part.

No risk has been detected from the consumption of mutagens produced by the different methods of cooking meat and fish, nor from food additives or pesticide residues. Some food additives may, on the contrary, have served to reduce risk (by avoiding food spoilage and hence improving nutrition, by avoiding contamination by carcinogen-producing micro-organisms, or by some antioxidant or other protective effect on the gastric epithelium).

Large bowel

- 11.1 per cent of all cancers and 11.0 per cent of cancer deaths.
- Sex ratio of rates 1.4 to 1. Age distribution, see Fig. 4.

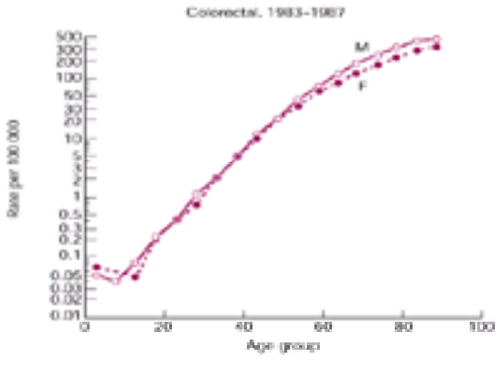

Fig. 4 Annual incidence of cancer of the large bowel by age and sex.

Cancers of the colon and rectum ought to be considered separately, as their causes are not identical. Cancer of the colon, for example, tends to occur more often in women than in men, particularly when it occurs on the right side, while cancer of the rectum is nearly twice as common in men. The geographical distribution also differs slightly, colonic cancer varying in incidence more than rectal cancer. Separate consideration may, however, sometimes be misleading as cancers commonly occur at the rectosigmoid junction and the site of origin of these cases is not recorded consistently. Moreover, there is a growing tendency to describe both diseases merely as 'cancers of the large bowel', which, according to the internationally agreed rules, are classed as cancers of the colon. The two diseases will, therefore, be considered together.

Over the past few decades the male incidence rates in both the United Kingdom and the United States have been approximately constant, while the female rates have decreased slightly. More recently, decreases in early middle age have begun to be seen in both sexes. In contrast, the incidence in Japan, which used to be very low, has begun to increase and the disease in Japanese migrants in Hawaii has become as common as in Caucasians. In most other parts of Asia, and in Africa and Eastern Europe, large-bowel cancer continues to be relatively uncommon (except in areas where chronic schistosomal infestation of the large intestine is prevalent; for example, high rectal cancer rates are found in Chinese counties in which *S. japonicum* was, until recently, a major cause of death). Incidence rates in different countries correlate closely with the per capita consumption of fat and meat and crudely with the consumption of processed foods from which the natural fibre has been removed. Ways in which these and other dietary constituents might influence the development of the disease have been discussed under diet. Other factors increasing risk are obesity and physical inactivity. A weak association with smoking has been observed in several cohort studies, which may be the result of confounding with the consumption of alcohol and a high fat diet. It is possible, however, that smoking may cause a few cases indirectly by causing the diet to be modified in the direction of a higher fat content.

Within Britain, there is no clear relation to socioeconomic status and no occupational hazard has been established. The association that has been reported with exposure to asbestos may be due to misdiagnosis as in the case of cancer of the stomach. Cases in childhood or early adult life occur as a complication of olyposis coli or (more rarely) Gardner's syndrome. These conditions are determined by dominant genes, which increase the susceptibility to the disease so much that it almost invariably develops before middle age. Many other cases develop from adenomatous polyps and a few occur as a complication of long-standing ulcerative colitis.

Anal intercourse causing infection with types 16, 18 or some other specific types of the human papilloma virus is a probable cause of some anal carcinomas, but patients who have sexually transmitted anal warts that are due to other types of human papilloma virus are not for this reason at special risk of anal cancer.

Liver

- 0.6 per cent of all cancers and 1.4 per cent of cancer deaths.
- Sex ratio of rates 2.1 to 1. Age distribution, see Fig. 5.

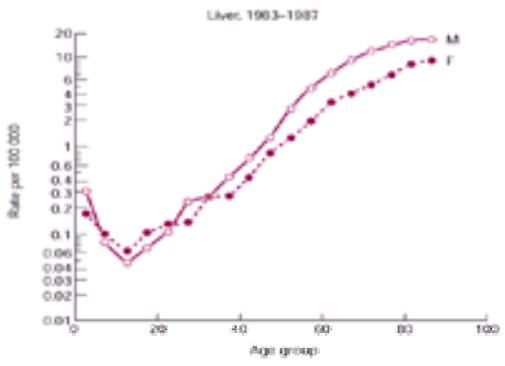

Fig. 5 Annual incidence of cancer of the liver by age and sex.

Incidence rates have tended to be overestimated in developed countries because the primary condition is often confused with metastases to the liver from cancer in various other organs, particularly over 65 years of age when carcinomas of the gastrointestinal and respiratory tracts are common. Recently, however, there has been a small increase in the United Kingdom and the United States from the very low level that had come to be recorded, which is probably due to an increased prevalence of infection with hepatitis C.

The disease is much more common in South-East Asia and tropical Africa; in China it accounts for about 20 per cent of all cancer deaths and in parts of Africa it is the most common cancer in men. Most cases derive from the main cells of the organ (hepatocellular carcinomas) and are attributable primarily to chronic active infection, established early in life, with the hepatitis B virus, exacerbated by consumption of some specific metabolite (e.g. aflatoxin) of particular types of fungi that contaminate stored foods. Neonatal vaccination against the virus produces a marked decrease in the proportion of children who, at 5 years of age, are chronically infected. This has begun in Japan, Taiwan, and parts of China and tropical Africa and has already produced a decreased risk of hepatocarcinoma at young ages. Some cases, however, are caused by the hepatitis C virus, which is an RNA virus spread by blood transfusion, and these cannot be avoided by immunization.

In developed countries, some cases are also due to infection with hepatitis B and C viruses, but more arise as complications of cirrhosis of the liver attributable to heavy and prolonged consumption of alcohol or, rarely, to haemochromatosis. Occasionally, liver cancer is produced by drugs. A few cases have occurred in young men who have taken androgenic-anabolic steroids to increase their muscular strength and a few from the use of steroid contraceptives, either arising *de novo* or from benign adenomas, which are themselves rare complications of the use of steroid contraceptives. Some can be attributed to smoking for an association has been observed in parts of China where little alcohol is drunk and case–control studies in Europe have shown an association after alcohol consumption has been taken into account.

A second histological type (cholangiosarcoma) arises from the intrahepatic bile ducts, tends to occur at a somewhat later age than hepatocellular carcinoma, and, although generally less common than hepatocellular carcinoma, nevertheless accounts for an appreciable proportion of cases. In China, Thailand, and other parts of Asia it can be produced by chronic infection with liver flukes (*Clonorchis sinensis* or *Opisthorchis viverrini*).

A third histological type that is extremely uncommon everywhere has been variously described as reticuloendothelioma or angiosarcoma. It was first recognized as a complication of the use of 'Thorotrast' as a contrast agent in neuroradiology, a long-abandoned practice that led to chronic retention of insoluble thorium radionuclides in the marrow, spleen, and liver. In 1973, the disease was found to be an occupational hazard for men exposed to vinyl chloride monomer. A few hundred cases have occurred throughout the world in men who were heavily exposed in the manufacture of vinyl chloride polymer, and it seems improbable that the minute amounts that have leached out of the plastic consumer products can have caused more than a dozen or so cases altogether in the general public, if indeed they have produced any. A third, and even rarer, cause is prolonged exposure to inorganic arsenic, such as used to result from the medical prescription of Fowler's solution. Despite these multiple causes only one case of hepatic angiosarcoma normally occurs annually in some 10 million people, which is why the recognition of new causes has been easy.

The relative rarity of cancer of the liver in most developed countries is intriguing, since most of the carcinogens thus far discovered in experimental animals induce, perhaps with other cancers, tumours of the liver. The lack of any high or increasing liver cancer rate in Britain and America consequently suggests that, on average, people have not been substantially exposed to the sort of chemical carcinogens that are currently recognized by such studies.

Gallbladder and extrahepatic bile ducts

- 0.5 per cent of all cancers and 0.4 per cent of cancer deaths.
- Sex ratio of rates 1.0 to 1. Age distribution like colorectal cancer.

Cancers of the gallbladder and extrahepatic bile ducts are nearly always classed together, which is unfortunate as the causes differ. The former is more than twice as common in women as in men, is strongly associated with obesity, and is usually preceded by (and probably caused by) cholelithiasis. The latter is slightly more common in men and is increased in incidence by clonorchiasis and (to a less extent) by long-standing ulcerative colitis. Both types are uncommon, and their aggregate varies only slightly from one population to another. Relatively high rates are recorded among Jewesses in Israel, especially among those born in Europe and America.

The incidence of cancer of the gallbladder has fallen sharply in the United States in the last 25 years, which may be partly due to the decreased consumption of animal fat and, perhaps more importantly, to an increase in the rate of cholecystectomy in people who, having gallstones, are at greatest risk of cancer of the gallbladder.

Pancreas

- 2.3 per cent of all cancers and 4.3 per cent of cancer deaths.
- Sex ratio of rates 1.5 to 1. Age distribution like stomach cancer.

Cancer of the pancreas is two to three times more common in regular cigarette smokers than in lifelong non-smokers. The chemicals in cigarette smoke that specifically cause pancreatic cancer have not been identified, but the volatile nitrosamines in smoke that are absorbed from the alveoli and carried to the pancreas in the bloodstream are likely candidates. The disease is twice as common in diabetics as in the population as a whole. It is, therefore, not surprising that the highest rate is recorded among New Zealand Maoris, who smoke heavily and are prone to obesity, hypertension, myocardial infarction, and diabetes.

Cancer of the pancreas is generally regarded as a disease of the developed world, but the diagnosis is difficult in the absence of a well-developed medical service and some of the relatively small geographical and temporal variations may be due to variation in diagnostic standards. Mortality rates in Britain and the United States have begun to decrease under 65 years of age, and this is more likely to reflect a reduction in incidence from reduction in smoking than to any improvement in treatment, as the 5-year survival rate remains well under 10 per cent.

Nose and nasal sinuses

- 0.1 per cent of all cancers and of cancer deaths.
- Sex ratio of rates 2.0 to 1. Age distribution like non-Hodgkin's lymphoma.

Surprisingly, in view of the widespread exposure of the human nose to tobacco smoke and other airborne toxins, cancers of the nasal cavity itself are extremely rare. Most arise from the paranasal sinuses. Several occupational hazards have been recognized, including the refining of nickel, processes giving rise to exposure to strong sulphuric acid mists, and the manufacture of hardwood furniture and leather goods. It would be wrong, however, to conclude that all contact with nickel, hardwood dust, and leather creates a hazard. The hazards have been observed in special occupational situations in which exposure has been intensive and prolonged. The nickel-refining hazard was first observed in South Wales where the nickel carbonyl process was used, but similar hazards were subsequently observed with other refining processes in Canada, Norway, and the Soviet Union. In the Welsh refinery the workplace exposures were much heavier before the Second World War, and (despite the continued use of the nickel carbonyl process in Wales) no hazard of nasal sinus cancer has been observed among men first employed there since 1950. The hazard in furniture workers was first observed in High Wycombe and appears to have followed the introduction of high-speed wood-working machinery early in the twentieth century. A hazard certainly affects some other groups of wood-workers, but should not be assumed to affect furniture workers in general.

Most nasal and nasal sinus cancers are squamous carcinomas, but the hazard from hardwood dust characteristically produced adenocarcinomas. In some of the groups exposed to this hazard, as many as 5 per cent of the men developed the disease. This meant that the risk of adenocarcinoma was increased 1500 times (as this histological type of the disease is normally very rare) and the hazard was, in consequence, easy to confirm once suspicion had been aroused.

Chromate workers are sometimes said to experience a hazard of nasal cancer, but this may be an error due to confusion with the characteristic 'chrome ulcer' of the

nasal septum. Such ulcers have not generally been found to become malignant.

Larynx

- 0.8 per cent of all cancers and 0.5 per cent of cancer deaths.
- Sex ratio of rates 5.7 to 1. Age distribution, see Fig. 6.

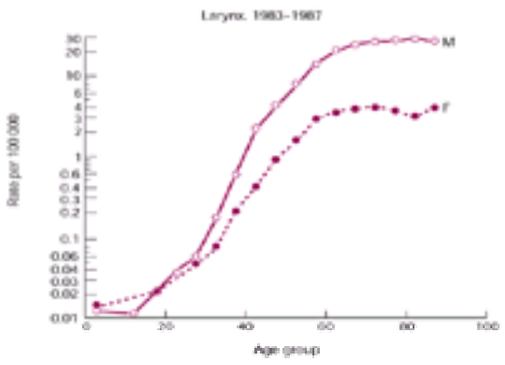

Fig. 6 Annual incidence of cancer of the larynx by age and sex.

Cancers of the larynx, like cancers of the oesophagus and buccal cavity, are closely associated with tobacco smoking and with the consumption of alcohol. The two agents act synergistically and in the absence of either the disease is rare. The different parts of this small organ are, however, related to the two agents differently. Cancers of the glottis are strongly related to smoking, particularly to cigarette smoking, and only weakly to alcohol; while cancers of the epilarynx resemble cancers of the neighbouring hypopharynx and are strongly related to both agents and to pipe and cigar smoking equally with cigarette smoking.

In Scandinavia, the incidence has increased in line with the increase in cancer of the lung. A similar increase has not, however, been seen in Britain and it seems probable that some other aetiological factor, perhaps nutritional in character, has become less prevalent. That there are other causal factors is evident from the relatively high incidence rates in parts of India, Turkey, North Africa and Brazil, which cannot be accounted for by tobacco and alcohol.

The disease has also occurred as an occupational risk in the manufacture of mustard gas and in processes that cause exposure to strong sulphuric acid mists.

Lung

- 13.6 per cent of all cancers and 22.2 per cent of cancer deaths.
- Sex ratio of rates 3.2 to 1. Age distribution, see Fig. 7.

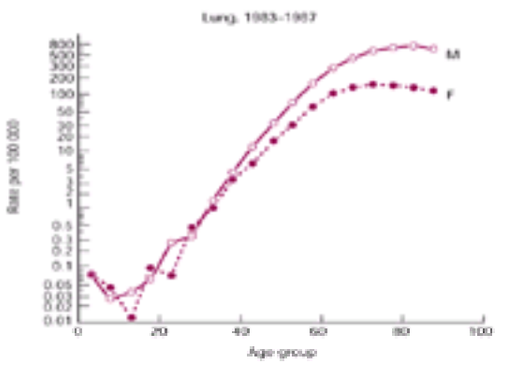

Fig. 7 Annual incidence of cancer of the lung by age and sex.

Nearly all lung cancers are bronchial carcinomas and should properly be so described. The term 'lung cancer' is, however, in such common use that it is used here as synonymous with bronchial carcinoma, although it actually includes a very small proportion of alveolar-cell carcinomas and other rare types of cancer with different characteristics.

Until the 1920s, lung cancer was uniformly rare (except in the Hartz mountains, see below). In the next two decades, German and then British pathologists began to comment on an apparent increase, but this tended to be dismissed as an artefact of the greatly improving methods of diagnosis and the establishment of special centres for thoracic disease. Gradually, however, the increase became so pronounced and the change in the sex ratio so marked that the increase could no longer be dismissed as wholly artefactual and, by the late 1940s when the age-standardized mortality rate in men in the United Kingdom had increased 20 times, it was clear that the developed world had begun to see an epidemic of lung cancer comparable in severity to, though with a longer time scale than, the epidemics of infectious disease of the past. Until the 1940s, the increase among British women was largely a diagnostic artefact, and so provides a useful indication of the quantitative extent to which such artefacts may have affected the male rates. Since 1950, however, diagnostic standards in middle age have changed very little, the increase in British men has been replaced by a decrease, while the increase among middle-aged women has continued for longer, before also reversing. As a result, the sex ratio (male rate divided by female rate) at, for example, 50 to 54 years of age, which rose from 1.8 after the First World War to 8.9 after the Second World War, was reduced to 1.6 in 1998. In the first quarter of the twentieth century, the male excess may have been largely due to the effects of pipe smoking which was an almost exclusively male habit in the nineteenth century.

Smoking

Changes in treatment have had little effect on the fatality rate, which remains extremely high, and real changes in mortality closely reflect real changes in incidence. These can be explained almost entirely by the effect of smoking tobacco, particularly in the form of cigarettes, which caused more than 90 per cent of all lung cancers in Britain in the early 1990s. Evidence of this effect was first obtained in the middle of the last century by comparing the smoking histories of patients with different diseases. It was found that the proportion of patients who had never smoked was much smaller if they had lung cancer than if they had some other disease, and the proportion who had smoked heavily was correspondingly greater.

Further evidence was obtained by asking large numbers of apparently healthy men and women what they smoked and then following them up to determine the causes of death of those that had died. Cohort studies of this type—in over a million American men and women studied by the American Cancer Society, in 34 000 male British doctors, in a regional population of nearly 300 000 Japanese, and in a random sample of the Swedish population—have all shown similar results, the risk increasing with the amount smoked, but varying quantitatively depending on the length of time cigarettes had been smoked. If attention is restricted to populations in which most cigarette smokers had been smoking cigarettes regularly since early adult life, lung cancer is about 20 times more common in regular cigarette smokers than in lifelong non-smokers and up to 40 times more common in very heavy smokers. At first the relationship was less marked in women than in men, but this was because female smokers who were old enough to have a high risk of cancer either had not begun smoking cigarettes so early in adult life or had smoked them less intensively when they began, and the sex differences in behaviour and risk have both been progressively eliminated with the passage of time.

No other exposure has been identified that can account for the extreme difference in lung cancer risk between regular cigarette smokers and lifelong non-smokers and most or all of the excess must have been caused by smoking. Further quantitative studies have found that the relative risk of lung cancer has increased with decreasing age of starting to smoke and decreased with the number of years that smoking has been stopped; that the national increases in incidence have appeared

at appropriate times after the increase in cigarette sales (after due allowance is made for a spurious increase due to improved diagnosis and appropriate differences in consumption by men and women), and that there is a general parallelism between the incidence of the disease in different countries and social and religious groups and the prolonged consumption of cigarettes. Furthermore, it has been found that when extracts of cigarette smoke are applied repeatedly to the skins of laboratory mice many tumours develop. Finally, and most encouragingly, the trend in mortality has reversed following reduction in smoking. By 1998, the mortality from lung cancer among men in their 30s in Britain was only about a quarter of that of men of the same ages some 40 years earlier, corresponding to the earlier changes in the prevalence of smoking. The reduction in tar delivery between 1939 and 1965 contributed to the reduction in lung cancer in young men after the war, but the later reduction had little effect because of changes in the way cigarettes were manufactured and in the way they were smoked to ensure an adequate intake of nicotine. At older ages the decreases are less striking, but they are now seen at all ages in British men, and up to 60 in British women.

Occupation

Several other causes of lung cancer have been discovered as a result of observations in industry. Many thousands of men and women have experienced significant hazards from exposure to asbestos or to polycyclic hydrocarbons (from the combustion of fossil fuel). The former has given rise to hazards in asbestos mines, asbestos textile works, and insulation work in the shipbuilding and construction industries and the latter to specific hazards in the manufacture of coal gas in coking ovens, in steel works, in aluminium foundries, and wherever substantial amounts of incompletely combusted fumes were released into the working environment. Much smaller numbers of men have experienced substantial hazards from radon in the air of mines (not only when mining radioactive materials, but also when mining haematite and fluorspar under conditions in which radon seeped into the mine air from streams and the surrounding rock), from the manufacture of chromates and chrome pigments, from the refining of nickel, from arsenic (in the manufacture of arsenical pesticides and in the refining of copper, which is always contaminated with arsenic), from the manufacture of mustard gas, and, to a small extent, from exposure to silica if sufficient to cause silicosis. In one extreme situation, the absolute risk of contracting lung cancer due to the occupational hazard of radon was so large that more than half the workers contracted the disease (in the cobalt mines of the Hartz mountains in Central Europe, that were subsequently mined for radium and uranium). In several other situations with heavy exposure to asbestos or the early stages of nickel refining, the occupational hazard has affected as many as 20 to 30 per cent of the exposed men.

Atmospheric pollution

Some of the materials responsible for these occupational hazards—particularly the combustion products of fossil fuels—are or have been widely distributed in the air of towns and it is still uncertain how far they have, in this way, contributed to the production of the disease in the general population. That lung cancer was more common in big towns than in small towns and rural areas is certain, but this held as strongly for Oslo and Helsinki, two relatively unpolluted cities, as it did for London, Birmingham, Manchester, Chicago, Los Angeles, and Pittsburgh. Differences between the largest towns and the least populated areas have seldom been more than three-fold and much of the difference can be accounted for by past differences in cigarette smoking, a habit which has tended to spread outwards from the major cities. Attempts to 'allow for' cigarette smoking have usually been inadequate, as it is impossible to take full account of such factors as the age of starting to smoke cigarettes, the amount smoked daily at different periods, and the method of smoking (number of puffs, depth of inhaling, etc.). It is clear, however, that in the absence of cigarette smoking any effect of urban pollution in developed countries is relatively small. Estimates, based on extrapolation from the heavy pollution with coal-smoke that used to occur in large towns, suggest that in such towns it may have contributed, in synergism with smoking, to as much as 10 per cent of the risk of lung cancer, but would have caused very little risk in non-smokers. On this basis, the present levels of pollution with benzo(a)pyrene and the other known lung carcinogens in town air can be only very small. Modern pollution with ultra-fine particles (<10 μm diameter) may, however, be more hazardous. Study of residents in six contrasting cities in the United States in which information about personal smoking habits had been obtained suggests that the risk in the most polluted city compared to that in the least polluted could be increased by about a quarter in both smokers and non-smokers. The position in some developing countries is different: notably in parts of China, where intense indoor pollution with smoke and fumes from heating and cooking more than doubles the risk of lung cancer in non-smokers.

The effect of another form of pollution—that of house air with radon leaked from underground rocks and building materials—can be estimated by extrapolation from the effects of the much larger doses to which some groups of underground miners have been exposed and by direct observation in case–control studies of people with and without lung cancer. Both methods suggest that indoor radon may contribute to about 6 per cent of lung cancers in the United Kingdom and 12 per cent in the United States. Most cases are caused in synergism with smoking, so that in the absence of smoking only few cases would be produced.

Geographic differences

The development of the male lung cancer epidemic and the early signs of its departure have been most prominent in Britain and Finland, since the switch of young men to cigarettes was largely complete in these countries by the 1920s. In the United States, where cigarette consumption doubled during the Second World War, the benefits of recent reductions in tobacco exposure are superimposed on the increasing lung cancer rates due to the delayed effects of past increases in smoking in early adult life by those who are now reaching middle and old age. Hence, it is thus far only among younger men in the United States that the benefits of reduced smoking and a switch to low-tar cigarettes are causing net decreases in lung cancer mortality. In some other developed countries, the development of the epidemic is still further behind and it is only just beginning to appear in many developing countries. Chinese males, for example, who now consume about 30 per cent of the world's cigarettes, experienced a three-fold increase in cigarette consumption during the 1980s that may well eventually cause almost a million cancer deaths a year when the young men of today reach middle age.

In women, the development of the epidemic has been later than in men. Only in the Maori population of New Zealand did it occur at the same time. In the United Kingdom, United States, and a few other developed countries, the female lung cancer rates are already substantial, but in others, such as France and Spain, the epidemic in women has scarcely begun. A relatively high risk has long been noted in Chinese women who are non-smokers, irrespective of their country of residence, which is probably due to their exposure to mutagens in the fumes from oils used in cooking with a wok and from the coal smoke with which many Chinese homes are heavily polluted.

Pleura and peritoneum

- 0.5 per cent of all cancers and 0.4 per cent of cancer deaths.
- Sex ratio of rates 6.0 to 1. Age distribution like laryngeal cancer.

The existence of a specific type of tumour arising from the pleura, or less commonly the peritoneum, was debated by pathologists until 1960 when Wagner and his colleagues reported that six African patients with a similar type of 'peripheral lung cancer' had all lived in villages that were heavily polluted with dust produced by the mining of blue asbestos (i.e. crocidolite). Since then, many cases have been reported throughout the world, the great majority of which have been specifically associated with exposure to asbestos at work. They are much less likely to be produced by white asbestos (chrysotile) than by brown asbestos (amosite) or blue, as the two last persist for longer in the lungs. A few cases arise from neighbourhood pollution with asbestos or secondary contamination (e.g. from household contact with asbestos workers) and some in Turkish villages are due to the weathering into the general atmosphere of mineral fibres in local rock that are physically similar to, but chemically different from, asbestos. A few cases have been caused by radiotherapy and natural ionizing radiations may be responsible for most of those that are not associated with asbestos. An SV-40 like virus has been found in some tumours; but it is uncertain whether it plays a part in causing the disease.

Mesotheliomas seldom occur less than 15 years after first exposure to asbestos, commonly occur 25 to 30 years afterwards, and may be delayed for 50 years or more. Almost all cases are fatal, so that the mortality would reflect incidence, if all cases were correctly diagnosed. Due to confusion with lung or other types of cancer, it is still uncertain how many cases have occurred each year and some of the large increase since 1960 may be artefactual. In the last few years, the recorded mortality under 70 years of age has begun to decrease.

Pleural mesothelioma is not related to cigarette smoking and the occupational hazard affects smokers and non-smokers alike.

Bone

- 0.1 per cent of all cancers and of cancer deaths.
- Sex ratio of rates 1.3 to 1. Age distribution, see Fig. 8.

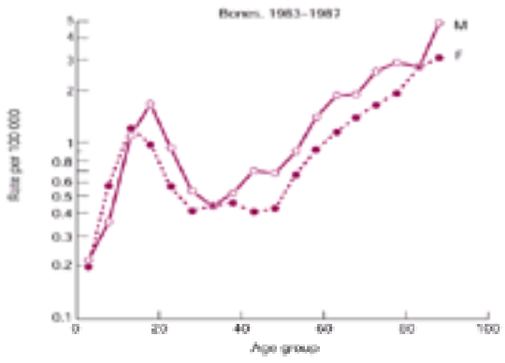

Fig. 8 Annual incidence of cancer of bones by age and sex.

Sarcomas can affect any bone, but characteristically affect the long bones in adolescence. After 45 years of age they occur most commonly in bones affected by Paget's disease (osteitis deformans), which predisposes to sarcoma so strongly that as many as 1 per cent of all people affected by the disease eventually develop a bone tumour.

Many different histological varieties occur, some of which appear to have different causes. Osteogenic sarcomas and chondrosarcomas are the most common, the former accounting for nearly all the adolescent peak. One rare type (Ewing's tumour) occurs only in childhood and adolescence and is almost unknown in black people, irrespective of the society in which they live.

Ionizing radiations are the only known extrinsic cause. Cases have been produced after intensive radiotherapy or the medicinal use of thorium (a bone-seeking radionuclide). In industry they have occurred in 'luminizers' who, in previous decades, used delicate paint brushes to apply radium compounds, and ingested radium, possibly as a result of 'pointing' the paint brushes in their mouths.

National statistics record a reduction in mortality over the last 50 years, but are unreliable indicators of incidence as many deaths attributed to tumours of bone are due to cancers that have metastasized from other sites. The recorded decrease in mortality is, therefore, largely an artefact due to improved diagnosis (though it has been contributed to in recent years by higher survival rates in childhood) and the true incidence may have remained roughly constant.

Connective tissues

- 0.4 per cent of all cancers and 0.5 per cent of cancer deaths.
- Sex ratio of rates 1.3 to 1. Age distribution, see Fig. 9.

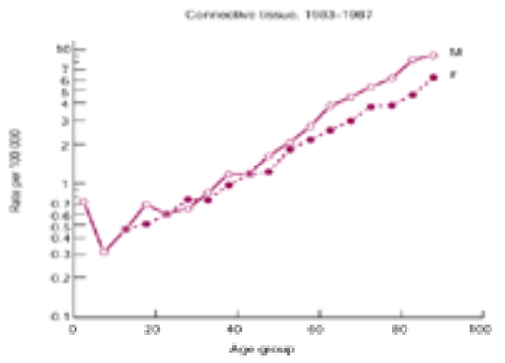

Fig. 9 Annual incidence of connective tissue sarcoma by age and sex.

Sarcomas of the soft tissues include a variety of different diseases, all of which are rare everywhere. Some are genetic in origin and others are caused by ionizing radiations. A few may be caused by intensive immunosuppression or exposure to chlorophenols, but the evidence is inconclusive.

Skin (melanoma)

- 1.8 per cent of all cancers and 1.0 per cent of cancer deaths.
- Sex ratio of rates 0.6 to 1. Age distribution, see Fig. 10.

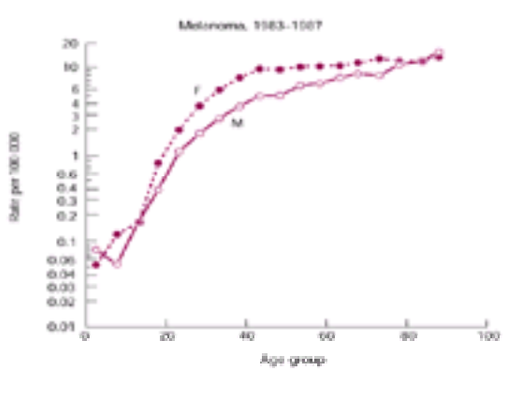

Fig. 10 Annual incidence of melanoma of the skin by age and sex.

The incidence of the disease varies inversely with the amount of skin pigmentation. In white people the tumour occurs most commonly on the legs (in women) and the trunk, head, and neck (in men). It is extremely rare in blacks in the United States, but is more common in Africa, where it occurs at the junction of the pigmented and unpigmented skin on the sole of the foot. Like basal-cell and squamous carcinoma of the skin, it is particularly common in sufferers from xeroderma pigmentosum.

Incidence rates in white people vary roughly in proportion to the flux of ultraviolet light in the countries in which they live. For all sites combined, the incidence is not, however, greater in outdoor than indoor workers (rather the reverse, in fact, perhaps due to the protective effects of a semipermanent suntan) and it seems to be associated with periodic bouts of sunbathing and sunburn. Incidence and mortality rates have increased in Britain, the United States, and in many other countries with mainly white populations. The increase began in cohorts born early this century, who exposed their skin to the sun more than their predecessors had done, and it still continues at ages over 60 years. The totality of the evidence suggests that ultraviolet light is the principal cause, but the relationship is not simple and other factors may also be important.

Skin (non-melanoma)

- 14.1 per cent of all cancers and 0.3 per cent of cancer deaths.

- Sex ratio of rates 1.5 to 1. Age distribution, see Fig. 11.

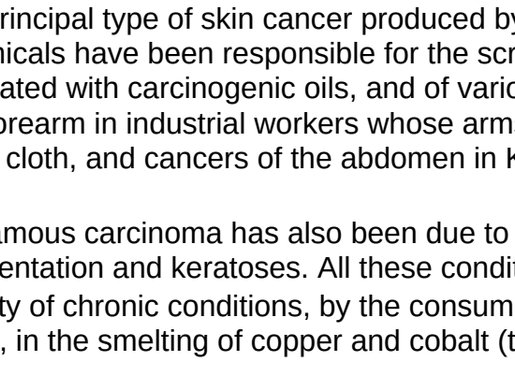

Fig. 11 Annual incidence of non-melanomatous skin cancer by age and sex.

Non-melanomatous skin cancers are of two main types, basal-cell and squamous carcinomas. The former, also known as rodent ulcers, are produced by ultraviolet light. They occur mainly on parts of the body that are regularly exposed to the sun and, in particular, on the face, head, and neck. They are more common in outdoor workers, such as seamen and farmers, than in indoor workers, more common in fair-skinned than in dark-skinned people, and are almost unknown in blacks (except those who suffer from albinism). Some few cases have been produced by exposure to X-rays, but the risk is very small unless the dose is very large and they seldom occur after normal courses of radiotherapy. People who suffer from xeroderma pigmentosum, a hereditary condition in which there is a defect in the enzyme responsible for the repair of the damage done to DNA by ultraviolet radiation, develop large numbers of skin tumours at an early age in response to even quite mild exposure to diffuse sunlight (see Chapter 23.1).

Squamous carcinoma is also produced by ultraviolet light, but less easily, so that it accounts for only about 20 per cent of cancers on the exposed skin. It is, however, the principal type of skin cancer produced by various carcinogenic chemicals, and particularly by polycyclic hydrocarbons in the combustion products of coal. These chemicals have been responsible for the scrotal cancers of chimney sweeps, who accumulated soot in the folds of the scrotum, of mule spinners, whose clothes were saturated with carcinogenic oils, and of various other groups of workers whose clothes were contaminated with tar. They have caused (and still do cause) cancers of the forearm in industrial workers whose arms are regularly splashed with tar or carcinogenic oils, cancers of the groin in India, localized by the continued friction of the *dhoti* cloth, and cancers of the abdomen in Kashmir associated with the habit of carrying a *kangri*, or small stove, inside the clothes in winter to keep warm.

Squamous carcinoma has also been due to prolonged exposure to arsenic, which is excreted by the skin and in the hair, when it may be accompanied by arsenical pigmentation and keratoses. All these conditions have been produced by prolonged medical treatment with inorganic arsenic, which used to be prescribed for a variety of chronic conditions, by the consumption of well water from arsenic-rich soils, and by occupational exposure, sometimes to as much as 1000 µg of arsenic/m^3 of air, in the smelting of copper and cobalt (the ores of which often contain arsenic), and in the manufacture of arsenical pesticides.

How large a part human papilloma viruses play in the development of squamous carcinoma of the skin is unclear. The type 5 virus is responsible for the warty lesions of epidermodysplasia verruciformis, some of which progress to cancer, and other types of the virus may contribute to the increased risk that follows the intensive immunosuppression given to permit the survival of organ transplants.

A third type is Kaposi's sarcoma, which is now classed as a skin cancer. It is associated with AIDS when AIDS results from homosexual intercourse, but probably only when this is accompanied by orofaecal contact. Frequent at first, particularly in the United States, the association has become progressively less common. Before the advent of AIDS, Kaposi's sarcoma was common in some parts of Central Africa, where it occasionally affected children, progressed rapidly, and could account for as many as 10 per cent of all hospital patients with cancer. Elsewhere it was rare, but indolent cases occurred occasionally in developed countries, principally on the legs of middle-aged and elderly men. The disease is initiated by infection with the human herpes virus type 8, but cofactors are required for tumour development.

Breast

- 12.2 per cent of all cancers and 8.6 per cent of cancer deaths.
- Sex ratio of rates 0.01 to 1. Age distribution, see Fig. 12.

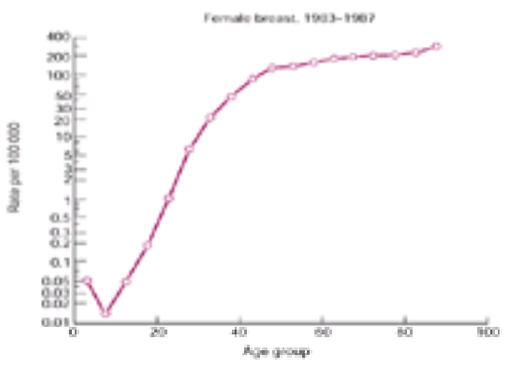

Fig. 12 Annual incidence of breast cancer in women by age.

Cancer of the breast was the most common fatal cancer in women throughout most of the developed world, but is now being displaced by lung cancer in the United Kingdom and the United States. It is less common in Eastern Europe and much less common in Asia and in black African populations south of the Sahara. Incidence rates have tended to rise slowly in many countries, but the changes have been relatively small and decreases have recently been recorded in young age groups. The geographical differences are unlikely to be chiefly due to genetic factors, as black women in the United States and Japanese women in Hawaii have rates that are similar to those in their white American compatriots and much greater than those in their countries of origin.

Hormonal factors are important in the production of the disease, particularly oestrogens, but others may also be important. The duration of ovarian activity is relevant, as the disease is particularly common in women who have an early menarche and a late menopause (the former being more important than the latter). Pregnancy produces a short-term increase in risk, followed after a few years by a lifelong decrease, particularly after teenage or early adult pregnancies. The incidence in later life increases progressively with a woman's age at the time of her first full-term pregnancy, being about three times greater when the first birth occurs after 35 years of age than when it occurs before 18 years. Full-term pregnancies after the first have an additional protective effect. Pregnancies that end in abortion have little or no effect, however, suggesting that the effects of pregnancy depend on the induction of lactation. The duration of lactation has an additional protective effect but is not marked unless it continues for a year or more.

Parity and menstrual differences are insufficient to account for the large variations in the incidence of the disease in different countries, which seem to be correlated with a 'high' standard of living: that is, with life in a developed country. Diet may play an important part, but the evidence is complex and inconclusive. Obesity is associated with a reduced risk before the menopause, as it tends to be associated with ovarian dysfunction. After the menopause, obesity increases both the incidence and probably the fatality of the disease. Oestrogens prescribed medically, as hormone replacement therapy (HRT) after the menopause, increase the risk by about 2 per cent for each year of use; combined with progestogens in the contraceptive pill they increase it by about 25 per cent during use, but the increased risk gradually disappears over 10 years, when use is stopped, as it does after HRT is stopped. Tamoxifen, an antioestrogen prescribed for the treatment of breast cancer, reduces the subsequent incidence of the disease in the unaffected breast.

Much of the recent increase in incidence is the result of intensive case finding in association with mammography and there is no reason to attribute it to any form of environmental pollution.

Cervix uteri

- 1.2 per cent of all cancers and 1.1 per cent of cancer deaths.
- Confined to women. Age distribution, see Fig. 13.

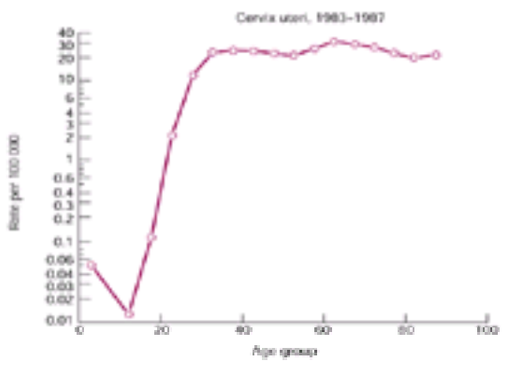

Fig. 13 Annual incidence of cancer of the cervix uteri by age.

Carcinoma of the cervix is the most common type of cancer throughout much of Africa, Asia, and Latin America, and used also to be common in Europe and North America. It has always been rare in Jewesses and has tended to be less common in Muslim women than in women of other faiths living in the same country (as, for example, Hindus in India).

Changes in incidence have been difficult to assess, partly because mortality data have not always distinguished between deaths due to cancer of the cervix and those due to cancer of the corpus (or endometrium), partly because the introduction of screening programmes has made it possible to diagnose and treat premalignant lesions (see below), and partly because hysterectomy for benign conditions has become progressively more common, with a corresponding reduction in the number of uteri in which the disease could occur. Despite these complications there can be no doubt that the disease has become substantially less common in Europe and North America than it was before the Second World War.

The rarity of the disease in Jewesses and its relative rarity in Muslims suggest that male circumcision may reduce the risk of its development, but this is unlikely as the state of circumcision of her husband has no substantial effect on a woman's risk of developing the disease in communities in which only some men are circumcised. Cleanliness is likely to be protective, as the disease is relatively uncommon in communities that practise ritual ablution before and after intercourse and, within each community, it becomes less common with rising socioeconomic status.

Squamous carcinoma, which constitutes the vast majority of all cases, is intimately connected with sexual activity. It almost never occurs in virgins and increases in frequency with the number of sexual partners that a woman or her partner has had. The great majority of cases are attributable in part to infection with some types of the human papilloma virus, most notably types 16 and 18.

The development of squamous carcinoma is preceded by pathological changes limited to the epithelium, known as cervical intraepithelial neoplasia (CIN) types I, II, and III. CIN III is associated with the same types of virus as squamous carcinoma, but CIN I and CIN II generally are not. The changes may progress from one to another, finally leading to carcinoma, but the early lesions (CIN I and II) commonly regress and even CIN III (previously known as carcinoma *in situ*) may do so occasionally. The lesions can be recognized in cervical smears and destroyed by lasers or extensive biopsy and the occurrence of clinical disease can be greatly reduced by the examination of all sexually active women every 2 or 3 years and the treatment of advanced CIN lesions.

Other factors associated with the production of the disease are the use of oral contraceptives and cigarette smoking. Both tend to be associated with behaviour conducive to venereal infection, but it is uncertain whether this tendency can wholly account for their association with the disease. That smoking may be responsible for some cases is suggested by the presence of mutagens in the cervical mucus of smokers that are not present in the secretions of non-smokers.

Adenocarcinoma of the cervix uteri is generally rare, but may have become somewhat more common recently. Its causes are unknown.

Endometrium (corpus uteri)

- 1.5 per cent of all cancers and 0.7 per cent of cancer deaths.
- Confined to women. Age distribution like cancer of ovary.

The epidemiological features of endometrial cancer are in many respects the opposite of those of cervical cancer. Histologically, it is nearly always an adenocarcinoma. It is common in developed countries, rare in poor populations, and is, if anything, becoming more common with the passage of time. It is inversely related to parity, but not otherwise related to coitus, and is unaffected by the number of sexual partners. Like cancer of the breast, it is positively associated with early menarche and late menopause.

The one factor known to produce the disease is regular exposure to oestrogens, unopposed by progestogens. This leads to endometrial hyperplasia and eventually, in some cases, to cancer. Known causes include oestrogen-secreting tumours of the ovary, the use of oral contraceptives in which oestrogens and progestogens are prescribed sequentially (types that have now been abandoned), the use of 'natural' conjugated oestrogens to relieve menopausal and postmenopausal symptoms, and adiposity. The last causes the disease because oestrogens are produced in the body after the menopause in adipose tissue from the adrenal hormone, androstenedione. Tamoxifen, an analogue of the natural oestrogens, which blocks oestrogen receptors in the breast and hence acts as an antioestrogen, can, due to differences between the hormone receptors in different tissues, have a pro-oestrogenic effect in some other organs, and slightly increases the incidence of endometrial cancer.

It is improbable that oestrogens are initiating agents. They are not mutagens *in vitro* and the changes that took place in the incidence of the disease in the United States following the increase and the subsequent reduction in the use of premarin (a conjugated oestrogen) for the treatment of menopausal symptoms occurred so quickly that they make sense only if oestrogens act on some late stage(s) of the carcinogenic process.

Ovary

- 2.0 per cent of all cancers and 2.9 per cent of cancer deaths.
- Confined to women. Age distribution, see Fig. 14.

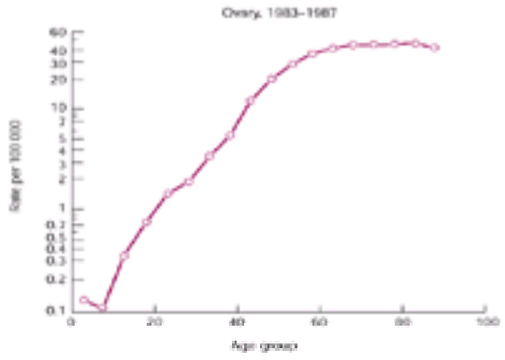

Fig. 14 Annual incidence of cancer of the ovary by age.

Prostate

- 7.4 per cent of all cancers and 6.3 per cent of cancer deaths.
- Confined to men. Age distribution, see Fig. 15.

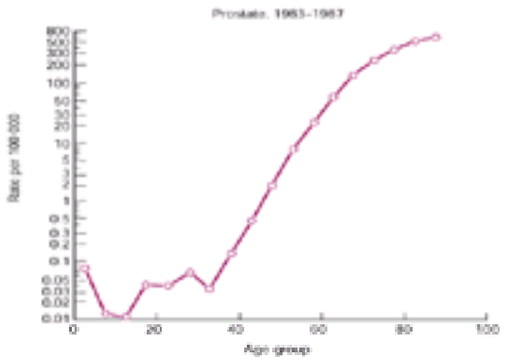

Fig. 15 Annual incidence of cancer of the prostate by age.

Cancer of the prostrate is more characteristically a disease of old age than any other cancer, so that it comes to play a much larger part in clinical experience as the proportion of old people in the population increases. It is unusual in that foci of cells resembling cancer can be found in a high proportion of clinically normal prostates, so that the recorded incidence is drastically increased by increasing the number of prostatic biopsies. Some increase in mortality has been recorded in Britain and North America, but the weight of evidence suggests that the disease is principally due to factors that have affected society for many years. What these factors are remains obscure. Associations have been reported with both increased and decreased sexual activity. On general grounds it seems likely that the disease is dependent on hormonal imbalance (particularly as castration slows the progression of clinical disease) but the nature of the imbalance is unknown. Vasectomy was thought to increase the incidence of the disease, but probably does not.

Two epidemiological observations stand out: the high incidence in black populations throughout the world, and the low incidence in Japanese. Both may be partly due to genetic factors, but they are not wholly so, as both Japanese and blacks have higher rates in the United States than they have in Japan and Africa.

Testis

- 0.5 per cent of all cancers and 0.1 per cent of cancer deaths.
- Confined to men. Age distribution, see Fig. 16.

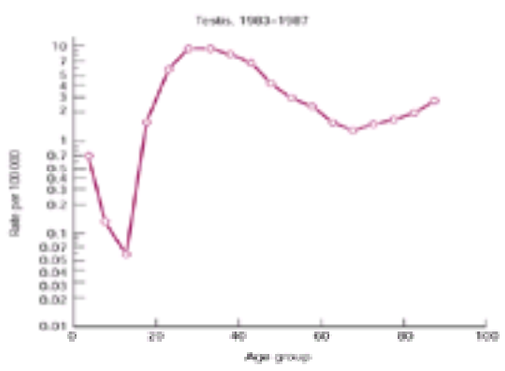

Fig. 16 Annual incidence of cancer of the testis by age.

Testicular cancers are of two main types. Seminomas, which are the more common, have a peak incidence at about 30 years of age and teratomas, commonly called embryomal carcinomas in the United States, which have a peak incidence about 10 years earlier. Tumours after 50 years of age are mostly lymphomas and are now classed as such. Both genetic and environmental factors are important. On the one hand, the disease is uniformly rare in black populations, whether in Africa or in the United States. On the other, it has increased in incidence in many countries, notably in Denmark and Britain. In Britain, the increase began in the 1920s and affected first the higher socioeconomic groups. The increase trebled the mortality at 15 to 34 years of age and produced a sharp peak in young adult life that had not previously been present. In the United States, the increase started later and has been less marked. The disease is much more likely to occur in an undescended than in a normal testis, but otherwise its causes are unknown.

Penis

- 0.1 per cent of all cancers and of cancer deaths.
- Confined to men. Age distribution like skin (non-melanoma).

Carcinoma of the penis is at all common only in some parts of tropical Africa and Brazil, where it has accounted for 10 per cent of all cancers in men. It is avoided almost entirely by circumcision at birth and is very rare if circumcision is carried out in boyhood. In developed countries it is rare even in the absence of circumcision if the glans, coronary sulcus, and foreskin are kept clean.

The oncogenic types of the human papilloma virus (principally types 16 and 18) can usually be identified in the malignant cells and are important causes of the disease.

Bladder

- 4.5 per cent of all cancers and 3.3 per cent of cancer deaths.
- Sex ratio of rates 3.6 to 1. Age distribution like gastric cancer.

Cancer of the bladder can be produced by cigarette smoking, occupational exposure to a group of chemicals classed together as aromatic amines, infestation of the bladder with *Schistosoma haematobium*, and the medical prescription of chlornaphthazine (*N*,*N*'-bis(2-chloroethyl)-2-naphthylamine) and cyclophosphamide. Most bladder cancers are transitional cell carcinomas, but those associated with schistosomiasis are characteristically squamous carcinomas. It is not surprising that the bladder should be affected by many chemicals, as any noxious small molecules in the blood will tend to be found at greatly increased concentration in the urinary tract. Cigarette smoke contains several mutagenic chemicals that enter the bloodstream and thence the bladder, so that when tested *in vitro* on bacterial DNA the urine of cigarette smokers is found to be mutagenic, while that of non-smokers is barely active.

Occupation

An occupational cause was first suspected in 1898 in Germany, when Rehn commented on a cluster of cases in men using aniline for the manufacture of dyes. Aniline, however, is not carcinogenic in experimental animals, more recent studies have failed to incriminate it epidemiologically, and it seems likely that other carcinogenic chemicals were present as impurities. Four aromatic amines that are carcinogenic in experimental animals have been shown to cause bladder cancer in humans: 2-naphthylamine, benzidine, 3,3'-dichlorobenzidine, and 4-aminobiphenyl. The first is one of the most powerful human carcinogens yet known and was responsible for the development of bladder cancer in all the 19 men who were employed in distilling it in a British factory. Its manufacture in Britain was stopped in 1949; but small amounts continued to be imported until the 1960s. Other aromatic amines that may cause bladder cancer include auramine, magenta, and, perhaps, 1-naphthylamine. The last is dubiously carcinogenic in experimental animals and it seems probable that the cases associated with its use have been due to a few per cent of 2-naphthylamine present as an impurity in the commercial material. These chemicals were used in the manufacture of dyes, in the rubber industry as antioxidants (1-naphthylamine and 4-aminobiphenyl) and hardeners (benzidine), and in laboratories as a reagent (benzidine). 2-Naphthylamine is also found in the combustion products of coal and may have been responsible for the hazard of bladder cancer in men who made coal gas. As many as 10 per cent of cases were, at one time, attributable to occupational causes in Britain and North America; but the proportion should now be much less.

Smoking

The most important cause numerically is cigarette smoking, which probably accounts for about half the total number of cases in Britain and North America. 2-Naphthylamine and 4-aminobiphenyl are present in cigarette smoke, but whether the amounts are sufficient to account for the carcinogenic effect is uncertain.

Medicines

The two medicinal causes have, by contrast, been responsible for only a handful of cases. Chlornaphthazine was used briefly for the treatment of myelomatosis, until it was found to be metabolized into 2-naphthylamine. Cyclophosphamide is used primarily for the treatment of malignant disease, but it is also used as an immunosuppressant. In large doses it may cause sloughing of the bladder mucosa and, occasionally, cancer.

Parasitic infection

Heavy infection of the bladder with *Schistosoma haematobium* has been found to be a cause of the disease, most notably in Egypt and Tanzania.

Diet

The evidence linking bladder cancer to diet is weak. Several case–control studies suggested a positive relation with the consumption of coffee, but the results were inconsistent and it is difficult to exclude the effect of confounding by the stronger relation with cigarette smoking. Artificial sweeteners came under suspicion because of the results of animal experiments in which, first, mixtures of cyclamates and saccharin and then saccharin alone were shown to cause bladder cancer in rats. The human use of cyclamates was banned before saccharin came under suspicion and it now appears that the 'positive' results of animal experiments with cyclamates alone were due to impurities. Saccharin has been shown to cause bladder cancer in rats in feeding experiments, especially when given over two generations and when given after a single instillation into the bladder of a powerful carcinogen. In both instances the quantities that had to be given were large, constituting a few per cent of the feed. The human evidence is extensive and could hardly be more negative, except that it does not cover lifelong use.

Kidney

- 1.8 per cent of all cancers and 2.0 per cent of cancer deaths.
- Sex ratio of rates 2.1 to 1. Age distribution, see Fig. 17.

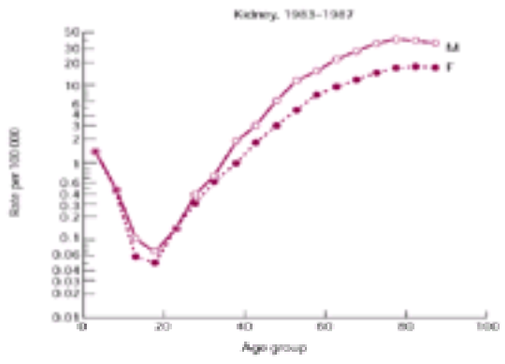

Fig. 17 Annual incidence of cancer of the kidney by age and sex.

Cancers of the kidney are of three main types: nephroblastomas (or Wilms' tumours), adenocarcinomas (or hypernephromas), and transitional- and squamous-cell carcinomas of the renal pelvis. The first are limited to childhood, occur with almost equal frequency everywhere, and apart from a few of genetic origin, are of unknown aetiology. The second constitute by far the majority of all cases, are more common in Western Europe and North America than in Africa and Asia, and have been slowly increasing in incidence. Cigarette smoking is one cause, but the association is weak and it does not account for more than about a quarter of the cases.

The third type of renal cancer (carcinoma of the pelvis) constitutes some 10 per cent of all cases. Three established causes are occupational exposure to the chemicals that cause cancer of the bladder, smoking, and the consumption of phenacetin in large enough amounts to produce analgesic nephropathy. In all three cases the hazards are relatively small (two to three-fold). A fourth cause, Balkan nephropathy (see Section 20.7) increases the risk several hundred-fold.

Brain

- 1.3 per cent of all cancers and 2.1 per cent of cancer deaths.
- Sex ratio of rates 1.4 to 1. Age distribution, see Fig. 18.

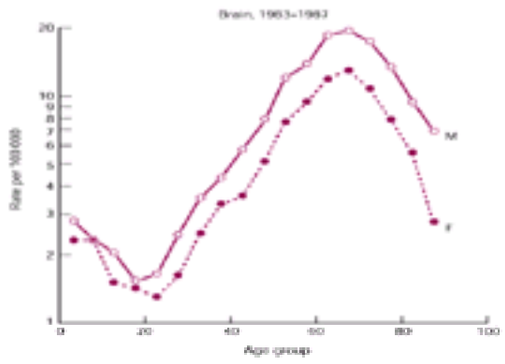

Fig. 18 Annual incidence of cancer of the brain by age and sex.

Tumours of the brain and nervous system are of several different histological types, some of which may not be clearly either benign or malignant. One type occurs characteristically in childhood (medulloblastoma), another in adult life (glioblastoma), and a third (astrocytoma) at all ages. Despite the overall male excess, one type (meningioma) is more common in women.

A moderately large increase in incidence in old age has been recorded in many countries, which can be attributed to improved diagnosis with computerized tomographic scans and nuclear magnetic imaging. Little or no increase in mortality has been reported in or before middle age and the recorded increases in incidence are certainly largely, and possibly wholly, artefactual. No new environmental cause has been established, but many have been suspected, including electromagnetic fields associated with the use of electricity (50–60 Hz) and mobile phones.

Thyroid

- 0.4 per cent of all cancers and 0.2 per cent of cancer deaths.
- Sex ratio of rates 0.5 to 1. Age distribution, see Fig. 19.

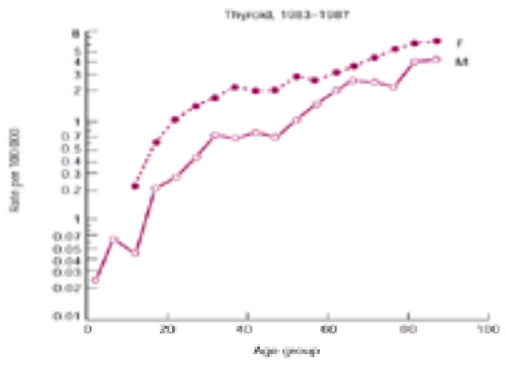

Fig. 19 Annual incidence of cancer of the thyroid by age and sex.

The thyroid is particularly sensitive to ionizing radiation in childhood. Substantial numbers of cases have occurred among the survivors of the atomic explosions in Hiroshima and Nagasaki, children who were exposed to large amounts of radioactive iodine following the Chernobyl accident, and young people whose necks were irradiated in infancy for the treatment of an enlarged thymus (a condition now considered to be perfectly normal, but at one time thought to be a cause of sudden death). Fortunately, the thyroid tumours produced by ionizing radiations are nearly all of the papillary and follicular types, which respond well to treatment. No causes are known of the medullary and anaplastic types, which have a high fatality and occur only in adult life.

The disease is several times more common in Iceland, northern Norway, Hawaii, Fiji, and Israel than elsewhere.

Hodgkin's disease (Hodgkin's lymphoma)

- 0.5 per cent of all cancers and 0.2 per cent of cancer deaths.
- Sex ratio of rates 1.6 to 1. Age distribution, see Fig. 20.

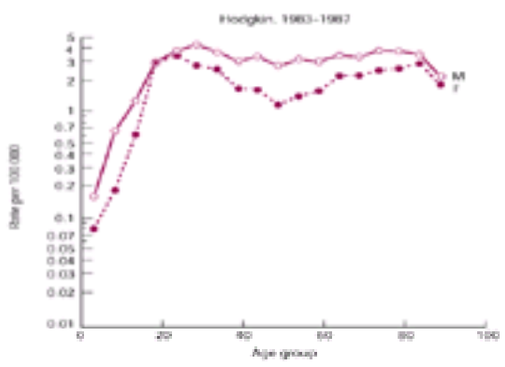

Fig. 20 Annual incidence of Hodgkin's lymphoma by age and sex.

Hodgkin's disease is best thought of as at least two diseases, one affecting primarily youths and young adults, the other primarily the middle aged and elderly. This division is suggested partly by the existence of two peaks in the age-specific incidence rates, partly by the histological appearances (younger patients tending to have the nodular sclerotic form of the disease and older patients the mixed cellular form), and partly by the clinical distinction that young patients show mediastinal involvement in more than 50 per cent of cases and infradiaphragmatic involvement in less than 5 per cent, while the reverse tends to be true in the elderly.

There are several reasons for thinking that the type characteristic of young people is infective in origin. In developing countries, Hodgkin's disease occurs in childhood, but as the standard of living rises, the childhood cases disappear and are replaced by a larger number in young adults. This is reminiscent of what happened to poliomyelitis in the first half of the century and suggests that the disease may be due to a ubiquitous infective agent that becomes less widespread as hygiene improves. That the agent was likely to be the Epstein–Barr virus (EBV or human herpes virus type 4) was suggested by the finding that the incidence was increased 5 to 20 years after a clinical attack of infectious mononucleosis and the virus has now been found in the DNA of the malignant cells characteristic of the tumour (the Reed–Sternberg and tumour reticulum cells). As with other virus-induced cancers, there are likely to be cofactors (at present unknown) that determine whether cellular infection leads to the production of a malignant clone.

Non-Hodgkin's lymphoma

- 2.8 per cent of all cancers and 2.9 per cent of cancer deaths.

- Sex ratio of rates 1.5 to 1. Age distribution, see Fig. 21.

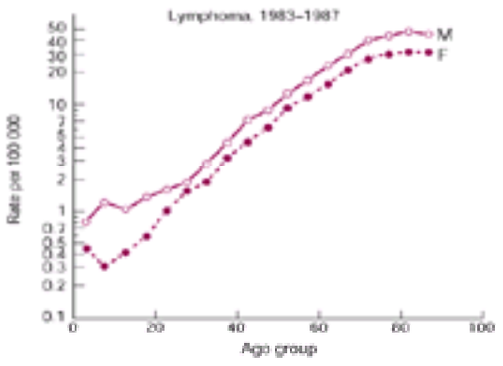

Fig. 21 Annual incidence of non-Hodgkin's lymphoma by age and sex.

Non-Hodgkin's lymphoma is a non-specific term that embraces several diseases with different histological appearances. The histological classification has, however, varied from place to place and from time to time, and it has been difficult to collect epidemiological information about the individual types.

One type that has been clearly distinguished is Burkitt's lymphoma, derived from B lymphocytes. This affects children everywhere, but is common only in a few areas in which malarial infection is both heavy and widespread. In parts of Uganda, Tanzania, and Nigeria the disease is 100 times more common than in Europe and North America. In high incidence areas, EBV can nearly always be recovered from the lymphomatous cells and part of its genome is identifiable in the cells' DNA. Infection with the virus is, however, not necessary for the development of the disease, as some cases occur in its absence; nor is it sufficient, as infection is almost universal and occurs at a very young age in high incidence areas. It seems, therefore, that EBV is a potential cause and that its carcinogenic effect is precipitated by the intense stimulation of the reticuloendothelial system that is characteristic of heavy and chronic malarial infection.

Another type occurs as part of the adult T-cell leukaemia–lymphoma syndrome that follows infection with the human T-cell leukaemia–lymphoma virus (HTLV-1). The disease is common in South Japan and the Caribbean, but may occur occasionally anywhere.

A third type, primary upper small-intestinal lymphoma (PUSIL), affects young people in many populations with a low standard of living, not only in North Africa and the Middle East (where its frequency gave it the earlier name of Mediterranean lymphoma) but also in South Africa and Central and South America. Malnutrition is not, however, a sufficient cause as it is uncommon in Bangladesh and several other malnourished populations.

A fourth type, the mucosa-associated lymphoid tissue tumour known as a maltoma, occurs in the stomach as a result of *H. pylori* infection and can be cured by aggressive treatment of the infection.

The remaining lymphomas, which constitute the majority in developed countries, should probably be divided further. Some in childhood might be better classed with acute lymphatic leukaemia from which they are distinguished arbitrarily only by the number of lymphocytes in the blood. At present, however, they have to be considered as a group. As such they constitute one of the few types of cancer that have been increasing in incidence at all ages.

Two factors that have contributed to the increase, but which cannot account for it all, are the use of immunosuppressive drugs and the spread of AIDS. Intense immunosuppression is followed within 1 or 2 years by an increase in the incidence of the disease of the order of 50- to 100-fold, and smaller increases follow the less intensive use of immunosuppressive drugs for the medical treatment of patients with arthritis, Crohn's disease, and other similar conditions. Many, but not all, of the lymphomas that occur in these circumstances are associated with EBV and some of these may, unusually, arise in the brain. Greatly increased incidence rates are also seen in a variety of rare hereditary disorders characterized by major immunological impairment, such as the Wiskott–Aldrich syndrome.

The rare hairy-cell leukaemia, of unknown aetiology, is now regarded as another type of lymphoma rather than as a leukaemia.

Myelomatosis

- 1.1 per cent of all cancers and 1.6 per cent of cancer deaths.
- Sex ratio of rates 1.5 to 1. Age distribution like large bowel cancer.

Myelomatosis has been much easier to diagnose since marrow puncture and then serum electrophoresis became standard diagnostic tools and since the improvement in the management of renal failure, which is often the presenting symptom. As a result it is difficult to be sure whether the increase that was recorded until recently, in both incidence and mortality rates, was due solely to improved diagnosis, or whether it also reflects the introduction of major new causes into Europe and North America between the two World Wars. In southern Sweden, where there has been a long-standing interest in, and search for, cases of myelomatosis, no large increase was seen over the same period; the rates were higher than in other developed populations, but in recent decades those in other populations have caught up.

The disease is uncommon in undeveloped areas, where it is almost certainly underdiagnosed. Genetic factors could be important, as it is twice as common in blacks in the United States as in whites and is rare in Japanese irrespective of where they live.

Leukaemia

- 2.1 per cent of all cancers and 2.6 per cent of cancer deaths.
- Sex ratio of rates 1.5 to 1. Age distribution, see Fig. 22.

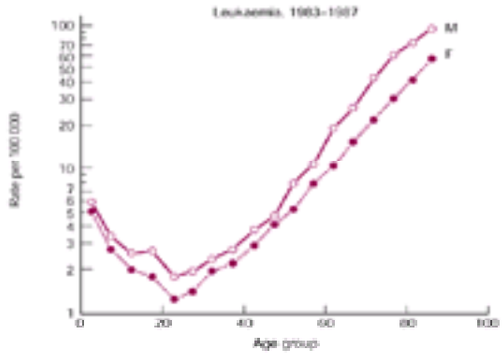

Fig. 22 Annual incidence of leukaemia by age and sex.

Leukaemia may be divided primarily into chronic lymphatic leukaemia (CLL), chronic myeloid leukaemia (CML), acute myeloid leukaemia (AML), and acute lymphatic leukaemia (ALL). CML, AML, and ALL are, in turn, amalgams of two or more different types, with different causes, different age distributions, and different prognoses, but the distinctions between them are still undergoing evolution and, with the exception referred to later, the epidemiological descriptions of each subtype are unclear.

CLL increases progressively with age in the same way as myelomatosis and most of the common epithelial cancers. It is extremely rare in Chinese, Japanese, and Indians, which is presumably due to genetic differences in susceptibility as it continues to be rare in these racial groups even when they migrate to other countries.

AML occurs at all ages. It becomes slowly, but progressively, more common from childhood on and is the most common type in young adult life. In this age group, its incidence is probably less variable throughout the world than that of any other reasonably common type of cancer. CML, by contrast, is very rare in youth, but becomes more common than AML in later middle age. The few cases that occur in childhood should perhaps be regarded as constituting a separate disease, as they lack the Philadelphia chromosome that normally characterizes CML in adult life.

ALL is the most common type of childhood cancer. Three main types can be distinguished. Common (c) ALL arises from B-lymphocyte precursors and is responsible for a peak incidence of the disease at 2 to 3 years of age. Null ALL also arises from B-cell precursors, but lacks the common antigen and accounts for most cases in the first year of life. T-cell ALL occurs more or less equally at all ages in childhood. ALL in adult life can be either B cell or T cell.

Many causes of leukaemia are known. The most important is ionizing radiation, which causes all types except CLL. The sparing of CLL may be because the relevant stem cells are so radiosensitive that they are killed by small doses that would otherwise be carcinogenic. The other main types are induced by ionizing radiation more easily than most other types of cancer and constitute about 10 per cent of all fatal cancers from exposure of the whole body to moderate doses.

Whether extremely low frequency non-ionizing radiation can cause leukaemia, particularly ALL in childhood, is uncertain. There is evidence to suggest that the risk of ALL is approximately doubled by exposure to power frequency magnetic fields of an intensity greater than 0.4 μT that occurs rarely in the United States but only very rarely in the United Kingdom. The evidence for a causal relationship is, however, inconclusive.

One type of the disease (adult T-cell lymphoma/leukaemia) is caused by a virus (HTLV/1) and has been described under non-Hodgkin's lymphoma.

Other causes include smoking, which causes a small increase in myeloid leukaemia, several chemicals, and genetically determined diseases. The most important chemical is benzene, which is used widely in industry. Prolonged occupational exposure to large amounts has caused a substantial risk of AML (particularly one of its subtypes, erythroleukaemia) and, less commonly, acute lymphatic leukaemia. Many cases are preceded by periods of aplastic anaemia and there is still some doubt whether leukaemia can be caused by small doses.

Two other chemicals, melphalan and busulphan, are used in the treatment of cancer and the small risk of AML that follows their use is unimportant in comparison to the benefit obtained if they are used appropriately. Melphalan is an alkylating agent and so presumably mutagenic. Busulfan, however, has been observed to produce a substantial risk of leukaemia only after being given in such high doses that it produces aplastic anaemia.

Of the hereditary causes, Down's syndrome is the most common and is probably responsible for the greatest number of cases, although the relative risk in some of the other rarer syndromes may be greater than the 20-fold increase in childhood leukaemia that occurs with Down's disease. Ataxia telangiectasia and Bloom's syndrome predispose to ALL, while Fanconi's anaemia predisposes to AML.

6.2 The nature and development of cancer

Andrew Coop and Matthew J. Ellis

Introduction

The disruption of proteins with pivotal roles in cell growth, death, and the regulation of gene expression is the underlying cause of cancer. The most common causes of these disturbances are somatic mutations that accumulate in cellular DNA over time, induced by chemicals in the environment (carcinogens), radiation, or simply the background rate of error in DNA replication. On occasion, carcinogenic mutations are inherited ('germline' mutations). The study of individuals with a genetic predisposition to cancer ('inherited cancer') has contributed greatly to our understanding of malignancy by pinpointing individual genes involved in this process (see Chapter 6.3). In a several instances, including Burkitt's lymphoma, Kaposi's sarcoma, cervical cancer, and hepatocellular carcinoma, cancer is initiated by viral infection, not somatic mutation ('endemic cancer'). 'Tumour viruses' encode proteins that either mimic or disrupt the functions of essentially the same set of cellular proteins whose genes are targeted by mutation in sporadic and inherited cancers.

Extensive functional and epidemiological studies of the genes responsible for cancer show that they can be broadly divided into two operational classes: oncogenes and tumour suppressor genes. Oncogenes are associated with mutant proteins demonstrating a gain in function, which overstimulate cell division or support the survival of genetically aberrant cells. In contrast, tumour suppressor genes are characterized by mutations that cause a loss of function. Typically, tumour suppressor genes encode proteins that suppress cellular proliferation, activate cell death pathways, or protect the integrity of the genome in the presence of DNA damage. In general, inactivation of both alleles of a tumour suppressor gene is required before aberrant cellular behaviour is evident. In contrast, gain-of-function mutations in oncogenes act in a dominant manner, so that typically only one allele is mutated. To qualify as an oncogene or tumour suppressor gene, there must be evidence for cancer-specific mutations in the gene concerned. Furthermore, introduction of the gene in question into appropriate recipient cells should either generate cellular responses typical of cancer cells (in the case of an oncogene) or suppress malignancy in cells that harbour defects in both alleles of the gene (in the case of a tumour suppressor gene).

In addition to cell growth and death, mutation in a oncogene or tumour suppressor gene causes disturbances in cellular physiology that ultimately lead to all the characteristics of a lethal tumour. These include an ability to acquire a blood supply (angiogenesis), tumour extension across anatomical boundaries (invasion), and growth in tissues beyond the organ of origin (metastasis). For several decades now, cancer researchers have focused on identifying the key genes responsible for these cellular processes. Their key assumption has been that the identification of so-called 'cancer genes' will lead to rational and more effective therapies. Today this is reality, with gene-targeted treatments a routine aspect of cancer management and clinical cancer research.

Cancer as a defect in cellular society

Unlike unicellular species, cells within a multicellular organism must co-operate in a way that favours the survival of the whole organism rather than that of the individual cell. If cellular co-ordination is disrupted, the unrestrained growth of even a single cell, by competing with its neighbours for space and nutrients, will eventually cause the death of the organism. Cancer is the term used to describe this breakdown in cellular society. Multicellular organisms must depend on complex gene networks that ensure full cellular co-operation. Unfortunately somatic mutation causes these networks to degrade over time, ultimately leading to cancer. Current research on the pathogenesis of cancer therefore focuses on the identification of genes that serve to maintain cellular order. Research has been greatly assisted by the recognition that cancer genes are organized into gene families that are conserved in evolution, from the simplest worm through to *Homo sapiens*. This observation has profoundly influenced the investigation of human cancer because the results of gene manipulation in experimentally tractable lower organisms, such as the nematode worm *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, mice, yeast, and even bacteria, have direct implications for their human homologues.

Cellular transformation

In many instances cancer cells can be grown in tissue culture, which has greatly facilitated the study of this disease. Unlike their healthy counterparts, cancer cells have been found to have some or all of the following *in vitro* characteristics:

1. Reduced requirement for growth stimulatory molecules, termed 'growth factors'.
2. Loss of contact inhibition, so that the cells tend to pile up and form foci.
3. Anchorage-independent growth, usually manifest as an ability to grow in soft agar.
4. The ability to divide indefinitely, a characteristic termed 'immortalization'.

When a cell has acquired these *in vitro* characteristics, it is referred to as 'transformed'. Empirically, cellular transformation can be achieved in human cells in tissue culture by disabling or disrupting the activities of four cellular components (Fig. 1). However, the process of becoming a cancer cell begins, not ends, with transformation. Not all experimentally transformed cells are capable of establishing a tumour when transplanted into a suitable host, and fewer still are capable of metastasis. The process of becoming a lethal, angiogenic, invasive, and motile cancer involves the activities of additional families of genes that serve these cellular programmes. For research purposes, the pathways involved in cancer tend to be categorized along functional lines, i.e. transformation, genetic instability, aberrant growth and survival, angiogenesis, tissue invasion, and cellular motility. While this provides an excellent framework for discussion, these distinctions are somewhat artificial because many of the genes implicated in cancer serve not one but several of these processes.

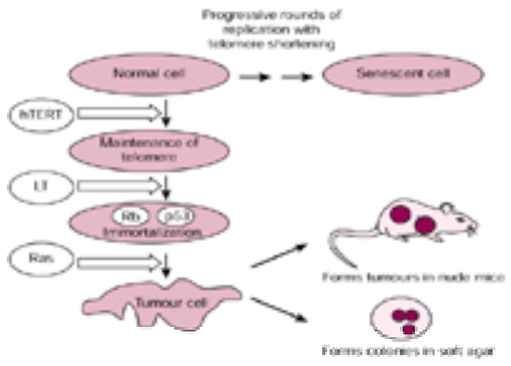

Fig. 1 *In vitro* experiments demonstrate that at least four events are required to convert a normal human cell into a tumour cell. Addition of the catalytic hTERT subunit of telomerase (event 1) prevents telomere shortening (normal telomerase expression results in progessive telomere shortening, until further replication cannot be sustained and the cells become senescent). Introduction of SV40 large T antigen (LT), an oncoprotein from simian virus 40, disrupts the Rb and p53 protein pathways, which are essential for normal cell proliferation control (events 2 and 3). Finally, introduction of the oncogene *ras* is sufficient to cause malignant transformation (event 4). That the cells are indeed malignant can be demonstrated by their ability to form tumours in nude mice and colonies in soft agar.

Somatic mutation and clonal evolution

The theory that cancer is a multistep or multigene process is supported by epidemiological evidence. The incidence of common cancers increases as individuals age, with kinetics dependent on the fourth or fifth power of elapsed time. This observation implies that a minimum of four to five events must take place before a tumour is evident clinically. If each event represents a somatic mutation, how does tumour evolution occur at the cellular level? Estimates of the rate of somatic mutation in normal tissues indicate that for any gene there is a one in a million chance of a somatic mutation each time a cell divides. The baseline somatic mutation rate is therefore very low and a somatic mutation that significantly affects the function of a 'cancer gene' must be a very rare event. In fact, the background rate of somatic mutation appears to be too low to be the driving force behind cancer. However, carcinogenic mutations favour the growth or survival of a cell at the expense of neighbouring cells. As a result, cancer-promoting mutations are subject to a powerful positive selection process that magnifies the impact of these low-frequency events. In the model depicted in Fig. 2, a mutation has occurred that stimulates growth. As a result, a clone of cells has arisen that has replicated the initial mutation thousands of times. As the size of the clone approaches 10^6 cells, the chance of a second growth-stimulating mutation in one of the cells in the clone increases significantly. When a second mutation does occur, the cell with two growth-promoting mutations begins to outgrow the original clone. In this way a tumour evolves continuously, with each successive mutation adding a new facet to the repertoire of cellular properties required for a cell to be malignant. This process continues after diagnosis, with treatment resistance also driven by somatic mutation. Evidence for the 'clonal selection ' theory of cancer abounds in the literature. For example, in Barrett's oesophagitis, where normal tissue, premalignant lesions, and cancers often coexist in the distal segment of the oesophagus, genetic analysis of oesophageal biopsies over time reveals multiple competing cell clones evolving simultaneously, each with a different complement of somatic mutations.

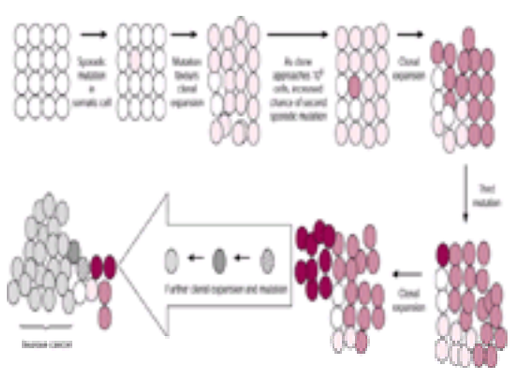

Fig. 2 Sporadic mutations which give a somatic cell a selective growth advantage encourage the outgrowth of mutated clones. Successive clones continue to accumulate growth-favouring mutations and outgrow preceding clones. The process of clonal expansion and mutation eventually results in a clone of cells with a malignant phenotype (invasive cancer). Even after the emergence of a malignant clone, the process of clonal expansion and mutation continues.

Gatekeepers and caretakers

As already pointed out, cancer-inducing mutations are rare events and despite the amplifying effect of clonal selection, the rate of somatic mutation in normal cells may still be insufficient to generate cancer at a high frequency. However, the evolution of cancer is also accelerated by 'genetic instability'. This term implies an increase in the rate of mutation in cancer cells when compared with normal cells, not simply that cancer cells possess a large number of mutations. A detailed mutational analysis of human tumours indicates that there are at least two general categories of genetic instability. In a minority of cancers there is instability at the nucleotide level, with a higher rate of nucleotide substitution, deletion, or insertion than in normal cells. More commonly, instability is observed at the level of the chromosome, with large-scale deletions, duplications, translocations, and amplification of entire chromosomal regions (Fig. 3 and Plate 1).

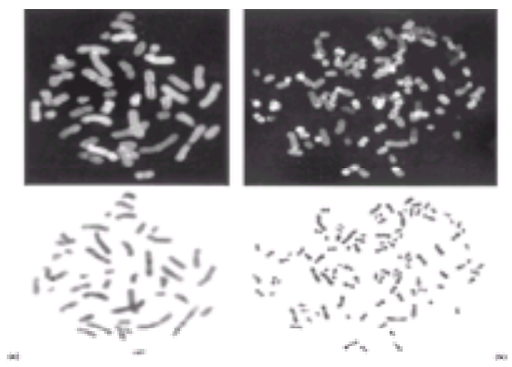

Fig. 3 In a spectral karyotype (SKY), each normal chromosome stains homogeneously with a single distinct colour, making translocations evident by the presence of more than one colour in a single chromosome. (a) Forty five chromosomes are visible in this karyotype (left) from a patient with Turner's syndrome. Despite the loss of the X chromosome, the spectral karyotype (right) clearly shows the homogeneous chromosomal staining pattern typical of normal chromosomes. (b) In contrast, SKY analysis of a metaphase spread prepared from a breast cancer cell line displays both numerical and structural chromosomal aberrations. (By courtesy of Dr Bassem Haddad, Department of Oncology, Georgetown University Medical Center.) (See also Plate 1.)

How does genetic instability arise? The integrity of DNA is protected by two classes of genes referred to as 'caretaker' and 'gatekeeper' genes. Caretaker genes are involved in recognizing and/or participating in the repair of damaged nucleotides or DNA strand breaks. Gatekeeper genes have a cell cycle arrest function that is triggered by DNA damage. Cell cycle arrest is coupled to DNA damage so that caretaker proteins can repair DNA before replication is reinitiated. If gatekeeper functions fail, replication continues through tracts of damaged DNA, generating mutations that are passed on to daughter cells, courting disaster in the form of

cancer-promoting mutations.

Gatekeepers function through 'checkpoint' signal transduction pathways that operate at transition states in the cell cycle, when the cell normally pauses for an analysis of DNA integrity and an integration of internal and external signals that either promote or inhibit progression of the cell cycle. Activation of gatekeeper pathways can prevent the onset of DNA synthesis (G_1 checkpoint) or entry into mitosis (G_2 checkpoint) or prevent completion of chromosomal segregation after chromosomes are aligned on the mitotic spindle (spindle checkpoint). Importantly, gatekeepers can also trigger cell death, so that if genetic damage is so extensive that it cannot be repaired, or the repair process fails in some way, genetically altered cells with the potential to become malignant are deleted. Cancer cells that possess both gatekeeper and caretaker defects can have astonishing rates of genetic instability and often display rapid progression towards a lethal tumour phenotype.

Genetic instability at the nucleotide level

Subtle nucleotide changes are frequently observed in cancer cell genomes and cause 'gain-of-function' or 'loss-of-function' mutations in oncogenes and tumour suppressor genes. The majority of these mutations are probably not due to defects in gatekeeper and caretaker functions, but reflect the impact of environmental carcinogens or the background rate of somatic mutation. Under two circumstances, however, defective DNA repair leads to errors in nucleotide replication at an abnormally high rate. Nucleotide excision repair is responsible for restoring the correct DNA sequence after damage by exogenous mutagens, particularly ultraviolet light. Individuals with inherited nucleotide excision repair defects (xeroderma pigmentosum, see Chapter 6.3) have a marked increase in the incidence of skin cancer. Interestingly, the incidence of internal cancer is not increased to the same degree as in the skin. Furthermore, xeroderma pigmentosum heterozygotes are not at increased risk for cancer. Thus, nucleotide excision repair appears to be relevant to genetic instability only in the rare circumstance of an inherited cancer predisposition syndrome.

In contrast to nucleotide excision repair, mismatch repair defects accelerate the mutation rate in both hereditary and sporadic cancers of the colon, stomach, and endometrium. Conclusions concerning mismatch repair defects originated from the observation that a group of colorectal tumours have frequent alterations in short polynucleotide tracts in their genomes ('microsatellites') and the term 'microsatellite instability' arose to refer to this type of error. The similarity of these changes to mismatch repair defects in bacteria and yeast led to the identifications of six human homologues of bacterial mismatch repair genes (*mutS* and *mutL*) which, when inactivated by mutation, cause human tumours with microsatellite instability. A mismatch repair defect can be detected in about 13 per cent of all colorectal, stomach, and endometrial cancers, and in virtually all tumours arising in individuals with inherited *mutS* and *mutL* defects (hereditary non-polyposis colon cancer). Microsatellite sequences can be found throughout the genome, frequently in non-coding regions. It is noteworthy that some genes with roles in growth suppression have been found to be mutated at microsatellite sequences within their coding sequences (Table 1).

Instability in chromosome number

In contrast to the relative rarity of nucleotide excision repair and mismatch repair defects, another form of genetic instability, characterized by gains and losses of large segments of chromosomes, occurs in most human tumours. True chromosomal instability appears to underlie this observation, since the rate of losses and gains of chromosomal material in cancer cells with aneuploid genomes (more or less DNA than the normal diploid DNA complement) are at least tenfold higher than in cells with a normal chromosomal complement. The 'average' aneuploid cancer cell of the colon, breast, or prostate loses up to 25 per cent of its alleles, with the figure exceeding 50 per cent in some cases. Interestingly, in colon cancer and endometrial cancer, there is an inverse relationship between chromosomal instability and mismatch repair defects, suggesting that the two routes to genetic instability are somewhat mutually exclusive. In both cases, the hallmarks of genetic instability can be detected early in tumorigenesis and increase markedly over time, as each wave of cell clones arises bearing a new set of mutations, with a relentless progression in tumour size, aggression, and the degree of genomic disorganization. The molecular basis of chromosomal instability is heterogeneous, and unlike mismatch repair defects, no unifying mechanism has been proposed. However, defects in several cell cycle checkpoints have been implicated. In one example, an aberrant mitotic spindle checkpoint is proposed in which an abnormal mitosis is tolerated despite the presence of a lagging chromosome, causing an imbalance in chromosomal segregation. Several 'spindle checkpoint' genes have been isolated, and in the case of *hBUB1* or *hBUBR1*, somatic mutations in tumours have been detected. Defects in a second checkpoint, referred to as the 'DNA damage checkpoint', is probably a more frequent cause of chromosomal instability. As discussed earlier, DNA damage checkpoints exist because gross structural alterations in chromosomes will occur if DNA replication occurs in the presence of single or double DNA strand breaks. As with mismatch repair defects and nucleotide excision repair, many of the genes within the 'DNA strand break pathway' have been identified through an association with an inherited predisposition to cancer and are further discussed below. A third, and by no means final, potential mechanism concerns disruption of centrosome function. Centrosomes nucleate the ends of the mitotic microtubule spindle along which the sister chromosomes segregate into two daughter cells. An abnormal number of centrosomes (i.e. more than two) have been observed in a variety of common cancers. When more than two poles form during mitosis, the potential for abnormal chromosomal segregation is high. Recently, overexpression of two centrosome-associated kinase genes, *STK15* and *PLK1*, both homologues of *Drosophila* genes known to regulate centrosome function, have been associated with an increase in centrosome number and defective chromosome segregation in human cancer cells. Despite considerable insights into these complexities, it is fair to state that for the majority of cancers the cause of aneuploidy is unclear. There are a number of pathways that lead to chromosomal instability, and perhaps this is the reason why chromosomal instability is so common in human tumours.

Chromosome translocation

There are two types of chromosomal translocations in human cancers. The first type is common and is without any clear pattern of repetition within tumours of the same histopathological type. The driving force behind this so-called 'complex' type of translocation is probably the same set of gatekeeper and caretaker defects that are a frequent cause of chromosomal instability. A favoured postulate is that these complex translocations reflect cells that enter mitosis before double-strand breaks are repaired, leading to random joining of free DNA ends through non-homologous recombination. The second pattern of translocation is referred to as the 'simple' type. These are common in leukaemia, lymphomas, and in a subset of sarcomas. The breakpoints in these translocations have been analysed and several distinct types of molecular effect have been identified. For example, when an oncogene is repositioned next to transcription regulatory sequences, overexpression occurs. In other cases, translocation generates a fusion gene that combines a coding sequence from the two genes at each end of the break point (Table 2).

Genetic instability is not thought to be the cause of simple translocations. In lymphoid cells, DNA strand breaks are generated as part of the normal recombination process that generates diversity in immunoglobulin genes and the T-cell receptor. The translocations characteristic of lymphoid malignancies are therefore thought to reflect low-frequency aberrations in physiological recombination events. The genesis of simple translocations in sarcoma is more enigmatic, however, as physiological gene rearrangement does not occur in the soft tissues from which sarcomas arise.

Gene amplification

Gene amplification occurs in late stage cancers and almost certainly reflects an aspect of genetic instability, because these aberrations occur at a higher rate in cancer cells than normal cells. Gene amplification is also thought to represent a relatively late step in the evolution of cancer and can lead to massive overexpression of oncogenes. It has been argued that the key defect underlying amplification concerns an inability to trigger a cell suicide or 'apoptosis' signal that usually deletes cells with amplified chromosomal segments. Table 3 lists a series of genes that are commonly amplified in human cancers.

Cell cycle deregulation

The cell cycle is governed by the activities of cyclin/cyclin-dependent protein kinases that oscillate through the cell cycle, orchestrating the complex process of cell division (Fig. 4). The activities of cyclin and cyclin-dependent protein kinase are closely regulated through checkpoint pathways that exist to monitor the integrity and replication status of DNA. Genes encoding proteins that promote cell cycle progression often operate as oncogenes, and are subject to activation in human cancers through gain-of-function mutations or gene amplification. In contrast, genes encoding the components of checkpoint pathways are tumour suppressors that may be inactivated during tumorigenesis. The importance of the restraining influence of cell cycle checkpoints is underscored by the finding that the tumour suppressor genes involved are amongst the most frequently mutated in human cancer.

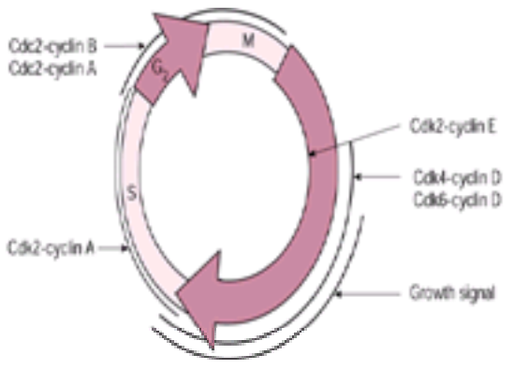

Fig. 4 Following growth stimulation, resting cells (G_0) move into and through the cell cycle. Cycle progression is tightly regulated by the temporal expression of cyclins and cyclin-dependent kinases, which are not expressed in the resting state.

The G_1/S checkpoint

Transition through the G_1/S checkpoint is promoted by the cyclin D family and their partner kinases, cyclin-dependent protein kinase 4 and 6 (Fig. 5). The cyclin D/cyclin-dependent protein kinase complex ('Rb kinase'), after activation by a cyclin-dependent protein kinase-activating kinase (**CAK**), phosphorylates the retinoblastoma tumour suppressor gene product, Rb. An increase in Rb phosphorylation releases a set of transcription factors termed E2F. E2F proteins stimulate the expression of genes required for the S phase, for example the nucleotide biosynthetic genes dihydrofolate reductase and thymidine kinase. E2F also activates the functions of cyclins A and B to promote further cell cycle progression. Finally, E2F activates a negative feedback loop through a gene called *CDKN2A*. The p16*CDKN2A* protein inhibits Rb kinase by interfering with CAK activity and disrupting the cyclin-dependent protein kinase 4/Rb complex. Mutations in these regulatory genes are frequently present in cancer cells, underscoring the importance of this pathway in the regulation of normal cell growth. Gain-of-function mutations may occur in cyclin-dependent protein kinase 4, or cyclin D may be subject to gene amplification, deregulating Rb kinase activity and increasing E2F-dependent transcription. Loss-of-function mutation in *Rb* or *CDKN2A*, both common events in tumorigenesis, also result in deregulated E2F.

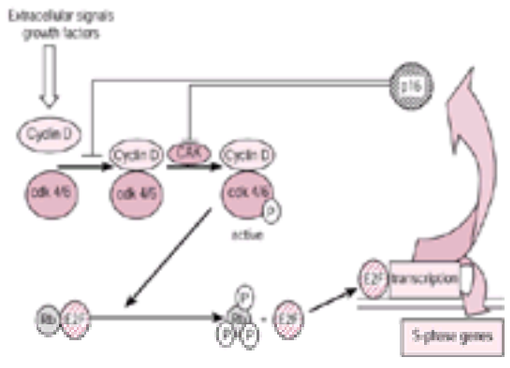

Fig. 5 Growth factor stimulation of cells promotes accumulation of cyclin D and the assembly of cyclin D and cyclin-dependent protein kinase 4 or 6 into complexes. Phosphorylation of the cyclin-dependent protein kinase component by CAK activates the complex, which phosphorylates the Rb protein. Phosphorylated Rb releases a transcription factor of the E2F family. E2F drives transcription of genes required for cell cycle progression as well as the gene *CDK2NA,* from which the inhibitory protein p16*CDKN2A* is translated. In a negative feedback mechanism, p16 disrupts activity of CAK and cyclin D/cyclin-dependent protein kinase complexes, marking the completion of the initial phase of the cell cycle.

The G_1/S checkpoint is also under strict control from a gatekeeper pathway activated by DNA strand breaks. The components of this pathway have recently been put together as a result of research on a series of inherited cancer predisposition syndromes (Fig. 6). Perhaps the most critical component of the DNA strand break pathway is the tumour suppressor gene *p53*. Mutations in *p53* are possibly the most frequent genetic lesion in cancer cells. This, and the critical role of p53 in the DNA damage pathway, has inspired the name 'the guardian of the genome'. In fact, *p53* is a member of a regiment of 'genome guards' that act in concert to protect the integrity of DNA. At the apex of the DNA strand break pathway is the ataxia telangiectasia gene product ATM. ATM is a phosphatidylinositol-3 kinase that is activated by double-strand DNA breaks and orchestrates the function of proteins that repair DNA and arrest the cell cycle. To achieve this, ATM directs the phosphorylation of a series of targets, including p53, CHK2, NBS1, and BRCA1. When p53 is activated through the ATM-dependent kinase CHK2, the expression of p53-regulated genes is greatly increased. It is the spectrum of p53-regulated genes that actually conduct the caretaker and gatekeeper functions associated with p53. For example, p53 activates the expression of ribonuclease reductase, the enzyme responsible for a rate-limiting step in the production of deoxyribonucleotide triphosphates, 'sending' nucleotides to repair DNA. The G_1/S checkpoint function of p53 is mediated by *CDKN1* gene activation. The p21*CDKN1* protein acts in a similar fashion to p16*CDKN2A*, inhibiting Rb kinase and preventing E2F activation. p53 is also instrumental in activating cell death after DNA damage. This is achieved in part by activating the expression of the cell death protein BAX (see below). *p53* mutations are therefore a major contributor to DNA instability since the cell continues to replicates in the presence of DNA strand breaks and fails to undergo cell death after DNA damage.

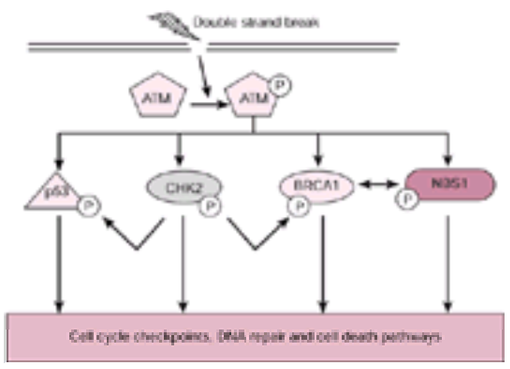

Fig. 6 Double-strand DNA breaks result in the activation of ATM. ATM activates, by phosphorylation, a variety of proteins (including p53, CHK2, BRCA1, and NBS1) whose checkpoint and repair functions prevent propagation of DNA damage. Each of the depicted proteins was identified as a product of a gene mutated in familial cancer syndromes. p53 (Li–Fraumeni syndrome), also activated by the ATM-dependent kinase CHK2 (Li–Fraumeni), increases the expression of genes including p21*CDKN1* and *BAX*. Interaction between BRCA1 (familial breast and ovarian cancer) and NBS1 (Nijmegen breakage syndrome) may co-ordinate DNA repair.

The G_2/M checkpoint

Normal cells arrest in G_2 in the presence of DNA damage. Cells mutant for p53 do not maintain arrest at G_2 and enter mitosis in the presence of DNA strand breaks or other types of chromosomal damage. A major component in sustaining p53-dependent G_2 arrest is the p53-regulated signalling protein 14-3-3s, an inhibitor of the cyclin B/cyclin-dependent protein kinase 2 complex required for the initiation of mitosis. The integrity of these biochemical events is thought to have a major impact on the action of cytotoxic drugs, because agents that disrupt the G_2 checkpoint selectively potentiate the cytotoxic effects of DNA-damaging agents on p53 mutant cancer

cells.

The discovery of oncogenes

A major feature of cancer cells is a loss of dependence on growth factor stimulation as a result of mutations in growth factor signal transduction pathways. Signal transduction genes were the first oncogenes identified, initiating the genetic revolution in cancer research in the late 1970s and early 1980s. In experiments initiated by Peyton Rous, retroviruses were isolated from chicken and rodent tumours that were capable of rapidly inducing cancer in infected animals. DNA sequence analysis of these 'acutely transforming' retroviruses showed that the transforming activity was due to a growth-stimulating 'oncogene' of non-viral origin that had been picked up in a rare recombination event from a host cell. The study of acutely transforming retroviruses led to the identification of a family of oncogenes that when subjected to gain-of-function mutations or overexpression induce aberrant signal transduction, cellular transformation, and tumour formation (Table 4).

Plasma membrane receptors as oncogenes

Ligand-activated, tyrosine kinase-linked plasma membrane receptors (receptor tyrosine kinases, **RTKs**) that operate as oncogenes include erbB2 and epidermal growth factor receptor. Amplification of the genes for these receptors occurs in a wide spectrum of common malignancies, including breast, lung, pancreatic, and head and neck cancer. Receptor overexpression reduces or bypasses the requirement for the presence of a ligand, removing dependence on external growth signals. For example, erbB2 normally signals as a heterodimer in partnership with a second member of the erbB2 family, because erbB2 cannot bind to a ligand directly. When overexpressed, erbB2 is forced into homodimers that are active in the absence of ligand. The RTK oncogenes c-*met* and c-*ret* are involved in a more limited spectrum of tumours, including papillary renal cancer (c-*met*) and medullary thyroid cancer (c-*ret*). In these cases, missense mutations introduce cysteine residues in the extracellular binding domain, resulting in inappropriate disulphide bond formation, dimerization, tyrosine kinase activation, and ligand-independent growth.

Plasma membrane receptors as tumour suppressor genes

The transforming growth factor b (**TGF-b**) pathway provides an example of a plasma membrane receptor that suppresses cell growth (Fig. 7). Transforming growth factor b is a peptide growth factor with complex effects on both tumour cells and on host stromal cells. Responses to TGF-b include inhibition of tumour growth, induction of cell death, extracellular matrix synthesis, and angiogenesis. Transforming growth factor b signals through a heterodimer of two receptors, TGF-b RI and TGF-b RII, both plasma membrane serine–threonine kinases. TGF-b RII binds TGF-b and then dimerizes with and phosphorylates TGF-b RI. TGF-b RI in turn phosphorylates the signal transduction proteins Smad2 and Smad3. Cytoplasmic Smad proteins then migrate to the nucleus to activate gene expression in concert with a third Smad protein, Smad4. One of the genes activated is p27*kip1*, a cyclin-dependent kinase inhibitor in the same family as p21 *CDKN1* and p16*CDKN2A* with roles in both cell cycle arrest and the induction of programmed cell death. Loss-of-function mutations, characteristic of tumour suppressor genes, occur in the TGF-b/Smad pathway. TGF-b RII is inactivated in 20 per cent of colorectal cancers with mismatch repair defects because of a vulnerable poly(A) microsatellite in the TGF-b RII coding sequence (Table 1). In addition, Smad4 is inactivated in up to 50 per cent of pancreatic cancers.

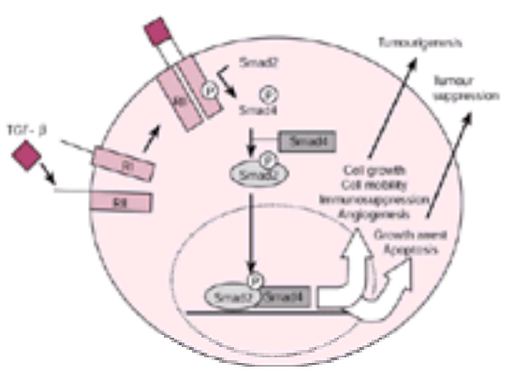

Fig. 7 On TGF-b binding to TGF-b RII, this receptor dimerizes with and phosphorylates TGF-b RI. Activated TGF-b RI phosphorylates the cytoplasmic proteins Smad2 and Smad 3 (not shown), which in turn interact with Smad4. The Smad complex migrates to the cell nucleus where, in concert with various transcription factors, it drives transcription of genes involved in both tumorigenesis and tumour suppression.

Cytoplasmic signal transduction components as oncogenes (*ras*)

When an RTK is activated by dimerization, the cytoplasmic portion of the receptor becomes autophosporylated and a variety of intracellular docking proteins are recruited to the cell membrane. These docking proteins create a scaffold in the inner surface of the plasma membrane around which signalling components congregate further downstream. Critical amongst these components is the 'Ras' family of proteins (K-, N-, and H-Ras). *ras* genes are frequently mutated in human cancer and at least partially bypass the need for RTK signalling in cell growth. Ras proteins operate a GTP-dependent switching mechanism that alternates between a GTP-bound active form and a GDP-bound inactive form. When an RTK is activated, docking proteins, together with a protein called SOS, stimulate the release of GDP from Ras, replacing it with GTP. Activated, GTP-bound Ras then signals to a host of downstream targets to stimulate multiple cellular changes, including activation of DNA synthesis, and changes in lipid metabolism, cellular morphology, cell adhesion, and gene expression (Fig. 8). The system is switched off by GTPase-activating proteins that stimulate the hydrolysis of Ras-bound GTP to GDP. Mutations in *ras* genes cause the protein to be held in the GTP-activated form, generating a continuous unregulated signal. K-*ras* and N-*ras* mutations are found in common solid tumours including lung, brain, colon cancer, and nearly 95 per cent of pancreatic cancers and 30 per cent of acute leukaemias. H-*ras* mutations are found only in a small subset of bladder and head and neck tumours.

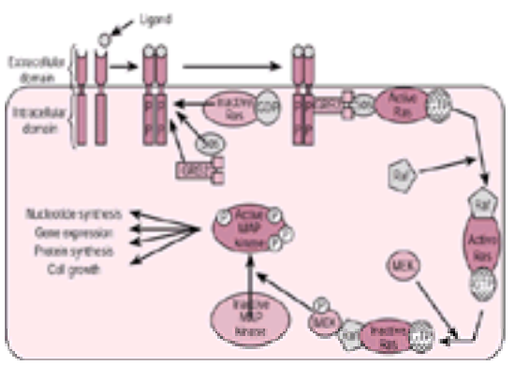

Fig. 8 Dimerization and activation of most cell surface receptor tyrosine kinases (RTKs) is dependent on ligand binding. The ligand-activated receptor autophosphorylates specific tyrosine residues in the cytosolic domain. These phosphotyrosine residues act as binding sites for a variety of proteins. GRB2 binds to both activated RTK and a protein called SOS. SOS facilitates the exchange of GDP for GTP, converting inactive Ras/GDP to active Ras/GTP. Active Ras binds to Raf (a serine/threonine kinase), and this complex binds to and phosphorylates the kinase MEK. MEK phosphorylates MAP kinase; MAP kinase subsequently activates proteins important for cell growth.

Cytoplasmic signal transduction components as tumour suppressor genes

Neurofibromatosis is caused by germline mutation of the tumour suppressor neurofibromin (**NF1**), a GTPase-activating protein. Loss of NF1 increases Ras activity; however, NF1 is not commonly targeted for mutation in common solid malignancies. The oncogenic consequences of NF1 inactivation are tissue specific since patients with type 1 neurofibromatosis do not have a marked increase in the incidence of common solid malignancies. The adenomatous polyposis coli (**APC**) gene

product is a stronger example of a cytoplasmic tumour suppressor gene that operates to downregulate a growth regulatory pathway (Fig. 9). The *APC* gene is mutated in most human colon cancers and germline mutations are associated with familial colon polyps and cancer. APC normally regulates the signal transduction protein b-catenin by targeted degradation, so that in an APC mutant cell, b-catenin accumulates abnormally. b-catenin is an essential component of a signal transduction pathway that connects cell adhesion and the extracellular matrix to the cell nucleus. b-catenin operates by activating the TCF/LEF family of transcription factors, leading to gene transcription and cell cycle progression. For example, in APC mutant cells, overexpression of cyclin D1 occurs because of deregulated b-catenin /LEF activity. b-catenin is also subject to somatic mutation, particularly in colon cancers without germline APC mutations, as well as melanoma, prostate cancers, gastric cancer, hepatocellular carcinoma, and medulloblastoma. Mutations in the b-catenin gene tend to stabilize the b-catenin protein, increasing TCF/LEF activity and cyclin D expression.

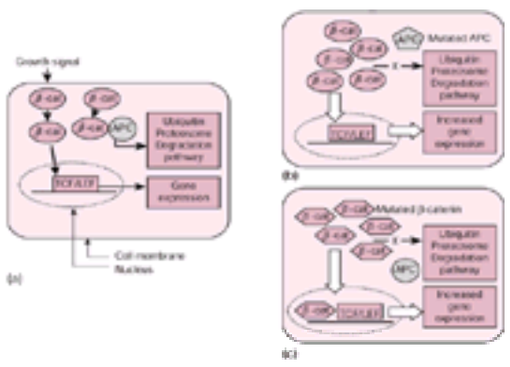

Fig. 9 (a) In the presence of a growth signal, cytoskeleton-associated b-catenin migrates from the inner plasma membrane to the nucleus, where it increases the activity of TCF/LEF transcription factors. APC binds b-catenin and targets it for degradation by the ubiquitin pathway. (b) Certain APC mutations disrupt interaction between APC and b-catenin. This prevents ubiquitin targeting, so that b-catenin accumulates and migrates to the nucleus, where the increased levels drive excessive transcription of TCF/LEF-regulated genes. (c) In a similar manner, certain b-catenin mutations disrupt interaction with functional APC, with the same consequences.

Transcription factors as oncogenes and tumour suppressor genes

Transcription factors regulate the rate of transcription by binding to specific DNA motifs in non-coding sequences, thereby recruiting a multicomponent protein complex that promotes (or represses) the activity of RNA polymerase. A broad spectrum of mutations activates the oncogenic potential, or disrupts the tumour suppressor functions, of transcription factor genes. In examples discussed already, point mutations inactivate or alter the functions of the transcription factors p53, b-catenin, and Smad4. In other instances, transcription factor genes are subject to activation through gene amplification, including c- *myc*, a gene required for cell cycle progression and cyclin expression, and amplified in breast cancer-1 (*AIB1*), a gene encoding a protein that boosts the transcriptional activity of steroid receptors.

Perhaps the most remarkable examples of aberrant transcription factors in cancer result from translocations that create transcription factor gene fusions (Table 2). For example, in promyelocytic leukaemia, the retinoic acid receptor a gene (*RARa*) on chromosome 15 is involved in a translocation with a gene on chromosome 17 termed *PML*. The resulting fusion transcription factor, RARa/PML, demonstrates aberrant localization within the cell nucleus where it acts as a 'decoy', binding normal retinoic acid receptor family members and inhibiting their role in myeloid differentiation. High doses of retinoic acid induce remission of PML by inducing the degradation of the RARa/PML fusion protein, thereby releasing normal retinoic acid receptors to activate the terminal differentiation of leukaemic cells. Ewing's sarcoma family of tumours provides further examples of transcription factor gene fusion, in this instance between the *EWS* gene and the ETS family of transcription factors, either FLI1 or ERG (95 per cent and 5 per cent of Ewing's tumours respectively). In these cases, the fusion ETS transcription factor becomes hyperactive because of the anomalous presence of *EWS* gene sequences. In a further example of transcription factor overactivity, the c- *myc* gene becomes overexpressed in Burkitt's lymphoma as a result of an 8®14 translocation that places the c- *myc* gene under the influence of immunoglobulin gene sequences.

Mutations in cell death pathways (Fig. 10)

Programmed cell death or apoptosis is an essential aspect of the ability of a multicellular organism to develop and survive (see Chapter 4.6). For example, during embryogenesis the targeted removal of cells in tissue remodelling is achieved through cell death programmes, generating digits and body cavities. In the immune system, apoptosis deletes lymphocytes that recognize 'self-antigens', thereby preventing the growth of B- and T-cell clones capable of autoimmune damage. Apoptosis is also essential for the deletion of cells with DNA damage, chromosomal aberrations, and abnormalities of mitotic spindle formation. These events stimulate the release of cytochrome C from mitochondria. Cytoplasmic cytochrome C activates a cascade of 'caspase' proteases that effect DNA fragmentation, plasma membrane destruction, and the characteristic morphological features of apoptosis (see *section 4.6*). Receptor tyrosine kinases play a critical role in cell survival by activating the signal transduction enzyme phosphatidylinositol-3-kinase. Phosphatidylinositol-3-kinase in turn activates a serine threonine kinase, AKT (an oncogene, discovered through the study of acutely transforming retroviruses). AKT promotes survival by phosphorylating and inactivating BAD, a protein that promotes mitochondrial release of cytochrome C. Excess phosphatidylinositol-3-kinase activity and aberrant survival are also consequences of loss-of-function mutations in a tumour suppressor termed PTEN (phosphatase tensin homologue deleted in chromosome 10). The *PTEN* gene encodes a protein phosphatase mutated in a wide spectrum of cancers, including breast, thyroid, lung, and a small proportion of lymphomas. When PTEN is lost through somatic mutation, AKT becomes constitutively active, holding the cell death-promoting protein BAD in an inactive conformation. The activity of BAD is also tightly controlled through the BCL2 family of BAD dimerization partners. BAD and BCL2 are members of a family of at least 15 proteins that promote or suppress cell death. BCL2 itself is an oncogene activated by a translocation that increases expression in indolent lymphoma. BCL2 is a very potent cell survival factor that binds to BAD (and other proapoptotic partners, BAX, BID, and $BCLX_L$) to prevent cytochrome C release, and when overexpressed BCL2 potently inhibits cell death. The tumour suppressor gene *p53* is also a key regulator of apoptosis. When *p53* is activated, the transcription of the proapoptotic gene *BAX* is increased, also promoting mitochondrial cytochrome C release after DNA damage.

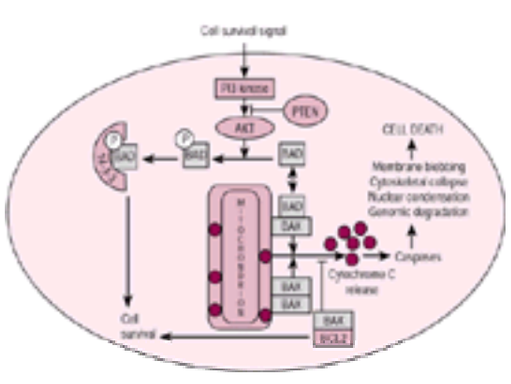

Fig. 10 Apoptosis is triggered by cytochrome C release from the mitchondrion which activates caspase proteases that destroy the cell. Cytochrome C release is therefore a tightly regulated process that is under the control of several signal transduction pathways that operate through the BCL2 family of cell death regulators.

Genetic programmes serving tissue invasion

Tissue invasion is a complex process that, like all other aspects of the malignant phenotype, is driven by a complex array of genetic lesions. Like many of the pathways described thus far, the molecular details of the cancer invasion pathway are incompletely resolved. Since non-invasive tumours are essentially benign, how tumour cells acquire an invasive phenotype is at the core of understanding what makes a tumour benign or malignant. Invasion requires tissue degradation and

several classes of enzyme have been identified that are expressed by invasive tumours, including metalloproteinases and collagenases. Inhibitors of these enzymes are currently in clinical trial as antimetastasis or anti-invasion agents.

Another important aspect of invasion is increased cell motility, required for a malignant cell to migrate away from its site of origin. Excess growth factor signalling, typical of cancer cells, promotes motility, and specific motility genes, for example the *C-MET* 'scatter factor' receptor, are subject to activation through somatic mutation. Building on the concept of cell cycle checkpoints, a checkpoint for invasion has recently been proposed based on a receptor–ligand pair termed amphoterin/RAGE (receptor for advanced glycation end products). Amphoterin assists in the generation of the protein-degrading protein plasmin, which then activates metalloproteinases. RAGE is the receptor for amphoterin, which promotes, through MAP kinase, motility, 'adhesion' receptors, and growth pathways. While genetic lesions in this pathway have yet to be described, the outline of a motility and invasion pathway is emerging. As part of this developing concept, 'invasion suppressor genes' are being identified. Mutations in the E-cadherin gene have been described in breast, colon, and gastric cancers and are associated with changes in cell morphology, increased motility, and activation of the b-catenin/LEF transcriptional pathway discussed in the context of the *APC* tumour suppressor gene.

Genetic programmes serving angiogenesis

Angiogenesis is also a critical aspect of the cancer phenotype. Due to the limitations of tissue diffusion, a tumour cannot increase beyond 1 mm in size without a blood supply. Exactly how a tumour manipulates the process of angiogenesis is beginning to be understood, and once again mutations in regulatory genes are at the root of the issue. Normal cells respond to hypoxia by increasing the expression of a set of hypoxia-inducible genes, of which that for vascular endothelial growth factor (**VEGF**) is a prime example. VEGF profoundly stimulates the growth of the endothelial cells that line blood vessel walls. The transcription factors concerned, hypoxia-inducible factors 1a and 2a (**HIF1a** and **HIF2a**), are tightly regulated by oxygen tension. Unlike normal cells, tumour cells may show HIF activity even when oxygen tension is adequate, i.e. the connection between hypoxia and HIF activity is severed. In tumours that arise in the cancer predisposition syndrome von Hippel–Lindau syndrome, as well as in sporadic renal cell carcinoma, uncoupling of hypoxia-inducible gene expression from hypoxia is due to loss-of-function mutations in the von Hippel–Lindau gene, *VHL*. The VHL protein normally targets HIF1a and HIF2a for degradation. When VHL activity is lost, excess HIF1a and HIF2a activity drives increased VEGF expression and excessive blood vessel formation. Of course, aberrant angiogenesis also occurs in tumours in which VHL is not mutated. VEGF is only one of many angiogenic factors. For example, fibroblast growth factors are also angiogenic, and the fibroblast growth factor-3 gene is subject to gene amplification in breast cancer, squamous cell carcinoma of the head and neck, and nasopharyngeal cancer.

Human cancers caused by infection

Up to 20 per cent of cancers worldwide may be due to viral infection. The discovery of infectious agents that induce cancer has proved invaluable for the identification of genes implicated in tumorigenesis. The insights gained from the study of acutely transforming retroviruses (RNA tumour viruses) were discussed earlier. As the name implies, these viruses are capable of causing tumours in the affected species within a few weeks to months of infection. As far as we know, such viruses are not a cause of human cancer. However, endemic retroviruses are strongly implicated in several malignant diseases of humans. Unlike the acutely transforming retroviruses, endemic retroviruses do not contain host (human) gene sequences and are associated with cancer only after a long latency period of years to decades. The most prominent example is the HTLV-I virus, associated with endemic T-cell leukaemia in Caribbean and Japanese populations. An HTLV-I viral protein essential for T-cell transformation, Tax, activates the transcription factor NF_B.

The immune system normally provides a considerable measure of protection from a class of viruses termed 'DNA tumour viruses'. By weakening this immune surveillance, the human immunodeficiency virus (**HIV**) is responsible for a significant cancer burden. Three DNA tumour viruses are prominently responsible for HIV-associated malignancies: Epstein–Barr virus (**EBV**), human herpesvirus 8 (**HHV-8**), and human papilloma virus (**HPV**). These viruses can also cause disease in individuals with apparently normal immune systems.

It has long been appreciated that EBV is capable of immortalizing B cells, thereby stimulating polyclonal populations of B cells in which secondary transforming events occur. In HIV-infected patients, lack of a T-cell-dependent antiviral response allows proliferation of EBV-infected polyclonal B-cell populations, from which highly aggressive lymphomas evolve. Through a similar mechanism, EBV is a cofactor in endemic childhood Burkitt's lymphoma in Africa. In this case, poor nutrition and malarial infection deplete the immune system, allowing an EBV-expanded population of lymphocytes to proliferate. Eventually a c- *myc*/immunoglobulin gene translocation generates an aggressive, poorly differentiated Burkitt's-type lymphoma. Finally, EBV is implicated in the pathogenesis of nasopharyngeal cancer, an endemic malignancy of the nasal sinus epithelium in southern China. The genome of EBV encodes up to 100 potential genes and several have oncogene-like properties, including BHRF1, a BCL2-like protein. While the exact role of all EBV-encoded proteins in transformation has yet to be elucidated, viral gene products are likely to initiate the malignant process, even if EBV genes may not be required for the continued growth of the malignancies that ultimately arise.

Like EBV, HHV-8 is a herpesvirus that is associated with malignancy, including Kaposi's sarcoma, primary effusion lymphomas, multiple myeloma, angioimmunoblastic lymphadenopathy, and Castleman's disease. Kaposi's sarcoma is an indolent sarcoma affecting the skin (and more rarely internal organs). At least 95 per cent of Kaposi's sarcoma lesions can be shown to contain the HHV-8 virus. While first recognized in eastern European males at the beginning of the twentieth century, Kaposi's sarcoma became a common problem only after the onset of the HIV epidemic. Sequencing of the HHV-8 genome reveals several genes that may be associated with malignant transformation, including a cyclin-like gene that inhibits the function of Rb, and a BCL2-like protein that inhibits apoptosis. Therefore, like EBV, HHV-8 may initiate Kaposi's sarcoma and other malignancies by encoding proteins that mimic several steps in the multistep carcinogenesis process.

HIV-infected individuals are also prone to develop squamous carcinoma of the anus and, in women, cervical cancer. Both diseases are caused by infection with HPV. Cervical cancer is an endemic disease that does not require an immunodeficient state for the virus to be pathogenic. The viral genome of HPV has been extensively examined, and two viral genes in particular have been implicated in HPV-induced cellular transformation, *E6* and *E7*. The E6 protein interferes with the function of p53 by targeting the protein for degradation. The E7 protein binds to and interferes with Rb. Thus, HPV mimics two of the most common loss-of-function mutations in human malignancy.

Another example of a strong link between malignancy and viral infection is the hepatitis B virus. In several parts of the world, including parts of China, hepatocellular carcinoma is the most common malignancy and reflects the very high incidence of hepatitis B infection in these areas. Portions of the hepatitis B virus can be found integrated into the genome of hepatocellular carcinomas. These hepatitis B virus 'X gene' fragments may be critical to carcinogenesis by providing viral promoter sequences that activate neighbouring oncogenes.

Epigenetic gene silencing in cancer

Epigenetic gene silencing is another non-mutational pathway for inactivation of tumour suppressor genes that has recently come into focus. In a number of instances, expression of tumour suppressor genes is lost in cancer cells, even though genetic analysis had shown that the sequence of the gene is intact. Tumour suppressor genes subject to gene silencing in cancer cells include *VHL*, *hMLH1* (a mismatch repair gene) *CDKN2A*, and *E-cadherin*. The mechanism for gene silencing involves methylation of cytosine residues in CpG dinucleotide sequences found within gene regulatory sequences. Methylation is believed to hold the gene in a closed conformation that cannot be accessed by RNA polymerase. How epigenetic gene inactivation is faithfully passed on to daughter cells during cellular replication is not clear. The mechanism may represent an aberration of the process that suppresses the expression of genes on the inactive X chromosome in females.

In addition to epigenetic gene silencing, there is also evidence for epigenetic oncogene activation due to loss of methylation. A good example is the gene for insulin-like growth factor 2 (**IGF2**). IGF2 is a potent growth factor that signals both cell growth and survival. Normally in adult tissues only the paternal IGF2 allele is expressed. The maternal allele is silenced through methylation, in an embryonic process termed 'imprinting'. In paediatric tumours (Wilm's tumour, rhabdomyosarcoma, and hepatoblastoma) the imprinting pattern is lost, with the occurrence of biallelic IGF2 expression and excess IGF2 activity in these malignancies. In these instances, loss of imprinting has been found to be due to mutation in the *H19* locus that is usually targeted for imprinting on chromosome 11p15, the vicinity of the *IGF2* gene.

Cancer therapy in the twenty-first century

The completion of the human genome project represents an enormous opportunity in medicine. Cancer therapy is likely to be an early beneficiary from this triumph because detailed information on the genetic nature of cancer will be translated into new, less toxic, and more effective cancer treatments. The recent development of a gene-targeted treatment for chronic myeloid leukaemia illustrates this potential well. Chronic myeloid leukaemia is characterized by excess proliferation of cells from the myeloid lineage. The hallmark of this disease is a reciprocal translocation between chromosomes 9 and 22 creating the so-called 'Philadelphia chromosome'. The

molecular consequence of this translocation is to fuse the c-*abl* gene, a nuclear tyrosine kinase, with the *BCR* gene. The fusion BCR–ABL gene product has enhanced tyrosine kinase activity. Having identified the enzyme target that drives chronic myeloid leukaemia, selective ABL tyrosine kinase inhibitors were developed that were able to cure up to 90 per cent of mice with human chronic myeloid leukaemia cells in their bone marrow and circulation. In early clinical trials with chronic myeloid leukaemia patients, the ABL tyrosine kinase inhibitor was highly effective, and certainly less toxic than the alternatives that include chronic treatment with interferon or allogeneic bone marrow transplant.

Like gene translocation, gene amplification also provides an opportunity for gene-targeted therapy. For example, a humanized antibody against the *erbB2* oncogene produces a 40 per cent response rate in breast tumours with *erbB2* gene amplification. Exposure to the erbB2 antibody downregulates erbB2 tyrosine kinase activity by internalization of the receptor/antibody complex. These early successes have spurred the development of new inhibitors of essentially the entire spectrum of signal transduction enzymes discussed in this chapter. Promising gene-specific therapeutic approaches are summarized in Table 5.

6.3 The genetics of inherited cancers

Andrew Coop and Matthew J. Ellis

Introduction

The description of families with multiple members afflicted by cancer provided an early and persuasive argument that the aetiology of cancer has a genetic component. This conclusion is now beyond doubt, since germline mutations responsible for inherited cancer syndromes have been identified, and a role for the encoded proteins in malignant transformation established. While the development of essentially every cancer is influenced by the genetic complement of the patient, only in these inherited cancer syndromes is the effect of a single gene mutation powerful enough to generate a mendelian pattern of cancer predisposition. The study of these diseases, despite their rarity, has provided critical insights into the genesis of more common forms of cancer because the same genes are frequently affected. In the case of sporadic cancer, however, mutations are not present in the germline but arise entirely through the process of somatic mutation and selection, whereby mutations that enhance cellular survival or proliferation accumulate in tissues over prolonged periods. DNA-based diagnostic tests are now available for gene abnormalities underlying inherited cancer predisposition syndromes. A positive test may mandate intensive cancer screening and, in carefully selected cases, surgery to remove organs at risk. Researchers are also examining the use of medications designed to prevent cancer (chemoprevention), allowing cancer-prone individuals to 'escape' their genotype. This chapter is intended to provide insights that will facilitate the recognition of cancer predisposition syndromes, help in understanding the clinical implications of the diagnosis, and render further study comprehensible. For a completely exhaustive list of familial cancer syndromes the reader is referred to the section on further reading at the end of the chapter.

The identification of cancer predisposition genes

Hereditary retinoblastoma: a classical example of a cancer predisposition syndrome

The first cancer predisposition genes were identified through the careful analysis of rare but remarkable syndromes. Hereditary retinoblastoma provides a classical example. A cancer of retinal cells, retinoblastoma usually occurs before the age of 3 years. One in 13 500 to one in 25 000 children are affected, with an equal sex distribution. About 40 per cent of patients have a family history of the disease, with an autosomal dominant pattern of inheritance. Eighty-five per cent of retinoblastomas presenting at less than 6 months of age affect both eyes and are likely to be the inherited form. The proportion of bilateral cases declines to 6 per cent by 24 months, when most cases are of the sporadic type, with no risk of genetic transmission. Overall only 10 per cent of patients with single tumours transmit susceptibility to the next generation. Individuals with hereditary retinoblastoma are at an incresed risk of developing a variety of cancers (especially osteosarcoma). Retinoblastoma illustrates the cardinal clinical features of inherited cancer predisposition syndromes: early onset, bilateral or multifocal cancer, and an association with similarly affected close relatives (see Table 1).

In a series of now classical studies, Knudson carefully examined family histories and tumour characteristics from patients with retinoblastoma and generated a 'two-hit' model to explain his statistical observations (Fig. 1). He hypothesized that the gene for retinoblastoma, *Rb*, is a tumour suppressor gene, whose function must be lost for a retinoblastoma to develop. In familial cases, he postulated that affected individuals had inherited an inactive mutant *Rb* allele. In these individuals every cell in the retina, indeed every cell in the body, carries an inactive copy of the *Rb* gene. As a result, a single second somatic mutation, or 'hit', in the remaining *Rb* allele is sufficient to inactivate *Rb* function and initiate a tumour. The barrier to the development of retinoblastoma in the absence of an inherited *Rb* mutant allele is much higher, as the coincidence of two somatic mutations (two hits) in a single cell to inactivate both *Rb* alleles is considerably less likely. This explains the low incidence, later onset, and absence of multiple tumours in non-familial retinoblastoma. The experimental verification of Knudson's model arose from studies that identified a region of chromosome 13 that was consistently lost in both inherited and non-inherited retinoblastoma. By examining multiple cases, investigators were able to identify the common region of loss on chromosome 13q14, and ultimately the gene concerned. True to Knudson's model, germline loss-of-function *Rb* mutations were present in familial cases, and the loss of chromosome 13 in familial tumours always eliminated the remaining wild type allele. Furthermore, sporadic adult onset cancers, for example of the lung, breast, and bladder, also have *Rb* mutant alleles, acquired as somatic mutations. This testifies to the importance of *Rb* in the formation of not just a rare childhood tumour, but common tumours as well. The final proof that *Rb* is a tumour suppressor gene came from studies that showed that malignant tumour formation can be suppressed when *Rb* function is returned to *Rb*-null cancer cells in gene transfer (transfection) experiments. These seminal studies on inherited retinoblastoma defined key experimental approaches and concepts that were subsequently used to identify other cancer predisposition genes.

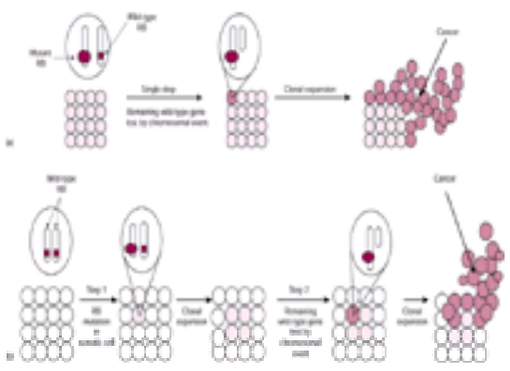

Fig. 1 Knudson's hypothesis. (a) In individuals with an inherited predisposition to retinoblastoma every somatic cell contains one intact *Rb* allele and one mutant *Rb* allele. A single somatic mutation is therefore sufficient for loss of *Rb* activity, with subsequent clonal expansion of the double mutant cell and tumour formation. (b) In normal individuals both copies of *Rb* must be targeted by somatic mutation for *Rb* function to be disrupted. Since the somatic mutation rate is low the risk of two *Rb* mutations occurring in the same cell is low. This explains the later onset and unifocal nature of retinoblastoma cases that occur in the absence of a family history.

Familial clustering of common cancers

Retinoblastoma is striking because cancer is a rare event in childhood, but up to 5 to 10 per cent of adults with cancers at commonly affected sites, such as breast and colon, have a family history of similar cancers. How many of these instances of 'familial clustering' are due to germline mutations in tumour suppressor genes?

Careful analysis of many of these family trees suggests that cancer predisposition is inherited in an autosomal dominant fashion. However, locating the genes associated with familial clustering is a daunting prospect. The presence of a family history of cancer alone is not particularly reliable evidence for an inherited cancer predisposition gene because many cases of familial clustering may be due to common exposure to environmental risk factors (smoking or poor diet for example). Other issues that frustrate the geneticist include small family size, incomplete knowledge of a relative's medical problems, or, in the case of breast and ovarian cancer, lack of female relatives in which the phenotype can be expressed. Geneticists also define the twin problems of 'incomplete penetrance' and 'phenocopy' as particularly awkward because they mask a mendelian inheritance pattern (Fig. 2). Incomplete penetrance refers to the situation where an individual has inherited a mutated tumour suppressor gene but does not develop cancer. By masking the presence of a mutant allele, incomplete penetrance generates confusing phenomena such as 'generation skipping'. The phenocopy problem arises because 'common cancers occur commonly'. A sporadic tumour can occur in an individual in a family with cancer predisposition who did not inherit the predisposing mutation. These false negative and false positive situations led to the development of statistical tools to predict the likelihood of mutations in tumour suppressor genes in any particular family. These models are now frequently used to help decide who should undergo expensive genetic testing. An example of one approach for breast cancer is provided in Table 2. A history of early onset or bilateral disease is used to weight these analyses, as these features substantially increase the likelihood that a cancer predisposition gene is present. Ethnic background is also taken into account. For example, certain mutations in the breast cancer genes *BRCA1* and *BRCA2* are more common in individuals with Jewish ancestry. These statistical approaches are critical because, unlike retinoblastoma, there were initially no cytogenetic clues from tumour analysis to help identify the chromosomes that contained the genes responsible for familial clusters of common tumours. Tumour chromosomes from common solid malignancies often show multiple gains and losses of chromosomal material, and no obvious single change associated with cases that arose in families with multiple affected members can be identified.

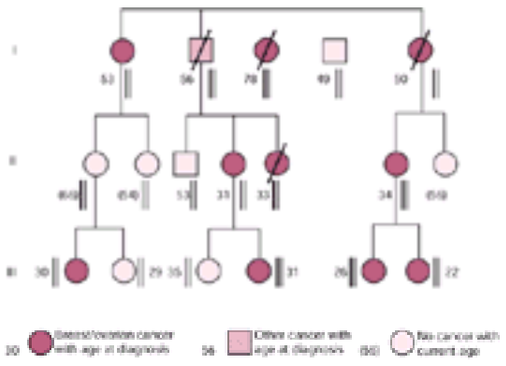

Fig. 2 Incomplete penetrance and phenocopies obscure mendelian inheritance patterns for cancer predisposition genes. In this hypothetical family, cancer predisposition is due to a mutant *BRCA1* allele on chromosome 17 (represented by the thick black line). Molecular analysis identified a 66-year-old woman in generation II who carries a mutant *BRCA1* allele but has not yet developed cancer. None the less she did transmit a mutant allele to one of her daughters who developed breast cancer at the age of 30. This is an example of incomplete penetrance that caused hereditary breast cancer to 'skip' a generation. In generation I, a 78-year-old woman developed breast cancer, but did not carry the mutant *BRCA1* allele. In this instance breast cancer was of the sporadic type, typically occurring in an older patient population. This case is referred to as a 'phenocopy' that mimicked the consequences of inheriting a disease allele.

Inherited cancer predisposition syndromes

These classical syndromes can be distinguished from the problem of familial clustering of common cancers because the frequent occurrence of cancer is not the only feature of these unusual but instructive diseases. A diagnosis of one of these syndromes should be considered when cancer arises in organs not commonly affected by sporadic cancer or when tumours have unusual 'premalignant' manifestations or other disease characteristics that suggest the presence of a disorder of tissue regulation or formation. An example that illustrates these concepts is neurofibromatosis type 1. In excess of 90 per cent of the individuals who inherit a mutated neurofibromatosis type 1 gene (*NF1*) develop *café au lait* spots and skin neurofibromas. Other clinical manifestations may also be present, but with much lower frequency, for example learning difficulties, skeletal abnormalities, and more deforming 'plexiform' neurofibromas. Cancer is actually fairly uncommon and occurs in less than 5 per cent of cases. Tumours arise at unusual sites, including the adrenal medulla (phaeochromocytoma), the central nervpus system (optic nerve gliomas, ependymomas, and meningiomas), and also within neurofibromas (neurofibrosarcomas). The reason for the extreme variability in the clinical features of neurofibromatosis is unclear. The effects of other genes (modifier genes) segregating within an affected family probably enhance or suppress the consequences of an *NF1* mutation. In addition, *NF1* mutations are diverse and lead to highly variable losses of coding sequence. Future studies may therefore define a relationship between the site of the mutation in the *NF1* gene and the clinical severity of the syndrome.

Linkage analysis

An effective, although labour intensive, approach to identifying genes that cause cancer predisposition is called DNA linkage analysis. Scattered throughout the human genome are sequence polymorphisms that are frequently heterozygous. Examples of these markers are single-nucleotide polymorphisms ('snips') or repetitive sequences (microsatellites) that can be identified through DNA sequencing or restriction fragment length polymorphisms. To identify the chromosomal location of a cancer predisposition gene these polymorphic markers are used in a genome-wide search to find a marker that cosegregates, or is 'linked' to the diagnosis of cancer because it is on the same chromosome. Once the chromosome carrying the cancer predisposition gene is identified, the segregation of further markers along the chromosome in question is determined. Because DNA is exchanged between chromosomes (recombination), the statistical association between a marker and the presence of cancer increases the closer the marker in question is to the disease locus. Eventually a marker is identified that is considered (statistically) close enough for the investigator to clone the segment of DNA that encompasses the marker and look for 'candidate genes'. Ultimately the gene is identified by sequencing each gene candidate to identify mutations that are present in individuals that have developed cancer but are not present in unaffected family members. Tumour DNA is examined for evidence for loss-of-function somatic mutations in the remaining wild type allele to confirm Knudson's postulate. The number of families necessary for linkage analysis depends of the nature of the disorder. For the breast and ovarian cancer genes *BRCA1* and *BRCA2*, a large number of families were required to generate sufficient linkage information because of the family history problems discussed above. For inherited cancer syndromes with characteristic clinical features and high penetrance, fewer families are required because affected and unaffected individuals within a family can be more reliably identified (which is just as well considering how rare these diseases are).

A classification of inherited cancer syndromes based on gene function

Textbook descriptions have classified cancer predisposition syndromes by mode of inheritance (dominant or recessive), by site of organ involvement (for example breast and ovarian cancer syndromes or colon cancer syndromes), or by the presence of associated clinical features (for example gastrointestinal polyps or neurofibromas). However, there is now sufficient insight into the function of genes associated with cancer predisposition to use a mechanistically based, rather than clinical, classification. This functional approach has the advantage of illustrating the relationship between gene function and the clinical manifestations of these disorders. The conversion of a normal cell to a cancer cell requires multiple mutations in genes that control the fundamental cellular processes of proliferation, cell death, and differentiation. An inherited mutation can therefore contribute to the process of malignant transformation by disrupting signal transduction, regulation of the cell cycle, chromosome stability, or DNA repair. All known cancer predisposing mutations, in which the function of the encoded protein has been established, involve one, or more than one, of these four cellular processes.

Cancer predisposition syndromes associated with mutations in signal transduction proteins (Table 3)

Signal transduction is the key to normal tissue homeostasis, and mutations in genes that encode components of these pathways are extremely common in cancer cells. Many cancer predisposition syndromes could really be considered inherited 'signal transduction disorders' because germline mutations in signal transduction proteins generate not only malignant tumours but also benign growths and unusual syndrome stigmata that represent the effects of abnormal signal transduction on the formation of normal tissue. Furthermore, tumours induced by mutant signal transduction proteins tend to arise in an organ-restricted manner, presumably reflecting the tissue-specific roles of the signalling pathways concerned. Examples of signalling proteins disrupted in these diseases include plasma membrane tyrosine kinases, cytoplasmic protein kinases, protein phosphatases, GTPase activating proteins, and transcription factors. All the conditions discussed in this section are autosomal dominant, but with variable penetrance, except ataxia telangiectasia, which is autosomal recessive.

Mutations in peptide growth factor receptors

Cell growth is regulated by peptide growth factors that bind and activate plasma membrane receptors. These receptors are enzymes that activate downstream cytoplasmic signal transduction proteins to alter gene expression and regulate the cell cycle. Four syndromes have been identified that are associated with activating mutations in either the RET or MET growth factor receptors, i.e. the mutation activates the receptor in the absence of the cognate peptide ligand (constitutive activation). These syndromes represent a major exception to Knudson's model, because the mutations concerned are 'gain-of-function'. As a result, there are no second mutational events in the remaining wild type allele. A fifth syndrome involves the *PTCH* gene that encodes a transmembrane receptor involved in body patterning. In this case the gene does conform to Knudson's postulate with respect to a 'second hit' and the germline and somatic mutations are all 'loss-of-function' in nature.

Multiple endocrine neoplasia types 2A and 2B and familial medullary thyroid cancer

Three disorders are due to activating mutations in the RET tyrosine kinase-linked cell surface receptor encoded by the *RET* gene at 10q11.2. RET is a neurotrophic pepide receptor and is predominantly expressed in cells of neural crest origin. Medullary thyroid cancer is common to all three conditions and about 20 per cent of all cases of this rare cancer are associated with a germline *RET* mutation. When no other stigmata are present, a diagnosis of familial medullary thyroid cancer is made. In the case of multiple endocrine neoplasia types 2A and 2B, additional unusual tumours arise including phaeochromocytoma and parathyroid adenomas (particularly in multiple endocrine neoplasia type 2A). Multiple endocrine neoplasia type 2B is associated with ganglioneuromas of the gastrointestinal tract and mucosal neuromas. In 95 per cent of cases of multiple endocrine neoplasia type 2A, mutations affect cysteine residues in the extracellular binding domain of RET, resulting in inappropriate disulphide bond formation, dimerization, and constitutive (ligand independent) activation of the RET tyrosine kinase. Familial medullary thyroid cancer results from mutations which similarly involve cysteine residues in the majority of cases but at different sites. The mutation found in multiple endocrine neoplasia type 2B is distinct and involves a methionine to threonine substitution in the ATP binding site of the receptor tyrosine kinase, leading to excessive receptor activity.

Familial papillary renal cell carcinoma

Some cases of this recently recognized syndrome, characterized by multiple bilateral papillary renal cell carcinomas, are due to germline mutations in the gene for MET tyrosine kinase at 7q31.1–q34. MET is a transmembrane tyrosine kinase receptor for hepatocyte growth factor or scatter factor, a peptide with essential roles in embryogenesis, cell motility, and tumour invasion. Germline *MET* missense mutations in cysteine residues, homologous to those involved in aberrant dimerization and activation of the RET receptor, are associated with familial papillary renal cell carcinoma. Monoallelic activating mutations in *MET* are also found the sporadic form of the disease. The spectrum of mutations found in sporadic papillary renal cell carcinoma is wider and includes activating mutations in the MET tyrosine kinase domain. However, recent studies have indicated that *MET* mutations occur in only about 15 per cent of sporadic papillary renal cell carcinomas.

Basal cell naevus syndrome (Gorlin's syndrome)

This condition should be considered in any patient presenting with a basal cell carcinoma before the age of 30, or with a personal or family history of multiple basal cell naevi/carcinomas. Associated abnormalities include abnormalities of skin, bone, and tooth formation (including polyostotic bone cysts, odontogenic keratocysts (jaw cysts), ectopic calcification, and palmar or plantar pits). An increased incidence of other cancers, including medulloblastoma, ovarian carcinoma, and sarcomas, may also occur. The incidence has been estimated at one in 55 600 in the United Kingdom. The gene believed to be responsible in the majority of cases, *PTCH* on 9q22.3, is a homologue of the *Drosophila* patched gene that encodes a transmembrane receptor for an extracellular ligand (hedgehog). This pathway is unrelated to classical peptide growth factor signalling and controls the fate of cells, body patterning, and growth by forming gradients in embryonic tissues. Initial analysis indicates that the *PTCH* gene behaves as a classical tumour suppressor gene.

Mutations in cytoplasmic signal transduction proteins

Plasma membrane receptors are linked to a highly complex array of cytoplasmic signal transduction proteins that transmit signals generated by an activated receptor to the nucleus to activate the cell cycle and alter gene expression. A number of highly characteristic syndromes are the result of loss-of-function mutations in proteins that have a negative role in signal transduction. The molecular genetics of these disorders generally conform to Knudson's model. However, disorders of tissue formation in these syndromes may occur in the absence of a second mutation, presumably because two normal functioning copies of the gene are required to maintain tissue homeostasis. In some cases, syndrome stigmata may arise because the mutated signal transduction protein interferes with the function of the wild type protein (a dominant negative effect).

Peutz–Jeghers syndrome

This autosomal dominant disorder has an incidence of one in 120 000. The syndrome stigmata are obvious with multiple pigmented spots on the lips and buccal mucosa, and multiple benign hamartomatous polyps throughout the gastrointestinal tract, most frequently affecting the jejunum. Malignant transformation of the gastrointestinal polyps is not common but may account for the increased incidence of colon cancer in these patients. In addition there is an increased risk of other cancers, including ovarian, cervical, testicular, and pancreatic cancer. The gene for Peutz–Jeghers syndrome, *STK11*, a serine threonine kinase, is located on 19p13.3. *STK11* is a tumour suppressor gene because germline mutations are predicted to disrupt the kinase domain of the protein. Molecular studies of hamartomas and gastrointestinal cancers associated with Peutz–Jeghers syndrome suggest that additional somatic mutation events are required for the transition of a hamartoma to an adenocarcinoma.

Neurofibromatosis type 1

The clinical features of neurofibromatosis were described in the introduction. The *NF1* gene (located on chromosome 17q11.2) encodes a guanosine triphosphatase activating protein known as the NF1-GAP-related protein, or neurofibromin. GAP proteins downregulate the activity of RAS, a critical mediator of the mitogenic response. An association between neurofibromin and the tropomyosin fibres of the cytoskeleton indicates a role in RAS-related signal transduction from the cell membrane to the cytoskeleton. A variety of mutations have been identified, and most result in a truncated protein. The rate of new germline mutations in *NF1* is high, with one-third to one-half of cases arising without affected parents. The *NF1* gene is prone to new mutational events because of its extremely large size (59 exons).

Neurofibromatosis type 2

This disease has an autosomal dominant pattern of inheritance. The neurological effects of neurofibromas predominate in neurofibromatosis type 2. There is a predisposition to development of tumours of the central nervous system, including schwannoma of the eighth cranial nerve ('acoustic neuroma'), meningioma, spinal cord schwannoma, and malignant gliomas. Deafness and tinnitus due to acoustic neuromas as well as muscle weakness and wasting due to spinal cord compression are not unusual. The *NF2* gene, located at 22q12.2, encodes a protein named schwannomin (or merlin). The majority of mutations within *NF2* result in the synthesis of a truncated protein. Schwannomin shows a close relationship to the family of ezrin–radixin–moesin proteins that link membrane proteins to the cytoskeleton and thus may function to maintain cytoskeletal organization. The incidence of neurofibromatosis type 2 is one in 35 000, of which half represent new germline mutations.

Tuberous sclerosis

Tuberous sclerosis is a disease of variable severity characterized by the development of multiple hamartomas involving many organs. Characteristic skin lesions often suggest the diagnosis. Often there is no family history since as many as 60 per cent of cases are due to a new germline mutation. There is a 5 to 15 per cent incidence of childhood brain tumours in affected individuals, mostly subependymal giant cell astrocytomas. In addition a weak association with renal cell cancer has been reported. A wide variety of benign tumours, including hamartomas, angiofibromas, and renal lesions, occur. Linkage studies have identified two genes, *TSC1* at 9q34 and *TSC2* at 16p13.3. *TSC1* encodes a protein called hamartin. Most mutations described within this gene result in a truncated protein. *TSC2* encodes tuberin, a protein showing some homology to GTPase activating proteins.

Von Hippel–Lindau disease

The diagnosis of von Hippel–Lindau disease depends on the presence of either coexisting central nervous system and retinal haemangioblastoma or one or other of these features, plus multiple renal, pancreatic or hepatic cysts, phaeochromocytoma, or clear cell renal cancer. Only one of these clinical features need be present if

there is a family history of von Hippel–Lindau disease. The incidence of the disease in the United Kingdom has been estimated as one in 36 000, with near complete penetrance by the seventh decade of life. Life expectancy is markedly reduced with death usually due to haemangioblastoma (benign vascular tumours) or renal cell cancer. The *VHL* gene at 3p25–p26 contains three exons that encode a 213 amino acid protein. The von Hippel–Lindau protein plays a role in the transduction of growth signals generated by changes in oxygen tension, promoting the translation of target genes that include vascular endothelial growth factor. *VHL* is a classical tumour suppressor gene, with a second, somatic mutation required for the development of cancer. Mutations in *VHL* are common in sporadic renal clear cell carcinoma.

Familial adenomatous polyposis or adenomatosis polyposis coli including Turcot's syndrome and Gardener's syndrome

Familial adenomatous polyposis (alternatively referred to as adenomatosis polyposis coli) has an incidence of one in 6000 to one in 13 000. Adenomatous polyps of the colon appear at an early age, with multiple polyps present in more than 90 per cent of cases by the age of 20 years. The polyps are premalignant, with the risk of adenocarcinoma of the colon approaching 100 per cent by the fifth decade of life. There is an increased risk of gastrointestinal carcinomas at other sites, thyroid cancer, childhood hepatoblastoma, and central nervous system tumours. Sometimes the combination of these tumours generates a recognizable syndrome. For example, multiple adenomatous colonic polyps in combination with a medulloblastoma is referred to as Turcot's syndrome. There is also an increased frequency of benign neoplasms including duodenal polyps, gastric polyps, and lipomas. In addition, there is an elevated risk for desmoid tumours. The gene for these disorders, *APC*, is located on chromosome 5q21–q22. Up to a third of cases are due to new germline mutations that usually cause protein truncation. Mutations mostly occur in the middle of *APC*, causing multiple colonic polyps appearing at puberty. *APC* mutations outside of this region are associated with fewer polyps and later onset. Some mutations correlate with the presence of unusual extracolonic syndrome stigmata, including congenital hypertrophy of the retinal pigment epithelium and benign bone tumours (osteomas). When these features are present the condition is referred to as Gardener's syndrome. These abnormalities occur in the absence of second mutations and may be due to the ability of mutant APC protein to interfere with the function of the remaining wild type protein (dominant negative effect). The APC protein is a negative regulator of b-catenin, a critical component of a signal transduction pathway that regulates cell–cell adhesion, cellular polarity, and tissue architecture.

Cowden's disease (gingival multiple hamartoma syndrome)

This autosomal dominant condition is most often recognized on the basis of characteristic skin lesions and intestinal hamartomas. Craniomegaly and mental subnormality occur in about 50 per cent of affected individuals. The pathognomic mucocutaneous lesions include trichilemmomas, acral keratoses, papillomatous papules, hyperkeratoses, and oral fibromas. Breast cancer occurs in 30 per cent of female gene carriers. Thyroid cancer is also prevalent (3 to 10 per cent), as well as glial masses that may present as cerebellar ataxia and seizures (Lhermitte–Duclos disease). The gene concerned, 'phosphatase tensin homologue deleted in chromosome 10' or *PTEN*, is located on 10q23 and is frequently deleted in sporadic breast cancer and glioblastoma. The PTEN phosphatase, by operating in opposition to the phosphoinositol-3-kinase pathway, inhibits cell survival and growth.

Ataxia telangiectasia

This rare recessive condition (one in 30 000 to one in 100 000) is not easily classified. Traditionally ataxia telangiectasia has been grouped with Fanconi's anaemia, Bloom syndrome, and other disorders associated with an increased rate of somatic mutation. Ataxia telangiectasia patients, however, have a distinct signal transduction defect, hence the inclusion of ataxia telangiectasia in this section. The *AT* gene, at 11q22.3, encodes a 350 kDa protein which contains a domain sharing homology to members of the phosphatidylinositol-3-kinase family. The AT gene product is believed to be a signal transduction protein that regulates cell cycle checkpoints. In the presence of DNA damage, cells with an AT mutation fail to activate p53-dependent cell cycle arrest (see next section). Although the precise connection to p53 and other cell cycle regulators is unclear, it is understood that AT-deficient cells exhibit extreme sensitivity to agents which damage DNA, genetic instability, and spontaneous chromosome aberrations. There is a 30 to 40 per cent lifetime risk of malignancy including epithelial tumours, solid tumours, chronic T-cell leukaemia, and lymphoma. Ataxia telangiectasia patients exhibit multiorgan defects including progressive cerebellar degeneration, general neuromotor dysfunction, and humoral and cellular immune defects. In fact, neurological problems and infection dominate the clinical picture. *AT* heterozygotes do not exhibit any of these defects, but may suffer a two- to threefold increase in the risk of cancer.

Mutations in transcription factors that control tissue-specific gene expression

The signal transduction pathways discussed above ultimately have an impact on the activity of DNA binding transcription factors that either activate or suppress transcription from target genes. At the time of writing there is only one example of a transcription factor involved in tissue-specific gene expression that functions as a tumour suppressor, the Wilm's tumour gene *WT1*. It is unclear why mutations in transcription factors that regulate tissue formation are rarely the cause of familial cancer, while mutant transcription factors occur frequently in sporadic cancer. One can extrapolate from transgenic experiments in mice that this disparity is explained by fact that the regulatory functions encoded by transcriptional suppressors are essential for normal embryogenesis.

Wilm's tumour (nephroblastoma)

Wilm's tumour is a poorly differentiated tumour of the kidney associated with developmental abnormalities of the genitourinary tract. Males and females are equally affected and usually present early in childhood, most often with an abdominal mass. Two sites of loss of heterozygosity have been identified in Wilm's tumours, *WT1* at 11p13 and *WT2* at 11p15.5. There are also rare familial cases in which linkage to neither 11p locus has been established (referred to as the ' *WT3'* group). In 10 to 30 per cent of patients, the disease is bilateral or multifocal, but less than 1 per cent of all cases are truly familial. Most cases of bilateral nephroblastoma are due to new germline mutations in *WT1*. The protein encoded by the *WT1* gene is a 'zinc finger' DNA-binding transcription factor. WT1 interacts with another tumour suppressor, p53, to bind and suppress transcription from the epidermal growth factor receptor and insulin-like growth factor 2 gene promoters. When WT1 function is compromised, transcription from these growth- and survival-promoting proteins is increased, initiating tumour development. *WT1* is not, however, a strictly Knudson-type tumour suppressor. Statistical analysis of age at diagnosis and proportion of bilateral and unilateral tumours does not follow the pattern described for retinoblastoma. Furthermore, the children of patients who survive Wilm's tumour are at lower risk of the disease than would be expected from a dominant-acting tumour suppressor gene. There is evidence that 'genomic imprinting' may explain some of these anomalies. Imprinting is a process of gene inactivation through DNA methylation that preferentially favours expression from genes inherited from one or other parental lineage. The reader is referred to the list of further reading for a comprehensive discussion of this complex issue.

Cell cycle checkpoint defects (Table 4)

Cell cycle checkpoint defects and cancer

The entry of a cell into the cell cycle is regulated by a 'G $_1$/S' checkpoint that controls the transition of cells from a resting (G $_0$/G$_1$) state into a DNA synthetic or S phase. When S phase is complete, cells enter premitosis (G $_2$). A second major checkpoint, G$_2$/M, regulates entry into mitosis (M phase). A major component of these two checkpoints is a family of regulatory proteins called cyclins that regulate the activity of enzymes called cyclin-dependent kinases. As the cell cycle progresses, cyclin and cyclin-dependent kinase activities oscillate, with peak activities corresponding to transition through each cycle checkpoint. Cyclin-dependent kinase activity is subject to negative regulation by Rb, p53, and a family of cyclin-dependent kinase inhibitors. These proteins operate to arrest the cell cycle in response to a wide variety of signals, including inhibitory factors, radiation, and other 'genotoxic' stresses. By blocking the cell cycle in cells that have undergone DNA damage, cell cycle inhibitory genes provide important protection against the development of cancer. Without this protection, cells exhibit genetic instability, with the accumulation of chromosomal deletions, translocations, and duplications. Cancer predisposition syndromes that are due to mutant cell cycle regulators are not generally associated with obvious clinical stigmata because cell cycle proteins do not regulate tissue-specific gene expression. Premalignant tumours may occur, however. Despite the fundamental role these genes have in cell cycle regulation, the pattern of tumour development is surprisingly restricted. This may be due to a major role for environmental stresses as a cofactor in tumour development (ultraviolet irradiation of the skin for example) or poorly understood tissue-specific roles for the genes concerned.

The retinoblastoma gene product Rb

The clinical features of retinoblastoma were described in the introduction. The *Rb-1* gene encodes a 928 amino acid protein. Rb functions by binding to the 'E2F' family of transcription factors. When Rb becomes phosphorylated by a cyclin-dependent kinase, E2F transcription factors are released to drive transcription from genes required for DNA synthesis. In addition, transcription of cyclins that stimulate entry into S phase is activated. Mutations in Rb therefore disrupt the ability of Rb

to interact with and inhibit E2F. As a result, the G_1/S checkpoint is lost and cells initiate unscheduled DNA replication.

Li–Fraumeni syndrome

This uncommon autosomal dominant disease exhibits a high incidence of a wide variety of early onset tumours, including rhabdomyosarcoma, osteogenic sarcoma, breast cancer, brain cancer, leukaemia, and adrenal corticoid carcinoma. Penetrance is high, with almost half of genetically affected individuals developing cancer by the age of 30 (compared with 1 per cent in the general population), rising to almost 90 per cent by the age of 70. Cancer at multiple sites is common. The clinical diagnosis is made by a patient with sarcoma under the age of 45, a first-degree relative under the age of 45 with cancer (not specified), and a third affected family member (first- or second-degree relative) with either sarcoma or any cancer under the age of 45. Approximately half of Li–Fraumeni syndrome families have mutations within the *p53* gene located at 17p13.1 resulting in a truncated p53 protein. *p53* is a classical tumour suppressor that stimulates transcription of cyclin-dependent kinase inhibitors in response to cellular stress. *p53* has been referred to as the 'guardian of the genome' because of a critical role in arresting the cell cycle in the presence of DNA damage.

Familial melanoma with or without dysplastic naevi

An autosomal dominant susceptibility to melanoma occurs in some families. Affected individuals in these families tend to have a large number of moles and are at risk for development of multiple melanomas and dysplastic naevi at a young age. Linkage to three loci, *CMM1*, *CMM2*, and *CMM3*, has been established. *CMM2* (9p21) encodes the cyclin-dependent kinase inhibitor 2A (known as p16). *p16* mutations are associated with a markedly elevated risk of both melanoma and pancreatic cancer and mutations occur frequently in a wide variety of sporadic tumours. Two transcripts are encoded by the same gene. One transcript, p16 (INK4a), induces a G_1 cell cycle arrest by inhibiting the phosphorylation of the Rb protein by cyclin-dependent kinases 4 and 6. The second (b) transcript encodes p14 (ARF), and is believed to function as a tumour suppressor by stabilizing p53 and leading to p53 accumulation. Mutation in the gene for cyclin-dependent kinase, identified as the gene at the *CMM3* locus 12q14, generates a dominant acting oncogene that promotes cell cycle progression. The gene responsible for the locus at chromosome 1p36, termed *CMM1*, has not been identified.

Hereditary breast/ovarian cancer (*BRCA1*)

In this condition there is an autosomal dominant predisposition to breast and/or ovarian cancer. Cancer occurs at a young age and is more frequently bilateral. Several hundred deletions, insertions, and point mutations have been identified within the *BRCA1* gene, with most predicted to result in truncated protein. The risk of breast cancer for individuals inheriting mutant forms of *BRCA1* is 3 per cent by the age of 30 years, 19 per cent by 40 years, and 85 per cent by 70 years. The risk for ovarian cancer is not as dramatic, but is increased greatly over that of the general population. An increased risk for colon and prostatic cancer is also present. The *BRCA1* gene on 17q21 has a role in the maintenance of genetic stability and the cell cycle response to DNA damage. This genetic surveillance role is similar to that of p53; BRCA1 and p53 are known to directly interact with each other.

Hereditary breast/ovarian cancer (*BRCA2*)

As in *BRCA1*, *BRCA2* mutations cause an autosomal dominant pattern of early onset breast and/or ovarian cancer predisposition. The onset of breast cancer in *BRCA2* families tends to occur earlier than in *BRCA1* families. Unlike *BRCA1*, there is an increased frequency of male breast cancer and pancreatic cancer in *BRCA2* patients. *BRCA2* has been localized to 13q12–q13. BRCA1 and BRCA2 share some homology and presumably serve similar functions in cell cycle checkpoint control and response to DNA damage.

Increased somatic mutation due to DNA helicase defects (Table 5)

The following recessive chromosome instability syndromes are rare and distinct from the classical cancer predisposition syndromes. There is no evidence for somatic mutation in these genes in tumours and so Knudson's model is not pertinent. The clinical features of these disorders overlap, with all three showing features of premature ageing. On a molecular level these syndromes are due to recessive mutations in a family of helicases that operate to maintain DNA topography during replication, recombination, and DNA repair.

Bloom syndrome

This an autosomal recessive disease of unknown incidence, more common in Ashkenazi Jews. Manifestations include growth retardation, sensitivity to the sun, skeletal abnormalities, and susceptibility to infection. An increased frequency of malignant neoplasms occurs throughout life, with dramatically reduced life expectancy. Lymphoma and leukaemia predominate before the age of 25; those that survive into their fourth and fifth decades are prone to a variety of common solid tumours. The age at diagnosis for these carcinomas is usually 20 or more years earlier than usually expected in the general population. Multiple mutations have been documented in the gene responsible, *BLM*, located on chromosome15q26.1. Loss of BLM, a RecQ DNA helicase, generates genetic instability with spontaneous chromosomal abnormalities and increased sensitivity to radio- and/or chemotherapeutic agents. Males are infertile due to a defect in meiosis. Heterozygotes do not seem to have an increased cancer risk, reflecting apparently normal genetic stability.

Werner syndrome

Werner syndrome is characterized by a multisystem premature aging phenotype also due to a RecQ helicase defect. The incidence is one in 50 000 to one in 100 000. Affected individuals have an excess of neplasms (especially osteosarcoma, meningioma, and thyroid cancer). A variety of loss-of-function mutations in the *WRN* gene located at chromosome 8p12–p11.2 have been identified. Loss of WRN helicase function leads to inappropriate expression of inhibitors of DNA synthesis, early cellular senescence, and genetic instability.

Rothmund–Thompson syndrome

This is the third recessive cancer predisposition syndrome due a defect in a RecQ-type DNA helicase (in this case, *RECQ4* at 8q24.3). The clinical features are similar to Werner and Bloom syndromes, comprising poikiloderma (marbleized pigmentation), telangiectasia, growth deficiency, cataracts, some aspects of premature ageing, and a predisposition to malignancy, especially osteogenic sarcomas and skin tumours.

Increased somatic mutation due to DNA repair defects (Table 6)

The fourth major class of cancer predisposition syndromes involves defects in DNA repair. Some of these defects cause severe problems in childhood and others are associated with a delayed onset, with cancer in adult tissues the major phenotype. These conditions can be recessive or dominant, depending on the consequences of the heterozygous state on the rate of somatic mutation. All promote the development of cancer by increasing the rate of somatic mutation. The genetics of these conditions is very complex—since DNA repair involves multiple protein components, a defect in any one will generate essentially the same phenotype.

Xeroderma pigmentosum

This is a spectrum of autosomal recessive disorders, with an incidence of one in 1000 000 in the United States. Childhood onset of photosensitivity and freckling leads to progressive degenerative skin changes and early development of skin and eye cancers. Approximately one-quarter of affected patients have concurrent neurological abnormalities. Basal cell and squamous cell carcinomas of the skin are increased 2000-fold and so the differential diagnosis includes Gorlin's syndrome. An increased risk of melanoma has also been observed. An increased risk of other tumours has been reported, including brain, lung, stomach, and haematological tumours. Benign neoplasms include conjunctival papillomas, actinic keratoses, lid epitheliomas, keratoacanthomas, angiomas, and fibromas. Defects of several enzymes involved in excision repair of ultraviolet light-induced pyrimidine dimers are responsible for this syndrome including *XPA* on chromosome 9q34.1, *ERCC3* on 2q21, *XPC* on 3p25.1, *ERCC2* on 19q13.2, *XPE* on 11p12–p11, *ERCC4* on 16p13.2–p13.1, and *ERCC5* on 13q32–q33.

Fanconi's anaemia

Fanconi's anaemia is another spectrum of recessive diseases characterized by a complex variety of developmental abnormalities, progressive marrow failure, and a

predisposition to acute myeloid leukaemia (15 000 times that of the general population). Fanconi's anaemia commonly presents in early to middle childhood with anaemia and bruising. Progressive pancytopenia and chromosome breakage, worsened by exposure to alkylating agents, is characteristic. Fanconi's anaemia homozygotes may develop a wide range of common cancers occurring at an early age, and are vulnerable to the hepatocarcinogenic effects of androgens used to treat Fanconi's anaemia. Squamous cell carcinomas, especially of the head and neck, oesophagus, cervix, vulva, and anus, occur with increased frequency, as do liver adenomas. Life expectancy is poor, around 12 years, with most deaths resulting from marrow failure and cancer. Approximately one-fifth of childhood aplastic anaemia is associated with Fanconi's anaemia. The heterozygote frequency is estimated to be one in 300 to one in 600, and is even commoner in Ashkenazi Jews. At the cellular level, Fanconi's anaemia homozygotes display chromosomal instability in response to DNA damage and reactive oxygen species and increased sensitivity to DNA crosslinking agents such as mitomycin C. Spontaneous chromosome aberrations are seen in a variety of cell types and an increase in chromosome deletion is seen. Five genes have been defined by complementation studies: *FA-A* at 16q24.3, *FA-C* at 9q22.3, and *FA-D* at 3p26–p22; *FA-B* and *FA-E* are currently unmapped. Several mutations have been found for *FA-C* and *FA-A*. The *FA-C* gene has been cloned but the function of the gene product is still not understood as it is a novel protein with no recognized functional motifs. However, the cellular phenotypes strongly suggest a role in DNA regulation or repair. Most studies have shown that Fanconi's anaemia heterozygotes do not display spontaneous genetic instability and do not have an increased risk of malignancy.

Hereditary non-polyposis colon cancer

This autosomal dominant condition may account for 6 to 10 per cent of all colorectal cancers. Clinically a diagnosis of hereditary non-polyposis colon cancer requires the following: three cases of colon cancer in a family in which two of the affected individuals are first degree relatives of the third; colorectal cancers occurring in two generations; and one colon cancer diagnosed before the age of 50 years. Five genes have so far been identified (located at 3p21.3, 2p22–p21, 2q31–q33, 7p22, and 2p16), each encoding proteins that participate in multimeric DNA mismatch repair complexes. Two of the genes, *hMLH1* and *hMSH2*, account for more than 90 per cent of cases of hereditary non-polyposis colon cancer. Most characterized mutations yield truncated gene products. The dominant inheritance pattern of these repair defects clearly distinguishes hereditary non-polyposis colon cancer from xeroderma pigmentosum and Fanconi's syndrome. Heterozygotes have 50 per cent expression of the mismatch repair protein in question, which presumably raises the somatic mutation rate sufficiently to increase the risk of cancer. Tumours that arise in patients with hereditary non-polyposis colon cancer exhibit very dramatic genetic instability in nucleotide repeat sequences (microsatellites). In fact, microsatellite instability can be used as a clinical test to distinguish adenomatosis polyposis coli from hereditary non-polyposis colon cancer. The lifetime risk of colon cancer for patients with hereditary non-polyposis colon cancer is 80 per cent, the average age at diagnosis is 45 years, and most cancers occur in the right side of the colon. Hereditary non-polyposis colon cancer is associated with an increased risk of other cancers, in particular endometrial adenocarcinoma, but also ovarian, gastric, small intestine, hepatobiliary tract and pancreatic cancer, skin cancer (sebaceous carcinomas), and transition cell cancer of the renal collection system. Glioblastoma multiforme is associated with hereditary non-polyposis colon cancer. 'Turcot's syndrome' of hereditary brain and colon cancer can therefore occur with both adenomatosis polyposis coli and hereditary non-polyposis colon cancer.

Syndromes in which the underlying gene defect has not been identified or the function of the gene has not been fully established (Table 7)

This review has focused on syndromes with established genetic aetiologies. Of course there are many other instances of familial clustering of common cancers that are under investigation, including those for prostate cancer, gastric cancer, carcinoid tumour, Hodgkin's disease, pancreatic cancer, and testicular cancer. In addition there are cancer predisposition syndromes with unusual phenotypes that should yield to genetic investigation soon, including oesophageal carcinoma with tylosis, Carney syndrome (hereditary myxoma), familial chordoma, osteochondromatosis, and familial paraganglioma. Again, the reader is referred to the further reading list.

Interventions for patients with inherited cancer predisposition

The role of clinical genetic testing in the management of cancer predisposition syndromes is in a constant state of flux. When the genetic basis for an inherited cancer syndrome is established there is an immediate opportunity to develop a reliable genetic test. However, genetic testing is fraught with methodological, psychological, and clinical difficulties and should not be applied without careful genetic counselling of the entire family concerned. In general, genetic testing is most rationally applied when the patient can be offered an intervention to prevent the cancer. This may simply be increased surveillance, a strategy most successfully applied when the target organ is easily accessible. For example, melanoma screening with regular skin examinations and sun avoidance for patients with hereditary melanoma syndromes is almost certainly successful in reducing the incidence of lethal melanoma. In contrast, for patients with Li–Fraumini syndrome, a condition in which cancers arise in a variety of internal organs with a high frequency, surveillance strategies are cumbersome and patients are generally reluctant to comply. A genetic test can be used to establish an indication for prophylactic surgery. For example colectomy should be offered to patients with adenomatosis polyposis coli or hereditary non-polyposis colon cancer and mastectomy and ovariectomy for patients with *BRCA1* or *BRCA2*. These are not easy decisions, however, since prophylactic surgery is disfiguring and/or is associated with significant functional and/or psychological impairment. The most hopeful approaches to these conditions involve the application of chemoprevention. Here a positive genetic test is an indication for a medication that attenuates the effect of a cancer predisposing mutation. The use of tamoxifen, an anti-oestrogen, to prevent breast cancer for patients with *BRCA* mutations is under investigation and inhibitors of prostaglandin synthesis have been shown to inhibit the development of polyps for patients with adenomatosis polyposis coli.

In the future it may be possible to develop preventative drugs specifically designed to interfere with the deregulated enzymatic activity generated by a mutant protein. For example, it is conceivable that RET or MET specific tyrosine kinase inhibitors could be employed to prevent the onset of cancer in multiple endocrine neoplasia type 2 and familial papillary renal cancer. Finally, using gene therapy strategies it may be possible to restore tumour suppressor function. Recent reports on p53 gene therapy certainly offer hope in this regard.

6.4Tumour metastasis

V. Urquidi and D. Tarin

Introduction

Tumour dissemination with colonization of distant sites in the body and the formation of secondary tumours, termed metastasis by Recamier in 1829, is an enigmatic phenomenon. It is also by far the most common cause of death in cancer patients, because of the failure of vital organs replaced by deposits of disorganized, malfunctioning tumour tissue.

In the human embryo, progenitor cells undergo complex migrations and interactions during the formation of body structure, but after arriving at their final positions, they remain fixed throughout adult life. The only normal cell lineages exempt from this fate are leucocytes which continue to patrol the blood vessels, tissues, and lymphatics. Neoplastic non-haematological cells can acquire the capability to do likewise, and the characteristic patterns of colonization displayed by specific types of tumours and cell lines derived from them demonstrate that tumour metastasis is not a random process. Such programmed disorderly behaviour by a subpopulation of host cells, compromising the regimented anatomy of the other cell lineages, is a unique phenomenon in animals. Its mysterious quality and its grave clinical implications both hinge upon the failure thus far to identify any properties unique to metastatic cells that can illuminate the mechanisms involved or help treatment to control or eliminate disseminated malignant disease.

The metastatic process

Formation of a secondary tumour colony in a new site is the culmination of a complicated series of sequential and highly selective events. It begins with the emergence within the expanding tumour cell population of one or more clones whose descendants can cross tissue boundaries and infiltrate adjacent cellular populations, progressively disrupting the structure and function of the organ. As the tumour grows it induces blood vessels to penetrate and arborize within it to supply its metabolic needs. This in turn provides opportunities for tumour cells with appropriate properties to break into the circulation and be carried away to seed distant sites. Survivors that attach to the vascular endothelium at a distant site gain access to the resources of the tissue or organ where they have alighted by diapedesing through the endothelium and focally destroying the surrounding sleeve of basement membrane. To complete the process and produce a secondary tumour or metastasis in this site they then proliferate and attract a new fibrovascular scaffolding from the host organ, to sustain growth and prepare for the next metastatic event.

Clinicopathological correlations of metastasis

Not only are molecular events within the spreading tumour cells responsible for the phenomenon of metastasis, but microenvironmental conditions within the mixed tumour cell populations, composing the organ in which the secondary deposits are established, also play an important role. This interaction between tumour and host cells causes characteristic patterns of organ distribution of secondary tumours, linked to the site of origin of the primary tumour, that are clinically well recognized. Thus, for instance, the distribution of metastatic deposits in patients with breast cancer most commonly involves the regional lymph nodes, the long bones, the lungs, and the liver. Similar, largely predictable, patterns of spread are seen in patients with colon cancer, prostate cancer, and many other common malignancies. These patterns are exceptionally useful clinically, in guiding physicians where to search in order to stage the degree of spread of the disease and seek early evidence of recurrence.

Many studies in animals and humans have demonstrated that these distribution patterns result primarily from preferential colonization of some sites rather than from simple vascular drainage patterns, although such mechanical factors can be superimposed on the biological processes involved. This 'seed and soil' synergy between the properties of the spreading tumour cells and the cells comprising the colonized organ dictating the distribution of secondary deposits, first recognized by Paget in 1889, has been corroborated by many converging lines of evidence in recent years and finally proven by studies in ambulatory humans. The cumulative evidence shows that the disseminating tumour cells are not omnipotent, and are still dependent upon co-operative interactions between them and the cells of the stroma and vasculature of the host organ in order to establish a secondary colony.

The routes of dissemination are also clinically and experimentally important in that the tumour cells sometimes preferentially go by lymphatic or transcoelomic pathways rather than by the blood vascular system. Additionally it has been shown that certain types of mouse tumours suppress the growth of dispersed micrometastases by the release of blood-borne antiangiogenic molecules that inhibit the growth of the secondary tumours. Removal of the primary tumour can result in the simultaneous and sudden growth of many secondaries in these model systems. However, although some anecdotal literature suggests that similar phenomena have been observed in humans, it is certainly not accorded sufficient clinical credence to alter the current best standard of clinical practice, which is to excise as much tumour tissue as one can without compromising vital functions of the patient.

Clinical consequences of metastasis

The clinical effects of metastasis relate to the exponentially increasing tumour burden in scattered locations, which ultimately leads to the failure of organs vital for survival of the host. These effects are compounded by the proven capability of the progeny of cells in metastatic colonies to metastasize again. This makes it impossible to effectively focus treatment on the expanding and leap-frogging tumour population and therefore increases the risk of collateral damage to surrounding normal tissue. The idiosyncratic metabolic and physical effects of this increasing tumour load, such as paraneoplastic effects, pain, anxiety, haemorrhage, pathological fractures, and compressed or eroded vital structures, also need to be alleviated. Furthermore, the significant possibility of recurrence of disease in a distant site long after successful eradication of a locoregional tumour necessitates careful and prolonged monitoring, sometimes assisted by appropriate tumour markers.

Therapeutic considerations relating to metastasis

The current practice of tailoring combined therapeutic approaches, incorporating various radiotherapeutic and/or chemotherapeutic regimens, after surgical excision to staging of disease in the patient is increasingly effective for some cancers. Spectacular successes can result if multimodality therapy is used fairly early in the course of the disease. However, the main difficulty of treating widely disseminated metastatic cancer remains intractable and its solution is the 'Holy Grail' of oncology. New research on genetic mechanisms offers the best currently available hope of finding target molecules for rational drug design, gene therapy, and novel approaches to biological therapy, all aiming specifically at the eradication of late stage disease. Meanwhile, however, some significant and useful advances in treatment of such patients have been made by:

1. combining therapeutic regimens (for example surgery and hormone therapy and/or chemotherapy for patients with breast cancer)
2. delivering chemotherapy by appropriate routes (for example intrathecally for cerebral deposits, intraperitoneally for ovarian carcinomatosis peritonei), and
3. increasing dose intensity within a short period.

Although very high-intensity chemotherapy with subsequent (autologous or heterologous) bone marrow transplantation has been effective for some haematological malignancies, recent trials have failed to show clear evidence of benefit in patients with breast cancer or other solid cancers. Radiotherapy, like surgery, remains more suitable for the management of locoregional disease or isolated secondaries.

The problem of deciding how much treatment is needed to eradicate dormant micrometastases (small collections of clinically undetectable tumour cells sprinkled in

many sites), otherwise known as minimal residual disease, without exposing non-neoplastic stem cells in many of the patient's tissues to irreversible toxicity, is a continually present dilemma. The detection and treatment of metastatic tumour deposits in the brain, leptomeninges, bone marrow, and bones pose particularly difficult challenges. In the neural axis, treatment is fraught with the problems of delivery of chemotherapeutic agents across the blood–brain barrier and the difficulty of adjusting the dose of radiation therapy to be effective without damaging sensitive, normal nervous tissue. Sampling difficulties complicate evaluation of whether the marrow is involved in a patient and recent advances in purging it of malignant cells using monoclonal antibodies vary in their efficacy, depending on the type of tumour. Bony involvement is effectively controlled by radiotherapy if it is localized, but widely scattered deposits are refractory to reduction or elimination by most therapeutic regimens.

Current metastasis research and its importance for clinical oncology

There is, therefore, a real need for novel research to identify special characteristics of metastatic cells that could render them susceptible to therapies controlling further spread. The prevention of escalating dissemination whilst the existing tumour deposits are attacked would be a valuable contribution to the therapeutic armoury. Current research on the mechanisms of tumour cell metastasis is opening promising avenues for such advances. These are still in their infancy, but new observations on cellular, genomic and postgenomic (gene expression) aspects of the metastatic phenotype permitted by recent technological advances (i.e. cDNA microarray and proteomic methods) are providing clues to the mechanisms involved. At the cellular and biochemical level, the data demonstrate that tumour-induced angiogenesis, proteolytic activity by tumour-derived matrix metalloproteases, and epithelial–mesenchymal interactions, dependent on specific growth factor receptor–ligand binding events, facilitate the metastatic process in many experimental tumour systems. Other studies have indicated the presence of putative metastasis suppressor genes on a variety of chromosomes, depending on the tumour system under investigation. Interestingly, to date, comparable information on metastasis promoting genes is less abundant, although some studies have provided data supporting this concept. Additionally, a substantial body of data has been published indicating that expression of individual effector molecules, such as integrins, selectins, CD44, and cadherins, may accomplish various parts of the metastatic process under the direction of co-ordinating genes, as yet unknown. Despite decades of research, no single consistent marker or effector of metastatic behaviour has yet been identified and modern emphasis has shifted to using high-throughput gene expression analysis, such as gene chips and spotted microarrays, to identify whether co-ordinated patterns of expression of clusters of genes are involved in this complex process.

As the basic events in the metastatic process are comparable in many different species and in individuals with tumours of differing histogenetic origin, it seems likely that the underlying causal mechanisms will be initiated and driven by the same group of regulatory genes. If this interpretation is correct, the recognition of patterns of gene expression meaningfully correlated with metastatic phenotypes should guide investigators to the identity of the co-ordinating genes governing the phenotype and more effective targets for therapy. Results from our own laboratory using gene chips and other methods of genome-wide expression analysis support this view and are revealing previously invisible reliable differences in mRNA species between metastatic and non-metastatic tumour cells cloned from a patient with breast cancer. Computational analysis of several such datasets, utilizing clustering algorithms, to screen for commonalities in gene expression within the metastatic versus the non-metastatic phenotype should facilitate identification of the functional implications of such associations. Using such methods, genes at ascending levels in the hierarchy of regulation of the phenotype will be catalogued. The ultimate objective of modern clinical cancer research is to identify better markers for reliable evaluation of prognosis and detection of disease recurrence and to develop improved targets and strategies for novel therapies.

Summary

Although considerable progress has been made in the clinical management of patients with cancer, the best immediate hope of surviving the grim sequelae of metastatic spread of cancer still lies in early detection of the primary tumour, before it has started to shed cells into the circulation. The hunt for molecules or combinations of molecules which indicate the imminent onset of malignancy and which are released into easily accessible body fluids (blood, saliva, sputum) and waste products (urine and faeces) therefore has practical and scientific appeal, although success may not necessarily provide much information on the underlying mechanisms of the metastatic process. For new methods to contain or eradicate cancer that has already begun to disseminate, we still need to understand the mechanisms involved. Suffice it to say for the present, however, that understanding the fundamental basis of the metastatic process will also profoundly illuminate how cellular societies, which compose all metazoan and especially vertebrate organisms, are assembled and kept in strict topographical and developmental order. Such an intellectual 'spin-off' adds a further level of interest to the challenge of finding a practical solution to the vexing and challenging biological problem of human malignant disease.

6.5Tumour immunology

P. C. L. Beverley

Historical perspective

The strategies that have been tried in tumour immunology are based on the idea that tumour cells harbour differences that can be detected by the immune system. The first is to use antibodies to distinguish between tumour and normal cells; this difference can then be exploited for diagnostic, prognostic, or therapeutic purposes. The second is to stimulate the host by specific or non-specific immunization to react more vigorously to autologous tumour. All these avenues have been pursued for close to a hundred years so that it is pertinent to ask why it is that immunology has had such a minor impact in oncology, and particularly in cancer therapy.

The early attempts involved experiments in tumour transplantation and the description of tumour rejection. Unfortunately, the tumour rejection experiments were carried out in outbred animals and it was later realized that allograft, rather than tumour rejection, was being demonstrated. Nevertheless, the experiments did show the power of the immune response to destroy a large, growing tumour mass. Non-specific stimulation with bacterial products (Coley's toxin) was also tried as therapy but later more rigorous examination of the effect of immunostimulation showed that the success rate was extremely low. After the second world war, the development of inbred animals allowed properly controlled experiments on tumour-specific immune responses to be performed and the theory of immune surveillance provided a stimulus and a basis for a new wave of experiments in tumour immunology. Nevertheless, although tumour-specific immune responses were soon detected, it remained difficult to define their target antigens until the development of monoclonal antibodies and methods for gene cloning. One other advance was also essential for understanding of antitumour immune responses, the realization that thymus-derived (T) lymphocytes can only recognize antigens processed inside cells and displayed at the cell surface in association with major histocompatibility complex (MHC) antigens (Fig. 1).

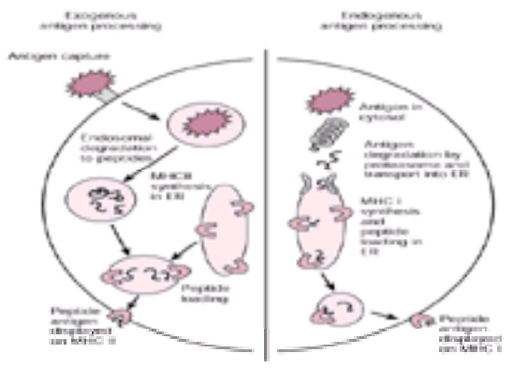

Fig. 1 Antigens recognized by T lymphocytes may be extracellular, in which case they are captured and internalized by antigen presenting cells to enter the exogenous antigen processing pathway. The antigens are broken down to peptides for loading on to newly synthesized MHC II molecules and translocated to the cell surface. Antigens synthesized within cells, which may originate from viral or self proteins, enter the endogenous pathway. They are broken down to peptides by proteasomal enzymes and the peptides are transported into the endoplasmic reticulum for loading and translocation to the cell surface.

Here are discussed immune surveillance, the evidence for immune responses to tumours, and aspects of immune function relevant to immunotherapy. Current understanding of the nature of tumour antigens recognized by the host immune system and how differences between tumour and normal cells may be exploited for diagnostic and therapeutic purposes are also reviewed.

Immune surveillance

The theory of immune surveillance postulated that tumours arise frequently but that most are eliminated by the immune system before becoming clinically apparent. Diverse evidence was adduced in support of the theory (Table 1) and many experiments performed to test it. Most of these were studies of the effects of immunosuppression, since the strongest prediction of the theory was that tumours should arise with overwhelming frequency in the absence of an immune response. Examination of congenitally immunodeficient or deliberately immunosuppressed mice supported the theory, since a higher frequency of tumours was observed than in controls. However, many tumours were characteristic of those caused by murine oncogenic viruses. Similarly, in man, deliberately immunosuppressed individuals or AIDS sufferers do have a greatly increased risk of tumours (Table 2) but not the most common types. Strikingly, viruses are implicated in the aetiology of most of the tumours types arising in immunocompromised individuals (Table 3). These data are clearly not in accord with a straightforward immune surveillance mechanism, since this would postulate an increased frequency of all tumours but in practice the strongest effects attributed to surveillance against tumour cells are most probably due to immune responses against potentially oncogenic viruses.

In spite of strong immune responses against oncogenic viruses, these agents do cause tumours in normal individuals as well as the immunocompromised. This may be because the virus-transformed cells adopt several strategies for escaping from immune attack (see below). In turn, this leads to the suggestion that the most effective means of preventing these tumours is by prophylactic immunization against the oncogenic virus, preventing infection and therefore transformation. Immunization against hepatitis B virus has already been demonstrated to decrease the incidence of liver cancer in endemic areas and vaccines against Epstein–Barr virus (EBV) and papillomaviruses are areas of active research.

In the case of many of the most common tumours, there is no evidence for a viral aetiology so that for these tumours the existence and importance of immune responses to tumour-associated antigen remains questionable. This is discussed below.

Tumour-specific immunity

The first convincing evidence that there were tumour-specific antigens came from experiments with inbred mice using chemically-induced tumours. Animals immunized with irradiated tumour cells or by grafting and then excising tumour, were protected against rechallenge with the same, but not a different, tumour line. Immunity could be transferred to naïve animals with cells but not serum. Notably, spontaneous tumours were usually much less immunogenic, raising the possibility that non-viral as well as virus-induced tumours may exhibit escape mechanisms.

In man, the evidence was rather slower to accrue but the development of the colony inhibition test, in which tumour cells were cocultured with patients' lymphocytes and the number of growing colonies counted, allowed an analysis of antitumour responses. Early studies showed that many patients were resistant to tumour and it was also suggested that 'blocking factors' present in serum might be responsible for the progressive growth of tumours in the face of a cellular colony-inhibiting response. Later results threw doubt on the specificity of the early research and it became clear that both normal and cancer patients' lymphocytes could often inhibit

the growth of tumour targets. This led to the definition of natural killer cells. These cells play a role in the early innate (non-specific) response to infectious agents but there is little to suggest that they play an important role in protection against non-viral tumours.

More persuasive evidence of specific T-cell responses to tumours became available following the realization that T cells can only recognize antigen in the context of self MHC (Fig. 1) and that specific immune responses can often only be revealed following an *in vitro* boost. Since that time, a number of authors have shown that both MHC class II restricted tumour-specific T-helper and class I restricted T-cytotoxic responses can be generated by coculture of lymphocytes and autologous tumour cells. Although it is clear that these responses occur in many tumour-bearing patients, the fact that they have been difficult to detect reproducibly indicates that they are often weak, in other words that there is a low frequency of responding T cells. That these responses may nevertheless play a role in host protection is suggested by the observation that loss of MHC molecules is very common in tumours. At least 50 per cent of human tumours show either down regulation of all class I or allele-specific loss. Clearly loss of MHC molecules which could present a tumour antigen is a very effective mechanism of tumour escape.

What are the tumour antigens recognized by T cells?

The nature of the tumour-specific antigens of non-viral experimental tumours and of most human tumours remained inaccessible until the development of gene expression cloning methods. In the 1980s Boon and his colleagues set out to identify tumour antigens of a mouse tumour, P815. The tumour was initially non-immunogenic in syngeneic DBA/2 mice, so that it grew readily even in preimmunized mice. A set of tumour variants were produced by treating the tumour with a mutagen. Some of these were highly immunogenic and unable to grow in preimmunized mice (tum– variants). From mice immunized with tum– cells, it was possible to isolate cytotoxic T-cell clones, which could kill only the immunizing tumour variant and not parental P815 or other tum– variants. The cytotoxic T-cell clones were used to screen parental P815 cells, which had been transfected with a cosmid library constructed from tum– variant cells. Eventually tum– antigen-positive transfectants were identified, the cosmid recovered, and, after subcloning, transfecting the subclones, and rescreening, the gene coding for the cytotoxic T-cell target antigen could be identified. Several different tum– antigens have now been cloned in this way and it has become clear that they fall into two categories (Table 4). The first is due to a genetic alteration in the coding sequence of a gene and the second to altered expression of a normal gene product.

Boon and his colleagues also investigated human tumour antigens in a similar fashion. Melanoma has long been recognized as capable of stimulating a relatively strong host T-cell response. Melanoma-specific cytotoxic T-cell clones were therefore produced and used to screen a melanoma cDNA library. They first identified MAGE-1 (melanoma antigen 1), belonging to the category of over-expressed, unaltered tumour antigens (Table 5). More remarkably, the antigen belongs to a large, previously undiscovered gene family which is widely expressed in tumours and seldom in normal tissues. Subsequently, Boon's group and others have cloned several other melanoma antigens as well as antigens of other tumours (Table 6). The majority of antigens identified by this methodology are unaltered. However, mutations and genetic rearrangements creating new sequences are common in tumours (Table 7) and computer analysis has shown that many of the neoepitopes formed could bind to common HLA alleles such as HLA A2. It has been shown also that some tumour patients and mice can respond to peptides of mutant *ras* oncogene and some cancer patient can generate cytotoxic T cells to the HER2/*neu* oncogene product. This work also established that most tumour antigens recognized by T cells are similar to other antigens recognized by T cells (Fig. 1, Table 4), that is they are short peptides presented by MHC molecules.

One other form of T-cell antitumour response is noteworthy. Mucins are heavily glycosylated molecules which are expressed at the surface of many epithelial cells and corresponding tumours. However, the glycosylation of the molecule is frequently altered in tumour cells leading to the detection of new epitopes by monoclonal antibodies on the tandem repeat structure of the protein core of the molecule. Cytotoxic T cells generated from breast cancer patients lyse tumour cells expressing the mucin but in a MHC-unrestricted fashion. The cytotoxic T cells may be CD4 or CD8 and have an ab T-cell receptor but unusually killing can be blocked a mAbs to the mucin tandem repeat. Exactly how these unusual cytotoxic T cells recognize their antigen remains to be determined.

The demonstration that many tumour patients make a cellular immune response to their tumour raises the question as to why tumours continue to grow and suggests that the response to tumours may be weak. This is discussed below.

Why are the responses to tumour antigens weak?

Just as for other T-cell-recognized antigens, several factors will determine whether a tumour antigen stimulates an immune response in the host. The first is that processed peptides from the molecule must reach the cell surface in association with MHC molecules. Whether a particular peptide does so depends on the amount produced by processing enzymes, the ability of the peptide to reach intracellular compartments where it may bind to MHC molecules, and its affinity for the MHC alleles expressed by the cell.

The second factor determining whether there is a response is that there must be T cells capable of responding. During normal development of T lymphocytes in the thymus, those cells that react with high affinity to self antigens are deleted to prevent the development of autoimmunity. It is, therefore, somewhat surprising that so many human tumour antigens detected by T cells appear to be unaltered self molecules. The most likely explanation is that thymic deletion and T-cell responsiveness in the periphery are governed by the affinity of the interaction of the T-cell receptor with peptide–MHC complexes. The thymic deletion mechanism selects against the highest affinity cells, while cells with lower affinity for self escape to the periphery. If the antigen is up-regulated, there may now be enough peptide–MHC complexes to stimulate lower affinity cells that have escaped deletion in the thymus. For antigens containing new sequences introduced through genetic alteration, there is in principle no reason why there should not be responsive T cells in the periphery. However, the frequency of T cells able to respond to a single epitope will be low (contrast this situation with that of a pathogen which has many proteins and even more peptide epitopes).

There is a second reason why responses to tumours may be poor. This is the need for 'danger signals' in initiation of immune responses. Recently, it has been recognized that activation of the innate immune system is essential for development of a subsequent, specific immune response. Pathogens carry 'danger signals' which perform this function. These are conserved structures such as bacterial carbohydrates, lipopolysaccharides, and signature DNA and RNA sequences that are recognized by conserved host receptors including complement components, receptors for carbohydrates (mannose and scavenger receptors) and lipopolysaccharides (CD14), and as yet ill defined recognition systems for nucleic acid sequence motifs. Interaction of danger signals with these conserved receptors leads to the production of cytokines by dendritic cells, macrophages, natural killer, and tissue cells that are essential for initiation of immune responses (Fig. 2).

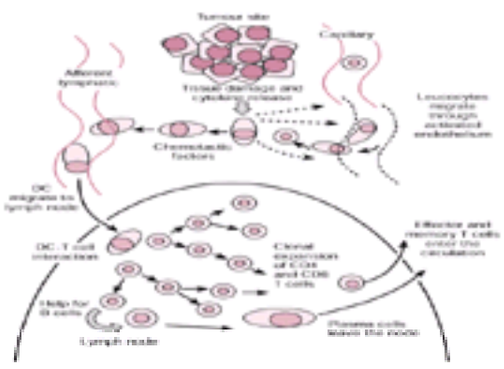

Fig. 2 Initiation of immune responses to pathogens is dependent on 'danger' signals carried by micro-organism, which stimulate production of cytokines by tissue cells and tissue-resident dendritic cells and macrophages, leading to influx of more leucocytes and migration of antigen-loaded dendritic cells to the draining node. Tumour sites are unlikely to stimulate these events until tissue damage and cell death occur as a relatively late event, so that the immune response to tumours may be delayed.

In the case of a tumour it is not clear what would provide such danger signals during the early stages of growth; later, tissue damage and repair processes would be expected to lead to cytokine production. Tumours may therefore be immunologically silent until a relatively late stage, by which time the tumour burden may be too great for the immune system to deal with, especially in the face of tumour escape mechanisms.

An important second stage in initiation of immune responses, induced by T-cell receptor–peptide–MHC contact, is the up-regulation of costimulatory molecules on both T and antigen presenting cells (usually dendritic cells) (Fig. 3). The interaction between CD28 and B7 is particularly important in promoting T-cell proliferation

and that between CD40 and CD40 ligand has recently been shown to play a key role in differentiation of cytotoxic T cells. It has also been shown that T-cell receptor–peptide–MHC interaction in the absence of costimuli may lead to inactivation rather than activation of T cells. Since most tumour cells lack costimulatory molecules, they are usually poor antigen-presenting cells. Even when activated effector cells return to the tumour site, the lack of costimuli may provide a mechanism for tumour escape, as may the production by tumour cells of down-regulatory cytokines, such as transforming growth factor-b (TGF-b). T lymphocytes isolated from tumour-bearing patients have been reported to show defects in signalling through the T-cell receptor, supporting the idea that tumours are indeed immunosuppressive.

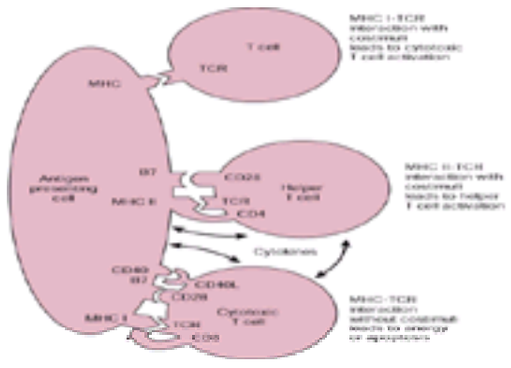

Fig. 3 Most T cells responses are initiated by contact between T cells and dendritic cells, which are specialized for antigen presentation and express key costimulatory molecules such as B7 and CD4O. Many tumour cells lack these and are therefore likely to be poor antigen-presenting cells.

Tumour antigens defined by antibodies

The exquisite specificity of antibodies has long persuaded investigators that it should be possible to use them to distinguish between tumour and normal cells. However, until the development of monoclonal antibodies (mAbs) there had been few successful examples. Many mAbs have now been raised against tumours and the vast majority recognize not tumour antigens but normal differentiation antigens. There are a few exceptions—antibodies to the idiotype of T and B cell tumours are tumour specific and antibodies to mutant forms of the p53 tumour suppressor gene product identify this as a tumour-associated molecule. In spite of this apparent failure, mAbs have proved extremely useful in studying the biology of tumours and lack of absolute specificity for tumour cells does not preclude their use as diagnostic or therapeutic agents.

More recently, serological analysis of tumour antigens by recombinant cDNA expression cloning (SEREX) has been developed. Sera from patients are used to screen cDNA expression libraries from fresh tumour material. Isolation of antigens detected by high titre IgG or IgA antibodies implies that there is a T helper cell response to the same antigen, as immunoglobulin class switching does not occur without this. That there is often a concurrent T-cell response when antibody to autologous tumour is present, is confirmed by the finding that some SEREX-defined antigens are identical to those recognized by T cells (see Table 6 and Table 8). The SEREX method has the disadvantage that it may not detect all conformational epitopes of a protein and does not identify carbohydrate antigens. Nevertheless, over 900 sequences of genes cloned using the SEREX method have already been deposited in a data base set up for this purpose. These include previously identified antigens such as MAGE-1 and tyrosinase, sequences identical (or nearly identical) to known genes not previously identified as eliciting an autoantibody response (e.g. kinectin, a transporter of golgi vesicles), and a large group of previously unknown genes (Table 8). A full description of the expression patterns of these genes in normal and tumour tissue, let alone a analysis of their functions, will be a major undertaking, but will eventually identify many new targets for immunotherapy.

The potential for immunodiagnosis and immunotherapy

Monoclonal antibodies have already found a place in the diagnosis of malignant disease (summarized in Table 9) although they seldom play a role in deciding whether a cell is malignant (although antibodies to some of the gene products identified by SEREX may eventually change this). So far, they have been most useful in cell identification. MAbs readily allow identification of single gene products in sections or smears and this is often a simple way of assigning a cytologically undifferentiated cell to a cell lineage. A relatively small panel of mAbs (Table 9) allows the identification of most tumours, which might otherwise cause diagnostic confusion. An extension of this is the detection of rare malignant cells. Thus, mAbs have been used to identify micrometastases in lymph nodes, blood, bone marrow, or cerebrospinal fluid, which are below the limit of detection by conventional histology or cytology. This data indicates that the presence of micrometastases at the time of diagnosis is much more common for many carcinomas than had been appreciated before. The clinical importance of this observation remains to be determined.

MAbs may also be used to provide prognostic information. Estimation of the proportion of cells expressing molecules associated with progression through cell cycle, such as the transferrin receptor or nuclear cyclins, correlates to some degree with the malignancy of tumours. However, it is not to be expected that expression of any single marker will correlate absolutely with tumour behaviour since one result of studies with mAbs is to reinforce the view that tumours are very heterogeneous. Nevertheless, as understanding of the function of gene products expressed in tumour cells improves, studies of tumours with carefully designed panels of mAbs will provide increasingly useful prognostic information.

Serological tests for a number of cancer-associated molecules have been developed; examples are carcinoembryonic antigen, a-fetoprotein, and prostate specific antigen. These are useful confirmatory diagnostic tests and can be used for follow up after treatment. A rise in serum antigen may indicate a recurrence of tumour.

Antibodies *in vivo*

As discussed above, there are few antibodies against molecules which are truly tumour specific. For *in vivo* use it is also necessary that the target antigen should be at the cell surface. In spite of these limitations, many mAbs have been used *in vivo* for diagnostic or therapeutic purposes. For both uses, the problems are similar. The first is to obtain sufficient penetration of antibody into tumour to give a useful signal-to-noise ratio. Penetration depends on the size of the molecule, its half-life in the serum, the vascularity of the tumour, and the abundance and availability of the antigen. The second problem is that heterologous antibody is immunogenic as are most of the larger molecules which are commonly attached to it, such as plant toxins. Both of these problems have been addressed by immunochemical or molecular engineering methods. It is possible to produce a variety of sizes of antibody fragments and to replace most of a rodent immunoglobulin by human sequences. This reduces greatly the immunogenicity of the antibody (although the idiotypic epitopes associated with the antibody binding site may remain immunogenic) but will not affect the ability of attached toxins to generate an antibody response. Strategies designed to circumvent this problem include further engineering of toxin moieties to render them less immunogenic, induction of tolerance to immunogenic molecules, and the use of a succession of different antibody–toxin or drug conjugates. Some of these strategies have now been explored in human clinical trials (see below). It should also be noted that the anti-idiotype response to an antitumour mAb can generate a further anti-idiotypic response (Ab3) which may react with the original tumour antigen. The presence of Ab3 has been associated with a favourable outcome in some studies.

Experience in man with antibodies for diagnosis suggests that their sensitivity is of the same order as that of computer assisted tomography. However, optimization of the antibody and radioisotope selection and coupling procedures will undoubtedly yield improvements.

For therapy, the problem of penetration into large tumour masses may dictate that antibodies are most useful in an adjuvant setting. In a randomized trial of a murine mAb to an epithelial differentiation antigen given at the time of surgery to colon cancer patients, treated patients showed significantly increased survival. Here the target is micrometastases, which would be expected to be relatively easily reached by serum antibody, and indeed it could readily be demonstrated that antibody had bound *in vivo* to tumour cells in the bone marrow. A number of other trials of antibodies have been carried out. In perhaps the most promising, a humanized antibody to the *neu* antigen (a member of the epidermal growth factor (EGF) receptor family) has been used alone or combined with chemotherapy to treat metastatic breast cancer; increased objective response rates have been reported. The antibody has received a licence from the Federal Drug Administration. Trials of anti-CD20 (a B lymphocyte differentiation antigen) mAb in lymphoma have also shown encouraging results.

CD20 antibody has also been used as a carrier for a radioisotope, as has an antibody to the mucin, MUC1, to deliver high doses of yttrium to the peritoneal cavity in

ovarian cancer patients with minimal residual disease after chemotherapy. In the latter trial, a significant benefit was seen compared to historical controls. A phase three trial is underway.

One possible avenue of progress in achieving antibody penetration is to target not the tumour itself but tumour vasculature. Endothelial cells respond to their microenvironment by changes in surface phenotype and the vessels of tumours may therefore express molecules which could be targeted. Initial animal experiments are encouraging. So also is the successful treatment of melanoma by limb perfusion with very-high-dose tumour necrosis factor (TNF-a), in which the tumour vasculature appears to be susceptible while normal endothelium remains unscathed.

T-cell immunotherapy

For those tumours in which a virus is implicated (Table 3), prophylactic vaccination would be the most obvious long-term solution. For other common cancers where there is no obvious viral target, T-cell-based therapy, if it does have a role, will have to be directed at established tumours. Viral antigens may also be targeted for active immunotherapy as has been tried in the case of carcinoma of the cervix, where the human papillomavirus transforming proteins E6 and E7 have been used (Table 10).

As discussed above, there is now good evidence for a specific T-cell response to at least some human tumours. In principle, it seems that any altered and expressed gene product, or even a normal but over-expressed product, may be recognized as a tumour antigen. It seems likely that most tumours will accumulate several possible tumour antigens during their evolution, though not all will be immunogenic in a particular individual because of the necessity for peptides of the tumour antigen to bind to self HLA molecules (genetic restriction). Although cataloguing the target epitopes present in tumours is a major task, it is certainly now possible and methodology will continue to improve. Given this increasing list of target epitopes, how can it be exploited?

Active immunization

One possibility will be to attempt active immunization against the antigens identified. This can be done using whole cells expressing the antigen, with recombinant viruses (most commonly recombinant vaccinia virus; see Table 10), with proteins or peptides, and most recently with DNA. Animal experiments have indicated that transduction of tumour cells with costimulatory molecules such as CD80 (B7) or cytokines (particularly GM-CSF and IL-2) reduces their tumorigenicity and renders them better able to immunize against subsequent tumour challenge. Recombinant viruses and DNA offer the possibility of introducing similar costimuli along with antigen and also ensure that the antigen can enter the class I pathway of antigen processing so that cytotoxic T cells should be induced. A related strategy is to isolate dendritic cells from patients and load them *in vitro* with tumour antigen before reintroducing them into the patient. Tumour antigen can range from tumour cell lysate, through recombinant antigens, to peptides, DNA, or RNA. Table 10 summarizes some of the approaches and antigens that have been tried in at least phase 1 trials. Inevitably, most of these trials have been performed in patients with advanced disease who have often received chemo- and radiotherapy. These patients are unlikely to make optimal immune responses, often have a large disease burden, and their tumours often show loss of HLA antigens. Nevertheless, objective clinical responses have been demonstrated in several trials.

Non-specific immunotherapy

Once cytokines became more readily available through the introduction of recombinant technology, several clinical studies were carried out. So far, the overall results have not been dramatic although high-dose IL-2, with or without lymphokine activated killer cells, does appear to cause some remissions in renal carcinoma and melanoma, but not without considerable toxicity. In retrospect, it is perhaps not surprising that the effects of high-dose cytokine therapy have been less than dramatic. Few cytokines are directly cytotoxic to tumour cells, although they may be cytostatic, and their effects are often transient because of receptor down-regulation. In addition, the indirect *in vivo* effects of high doses of cytokines are little understood. Much more work on the biology of cytokines is needed if they are to be used for tumour therapy in a rational fashion.

Cytokines have found application in cancer therapy, since colony stimulating factors can significantly shorten the period of aplasia following bone marrow transplantation. Another possibility is to use cytokines as vehicles for targeting. A recombinant IL-2–diphtheria toxin molecule has been engineered and shows some promise as an immunosuppressive agent. In principle, such a recombinant molecule can be used to target IL-2-receptor-bearing tumours such as those caused by HTLV-1.

Non-specific immunotherapy has a long history, dating back to the experiments of Coley. More recently Matthé used BCG to treat leukaemia, though with uncertain effect. However, there is now good evidence that intravesical BCG is an effective treatment for bladder cancer. Large-scale clinical trials have show that BCG can give very high response rates in recurrent superficial transitional cell carcinoma and the duration of remission is significantly prolonged. The mechanism of action of BCG remains incompletely understood but is presumed to be a consequence of altered local cytokine production in the tumour environment.

Passive immunotherapy

An alternative may be to develop passive immunotherapy. T-cell lines can be grown to very large numbers *in vitro* and in animal models tumour-specific cells can be effective especially when given with recombinant interleukin-2. Definition of tumour antigens will make it easier to isolate human tumour-specific clones and grow the large numbers of cells required for this strategy. Initial experiments using marker genes have shown some localization of *in vitro* expanded tumour infiltrating lymphocytes. More encouragingly, cytotoxic T cells against EBV antigens have been demonstrated to be effective in eliminating post-transplant lymphoma. To circumvent the difficulty of growing tumour specific T cell clones, methods are being developed for introducing genes for tumour-antigen-specific receptors into normal lymphocytes using retroviral vectors. A potential advantage of *in vitro* grown cells is that they might also be used to carry damaging molecules to the tumour. A disadvantage is that this method will always be labour intensive and will have to be carried out individually for each patient.

Conclusions

In non-malignant disease, immunological manoeuvres have been most effective when applied prophylactically. It is not expected that immunotherapy of established tumours will be easy. Antibody-based therapy shows promise and some antibodies may become standard adjuvant therapy in the near future. The future of T-cell-based therapy is less clear. Although active immunization against tumour antigens is now possible, its effectiveness will depend on the frequency of responding T cells and how quickly tumour escape mutants develop. Much work remains to be done to optimize immunization schedules and methods for monitoring the success of immunological approaches in cancer patients. New methods, such as the use of MHC tetramers and sensitive elispot assays, will help in enumerating tumour-antigen-specific cells.

6.6 Cancer: clinical features and management

R. L. Souhami

Introduction: cancer in general medical practice

Cancer is a common disease—approximately 20 per cent of the population of the United Kingdom will die of cancer. It is a source of concern and perplexity to oncologists that so many of their patients are referred to them late in the disease. Symptoms may have been present for a long time, during which their significance has been overlooked, or multiple (and sometimes futile) investigations have been performed with a failure to appreciate the need for speed. To this delay can be added a frequent lack of understanding of the possibilities of treatment and a failure to inform patients either of the nature of the diagnosis or of its implications and possibilities for therapy.

Almost every specialist sees patients with cancer affecting their particular field; unfortunately, these specialists may not have been taught the principles of cancer medicine. Oncologists therefore frequently see patients with advanced disease, who have not had a proper explanation of their illness, and who have little idea of what treatment might involve. Many patients dying with lung cancer in the United Kingdom have never seen a specialist in cancer medicine at any stage in their illness. While some will have had disease so far advanced that nothing but palliative treatment was needed, others may have been denied the opportunity for treatment and prolongation of life. The principles of cancer management are important for every physician.

Management of suspected cancer would be improved greatly if the following simple rules were adhered to:

1. Cancer should be suspected with any unexplained illness, especially in the elderly.
2. Imaging with isotopic and computed tomography (**CT**) and magnetic resonance imaging (**MRI**) (see Chapter 6.5), will often accelerate diagnosis. However, a tissue diagnosis cannot be made by these means and every attempt should be made to make a histological or cytological diagnosis expeditiously.
3. Patients with many tumours should start a planned programme of treatment within days and not weeks of diagnosis. The need for speed in diagnosis and treatment is tacitly recognized in specialist centres for breast cancer where patients can, in well-regulated clinics, reasonably expect to have a diagnosis made within a few days of first consultation and to begin definitive treatment within 2 weeks. This admirable efficiency should be attainable for nearly all cancers.

Common symptoms and signs of cancer

Many of the symptoms and signs of cancer are due to the local effects of the tumour infiltrating surrounding tissues and causing pressure and distortion of neighbouring structures. Tumours also produce symptoms that are, to some extent, common to all cancers. These are general symptoms due to the metabolic disturbances caused by the tumours and specific symptoms related to hormonal effects and immunological effects of the particular tumour—so-called paraneoplastic syndromes.

Pain

Most patients with cancer experience pain at some stage in their illness, either as a direct result of the tumour or of its treatment. Pain is a feature at presentation in about 30 per cent of patients with cancer, but the incidence varies greatly with the site of the tumour. For example, over 90 per cent of patients with primary bone tumours or with metastases to bone have pain, and this has the characteristic feature of being worse at night-time. In contrast, only 5 per cent of patients with leukaemia develop pain. Pain also varies according to the rate of progression of the disease and is more likely to occur with rapidly growing tumours. No symptom of cancer causes greater demoralization than unremitting pain. Any patient with unexplained, persistent pain should be suspected of having malignant disease and appropriate investigations performed. In pain clinics, 80 per cent of patients seen with cancer have pain due to direct tumour infiltration. If the pain is due to neurological infiltration it may be felt at the distribution of the nerve root. Certain pain syndromes are sufficiently common and misleading to warrant separate consideration.

Direct tumour infiltration of bone

The origin of the pain that occurs with tumour infiltration of bone is not fully understood. The periosteum is a pain-sensitive structure and may be the source in many patients. It is probable that osteolytic processes involving prostaglandins are also involved. Pain is a common feature of metastasis at the base of the skull. If the tumour is situated around the jugular foramen, pain is often referred to the vertex of the head and the ipsilateral shoulder and arm. Movement of the head may exacerbate the pain and, later, cranial nerve involvement may cause hoarseness, dysarthria, and dysphasia. Involvement of the 9th to the 12th cranial nerves, and the development of ptosis and Horner's syndrome indicates involvement of the sympathetic nervous system extracranially adjacent to the jugular foramen. When metastases occur in the sphenoid sinus, severe headache, usually felt in both temples or retro-orbitally, is a common feature. There may be a full sensation in the head, nasal stuffiness, and a 6th nerve palsy.

When metastases occur in vertebral bodies the pain frequently precedes neurological signs and symptoms. Persistent thoracic vertebral pain and a positive bone scan is an indication for urgent investigation and treatment. In small-cell lung cancer, for example, a patient with thoracic vertebral pain and a positive bone scan has a 30 per cent chance of developing a paraplegia. Ninety per cent of patients who have epidural spinal cord compression have vertebral body metastasis as the source of the epidural tumour (the management of spinal compression is described later). With metastasis to the odontoid process, patients complain of severe neck pain and stiffness radiating over the skull, up to the vertex. This is then followed by progressive neurological signs, often associated with autonomic dysfunction. In the

lower cervical vertebras pain is felt as an aching sensation, often radiating over both shoulders. If nerve root compression occurs at this site, there will be pain in the root distribution felt in the back of the arm, the elbow, and the ulnar aspect of the hand. The association with Horner's syndrome suggests involvement of the paravertebral sympathetic system. Lumbar metastases are associated with local pain, worse on lying or sitting and relieved by standing. In lesions in L1 the pain is often felt over the superior iliac crests. In the sacrum, pain may be accompanied by neurological signs with symptoms of bowel and bladder dysfunction and perianal sensory loss and impotence.

When tumours infiltrate peripheral nerves they are often accompanied by an alteration in sensation, with hyperaesthesia, dysaesthesia, and sensory loss. This is a particularly common presentation when tumours invade the paravertebral or retroperitoneal region. Here the pain is often in a root distribution and is unilateral. Another common site is when a metastasis in a rib entraps the intercostal nerves. When tumour infiltrates the brachial plexus the pain is felt in the C7 or T1 distribution. Pain in this site is frequent with the Pancoast syndrome, where an apical lung cancer infiltrates the lower brachial plexus roots. Pain in the C5 distribution occurs with upper root infiltration.

Visceral pain is a frequent symptom of cancer; it can cause diagnostic confusion and be difficult to control when a tumour has already been diagnosed. Poorly localized abdominal pain is a frequent feature of ovarian and pancreatic cancer and of peritoneal carcinomatosis. Retroperitoneal pain may be particularly difficult to diagnose. It may vary greatly in position (being relieved on leaning forwards) and be felt variably in the back. Left upper quadrant pain may be a presenting feature of carcinoma of the tail of the pancreas involving the mesentery of the splenic flexure of the colon.

Weight loss

Weight loss is an invariable accompaniment of advanced cancer and also a frequent presenting symptom. Often it results from the physical presence of the tumour interfering with gastrointestinal function, such as in carcinoma of the stomach, pancreas, or colon, or with peritoneal carcinomatosis. Mechanical obstruction of the bowel and loss of appetite commonly accompany these tumours. Loss of appetite is a frequent symptom of any cancer that has metastasized to the liver and usually appears at a point when metastasis is replacing much of the normal liver tissue. The mechanism is not known. Pancreatic cancers, and cancers metastatic to the porta hepatis, cause weight loss from a malabsorption syndrome due to obstructive jaundice or blockage of the pancreatic ducts.

Nevertheless, many tumours cause weight loss without direct involvement of digestive organs. It is well recognized that a weight loss of more than 5 per cent is a very adverse prognostic feature in almost all cancers. Usually it indicates that the disease is more widespread than is apparent on clinical investigation, but the mechanisms of this symptom, which is often accompanied by alteration of taste, anorexia, and a general feeling of ill health, are obscure. Sometimes quite profound weight loss can accompany non-metastatic tumours, which are relatively small. As with advanced cancer, the cachexia syndrome is then accompanied by anorexia and altered taste. These tumours may produce circulating factors responsible for the weight loss and loss of appetite. Tumour necrosis factor-a and interleukin 1b have both been shown to produce cachexic syndromes experimentally. Tumours may themselves contribute to weight loss by alteration in protein and energy metabolism. Negative nitrogen balance has been frequently documented in patients with cancer, particularly when advanced. An increase in whole-body glucose recycling via pyruvate and lactate has also been described in patients with cancer.

The loss of body weight is therefore due to an accumulation of events involving direct interference with digestive function, production of factors leading to weight loss and anorexia by the tumour, and possible alteration in protein and energy metabolism. Later in the course of the illness, antineoplastic treatment with chemotherapy, radiation, and surgery may exacerbate weight loss.

Tumour mass

It is astonishing that patients sometimes report the appearance of a swelling only to have the significance of the finding overlooked by their doctors. The appearance of any mass should lead to prompt investigation. Although imaging techniques can sometimes distinguish benign from malignant swellings, a biopsy will usually be necessary and should be taken without delay. Nowadays it is often unnecessary to undertake surgical excision biopsy. Indeed, doing so may sometimes make subsequent management almost impossible. Where there is doubt about the nature of a swelling the correct procedure will usually be needle biopsy. Biopsy is in general preferable to aspiration cytological diagnosis because the precise diagnosis of many cancers depends on architecture as well as on cytology. The great advantage of early biopsy diagnosis is that a planned approach to treatment can then be undertaken by oncologists, radiotherapists, and surgeons together. Injudicious, and often marginal, surgical excision may lead to a greatly increased risk of local recurrence of the tumour. This is a particularly frequent occurrence in sarcomas where an avoidable amputation may then be necessary or the local recurrence provoked by inadequate excision prove uncontrollable and fatal. Furthermore, for some tumours chemotherapy may be the first line of treatment and will allow assessment of response to drug treatment before surgery is undertaken; a good response may modify the need for surgery.

Fever

In cancer, fever is usually caused by infection. However, about 30 per cent of patients with cancer develop fever at some stage in their illness and it may be the presenting feature of some tumours, particularly lymphomas, renal carcinoma, and any cancer metastatic to the liver. The fever may be accompanied by sweating, particularly at night. The characteristic feature of the sweats that accompany malignant lymphomas and other cancers is that the patient falls asleep and wakes in the middle of the night to find themselves drenched with sweat. Rigors are very uncommon with febrile episodes in cancer, and should always lead to a suspicion that an infective complication is present. Characteristic patterns of fever are seldom observed; usually it is of a low-grade remittent type. The Pel–Ebstein fever of Hodgkin's disease, in which febrile periods are interspersed with several days of normal temperature, is well known but very uncommon.

The cause of the fever of malignant disease is unknown. Endogenous pyrogens may be liberated from mononuclear phagocytes in the liver or bone marrow. Tumour cells have also been shown to produce 'pyrogens'. The nature of the cytokines responsible is not clear. Exogenously administered tumour necrosis factor and interleukin 2 both produce fever and may be secreted in patients with cancer.

The fever of malignant disease may respond to simple antipyretics such as aspirin or paracetamol. In malignant lymphoma it will disappear with successful treatment of the tumour. In advanced cancer non-steroidal anti-inflammatory agents may also help, but corticosteroids are more effective, at least for a short period.

Anaemia

The anaemia of malignant disease is multifactorial (see Section 22). Chronic blood loss may occur in cancer of the gastrointestinal tract, as a result of vaginal bleeding, or because of malabsorption of iron. Usually the anaemia is normochromic, or slightly hypochromic in nature, and the plasma transferrin and serum iron are low. The iron stores are not reduced as judged by stainable iron in the bone marrow. The mechanism is discussed in Section 22.

Hypercalcaemia

Malignant disease is responsible for most of the very severe cases of hypercalcaemia seen in clinical practice. The patient will usually have widespread skeletal metastases, but occasionally the syndrome is paraneoplastic (see below). Parathyroid hormone-related protein (**PTH-rP**) may contribute to the pathogenesis of both paraneoplastic hypercalcaemia and that produced by bone metastases. For some cancers it appears that metastases in bone release PTH-rP locally and stimulate osteclastic resorption of bone. Resorption releases cytokines such as transforming growth factor-b and insulin-like growth factor 1 which, in turn, provokes more release of PTH-rP from the metastatic tumour. These cytokines may also cause proliferation of the tumour. Bisphosphonates may arrest the process by decreasing the activity of the osteoclasts. In the same way, bisphosphonates interrupt the activity of PTH-rP when this is liberated from a non-metastatic tumour as a paraneoplastic phenomenon. Bisphosphonates are important both for the treatment of hypercalcaemia and containing growth of bone metastases.

Hypercalcaemic symptoms include anorexia, weight loss, and mental confusion, all of which may simulate metastatic disease. The symptoms and signs of hypercalcaemia and its management are discussed in Section 12 and Section 22.

Paraneoplastic syndromes

Many patients with cancer have complications that are not due to direct invasion of adjacent tissues by the cancer or its metastases. The tumour produces hormones or cytokines, which are responsible for symptoms at a remote site. Alternatively, the tumour provokes an immune response to altered cellular constituents and the paraneoplastic syndrome arises from the resulting immunological reaction. Paraneoplastic syndromes are not rare but each syndrome only occurs in a minority of

patients with cancer. Furthermore, although some syndromes, such as the production of parathyroid hormone-related peptide, are found in many cancers, others, such as Cushing's syndrome, are found in a few neuroendocrine tumours.

It is important to be aware of paraneoplastic syndromes because their appearance may be the first sign of malignant disease. Furthermore, they may lead the physician into believing that the patient has metastases and thus alter management inappropriately. The syndromes themselves may cause considerable disability, which is amenable to treatment. The diversity of paraneoplastic syndromes is such that only a brief description can be given in this chapter. A summary is shown in Table 1.

Cancer can cause almost any clinical syndrome, however bizarre, and should, therefore, enter the list of differential diagnosis in any unusual clinical disorder. There are, however, dangers in making a diagnosis of a paraneoplastic syndrome as a cause of symptoms. For example, most neurological problems in cancer are not due to paraneoplastic manifestations but to the local presence of the tumour. This means that spinal cord signs in a patient with cancer are much more likely to be due to direct compression of the cord than due to transverse myelitis as a paraneoplastic syndrome. Prompt treatment of the space-occupying lesion is essential and a mistaken diagnosis of paraneoplasia is potentially disastrous. Similarly, endocrine syndromes from cancer are often caused by resectable endocrine cancers themselves. Anaemia or thrombosis may be paraneoplastic in origin but more frequently a deep venous thrombosis is due to a direct compressive effect of cancer in the pelvis and iron-deficiency anaemia should always raise the possibility of occult bleeding. Unless obviously paraneoplastic in nature, symptoms from cancer should, in the first instance, be regarded as likely to be produced by a direct effect of the tumour since this distinction has important therapeutic consequences. Some of these syndromes are described in detail in later sections: endocrine in Section 12, renal in Section 20, and neurological in Section 24.

Investigation and staging

Histopathological diagnosis

The foremost investigation of a cancer is to verify that the diagnosis is correct. Oncologists are completely dependent on the quality of the histopathological examination. Errors are not common but may be very serious, as they may lead to inappropriate investigation or the denial of curative treatment. The latter merits fuller consideration.

Misdiagnosis of a lymphoma

Lymphomas may present with histological appearances that resemble anaplastic or undifferentiated carcinoma. The diagnosis should therefore always be considered when this is the pathology report. Nowadays diagnosis of lymphoma has been made much easier as a result of immunohistochemical techniques. An example is shown in Fig. 1. The use of antibodies to leucocyte common antigen, or a combination of B-cell and T-cell markers are invaluable in diagnosis. If tumour cells do not stain, it makes lymphoma unlikely, but does not rule out the possibility. If positive, the diagnosis of lymphoma is virtually certain. Nevertheless, histologists may have difficulty either because the immunohistochemical technique is not sufficiently standardized in the laboratory, or because they mistake infiltrating lymphocytes for the tumour cells. Some undifferentiated pleomorphic lymphomas may be negative for leucocyte common antigen. These present formidable diagnostic difficulties, which may be resolved by examination of the tissue by molecular genetic techniques looking for rearrangement of the T-cell receptor genes or for immunoglobulin gene rearrangement. Other situations in which lymphoma may be overlooked, or a mistaken diagnosis made, are in the pulmonary lesions (or metastases) from small-cell carcinoma, which may be mistaken for lymphoma, or in biopsies from gastric ulcers where malignant lymphoma cells may wrongly be regarded as a chronic inflammatory cellular infiltrate. As non-Hodgkin's lymphomas can present in many different sites, where the diagnosis is not clear a prudent physician will always ask the pathologist whether the diagnosis of lymphoma has been firmly excluded when a diagnosis of chronic inflammation is made in an atypical clinical setting.

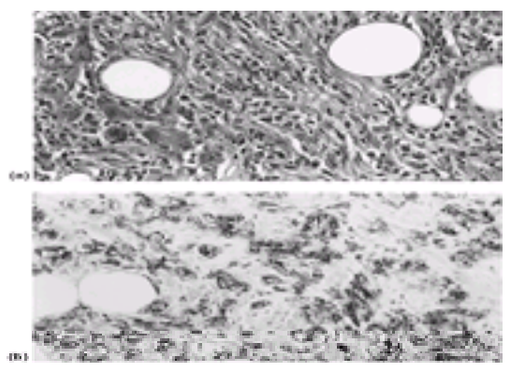

Fig. 1 (a) Section stained with haematoxylin and eosin of excision specimen of a retroperitoneal mass. The tumour is poorly differentiated, with fibrosis and infiltration of retroperitoneal fat. (b) Immunostaining with an antibody of CD20 (a B-lymphocyte marker) shows intense staining of tumour cells confirming that this is a B-cell non-Hodgkin's lymphoma.

Mediastinal or metastatic germ cell tumours

These tumours may be mistaken for anaplastic carcinoma, but the recognition of a germ cell tumour is exceedingly important because many of them are curable. Mediastinal germ cell tumours typically present in young adults and with cervical node metastases. Special stains or serum tests for a-fetoprotein or b-human chorionic gonadotrophin may be very helpful, but if negative, do not exclude the diagnosis. Several reports have indicated that the use of intensive combination chemotherapy, as for germ cell tumours at other sites, may result in lasting remissions of mediastinal poorly differentiated tumours in young adults, even when there were no other features of the germ cell nature of the neoplasm. In contrast, poorly differentiated adenocarcinoma in the mediastinum of young adults can seldom be ascribed to germ cell tumour, although occasional cases may respond dramatically to chemotherapy.

Investigating the local extent of the tumour

Following diagnosis, clinical staging is the most important first procedure. Clinical examination will often establish the likely extent of the tumour. This may require specialized techniques such as ear, nose, and throat examination and bronchoscopy. The extent of infiltration and fixation to surrounding structures is assessed. CT scanning and MRI have greatly improved the preoperative determination of tumour extent. They have largely replaced more invasive techniques such as angiography and lymphangiography. MRI is particularly valuable in the staging of sarcomas and central nervous system tumours. Both techniques show the extent of the tumour and infiltration of surrounding structures (Fig. 2(a) and Fig. 2(b)). CT scanning is a particularly valuable aid to needle biopsy diagnosis of deep-seated tumours.

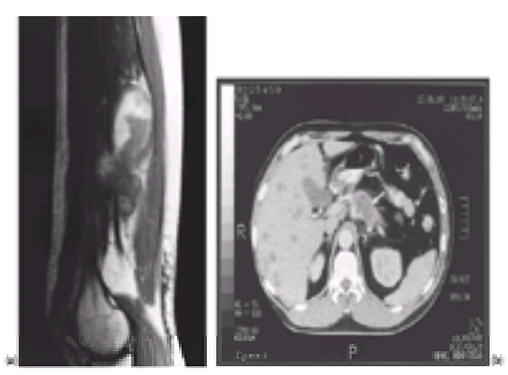

Fig. 2 (a) Longitudinal MRI of lower thigh. A large, soft tissue mass is seen displacing the muscle groups posteriorly. It lies behind the femur and the femoral artery is in close proximity to the mass, which at one point surrounds it. (b) CT scan of abdomen. A carcinoma of the body of the pancreas is shown (arrowed). The liver

contains numerous small metastases.

Staging of lymph node spread

Spread to adjacent lymph nodes may be noted clinically or on straightforward investigations, such as chest radiography. Lymphangiography was used formerly to examine pelvic and lower para-aortic nodes but has largely been supplanted by CT. In fact the two techniques give slightly different information, as a CT scan will show enlarged lymph nodes (the assumption being that these are replaced by tumour when the lymph nodes become more than 2 cm in size), while lymphangiography may show abnormal appearances even when the nodes are not enlarged but contain foci of tumour cells within them.

Staging for distant metastases

Bone metastases are usually demonstrated by $^{99}Tc^{m}$-polyphosphate isotopic scanning. The sensitivity of the examination is high and abnormalities frequently precede detectable changes on plain radiography. However, the specificity is rather lower because any traumatic or inflammatory disorder in bone can give areas of increased uptake. When areas of increased uptake are seen on technetium scanning it is important to follow up with plain skeletal radiography, particularly in the long bones of the limbs. This is because isotope scanning gives no indication of the structural integrity of the bone and the risk of pathological fracture in a limb cannot be assessed on an isotope scan.

Liver metastases are detected by an increase in circulating enzyme levels, particularly alkaline phosphatase and serum glutamic oxaloacetic transaminase. Lactic dehydrogenase is also elevated in a somewhat greater frequency. Nevertheless, liver metastases can be present without alteration in serum enzyme levels and ultrasound scanning is an invaluable non-invasive method of detecting liver metastases. CT and modern ultrasound scanning are approximately equal in sensitivity. Metastases down to 1 cm in size can be detected reliably.

Pulmonary metastases may be detected on chest radiograph but may be present even when the chest radiograph is normal if they are below 1.5 cm in size. Metastases larger than this may also be overlooked if they are situated behind the heart or behind the diaphragm. CT scanning is the best method for demonstrating pulmonary metastases and lesions as small as 0.4 cm in diameter may be seen. CT scanning is therefore an essential investigation in patients who are to undergo extensive or mutilating surgery, such as for sarcomas where metastases to the lungs are particularly frequent and the presence of metastases may influence the surgical decision.

Brain metastases are detected by CT scanning or, more reliably, by MRI. In a patient who is neurologically normal there is only a low chance of detecting asymptomatic cerebral metastasis by these methods (about 5 per cent). For this reason the technique is not worthwhile as a routine investigation of most cancers.

Surgical staging of cancer

Surgery specifically for staging rather than treatment is reserved for a few specific tumour sites. In lung cancer, investigation of the mediastinum is extremely important in deciding whether a tumour is operable. CT scanning may demonstrate inoperability either because the tumour is infiltrating the mediastinum or because there is lymph node spread to both ipsilateral and contralateral hilar nodes. However, in other patients, the mediastinum may appear normal and a mediastinoscopy may reveal tumour in mediastinal nodes implying the inoperability of the condition. Staging laparotomy used to be performed in localized Hodgkin's disease, but is now reserved for specific indications. In ovarian cancer thorough surgical staging is performed at the time of the initial resection, but surgical staging is in this case (as in many other tumour resections) part of the treatment.

An important recent development has been the introduction of so-called 'sentinel node' biopsy. In this technique a radioactive tracer, or a blue dye, is injected in the vicinity of the tumour, or into the tumour itself, and the lymph node at the first adjacent site of uptake is sampled, either by biopsy or surgical removal. In the case of breast cancer, the disease in which the technique is exciting most interest, the sampling may be at the time of operation. The presence or absence of tumour cells in the lymph node is taken as an indication of whether lymphatic spread has occurred and surgery, and subsequent treatment, can be modified accordingly. There are unresolved issues about accuracy of the technique, and the confidence with which the results can be used to plan therapy, but it is likely that the procedure will become part of the lymph node staging of some cancers.

The use of a staging notation

This has been valuable in the reporting of results of cancer treatment and is also helpful, in an individual patient, in focusing attention on the extent of the disease and the subsequent planning of treatment. A widely used system is the **T** (tumour) **N** (nodes) **M** (metastasis) system. This is particularly valuable for tumours that follow an orderly progression of spread from the primary site to adjacent lymph nodes and then to metastatic sites. Thus, tumours of the head and neck, breast, non-small-cell lung cancer, renal carcinoma, bladder carcinoma, and rectal carcinoma are all well-defined by this means. In addition to the TNM system, many classifications contain a stage grouping, by which tumours with varying TNM assignments are grouped together because of equivalence of prognosis or similar approaches to management. An example of the TNM staging system and stage grouping for lung cancer is given in Table 2.

Not all tumours can be summarized by the TNM system. For example, small-cell lung cancer is usually widely metastatic at the time of presentation and a simpler classification into limited (confined to one side of the thorax with ipsilateral supraclavicular node) or extensive (disease that is bilateral within the chest or metastatic) is used. This simple classification serves to separate patients in whom radiation treatment may be worthwhile and those in whom it is unlikely to have any benefit. In leukaemia and myeloma, other staging criteria, which are based on prognostic factors and are not related to anatomical stage, have been developed. In Hodgkin's disease and non-Hodgkin's lymphoma, the presence (B) or absence (A) of constitutional symptoms is added to the anatomical staging system, which is used to define the degree of lymph node spread. These additions were made because the presence of constitutional symptoms confers an adverse prognostic significance in addition to the prognosis related to the anatomical stage (see also Section 22).

Principles of cancer management

The principles and details of cancer chemotherapy are discussed elsewhere. This section summarizes an integrated approach towards cancer management.

Nowadays the management of cancer will nearly always involve more than one specialist and more than one type of treatment. Increasingly, patients with cancer are being seen in joint clinics where surgeons, medical oncologists, and radiotherapists plan treatment. Often there will be several possible approaches towards treatment, and these require discussion and assessment by the appropriate experts. It is of inestimable value if a patient is referred for expert opinion before any definitive procedure is undertaken. For example, more information about gynaecological malignancy can often be obtained if a patient with abdominal swelling and ascites and an ultrasound-demonstrable mass in the pelvis is assessed preoperatively by a gynaecological oncologist. The subsequent laparotomy is likely to reveal much more information than if it is carried out as an emergency by an inexperienced surgeon. Similarly, a mass on a limb should be investigated thoroughly, including a biopsy diagnosis, before surgery is undertaken, because the nature of the histological diagnosis may profoundly alter management in the case of a sarcoma. Table 3 lists tumours in which radiotherapy and chemotherapy have an important part to play in management and where these modalities of treatment may sometimes be curative.

Surgery

Surgeons see over 80 per cent of patients presenting with cancer for the first time. Following diagnosis and staging to exclude metastases, curative surgery may be undertaken, for example in breast or colorectal cancer. The aim of the operation is complete excision of the tumour with a margin of normal, uninvolved tissue around the main tumour mass. The risk of local recurrence is very high with a marginal excision in which a tumour has been 'shelled out' because the pseudocapsule around the tumour is likely to be infiltrated with tumour cells. Removal or sampling of the draining lymph nodes will often be undertaken, for example in breast cancer and other tumours where involvement of regional lymph nodes is likely (see the discussion of sentinel node biopsy above). In some cancers, such as breast cancer, it has become clear that very extensive primary tumours are usually accompanied by distant metastasis. In this situation the role of surgery is to prevent local recurrence rather than to be curative. With other tumours, for example of the head and neck, extensive surgery may be the only means of gaining effective control and in these cases a considerable degree of surgical expertise is necessary. In some situations the tumour may be approached either by surgery or by radical radiotherapy and

there may be little to choose between the results. An example is in early prostate cancer where the results of radical radiation and surgery are probably equivalent, and in operable oesophageal cancer, particularly of squamous histology, where long-term results of radiation may be the same as those of surgery. In these situations the benefits of local control, survival, and long-term side-effects have to be judged together in making a decision.

Nowadays local treatment frequently involves surgery and radiation to maximize the chances of local control. Wide local excision is increasingly practised in carcinoma of the breast and radiation to the breast and to axillary nodes is used as an adjunct. Radiation reduces the risk of local relapse, both in the breast and in the axilla. 'Lumpectomy' and radical radiotherapy have now replaced mastectomy for many patients with small primary breast cancers. Preoperative radiation of soft tissue sarcoma may increase the chance of successful compartmental excision of the tumour, and postoperative radiation decreases the risk of local recurrence in patients in whom the excision has been marginal. These are two examples of the way in which the definitive local management of the primary tumour is a matter of discussion between surgical and radiation oncologists.

Optimum local management has become further complicated by the successful use of chemotherapy in many tumours. An example is the treatment of Ewing's tumour. In this highly malignant round-cell tumour of childhood, initial chemotherapy usually produces a prompt regression of the main tumour mass, both in the bone and in the surrounding soft tissues. However, the tumour permeates widely through the bone, and local irradiation, given after initial chemotherapy, is a standard means of maintaining local control. There is an increasing tendency to continue both chemotherapy and radiation synchronously. However, in large tumours, even with full-dose radiation, the risk of local relapse is still present. For this reason surgery is being used increasingly, provided that the cosmetic and functional results are reasonable. Surgical excision alone may be successful after chemotherapy, but frequently, because of the permeating nature of the tumour, viable tumour is present right up to the resection margins of the bone. In this situation radiation will be needed in addition to the chemotherapy and surgery. In these tumours, very detailed planning of the approach to treatment by experienced specialists is essential for optimum results.

Specific management problems

Spinal cord and cauda equina compression

Cord and cauda equina compression are common and devastating complications of metastatic cancer. For successful management it is essential to remember one rule—every hour counts. Even if early treatment is not always successful, delay ensures that the patient will end his or her days bed- or chair-bound, paralysed, and incontinent.

The metastasis often develops in a vertebra, from which it spreads directly or via the intervertebral foramina to compress the cord (or cauda equina below L1) from the extradural space (Fig. 3). Alternatively, the malignant mass may originate in a mass of retroperitoneal nodes, or the primary tumour (for example a bronchial carcinoma) may be in the posterior mediastinum or retroperitoneum (Fig. 3). Damage to the cord is by direct compression and by interruption of the arterial supply leading to infarction. It is uncommon for the tumour to be metastatic to the cord itself, although meningeal spread occurs and may cause compression (see carcinomatous meningitis, below). Cord compression may be the first manifestation of cancer but more commonly arises with metastases from a known primary.

Fig. 3 MRI of thoracic vertebras showing destruction of the body of T10 by a mass of Hodgkin's disease. The tumour extends posteriorly and compresses the spinal cord. The tumour mass has passed to the side of the vertebra (not shown), and is also compressing the cord posteriorly after infiltrating into the intervertebral foramen.

Pain often precedes the onset of neurological symptoms. In the case of cord compression it is felt in the thoracic and cervical vertebras. It is worse on coughing. An exceedingly sinister symptom is vertebral pain with a root distribution. A patient with this symptom needs urgent investigation, as cord compression may be imminent. The next symptom is usually weakness of the legs combined with sensory loss, of which loss of proprioception is especially characteristic. Loss of bladder and bowel sensation is late and once weakness and bladder disturbance begins, progression to irreversible paraplegia occurs in hours or a few days.

The patient often has a sensory level, motor weakness, brisk leg reflexes, and extensor plantar responses. The bladder may be palpable. Radiography of the spine often shows vertebral destruction—loss of a pedicle or compression of the body being typical. Myelography will demonstrate the block, but MRI (and, less reliably, CT scanning) is very valuable and has now largely replaced myelography. Treatment usually consists of surgical decompression, although for radiation-sensitive tumours such as lymphoma or Ewing's sarcoma, high-dose corticosteroids and radiation will produce quick relief of compression. If there are multiple sites of block, radiation and steroids may be the only feasible option. The surgical approach to decompression varies according to the nature of the lesion—whether anterior or posterior, cervical or thoracic. Anterior decompression may involve removal of part of the vertebral body, but the risk of destabilization of the spine means that immediate stabilization may be necessary. It is not clear whether radiation is inferior to surgical decompression in patients with tumours that show sensitivity to radiation. Radiation is, in any event, usually given after laminectomy.

Outcome is crucially dependent on the functional state of the patient before treatment. Less than 10 per cent of those who are paraplegic before treatment will be able to walk later, 25 per cent will do so if they have some motor function preserved, while almost all patients who can still walk will continue to be able to do so.

Cerebral metastasis

Cerebral metastasis is clearly a serious complication of cancer occurring in about 30 per cent of all patients. Metastases are over 10 times as common as primary brain tumours. About 15 per cent of patients with cancer will develop symptomatic brain metastases during life. Thus, there will be approximately 15 000 deaths each year in the United Kingdom of patients with symptomatic cerebral metastasis. Metastasis at this site is life-threatening and disabling, causing severe deterioration in quality of life and great difficulty for the patient and his or her carers.

Most cerebral metastases are intradural, usually in the substance of the brain extending to the meningeal surface. About 80 per cent of these are situated in the cerebrum and the rest in the cerebellum and other regions. Lung cancer and breast cancer are the most common primary sites, and certain tumours are particularly associated with single metastases (cancer of the breast, ovary, and kidney). Usually cerebral metastases occur following diagnosis and treatment of a primary tumour.

In the brain substance, the metastases are vascularized from the cerebral circulation, but there is no evidence that a vascularized metastasis maintains a 'blood–brain' barrier—the vascularization is, after all, of non-nervous tissue without the tight endothelial junctions which characterize cerebral capillaries. Indeed, capillary leakiness appears to be a feature of cerebral metastasis and is responsible for the substantial amount of oedema of the brain, which typically accompanies cerebral metastasis. The blood–brain barrier may, however, be an important impediment to cytotoxic treatment when the metastasis is being established before it is vascularized and at the periphery of an established metastasis. It will be a very significant factor in failure of treatment of leptomeningeal cancer.

Symptoms and signs

The typical signs are headache, disturbance of cognitive function and effect, focal fits or grand mal convulsions, and limb paresis. Headache usually reflects a rise in intracranial pressure. It is typically present in the morning and increases in duration and frequency until other signs of raised intracranial pressure become apparent.

Focal weakness is present in about half of all patients, and disturbance in higher cerebral function in about 60 per cent.

Investigation

CT scanning or MRI is the essential diagnostic investigation. On a CT scan most metastases appear hypodense but enhance with contrast material. Typically there will be oedema around the metastases. Occasionally CT scans may be normal even in patients whose symptoms strongly suggest cerebral metastasis and where cerebral metastasis is sometimes proved by further scanning some weeks later or at autopsy. In these patients there may be multiple small metastases without oedema or leptomeningeal spread. MRI has a greater degree of sensitivity and is particularly valuable in detecting leptomeningeal spread of tumour. In the presence of a known primary it is not usually necessary to subject patients to histological confirmation of the tumour. However, after a very long disease-free interval, or where the primary is unknown, histological diagnosis will be essential.

Treatment

Dexamethasone is started as soon as the diagnosis is made. The usual dose is approximately 16 mg/day, although higher doses can be used if the patient does not respond. The clinical effects are rapid and usually noticeable within 24 h. The maximum effect is achieved in about 4 days. Approximately 80 per cent of patients will respond. Phenytoin or carbamazepine are used to control focal fits.

The most useful non-surgical treatment is radiation therapy. The therapeutic doses depend on the likely primary site, but usually consist of 30 Gy in 10 fractions in 2 weeks, or 40 Gy in 15 fractions in 3 weeks. The former is the most widely used schedule in the United Kingdom and no schedule has been proved to be superior over another. Solitary cerebral metastases may be removed if they are in an accessible site. The criteria for operation are usually that a solitary metastasis is present, that the diagnosis is uncertain, or that the response to radiation is unpredictable because of doubt about the nature of the primary tumour. The patient must be clinically fit in other respects to undergo surgery, and without life-threatening metastatic disease elsewhere.

There has been recent interest in the use of chemotherapy in the treatment of cerebral metastasis, as it is now clear, for example in small-cell lung cancer, that the response to chemotherapy in cerebral metastases is equal to that in metastases at other sites. Responses to chemotherapy in tumours such as small-cell lung cancer may be rapid and dramatic but cranial radiation will usually be necessary as an adjunct to chemotherapy.

Prognosis

The prognosis depends on the clinical setting. If there is a solitary metastasis with no disease elsewhere then a long disease-free interval may result, particularly if the metastasis has occurred after a considerable interval following the primary treatment. In other tumours, where multiple metastases occur either synchronously with the primary tumour or after a short disease-free interval, and where the tumour is a particularly difficult type to treat (such as melanoma and non-small-cell lung cancer), the prognosis is very poor indeed. Overall, only 30 per cent of patients will be alive at 1 year and the median survival is about 7 months. A small randomized trial has suggested that surgical resection of a solitary metastasis adds to survival when compared with radiation and steroids alone.

Carcinomatous 'meningitis'

Leptomeningeal spread of cancer seems to be increasing in frequency. In autopsy series about 4 per cent of patients dying of advanced cancer have leptomeningeal spread. The frequency is higher in breast cancer (5 to 10 per cent). This complication is increasing in lymphoma, small-cell lung cancer, ovarian cancer, and some sarcomas. Curiously, adenocarcinomas seem to have a greater propensity for this form of metastasis than other epithelial tumours. There may or may not be intracerebral metastasis at the same time. Malignant cells may enter the cerebrospinal fluid from intracerebral tumour via the arachnoid, or from vertebral deposits growing along nerve roots into the subarachnoid space. However, the most likely source of seeding appears to be directly from the bloodstream. Tumour is present as a thin covering of malignant cells, but in some cases the tumour cells penetrate deeper into the substance of the brain along blood vessels. The tumour may also penetrate cranial and spinal cord nerves as they pass through the subarachnoid space.

Clinical features

The onset is usually over a few weeks and may be subtle at first. Headache is often severe and is due to raised intracranial pressure. Cranial nerve dysfunction is frequent, with diplopia, hearing loss, and facial numbness. There is often back pain and sometimes bladder and bowel dysfunction. A change in mental state may occur. Focal fits are uncommon. On examination there may be an abnormal mental state, signs of raised intracranial pressure, and extensor plantar responses. Focal neurological signs in the limbs are uncommon. Cranial nerve weaknesses are frequent, the most common being ocular muscle palsy, facial weakness, and hearing loss.

Diagnosis and treatment

The diagnosis is made by examining the cerebrospinal fluid. Typically, the opening pressure is high, the white count is raised, the cerebrospinal fluid sugar low, and the protein increased. Cytological confirmation on the first lumbar puncture is obtained in about 60 per cent of patients, but a negative examination does not exclude the diagnosis. Myelography may show typical appearance of multiple small tumour seeds in the subarachnoid space, but MRI is proving invaluable and is now the preferred initial investigation if cerebrospinal fluid cytology is negative and the diagnosis strongly suspected.

Treatment is difficult and often unsuccessful. Temporary improvement can be obtained by the insertion of an intraventricular reservoir to deliver chemotherapy. Chemotherapy administered by lumbar puncture is uncomfortable and may not be effective if there is meningeal invasion supratentorially, since the drugs do not penetrate in high concentration beyond the foramen magnum. In breast cancer and lymphoma, intrathecal methotrexate is effective and may be administered in combination with thiotepa or, in the case of lymphoma, cytosine arabinoside. In addition, whole-brain irradiation is often given if the patient is improving and the clinical situation indicates that this treatment would produce further benefit. In general, however, the prognosis is poor when the meningeal infiltration is from an epithelial tumour, with a median survival of only 4 months.

Pleural effusion

Malignant pleural effusions occur either as a sign of metastasis or due to direct invasion of the pleural space from an underlying primary bronchial carcinoma, or pulmonary metastasis. The effusions are typically exudates with a protein content of more than 3 g/dl. There is increased capillary permeability through inflammation and abnormal capillary endothelium in the tumour lining the pleural space. Typical primary sites are: breast and ovarian cancer, as common epithelial tumours metastasize into the pleural space; lung cancer, as a cause of pleural effusion with underlying lung disease; and sarcomas, as a cause of pleural effusion due to invasion of the pleura by pulmonary metastasis.

Clinical features

The typical features are dyspnoea, which is directly related to the size of the effusion, dry cough, and chest wall discomfort. Even a small effusion may cause dyspnoea in a patient who has underlying lung disease such as chronic bronchitis and emphysema. Many patients have asymptomatic pleural effusions detectable on chest radiograph. The sequence of radiological appearances includes blunting of the costaphrenic angle (with volumes of 2 to 3 ml), increasing effusion, and, finally, mediastinal shift, which usually occurs when amounts in excess of 2 litres have accumulated. Ultrasound examination may assist in localizing the effusion and any loculi, which may influence the procedure for aspiration.

Diagnosis

The diagnosis, if the primary tumour is not known, is made by demonstrating malignant cells in the pleural fluid. The rate of positivity, in patients known to have an underlying cancer, is about 60 per cent with a low false-positive rate. If pleural cytology is negative on the first aspiration it should be repeated using fresh aspirates. Occasionally, pleural biopsy will be necessary to make a diagnosis, and the combination of the two increase the diagnostic yield to about 90 per cent. If both techniques fail, thoracoscopy is more successful, but is, of course, more invasive.

Treatment and prognosis

The primary tumour should be treated if possible. When a pleural effusion persists after treatment of the primary tumour, or if such treatment has been unsuccessful, treatment may need to be directed to the effusion itself. Frequently the effusion will need to be aspirated in order to make the patient comfortable, and pleural sclerotherapy considered. For best results of sclerotherapy it is important to drain the pleural cavity as completely as possible. A small flexible chest drain is ideal and is left in place for some time (12 to 24 h if possible) to allow the fluid to drain as far as possible. If there has been loculated effusion, the insertion of the drain is best done under ultrasound control. Sclerosis of the two pleural surfaces can be achieved by a variety of means; all give approximately equivalent results. The most favoured techniques are the instillation of talc, tetracycline, bleomycin, or *Corynebacterium parvum*. They all cause an inflammatory reaction in the pleural space and have an approximately 60 per cent success rate in preventing immediate recurrence of the effusion. When pleural effusion complicates an underlying bronchial carcinoma it is more difficult to control than when it is a metastatic manifestation of a distant neoplasm, such as ovarian cancer. If the effusion is recurrent and is the major cause of morbidity, pleuroperitoneal shunting can be carried out, whereby the pleural fluid drains into the peritoneal cavity.

Pericardial effusion

The most common malignancies to cause pericardial effusion are breast, lung, ovary, and gastrointestinal cancers and non-Hodgkin's lymphomas. Pathologically, the pericardium may be infiltrated with tumour or diffusely nodular. The accumulation of fluid is due to obstruction of lymphatic and venous drainage of the pericardium.

Symptoms and signs

The symptoms are usually vague in onset, including orthopnoea, dyspnoea, and cough. Fatigue and dizziness also develop. If cardiac tamponade occurs it is associated with severe dyspnoea, vague central chest pain, and anxiety. The physical signs are usually minimal, although when tamponade occurs there will be jugular venous distension, pulses paradoxus, hypotension, and tachycardia.

Investigation

Investigations include a chest radiograph, which shows enlargement of the cardiac silhouette, and echocardiography, which is a rapid non-invasive technique for demonstrating pericardial effusion.

Diagnosis and management

The diagnosis is made by finding malignant cells in the pericardial fluid. False negative results occur and the test may need to be repeated. Once the diagnosis has been established, the pericardial fluid may need drainage using a small rubber catheter. Installation of sclerosants can be carried out as for pleural effusions, but troublesome pericardial effusions can be controlled by the formation of a pericardial window through a small left anterior thoracotomy. Some patients, particularly those who have lymphoma, will respond to external-beam radiation with a dose of approximately 30 Gy given in 15 fractions over a 2- to 3-week period. Radiation is also considered for control of chronic pericardial effusion in breast cancer. The management of cardiac tamponade is discussed in Section 15.

Metastatic cancer from an unknown primary site

Approximately 3 per cent of patients present with a metastasis from a cancer where the primary site is not known after full history, physical examination, blood count, and chest radiograph. This clinical situation requires considerable clinical expertise, as the diagnosis creates especial anxiety for the patient. The clinician has to decide on the most effective therapy and to sustain the patient without indulging in futile, invasive, and expensive investigations which will not alter management. The problem with extensive investigations is that they seldom alter management and the overall prognosis in this position is poor (4 to 6 months median survival). As one investigation after another fails to reveal the primary site, the patient and the doctor may come to consider this a failure and confidence can be badly shaken. Nevertheless, some tumours are potentially curable and, for these, investigation is justified. The common primary sites, when one is discovered, are cancers of the lung, pancreas, liver, gut, and stomach. The tumours for which therapy is possible, and which therefore must not be overlooked, are listed in Table 4.

Presentation

If the presentation is exclusively in cervical nodes, a full ear, nose, and throat examination is mandatory as local treatment with surgery and/or radiation may produce prolonged survival or even cure. The higher the cervical node, the more likely it is that and ear, nose, and throat tumour is the primary source. Supraclavicular lymph nodes carry a worse prognosis because the likely primary site on the right-hand side is the lung or breast, and on the left-hand side intra-abdominal malignancy via the thoracic duct. Patients presenting with lymph node enlargement in the axilla are likely to have breast cancer as the primary site and this may not be excluded even with normal mammograms. Malignant melanoma is another possibility at this site and a careful examination for skin lesions should be made. Inguinal lymph nodes usually point to a primary site in the pelvis, vulva or rectum, or prostate. Malignant melanoma may present with an inguinal mass. Cutaneous metastasis typically occurs from carcinomas of the lung, breast, and melanomas. A pulmonary metastasis may arise from a variety of different sites, including breast, kidney, gut, melanoma, and sarcoma. In the liver, the likely source for the primary will be the gastrointestinal tract, although breast and lung primaries are other possibilities. A metastasis presenting in bone is particularly likely to occur from a cancer of the lung, breast, or prostate, the last being particularly likely if there is a mixed lytic and osteoblastic radiological appearance.

Investigation

The most important single investigation is a review of the histology. The clinician should discuss the diagnosis with the pathologist so that appropriate tests can be carried out. It is absolutely essential to distinguish between an epithelial tumour, a sarcoma, and a lymphoma. Immunohistochemistry may be invaluable in this respect. If there is any question of a germ cell tumour, the section should be stained for a-fetoprotein, b-human chorionic gonadotrophin, and placental alkaline phosphatase. If the histology is that of adenocarcinoma, the diagnosis will be more difficult and special stains may not serve to elucidate the diagnosis further. Where possible, the tissue should be examined for the presence of oestrogen or progesterone receptor, as this would make carcinoma of the breast or ovary more likely. The protein S100 is typically present in melanoma and may be invaluable in distinguishing this diagnosis from anaplastic carcinoma.

Further investigation and management

Investigation must be selective. Since there is specific treatment available for breast and prostate cancer, these diagnoses must always be considered when the histology is adenocarcinoma. Mammography is therefore justifiable, and measurement of serum acid phosphatase and prostatic specific antigen are simple and non-invasive. A pelvic ultrasound may show an ovarian mass, which may influence management as platinum-based combination chemotherapy might then be used, whereas it would not be contemplated in many patients with metastasis from an unknown primary site in view of its toxicity. The possibility of a germ cell tumour must always be considered in a young person, and in these circumstances full investigation is necessary if this diagnosis is possible.

Treatment follows pragmatic lines. Locally troublesome or painful metastases are treated with irradiation. If breast cancer seems a possible diagnosis a trial of hormone therapy is fully justified and, similarly, hormone treatment of prostatic cancer should be introduced if this seems a likely diagnosis. As mentioned above, radiation is frequently given to patients with enlarged cervical nodes when the diagnosis is poorly differentiated carcinoma, even if a head and neck primary has not been found.

The use of combination chemotherapy when the primary site is not known is much more controversial. In general, responses are infrequent and are not long lasting. This drug treatment should be reserved for patients with more than one lesion and particularly when symptoms occur. It is important not to be dogmatic about this issue because many patients find it quite unacceptable to be told that no treatment of any kind is available to them, and are willing to accept the possible toxicities of chemotherapy in exchange for the chance of response. Most chemotherapy programmes will include an alkylating agent and some include doxorubicin or a taxane.

Supportive care of the patient with cancer (see alsoSection 31)

Psychological support

Nearly everyone will have had friends or relatives who have had cancer and who may have died of it, and they will have read articles and seen television programmes about cancer and its management. Many patients will have been worried about the possibility of cancer before they ever consult their general practitioner, or are subjected to a series of diagnostic tests, the effect of which may be to increase their anxiety. At each stage in the diagnostic process physicians should be aware of patients' feelings and be prepared to talk openly to them about why investigations are being performed. When the diagnosis is established it is essential for the physician to sit quietly with the patient, explaining the nature of the diagnosis and the broad principles that treatment will follow. Sometimes patients will like to have a member of the family with them during this conversation, in case they forget aspects of what is said. The conversation should take place quietly, not on a ward round, with both the patient and the physician seated and the physician calm and unhurried in approach. Avoidance of the word 'cancer', body language that indicates discomfiture or embarrassment, and evasion and vagueness are very likely to be interpreted by the patient as signs of a serious or hopeless outlook.

Many patients will be unable to take in all that is said in the first conversation, and the physician needs to make it quite plain that he or she will be very pleased to talk again the next day, to go over points that need further clarification. There is much useful literature for the patient to take home, there are professional and expert support groups that the patient can contact and, in many hospitals, skilled counsellors who can provide follow-up support after the physician has outlined the basis of treatment. It is essential that all members of the medical team understand what was said and what words were used. The members of the family also need to understand exactly what information has been imparted. It may be necessary to hold back on a precise prognosis; first, because one may not be known until treatment starts, and second, because patients naturally tend to become fixated on the numerical prognosis, which is likely to be extremely inaccurate. If referral to an oncologist is to be made it is critical to indicate exactly what has been said to the patient. Oncologists are put in an extremely difficult position when patients arrive with a diagnosis of cancer, without any indication at all of whether they know the diagnosis, or what words have been used.

A new difficulty in communication is now displacing that which formerly arose from concealment of the diagnosis. Modern cancer management is often complex, with equivalent results sometimes being obtained from approaches that have different early and late effects. A well-intentioned wish to 'share' the treatment decisions with the patient, and an increasing resort to litigation when events don't turn out well, has led doctors sometimes to present treatment options as a series of uncertainties in which the outcome will be strongly influenced by chance and fate. It is bad enough to be told you have cancer. Worse still if your treatment seems mired in uncertainty. For some patients, treatment options will have been made even less clear by access to unfiltered advice on the internet, from reputable sources, charlatans, and cranks. There is nothing paternalistic in sensible advice from a well-informed, kind, sensitive, and experienced specialist. Questions which arise from complexity of choice and outcome in management increase the need for competent advice; they are not answered by passing the problem to the patient. Much distress, and a feeling of being abandoned, can come from lack of clear guidance.

When treatment is to be palliative, after relapse or with widespread metastatic disease, it should none the less be made clear to the patient that it is 'treatment'. Patients dislike feeling that they are being abandoned. Indeed, many wise oncologists see their patients more frequently when they are having palliative treatment than they do during routine treatments or follow-up. They do this because palliative treatment requires great attention to detail, especially with respect to control of pain and other symptoms, and also to provide psychological support for the patient and the family. One of the most common reasons for patients seeking second opinions is that they have been given no feeling that there are possibilities for treatment in their case. Continuity in management is one of the most rewarding aspects of cancer medicine for the physician and for the patient. There is no place for impersonal clinics where patients see different doctors each time they attend, and where the emotional component of their illness cannot be properly explored.

Management of cancer pain

Pain is a common and distressing feature of cancer. A careful history is essential to determine the exact site and nature of the pain and to establish a close and trusting relationship with a patient who feels that the symptom is being taken seriously. Exacerbating factors should be noted and an anatomical diagnosis made as far as possible. If the pain is arising in a bone it may be quickly and effectively helped by radiation treatment. The primary tumour or metastasis may be responsive to treatment with irradiation or chemotherapy. If specific antitumour treatments of this kind are not appropriate, then the only approach is to control the pain with analgesics.

Non-narcotic analgesics are used for mild or moderate pain. Useful agents include aspirin, paracetamol, and non-steroidal anti-inflammatory drugs such as ketoprofen or naproxen. A combination may be useful. Combination drugs such as co-proxamol or co-dydramol are also helpful. Although prescribing each drug separately allows greater control over the constituents, in practice this may not be helpful, particularly for elderly patients who often find it difficult to take multiple medication. The aim of treatment should be to prevent pain as far as possible by taking regular analgesics, and to have additional analgesics on hand for an acute exacerbation. Side-effects of non-opiate analgesics include gastric irritation (and they should therefore be used cautiously if steroids are being used at the same time), nausea, and constipation, particularly with codeine, oxycodone, or propoxyphene.

If these analgesics do not control the pain, opiate analgesics are essential. Two preparations have made an enormous contribution to pain relief. The first is long-acting morphine sulphate, which can be given twice daily, and the second is short-acting morphine sulphate (Sevredol). The former has a duration of action of 8 to 12 h and the latter of about 4 h. One curious feature of the use of morphine-like drugs is that the dose required to control pain varies greatly from person to person. It must therefore be found by trial and error and the patient must be prepared to increase the dose under medical supervision. The aim is to produce background pain relief for most of the day and night. Sevredol is particularly useful for dealing with acute exacerbations of pain.

If oral opiates are unable to control pain fully, continuous subcutaneous infusion is a useful alternative. This approach is particularly valuable in patients who cannot tolerate oral analgesics because of gastrointestinal symptoms, or where the tumour causes nausea or intestinal obstruction. Many pumps are now available, which are designed for continuous infusion through a small-gauge butterfly needle implanted subcutaneously. Patients can manage at home with these infusion pumps, with a nurse calling daily to change the infusion mixture.

Specialized forms of analgesia

A detailed discussion is beyond the scope of this chapter. Amongst the specialized techniques available are continuous epidural and intrathecal opiate infusion, nerve block procedures (including coeliac plexus block, peripheral nerve block, and epidural blocks), neurosurgical procedures, such as ablation of the peripheral nerve by neurectomy or, more radically, interruption of pain pathways by cordotomy. Each of these procedures has its value and limitations and the advice of specialists in the field of pain relief will be necessary.

6.7 Cancer chemotherapy and radiation therapy

Michael L. Grossbard and Bruce A. Chabner

The last two decades have brought significant improvements in cancer therapy. Patients with previously fatal diseases, including acute leukaemia, non-Hodgkin's lymphoma, Hodgkin's disease, and germ cell tumours, can have a reasonable expectation of cure. For patients with commonly occurring solid tumours, including lung cancer and breast cancer, several new chemotherapeutic agents have been developed which offer improved treatment options and enhanced survival. An increased understanding of tumour biology and the explosion in knowledge in molecular biology have paved the way for new developments in cancer treatment.

Nevertheless, cancer remains the second leading cause of death in the United States. Although exciting advances continue to be made in cancer therapeutics, nearly 40 per cent of patients diagnosed with cancer will die of their disease. An estimated 1.2 million new cancer cases will occur in the United States in 2000 and 552 000 patients will die cancer-related deaths. Virtually all patients diagnosed with advanced stage solid tumours will succumb to their tumour or complications of its therapy. Because a medical oncologist and radiation oncologist will manage many patients diagnosed with cancer only after initial referral from an internist or surgeon, it is critical for the primary care physician to understand the general principles of cancer therapy. The dramatic increase in the number of effective chemotherapy agents since nitrogen mustard was introduced more than 50 years ago has made this challenge greater.

Chemotherapy and radiation therapy, together with surgery, are the major modalities of cancer therapy. Chemotherapy has the advantage of targeting tumour cell throughout the patient, while external beam radiation therapy acts to provide local control. Often, the two modalities are combined to take advantage of synergistic cytotoxicity. This chapter will describe major principles of chemotherapy and radiation therapy.

Chemotherapy

A knowledge of cancer chemotherapy requires an appreciation of some general principles of tumour biology. Cancer results from the uninhibited growth of a single clone of cells. As cancer cells grow, they move through the cell cycle, characterized by several phases: resting (G0), pre-DNA synthesis (G1), DNA synthesis (S), post-DNA synthesis (G2), mitosis (M). Most chemotherapy drugs are active in the S phase of the cell cycle, although some directly block cells entering mitosis and most directly promote apoptosis (programmed cell death).

Chemotherapy can be used in several different settings (Table 1). Foremost, chemotherapy is applied as primary therapy for the treatment of advanced-stage cancer. A few diseases, including leukaemias, lymphomas, and advanced-stage germ cell tumours are sensitive to multiple chemotherapy agents and can be cured with combination chemotherapy. More often, combinations of therapeutic agents are used to diminish tumour-related symptoms, improve the quality of life, and extend survival in patients with advanced-stage tumours. For example randomized clinical trials of chemotherapy versus best supportive care have demonstrated a survival advantage and quality of life improvement when patients with advanced-stage lung cancer receive chemotherapy.

Second, chemotherapy can be used as neoadjuvant therapy, given prior to radiation or surgery for locally advanced disease. In this setting, the drugs are used to decrease the tumour mass, reduce the extent of the subsequent surgery or radiation, and to determine disease sensitivity to drugs. Clinical trials have identified a potential role for neoadjuvant therapy in the treatment of lung cancer, oesophageal cancer, and locally advanced breast cancer, among other diseases. In the case of osteosarcomas, neoadjuvant therapy can provide important information about tumour sensitivity, thereby permitting a more tailored approach to further management. Finally, the drugs can be used as adjuvant therapy, administered after the completion of local definitive surgery and/or radiation therapy in order to decrease the risk of recurrence. For instance adjuvant chemotherapy reduces the risk of tumour recurrence and improves survival in node-positive colon cancer and in breast cancer following surgical resection. In all of these settings, chemotherapy can be administered in conjunction with radiation therapy to optimize local effects of treatment.

Only in rare circumstances, such as the use of methotrexate as therapy for choriocarcinoma, can therapy with single agents cure advanced-stage cancer. Single agents tend to select for drug resistant cells. Most often, therapy with multiple drugs has been required to effect cure. In combining drugs, it is imperative to employ agents that have independent activity, have toxicities that do not overlap significantly, and that can be used at an optimal dose and schedule. Chemotherapy schedules are designed to permit marrow recovery prior to the next dose administration. Typically, peripheral blood counts will reach a nadir at 5 to 10 days post-therapy, with recovery seen by day 21.

Combinations of drugs may circumvent tumour cell resistance, so treatments have been designed in which non-cross-resistant drugs are administered either together or in sequence. One of the earliest combination therapy programmes to cure a cancer was the use of MOPP (mechlorethamine, vincristine, prednisone, and procarbazine) for the treatment of Hodgkin disease. Similarly, acute lymphoblastic leukaemia can now be cured in 80 per cent of children using multidrug chemotherapy administered at frequent dosing intervals to avoid the development of resistant cells. Alternatively, extremely high doses of therapy can be used to overcome tumour resistance, but this may obligate the use of stem cell support to overcome the resulting profound bone marrow toxicity.

Because of the potentially severe toxicities of chemotherapy, physicians should administer regimens that have been reported in the peer-reviewed medical literature. Alternatively, the development of new regimens in the context of well-designed institutional review board approved clinical trials can permit the development of novel investigational treatment programmes. Clinicians should not routinely administer drug combinations based on anecdotal evidence.

Classes of chemotherapy agents

There are several distinct classes of chemotherapy agents (Table 2). Because these drugs can have major side-effects, only physicians knowledgeable in their dosing and side-effects should administer them. In order to reduce variability in exposure to drugs, doses of most chemotherapy agents are administered based on the patient's body surface area, a calculation determined by the patient's height and weight. In addition, doses of chemotherapy need to be adjusted for renal (methotrexate, bleomycin, fludarabine) and hepatic function (anthracyclines, vinca alkaloids, taxanes).

Adequate intravenous access must be secured since many of the drugs are vesicants and extravasation can lead to tissue necrosis. Similarly, patients must be adequately hydrated prior to the administration of cisplatin and cyclophosphamide, to prevent renal toxicity and bladder toxicity, respectively. Careful attention must be given to fluid and electrolyte balance with the administration of many agents. Cisplatin renal toxicity can cause profound hypomagnesaemia.

Antimetabolites exert their cytotoxicity by serving as substrates in pathways vital to cellular function and replication. Many of these agents are incorporated into DNA or RNA or act on enzymes involved in the synthesis of nucleic acids. Methotrexate acts by inhibiting the enzyme dihydrofolate reductase, which maintains intracellular pools of reduced tetrahydrofolates required for the synthesis of purine nucleotides and thymidylate. 5-Fluorouricil is another commonly used antimetabolite. A metabolite of this drug, fluorodeoxyuridine monophospate inhibits thymidylate synthase, an enzyme required for the synthesis of deoxythymidine triphosphate and DNA. In addition, fluorodeoxyuridine triphosphate is incorporated into RNA, interfering with its function, and fluorodeoxyuridine triphosphate is incorporated into DNA, leading to strand breakage.

A third important antimetabolite is cytarabine (ara-C) which is converted to cytarabine triphosphate (ara-CTP) in the cell. Cytarabine triphosphate is incorporated into DNA and serves as a chain terminator. A related deoxycytidine analogue, gemcitabine, has the additional actions of inhibiting the conversion of ribonucleotides to

deoxyribonucleotides, which are DNA precursors. Prolonged exposure of tumour cells to some of the antimetabolites, such as 5-fluorouracil and cytosine arabinoside, through continuous intravenous infusion may be more effective than bolus injections alone.

Purine analogues also have important roles as antimetabolites; 6-mercaptopurinre (6-MP) and 6-thioguanine (6-TG) are converted in the cell to monophosphates which inhibit the first step of purine synthesis. Moreover, the triphosphate nucleotides of 6-mercaptopurinre and 6-thioguanine are incorporated into DNA resulting in an increase in strand breaks. Another purine analogue is fludarabine phosphate, which serves as an adenosine analogue. Fludarabine is converted to 2-fluoro-ara-A in plasma and subsequently is phosphorylated intracellularly. The resulting triphosphate inhibits DNA polymerase and ribonucleotide reductase, interfering with DNA and RNA synthesis.

Alkylating agents exert their cytotoxicity by binding to DNA and forming DNA adducts which alter DNA structure and function enough to disrupt DNA replication and transcription. They act throughout the cell cycle, but have their greatest activity on rapidly proliferating cells. These agents, including cyclophosphamide, nitrogen mustard, melphalan, busulfan, and chlorambucil were among the first chemotherapy drugs and remain important agents in cancer therapy, with particular activity in haematological malignancies and breast cancer. In a similar manner, the platinum derivatives bind to and cross-link DNA, leading to DNA breaks and apoptosis.

The anthracyclines intercalate into DNA and disrupt DNA synthesis. The antitumour activity of doxorubicin and daunorubicin, the two most commonly used agents in this drug class, results in part from triggering of topoisomerase II dependent DNA breaks. Etoposide also inhibits topoisomerase II. In a similar way, other topoisomerase inhibitors interfere with topoisomerase I, which is critical in the repair of normal DNA; these agents include irinotecan and topotecan. Vinca alkaloids interfere with microtubule formation and disrupt cell division. In contrast, the taxanes stabilize microtubule assembly, also inhibiting mitosis.

Along with the traditional cytotoxic agents, hormone-directed therapy can be critical in the regulation of tumours. The growth of many normal tissues and tumours is influenced by hormone exposure. Many breast cancers express receptors for oestrogen and progesterone and most prostate cancers have androgen receptors. Depriving these tumours of the hormonal stimulus can exert both cytocidal and cytostatic effects on the cell. Thus, more than 50 per cent of breast cancers expressing the oestrogen receptor will respond to treatment with tamoxifen, an antioestrogen. Similarly, the use of luteinizing hormone releasing hormone (LHRH) agonists (which reduce testosterone synthesis) or antiandrogens can have dramatic effects on prostate cancer growth.

Chemotherapy resistance

Unfortunately, there are several mechanisms by which tumours may become resistant to the effects of cytotoxic chemotherapy (Table 3). Decreased accumulation of drug in the cell through alteration in transport mechanisms permits resistance to methotrexate. Alternatively, the intracellular target for methotrexate may be altered, as in the case of amplification of dihydrofolate reductase. Similarly, with 5-flurouracil, the target enzyme thymidylate synthase may be amplified. Altered drug metabolism, as occurs with ring reduction of 5-fluorouracil, can contribute to drug resistance. In tumours resistant to alkylating agent, the alkylating agents may be inactivated through reactions with thiol-containing compounds or through enhanced DNA repair.

A particularly important mechanism of resistance, conferred by a P-glycoprotein, leads to resistance to multiple drugs. Multidrug resistance results from enhanced drug efflux from the cell secondary to P-glycoprotein over-expression. In this setting, the cancer cells becomes resistant to anthracyclines, vinca alkaloids, taxanes, etoposide, and other drugs simultaneously. Several agents currently in clinical trials are designed to inhibit the multidrug resistance pump. A different type of multidrug resistance can occur with the topoisomerase inhibitors where quantitative and qualitative changes in topoisomerase II activity have been associated with decreased tumour sensitivity.

Side-effects of chemotherapy

The commonly used chemotherapy agents have several side-effects in common (Table 4). Myelosuppression occurs with virtually all agents, although the timing of its onset and its duration differs with different groups of drugs. Cyclophosphamide causes an acute, short-onset depression in counts, affecting the white blood count more than platelets. By contrast, the nitrosoureas lead to delayed-onset reductions in both neutrophils and platelet with nadir counts typically reached 4 to 6 weeks after therapy.

Nausea and vomiting remain a troubling side-effect of chemotherapy, though the present use of serotonin uptake inhibitors has diminished the incidence of vomiting with the most emetogenic agents, including cisplatin. Alopecia is a major cause of concern to patients and occurs uniformly with some agents such as doxorubicin, but rarely with agents such as methotrexate and fludarabine. Profound neuropathy frequently accompanies the use of vinca alkaloids, and occurs less frequently with cisplatin and paclitaxel.

Moreover, many of the agents have unique side-effects that are of concern to the practising internist. Doxorubicin can cause cardiac toxicity, including an acute syndrome characterized by arrhythmias and congestive heart failure. In addition, doxorubicin can cause a cumulative, dose-dependent decline in left ventricular ejection fraction, with a higher incidence of myocardial dysfunction seen in patients receiving a cumulative dose of greater than 500 mg/m ^{2}. Bleomycin causes lung toxicity, including pneumonitis, which can progress to interstitial fibrosis. The carbon monoxide diffusing capacity of the lung diminishes with increasing cumulative bleomycin doses. Methotrexate in high doses can cause acute renal failure due to drug precipitation in the renal tubules. The administration of paclitaxel can cause anaphylaxis in response to cremaphor, the vehicle in which it is delivered. Hence, premedication with dexamethasone and antihistamines is required to reduce the risk of adverse reactions. Cytarabine administered in high single doses (3 gm/m ^{2} or greater) can cause irreversible cerebellar dysfunction, so a neurological exam should be performed daily on patients receiving therapy so that it can be discontinued at the earliest sign of such toxicity.

A major, delayed side-effect of cancer chemotherapy is the development of secondary leukaemias due to therapy. These are most commonly seen in patients receiving therapy with multiple alkylating agents, as was the case for the treatment of Hodgkin disease with MOPP chemotherapy. Five to six per cent of patients receiving this therapy developed leukaemia as a consequence of therapy. Newer regimens for Hodgkin disease treatment avoid this devastating complication of therapy. More recently, topoisomerase II therapy (etoposide, anthracyclines) in high total doses has been associated with a risk of secondary leukaemias. High-dose therapy followed by autologous stem cell infusion has a risk of secondary leukaemias that exceeds 10 per cent. As survival rates are improved with combination chemotherapy regimens used in the treatment of diseases such as leukaemia and lymphoma, the long-term complications of cancer chemotherapy become more evident.

Finally, infertility occurs with many chemotherapy regimens, especially when patients are treated with alkylating agents or high-dose therapy. While reduced sperm counts may occur only transiently in males, most alkylating-induced azoospermia is irreversible, and a discussion should be initiated regarding the possibility of banking sperm for any patient at risk. For premenopausal woman, the risk of infertility and early menopause increases with age. These fertility issues must be addressed with patients prior to the administration of chemotherapy.

Biological therapy

Cancer chemotherapy not only refers to the traditional, cytotoxic agents but also encompasses novel biological therapies including monoclonal antibody-based treatments and cytokine therapies. Currently, two unconjugated monoclonal antibodies are available for commercial use in the United States. Rituximab binds to the CD20 antigen that is expressed on the surface of both normal and malignant B lymphocytes. Nearly 50 per cent of patients with low-grade B-cell lymphoma respond to this targeted therapy, which lacks the typical myelosuppressive side-effects of chemotherapy as well as the typical alopecia and emesis. The most common side-effects with antibodies are infusion-related fevers, chills, and hypotension. Another biologically active antibody is herceptin, which binds to the Her-2 receptor that is over-expressed in 15 to 20 per cent of breast cancer cases. When given in conjunction with paclitaxel, the combination appears to prolong survival for patients with metastatic breast cancer.

The two most extensively studied cytokine therapies are interferon and interleukin-2 (IL-2). The interferons are a class of proteins produced by the body in response to viral infections. These agents have relatively disappointing antitumour activity, although they can induce major responses in patients with low-grade lymphoma and hairy cell leukaemia. Toxicities include fevers, chills, liver function test abnormalities, and cytopenias. IL-2 is a cytokine produced by activated T cells that plays a role in triggering the immune system. IL-2 has activity in renal cell carcinoma and melanoma, with occasional patients achieving long-duration remissions. However, its toxicities include fevers, renal dysfunction, and capillary leak syndrome.

Recent advances in molecular biology have led to the development of additional therapies which are currently in clinical trials. Antisense oligonucleotides of 15 to 20 bases in length can be used to target specific messenger RNAs. A bcl-2 antisense compound has shown biological activity against low grade non-Hodgkin's

lymphoma (which over-express the bcl-2 protein). Another exciting class of compounds target new blood vessel formation, which may be critical for the implantation and growth of tumour cells. These antiangiogenic compounds also are in clinical trials.

Radiation therapy

Understanding the cytotoxicity of radiation therapy requires knowledge of radiation physics and tumour biology. Over the last two decades, the ability of CT scans and MRI scans to carefully localize the tumour within the patient, along with technical improvements in treatment machines, have radically improved the accuracy of radiation therapy.

Electromagnetic radiation, used most commonly in patient care, consists of roentgen (X-rays, photons) and gamma radiation. In general, gamma rays are produced by the degradation of nuclear isotopes while electrical machines produce photons. Alternatively, electron beams can be used for the treatment of superficial tumours (such as cutaneous lymphoma) because of the sharp reduction in dose that occurs beyond a certain tissue depth. Proton beam therapy can be used to delivery high treatment doses to a highly localized lesion because of its very sharp margins of dose deposition, and has particular relevance in the treatment of spinal tumours and some central nervous system tumours.

The dose of irradiation is defined as the unit of energy absorbed by each kilogram of tissue. This is conventionally expressed in 'Grays' (Gy). As the dose of radiation is increased the percentage of cells that is killed increases.

Radiation used for the treatment of patients generally consists of either external beam irradiation delivered from outside the body or brachytherapy, in which the radiation device is placed within or near the target tumour. Brachytherapy has been used effectively in the treatment of head and neck cancer, cervical cancer, and endometrial cancer. At some centres, intraoperative radiation therapy can be used to deliver a single, large fraction of radiation directly to the tumour bed. In some circumstances, radioisotopes themselves can be used for systemic treatment. For example iodine-131 is taken up by thyroid tissue both locally and at sites of metastatic disease.

The target for radiation-induced cytotoxicity is DNA. Radiation therapy generates free radicals that damage DNA. Because the presence of oxygen is important in the generation of free radicals, hypoxic tissues are less sensitive to the toxic effects of radiation. Thus, well vascularized tissues are most sensitive to radiation therapy. A theoretical advantage of preoperative radiation is the chance to treat a tumour while its vasculature remains intact. However, resection of a larger, poorly vascularized tumour may improve the chances of curing a locally advanced head and neck cancer with irradiation.

The delivery of radiation therapy requires careful planning. CT scans or MRI scans are used to identify the target tissue and surrounding normal tissues accurately. Next, treatment technique and volume are tested on a radiation simulator. The simulator duplicates the treatment plan, but uses only superficial radiation for imaging and accurately assessing the location of the treatment beam. To make certain that treatments are delivered to the same tumour volume each day, tattoos are placed on the patient. Blocks are made to exclude treatment from normal tissue such as the heart and lungs. Often the maximum tolerated dose of radiation is administered to the total treatment volume with a boost administered to the treatment bed.

Radiation doses are usually delivered in a number of daily fractions with the total fractionated dose dependent on tumour sensitivity and normal tissue tolerance. Seminoma is an exquisitely radiation sensitive tumour and requires a lower therapy dose (30 Gy) than solid tumours such as lung cancer (60 Gy). Some tumours, such as melanoma, are relatively radioresistant.

Within 6 h after radiation, cells begin to recover from the effects of therapy. Thus, fractions placed too close together can offer increased toxicity to normal tissues, but those too far apart can permit repair of sublethal damage. While conventional therapy usually provides a daily radiation fraction of 1.8 to 3 Gy over 15 to 35 treatments, to total doses of 40 to 65 Gy, alternative schemes have been investigated. In hyperfractionated therapy, a smaller fraction size is used, and more fractions are administered. This permits a higher total radiation dose to be administered. For palliation of painful bone metastases, radiation therapy can be given in either a single large dose or four to five moderate doses to minimize the patient's travel to the treatment centre. More recently, radioisotopes such as iodine-131 have been conjugated to antibodies, with radiation delivered directly to the surface of the targeted cell. In this scenario, low-dose continuous radiation therapy is effectively delivered at the tumour site.

Complications of radiation therapy

Adverse effects of radiation therapy can be considered with respect to both acute and delayed toxicities. Tissues that normally proliferate rapidly, such as skin, mucosal linings, and bone marrow, are most susceptible to radiation cytotoxicity. Thus, erythema and desquamation are important acute, local effects of therapy. For patients receiving radiation therapy for gastrointestinal tumours, diarrhoea, nausea, and vomiting are common. If a significant radiation dose is delivered to the bone marrow, patients may develop cytopenias. In the case of whole body irradiation, the lymphocyte count falls and significant immune suppression occurs. On occasion, these acute side-effects are severe enough to require delays in treatment to allow the normal tissues to repair themselves. When patients receive irradiation to the lung, a resultant radiation pneumonitis may occur characterized by fevers, cough, dyspnoea, and pulmonary infiltrates. Occasionally, this may require treatment with corticosteroids.

Long-term sequelae are tissue specific and occur most commonly if normal tissue tolerance is exceeded. Thus, careful dosimetry and radiation planning must be done to verify that tissues do not receive treatment beyond their maximum tolerated dose. For example radiation doses to the spinal cord in excess of 45 Gy can cause myelitis, doses to the small bowel in excess of 45 Gy can cause strictures, and doses to the kidney above 20 Gy can cause renal dysfunction. The liver tolerates radiation therapy poorly. Accelerated coronary artery disease has been seen in patients with Hodgkin disease who received radiation to the heart in an effort to encompass a mediastinal mass.

Perhaps the most severe side-effect of radiation therapy is the development of secondary tumours. Ordinarily, this is not an issue for patients with metastatic cancer receiving radiation therapy for palliation of disease related symptoms since their survival will be short. However, in patients with Hodgkin disease, who can be cured with radiation therapy, the development of second solid tumours in the radiation field, including sarcomas, lung cancers, and oesophageal cancer, can limit survival.

Role of radiation therapy in cancer treatment

In the clinical management of patients, radiation therapy is used as primary therapy for tumour treatment, as an adjuvant or neoadjuvant therapy either alone or in conjunction with chemotherapy (which often acts as a radiation sensitizer), and as palliative therapy for advanced stage treatment (Table 5).

Radiation therapy has a role in the management of several acute complications of cancer. Radiation can be valuable in the treatment of bone metastases, both to decrease painful lesions and to diminish the risk of pathological fractures. Radiation therapy can be delivered as an emergency procedure in patients with spinal cord compression to reduce the risk of permanent neurological toxicity. Likewise, radiation has an important role in the management of brain metastases, either as primary therapy for patients with multiple lesions or as a prophylactic therapy for patients undergoing excision of a solitary brain metastasis. In lung cancer, radiation can be used to palliate obstructive symptoms. In bleeding tumours, radiation therapy can often assist in local control of haemorrhage.

In the management of several tumours, radiation therapy can serve as the definitive treatment. In early-stage Hodgkin's disease, patients can be cured with either mantle radiation therapy alone or with mantle and para-aortic radiation. Similarly, 35 to 50-Gy doses of radiation therapy can induce long-term remissions in 50 to 60 per cent of patients with stage I/II low-grade non-Hodgkin's lymphoma. Seminoma is an exquisitely radiation sensitive tumour and early stage disease can be cured in a high percentage of patients with radiation therapy alone. Radiation therapy can provide equivalent long-term survival to surgery in patients with prostate cancer and laryngeal cancer, with potentially reduced morbidity as compared with surgery. Finally, in early-stage breast cancer, lumpectomy and radiation therapy provides an equivalent survival outcome to a modified radical mastectomy.

In other diseases, such a squamous cell carcinoma of the anus, combined modality therapy using radiation therapy in conjunction with 5-FU and mitomycin C chemotherapy yields a high cure rate without surgery. Similarly, in patients with limited stage small cell lung cancer, combined modality therapy using cisplatin-based chemotherapy and radiation therapy reduces local tumour recurrence and improves survival. Likewise, in cervical cancer, a combination of cisplatin and radiation post-resection reduces tumour recurrence.

Radiation therapy also has an important role in adjuvant therapy. In the adjuvant treatment of rectal cancer, randomized clinical trials have demonstrated that radiation

therapy administered in conjunction with 5-FU chemotherapy can reduce local recurrence and systemic recurrence and can improve both disease free and overall survival. In node-positive gastric cancer, a combination of 5-FU based chemotherapy administered as adjuvant therapy can reduce the risk of recurrence and improve survival. Recent studies have demonstrated that the administration of prophylactic cranial irradiation to patients with small cell lung cancer who achieve a complete remission can reduce the risk of central nervous system spread of disease and improve survival. In the neoadjuvant setting, radiation in combination with cisplatin-based chemotherapy has been shown to improve survival in patients with stage IIIA lung cancer and oesophageal cancer.

As noted earlier, the gamma radiation from radioactive isotopes also can be used to treat tumours. Well-differentiated thyroid cancer metastases take up iodine-131 which then can offer tumour-specific toxicity. Antibodies have been conjugated to iodine-131 and yttrium-90 to deliver targeted radiation therapy to the surface of lymphoma cells.

Conclusions

Advances in radiation therapy and chemotherapy have revolutionized the care of cancer patients. Significant improvements in supportive care and the development of new, active anticancer agents have improved the prospects for long-term survival even for patients with metastatic disease. The internist has a pivotal role in co-ordinating care for such patients and should be aware of these advances and new option for patients.

7.1 The clinical approach to the patient with suspected infection

David Rubenstein

Presentation of illnesses and the history

Most systemic infections produce fever but not all fevers are, at cause, infectious. Patients with systemic infections range symptomatically from apparent full fitness to near moribund and initial appearance will indicate the speed of clinical response required. Appearances can be deceptive and many serious, potentially fatal infections do not present acutely. This gives time for more careful assessment although not for too much delay.

The standard undergraduate history produces a reliable range of questions covering all systems, which usually indicates the system or systems at fault (except perhaps for over- and underactivity of the thyroid) and should always be completed thoroughly. Where infection is common or possible, the addition of a detailed travel history can be invaluable, particularly as some infections occur in local geographical pockets, for example schistosomal infection from swimming in Lake Malawi, histoplasmosis along the Ohio river valley, and coccidioidomycosis in the San Joaquin Valley, California. Also air passengers may contract illness either during travel, from air droplet transmission, and even after a very brief stop-over. A detailed drug history is also most important. Not only do drugs produce fever but prophylactic agents may themselves be the cause of illness. As general physicians, in parallel with the rest of humanity, we have blind areas and ours are ear, nose, and throat, gynaecology, and sexually transmitted diseases, all of special importance when considering infection sites, if not obvious on initial history taking. The past and social history rarely give a pointer to the cause of infection, but previous surgery has commonly created a site of infection even weeks or months after operation, and social and sexual contacts and their illness may offer an important clue—HIV infection now occurs worldwide.

Examination

A complete and well learned and rehearsed examination system is an essential component of a clinician's skill. With time this becomes almost second nature and will prevent serious omission. ('The more I practise the better I get'—Arnold Palmer, but also variously attributed.)

The initial history almost invariably focuses the examiner on the likely site of infection, but occasionally a clinical finding will add to the clinical picture. If so, this will guide further management, but if not, it is essential to assess lymph nodes carefully at all common sites, and listen to the heart for murmurs. Careful examination of the skin may give important clues. The ear, nose, and throat region and the pelvis may hide infection as can the abdomen and re-examination should be performed daily to include these and the 'physician's blind areas' of the midline—the epigastrium, umbilical, and suprapubic regions. I have on first examination missed enlarged lymph nodes, heart murmurs, suprapubic masses, splenic enlargement, scrotal ulcers, and circinate balanitis—and probably many other signs, but the chance of missing a key sign is greatly reduced by repeated examination and by different observers.

Key investigations

> 'Ned, why do you keep robbing the banks?'
>
> 'Well, Judge, that's where all the money is'
>
> (Ned Kelly, Australian bush ranger, nineteenth century and variously attributed.)

The history and examination findings usually point to the system involved and often the diagnosis and investigation is aimed at confirming clinical suspicion. This is rarely a problem as most patients present with both a fever and some other marker, such as rash, vomiting, diarrhoea, cough, and sputum. It becomes more difficult when there are no key features other than fever. In all cases it is worth rechecking the drug and travel history, particularly if malaria is suspected, and all patients require a full blood count, blood cultures, a routine urine check, and a chest radiograph. At the same time and for future reference, studies may reveal early evidence of dehydration, a common feature of acute infectious diseases.

The white blood count is of particular value in septicaemia/bacteraemia and also in returning travellers, as the neutrophil count is not raised in malaria. The presence of a neutrophilia does not exclude malaria but suggests bacterial or amoebic infection. Some returning travellers have both. Blood cultures will allow confirmation of bacterial blood infection and guide antibiotic therapy, particularly alteration in antibiotic cover if the initial choice is ineffective. Routine urine testing and culture is often revealing even in the absence of urinary tract symptoms. As it is now simple, it is often omitted—even on renal units. In fairness, blood may not be sent for culture prior to treatment even on specialist infectious disease wards. A chest radiograph in the absence of respiratory symptoms may reveal tuberculosis, an abscess, or hilar lymph node enlargement, this being the first indication of tuberculosis, lymphoma, or sarcoid. If the diagnosis remains uncertain, more detailed studies including serology and ultrasound CT or MR scanning should be guided by clinical suspicion and probability, followed if indicated, by guided biopsy. Persistent fever has many causes, some of which are non-infectious and investigation of these should continue in parallel if clinical suspicion is sufficient (see Chapter 7.2).

Management

This is guided by the clinical picture and investigation findings. It becomes more difficult if the patient is too ill to wait for results or if these initially fail to reveal the diagnosis. This is commonly encountered in 'ill' patients with suspected septicaemia. This is a medical emergency and treatment should not be delayed until results are through. Antibiotics chosen to cover the likely infective organisms should be given intravenously as soon as key investigations, including blood and urine for culture, have been taken. Results and the patient's progress may change the plan, but delay may have serious consequences.

It is essential not to forget the important general supportive measures of rehydration and short-term anticoagulation for bed-bound and dehydrated patients. Good communication and reassurance are also very important, but nothing like as important as getting the right answer and starting the right treatment.

The future

New infectious diseases

These continue to appear and Lassa fever, legionnaire's disease, Lyme disease, and HIV infection were little recognized or unknown 30 years ago. Remaining alert to new diseases is critical but almost impossible for any single clinician, who must remain up to date with the literature and particularly the regular and superb publications from the Centers for Disease Control, Atlanta, the Public Health Laboratory Service in London, the World Health Organization, and the Pro Med web site.

Prevention

This is the key to future success and currently at a very exciting phase. Smallpox is we hope eradicated, although some of us remain slightly nervous in the era of

biological warfare. Current research, if fruitful, may produce successful vaccines against a wide range of infections—malaria, leishmaniasis, and even HIV are all good candidates.

Advanced diagnostic technique

It is impossible for our generation to appreciate the 'miracle' of chest radiography. Likewise, those of us who practised prior to scanning, particularly CT and now MR scanning, still remain amazed at the detail and accuracy of current radiology and the great improvement in diagnostic accuracy which can be quickly, safely, and almost atraumatically achieved. No doubt future advances, and greater availability with lowered cost, will make these techniques much more widely available. The polymerase chain reaction is now well established, but not universally available. Of perhaps even greater diagnostic help may be results of research into the use of 'antigen strips'. If the example of urine dipsticks is a guide, these may become a universally available, accurate, inexpensive, and possible bedside aid.

Final thoughts

Given sufficient knowledge and experience, your initial diagnosis is probably right and investigation will be aimed at confirmation. If the answer remains obscure after careful reassessment of history, examination, and clinical notes, seek a second opinion. In the hour of need, microbiologists and dermatologists make excellent friends.

Always consult with ease but selectively, remembering that colleagues who refer everyone or no one might have something to hide. Working alone makes clinical medicine a scary occupation and the best clinicians hunt in packs. It makes for more certain diagnosis, finer tuned investigation, better overall therapy, and peace of mind.

7.2Fever of unknown origin

David T. Durack

Febrile episodes are common, often transient, and often due to an obvious cause. In many cases the cause is obvious, such as an upper respiratory infection in a child. In a few cases, fever is persistent and the cause is not easily diagnosed. Such episodes are termed 'fever of unknown origin' (**FUO**) or 'pyrexia of unknown origin'.

Definitions and terminology

Normal body temperature is 37.0 °C or 98.6 °F. The normal range is quite wide, being affected by site of measurement, diurnal variation, heavy exercise, hormonal and menstrual status, individual variation, and environmental factors. A patient's body temperature is often estimated by measurements taken in the mouth for reasons of convenience, but oral temperatures can be affected by mouth-breathing, by the respiratory rate, and by recent drinking of hot or cold liquids. Many modern thermometry instruments take readings from the ear canal, so that the temperature is not affected by these factors. The core body temperature is more closely reflected by rectal measurements, which are usually 0.3 to 0.6 °C higher than oral measurements. Heavy exercise can temporarily raise the core temperature of healthy people by 2 °C or more. Another factor is normal circadian variation, which cycles through a range of approximately 0.5 °C (0.9 °F) daily, with the lowest temperatures occurring between 0400 and 0600 h and the highest between 1600 and 2000 h. The normal circadian rhythm varies between individuals and is likely to be affected by jet travel between time zones, by work and sleep patterns, and by illnesses. The menstrual cycle alters the baseline temperature of normal women by 0.3 to 0.5 °C, with a small spike at ovulation and higher temperatures from about the 15th to the 25th days of a 28-day cycle. In addition to these factors, there is considerable variation in normal temperature patterns between individuals. Some normal young people, especially women, persistently exhibit slightly 'high' temperatures that are of no pathological significance. This common normal variant, which does not require investigation, may be termed 'habitual hyperthermia'.

Fever and hypothermia may be defined, respectively, as core body temperatures above or below the normal range, allowing for all the factors listed above. For practical clinical purposes, oral or rectal temperatures falling outside the range of 35.5 to 38.0 °C (95.9–100.4 °F) can be regarded as abnormal. Specific circumstances should be considered; for example, an oral temperature of as low as 37.5 °C taken at 0600 h in an elderly patient could represent a clinically significant fever.

FUO has many possible causes. To help classify these, four distinct types of prolonged fever have been defined: classical FUO, nosocomial FUO, neutropenic FUO, and human immunodeficiency virus (**HIV**)-associated FUO.

Symptoms and signs of FUO

The symptoms and signs of FUO are highly variable. Some patients have mild feverish symptoms, while others may be incapacitated by debilitating chills, rigors, and sweats. The clinical findings may be limited to manifestations of the fever itself, or may also reflect the underlying disease. The physician should evaluate every symptom or sign, especially new ones, as potential clues to the primary diagnosis.

Certain diseases can produce characteristic patterns of fever, notably malaria, brucellosis, typhoid fever, and some lymphomas, but in practice the shape of the fever curve is seldom of major value in the diagnosis of FUO. Individual host reactions to disease and the common use of antipyretic analgesic drugs confuse the picture. There is a common misconception that drug-induced fevers are usually low-grade ones, with relatively little variation from peak to trough and a relatively low pulse rate, but in fact the clinical characteristics of drug-induced fevers are highly variable.

Classical FUO

Most of the many causes of classical FUO can be classified into five categories: infections, malignancies, connective tissue diseases, miscellaneous conditions including factitious fever and habitual hyperthermia, and undiagnosed cases. Within the first three categories, certain diagnoses predominate (Table 1 and Table 2). The leading infectious aetiologies for classical FUO are intra-abdominal infections, complicated urinary tract infections, tuberculosis, and infective endocarditis. The leading malignancies are lymphomas, leukaemias, and some solid tumours, including adenocarcinomas and hypernephromas. Vasculitides, including the temporal arteritis–polymyalgia syndromes, Still's disease, systemic lupus erythematosus, and rheumatic fever, are important among the connective tissue diseases. Among the miscellaneous conditions that can cause FUO, alcoholic hepatitis and granulomatous conditions such as sarcoidosis or granulomatous hepatitis are important. Self-induced or factitious fever is surprisingly common. Some of the many other miscellaneous, uncommon, or rare diseases that can cause FUO are listed in Table 2. In all published series, a sizeable subgroup of patients with FUO remains undiagnosed.

FUO in children

The proportion of cases of FUO due to infections is higher in children, and the proportion due to malignancy is correspondingly lower. Viral syndromes and urinary tract infections are particularly common infections in children. Still's disease and rheumatic fever are more likely to cause FUO in children than in adults, and children are less likely to have factitious fever. The overall mortality of FUO in children is lower than in adults.

FUO in the elderly

In patients over 65 years of age, intra-abdominal abscesses including hepatic abscesses, malignancies, and vasculitides cause a higher proportion of cases of FUO. The proportion of FUOs that remain undiagnosed in the elderly is lower, being only about half that in children and younger adults. The higher rate of underlying malignancies in any series of elderly patients with FUO means that the long-term prognosis is less favourable than in a younger group. The temporal arteritis–polymyalgia rheumatica syndromes are particularly important because they are common in the elderly, and their many non-specific symptoms may be missed or misdiagnosed. This diagnosis is easily suspected if the erythrocyte sedimentation rate (**ESR**) is over 100 mm/h, but is easily overlooked if an ESR is not obtained. Another hint is a high platelet count. Other connective tissue diseases are less common than in younger patients. Bacterial prostatitis and related urinary tract infections are more common in elderly men due to prostatic hypertrophy. In developed countries, infective endocarditis has become more common in older patients. Occult pulmonary emboli always should be considered in the differential diagnosis. Factitious fever is rare in the elderly.

Nosocomial FUO

Fever that develops after a patient has been admitted to hospital, and which remains undiagnosed, is termed 'nosocomial FUO'. These patients are usually being treated for one or more major pre-existing conditions, and have multiple possible reasons for developing fever. Several of these factors may be contributing simultaneously to the development of fever. After common bacterial infections such as pneumonia, urinary tract infection, and bacteraemia have been excluded, many other conditions remain in the differential diagnosis: for example, local or disseminated candidiasis, *Clostridium difficile* diarrhoea or colitis, cytomegalovirus infection,

hepatitis, sinusitis (especially if the patient is intubated), intravascular catheter-related local or bloodstream infections, and infective endocarditis. The possibility that a non-infectious inflammatory condition such as acalculous cholecystitis, gout, or pseudogout has flared during hospital admission for another condition should be considered. Occult pulmonary emboli are an important cause of nosocomial FUO. Drug fever is especially common in this patient group.

Neutropenic FUO

The number of patients with neutropenia caused by cytotoxic chemotherapy for various diseases is increasing, although the duration of neutropenia is now often curtailed by the timely administration of colony-stimulating factors. Fevers in neutropenic patients are very different from the classical FUO defined above. The leading causes of neutropenic FUO are bacteraemias, pneumonias, and skin/soft tissue infections. Urinary tract infections are less common than in nosocomial FUOs (above). Focal bacterial infections of intravascular lines and puncture wounds, skin folds, and the perianal area all are common, and often associated with bacteraemia. In the early stages of neutropenia, fevers are usually caused by bacteria, but if neutropenia persists, fungal, viral, and other conditions become relatively more common. However, this well-known sequence loses diagnostic value when the patient has received multiple cycles of chemotherapy and antimicrobial drugs.

The duration of neutropenic FUOs tends to be much shorter than that of classical FUOs. The onset of fever often occurs within days of the onset of neutropenia; immediate empirical antimicrobial treatment is usually given, and improvement is frequently rapid. The aetiology of these FUOs often remains unconfirmed. In the majority of neutropenic FUOs the fever is probably due to infection, but the aetiological organism(s) will be identified in only 40 to 60 per cent of cases. Recurrent episodes are likely to occur for as long as the patient remains neutropenic.

HIV-associated FUO

A self-limited episode of fever often occurs during primary HIV infection. After a long asymptomatic interval, fevers and FUOs become extremely common during the later stages of HIV infection. This justifies the introduction of the term 'HIV-associated FUO' in the definitions listed above. The single most common cause of FUO in this setting is mycobacterial infection (tuberculosis in developing countries, *Mycobacterium avium* complex (**MAC**) in the developed world). MAC infection eventually affects up to 40 per cent of patients with acquired immunodeficiency syndrome (**AIDS**) in developed countries. Many other diagnoses must be considered, especially *Pneumocystis carinii* infection, cytomegalovirus infection, disseminated cryptococcosis, toxoplasmosis of the central nervous system, lymphomas, and nocardiosis. In the appropriate geographical regions, disseminated leishmaniasis, histoplasmosis, coccidiodomycosis, and *Penicillium marneffei* infection must be considered. Recently, *Bartonella* species, which cause bacillary angiomatosis and peliosis hepatitis, have also been found to cause febrile bacteraemic syndromes and endocarditis in patients with AIDS.

Investigation of FUO

At the first encounter with the patient, a meticulous history should be taken and a complete physical examination performed. The theme should be attention to detail: for example, careful ophthalmoscopy after dilating of the pupils could reveal Roth spots or retinal tubercles in patients with classical FUO, retinal candidiasis in those with nosocomial FUO, or cytomegalovirus retinitis in cases of HIV-associated FUO. Routine test results (chest radiograph, routine blood count, differential cell count, erythrocyte sedimentation rate, and serum biochemistry) should be scanned for clues. A raised serum uric acid level could signal rapid cell turnover in lymphoma, and a raised alkaline phosphatase level can indicate liver involvement. The peripheral blood smear should be carefully examined for abnormalities such as thrombocytosis, leukaemoid reactions, the presence of nucleated red blood cells, and other clues that the marrow is reacting to a pathological stimulus. The initial findings should be reviewed in relation to the tempo of disease progression before deciding upon the next round of investigations. What major tests have already been performed elsewhere? Repetition of costly radiographs and scans may be unnecessary. Can further testing be safely postponed? Sometimes more will be learned by waiting, or the FUO may resolve spontaneously.

The next level of investigation will usually involve blood cultures, skin testing for delayed hypersensitivity to tuberculosis, and selected serological tests for infections and connective tissue diseases. In older patients, tests for prostate-specific antigen and carcinoembryonic antigen should be obtained. Echocardiography should be performed if any clues are found that increase the pretest probability of infective endocarditis (for example, unexplained heart murmurs or emboli).

Selection of further investigations requires careful consideration of the likely yield, risks, and costs of each. Because many FUOs are associated with intra-abdominal conditions, computed tomography (**CT**) of the abdomen often is valuable. Sinus radiographs and pulmonary CT can reveal the lesions of Wegener's granulomatosis. Radiographs of the bowel with contrast can reveal abnormalities needing further investigation. Gastrointestinal endoscopy with biopsy is often appropriate if symptoms or imaging studies suggest enteric conditions such as inflammatory bowel disease or cancer. Adjunctive imaging with magnetic resonance imaging scan and/or ^{67}gallium- or ^{111}indium-labelled leucocytes can be helpful, but these tests should be used selectively because they are costly and of limited sensitivity; the chance that one of these will reveal a diagnosis is quite low if radiographs and CT scans are negative. Positron-emission tomography using isotopic fluorodeoxyglucose (**FDG-PET** scan) is a new imaging technique which may prove better than older scanning methods. Transoesophageal echocardiography should be performed if the transthoracic echocardiogram is normal or indeterminate but endocarditis still seems likely.

Biopsies of bone marrow, lymph nodes, lung tissue, liver, skin, and temporal arteries or other vessels are essential for the diagnosis of many FUOs. Exploratory laparotomy, previously often performed for the diagnosis of FUO, is now rarely necessary because of improved imaging techniques and directed biopsies. Abnormalities of cytokine levels in blood occur in over two-thirds of patients with FUO, but this finding has not yet proven useful in diagnosis.

For HIV-associated FUO, if the chest radiograph is abnormal or the patient is hypoxic, bronchial washings or biopsy may reveal *Pneumocystis* spp. *Mycobacteria* spp. *Cryptococcus* spp. or cytomegalovirus infection. Direct staining of stool may reveal the presence of *Mycobacteria* spp. If the patient is stable, the results of blood cultures for *Mycobacteria* spp. and unusual bacteria such as *Rhodococcus* or *Bartonella* spp. should be awaited before further invasive tests are done. If the fever remains undiagnosed at this stage, bone marrow and liver biopsies are most likely to be informative.

Approach to treatment

Treatment of the fever itself is indicated if fever distresses the patient, exacerbates heart failure, or is severe enough to cause catabolism and wasting. Otherwise, the temperature curve can be observed in the absence of treatment, often yielding useful new information while investigations continue. If the fever must be treated, aspirin, paracetamol, or a non-steroidal anti-inflammatory drug in standard doses will usually suffice. A regular dosage schedule rather than occasional or 'as required' dosing is recommended.

Treatment of classical FUO

If an aetiological diagnosis cannot be made at first, it is usually best to withhold treatment while observing the patient's progress at frequent intervals. Ideally, a diagnosis will eventually be made, so allowing specific therapy. If an undiagnosed patient is too ill to permit prolonged observation, empirical treatment for FUO may be considered. The most common choice for an empirical therapeutic trial is a corticosteroid. The recommended dose for an adult is prednisone 30 mg orally twice daily initially, or the equivalent dose of another corticosteroid. The possibility that the fever may be eliminated by empirical corticosteroid therapy while the primary disease is unaffected (or even exacerbated) should be kept in mind. The next most common choice for empirical therapy is a broad-spectrum antibiotic such as oral amoxicillin or a fluoroquinolone, or a parenteral regimen such as ampicillin plus gentamicin. In patients who are desperately ill, a combination of parenteral corticosteroid plus antibiotics may be administered. Less commonly, empirical therapy for possible tuberculosis may be tried.

Treatment of neutropenic FUO

After performing a focused physical examination, obtaining a chest roentgenogram, and sending two blood samples and a urine sample for cultures, empirical broad-spectrum antibacterial therapy should be started immediately, before the results of laboratory tests are available. If initial cultures are positive, an antibiotic regimen specific for the aetiological micro-organism can be chosen. If necessary, antifungal or antiviral therapy may be added or substituted, according to the patient's progress and the results of investigations.

Treatment of HIV-associated FUO

HIV-infected patients with an acute onset of fever and hypoxia will usually be treated immediately for possible *Pneumocystis carinii* infection, even if the chest

radiograph is normal. Ideally, a diagnosis should be made as soon as possible through standard investigations. Once the cause of HIV-associated FUO has been diagnosed, specific treatment regimens as described in Chapter 7.10.21 can be prescribed. For patients who remain undiagnosed, various empirical treatments may be tried. Antimycobacterial drugs are commonly included because of the high prevalence of both tuberculous and non-tuberculous mycobacterial infections in HIV-infected subjects.

Prognosis

Classical FUO is a serious condition. Although most of the causes of this type of FUO can be treated, the 1-year mortality is still between 20 and 30 per cent. Obviously, the prognosis varies depending upon the underlying disease and the age of the patient. If FUO persists undiagnosed for more than 6 to 12 months, the likelihood that a specific diagnosis will ever be made decreases, and the prognosis improves greatly, to less than 5 per cent mortality.

The prognosis for nosocomial FUO depends largely on the underlying diagnoses. The short-term prognosis for neutropenic FUO is excellent, with over a 90 per cent response to initial empirical antimicrobial therapy (with appropriate modification as laboratory results return). Again, the long-term prognosis is determined largely by the underlying disease.

Most of the causes of HIV-associated FUO can be treated, but these patients have a relatively poor prognosis, with death likely within 2 years because HIV disease is usually advanced by the time the patient has FUO. The prognosis has improved somewhat with the introduction of highly active antiretroviral therapy. Atypical *Mycobacteria* spp. (which are the commonest cause of HIV-associated FUO) can be suppressed but seldom eliminated, and are likely to develop resistance during therapy.

7.3Biology of pathogenic micro-organisms

T. H. Pennington

Why clinicians need to know about the biology of pathogens

Joseph Lister in Glasgow in the late 1860s was the first successfully to apply a hypothesis about the biology of pathogenic micro-organisms to the management of individual patients. It was that 'putrefaction.... as it occurs in surgical practice'. is caused by the 'germs of various low forms of life' that could be 'deprived of energy' by various chemicals without seriously injuring patients. The subsequent development of microbiology paved the way for the replacement of his antiseptic method by aseptic procedures—one of the most successful innovations in direct patient care that has ever happened—as well as the rational development of vaccines. Antibiotics followed. All of these have been enormously successful. But, even in the richest countries, the current importance of nosocomial infections, the long list of organisms for which vaccines are still desired, and increasing antibiotic resistance show that, despite a successful track record, much unfinished business remains. In poor countries, infections such as tuberculosis are still common causes of premature death. Capping all these things is the regular— but unpredictable—appearance and intercontinental spread of totally new pathogens such as HIV.

Progress towards resolving these problems will very often depend on achieving a better understanding of the relevant pathogens. Genomics promises much. Equally important for practitioners and for medicine, however, is the more effective application of the science that is already known. Both of these considerations explain why a general understanding of the biology of pathogens is important in clinical practice.

The ecology of pathogens

For a parasite to be successful, it must be capable of invading and maintaining itself in a host population. For it to spread, its basic reproductive rate— the average number of progeny that it produces— must be greater than one. Our aim for pathogens is to reduce this below unity, both in patients and in human communities. World-wide, polio may be eradicated soon, but smallpox is our sole success so far. Only infecting humans, it had a low efficiency of transmission which could effectively be interrupted by isolating patients and surrounding them with a ring of individuals made resistant to infection by immunization— which had already reduced the number of susceptibles to a very low figure. These factors— host range, patterns of transmission, and those affecting susceptibility—are key biological parameters for understanding why infections occur and for devising countermeasures. Knowledge about them enables us to explain why, for example, the pattern of *Salmonella* infections has undergone such a dramatic change in Britain since the end of the nineteenth century. It is a reasonable estimate that the overall incidence of human infections with species of this genus was much the same in 1880 as 1990. But infections with *S. typhi*—which accounted for nearly all those contracted in 1880—have almost completely disappeared to be replaced by those caused by *S. enteritica* serovars. This is because the human-to-human faecal–oral spread of *S. typhi* has been interrupted by the provision of clean water and safe sewers, while the recent cultivation of poultry on a massive scale in crowded hen houses with ample opportunities for faecal–oral spread, and subsequent processing that contaminates carcasses with gut contents, has provided bacterially contaminated food on a grand scale.

The lists of important transmission routes and sources of pathogens are short. Person-to-person skin contact, sex, mother to fetus transmission, inoculation of pathogens by arthropod or animal bites and other wounds and by needles, ingestion in food and water, inhalation in droplet nuclei, and transmission by fomites are the important routes. Exogenous sources of infection are other individuals, animals, the environment, and arthropods (as an intermediate but replicative step in transmission from other humans or animals). Many bacteria and viruses are facultative pathogens. Organisms such as *Staphylococcus aureus* and *Streptococcus pneumoniae* spend most of their time living harmlessly on the skin or in the throat, and a significant proportion of the clinically important infections they cause are endogenous, in that they occur in the individuals who carry them. Consideration of these factors provides explanations as to why some public health measures have been much more successful than others, and why current problems, such as nosocomial infections, still occur. Thus, it is easier to filter and chlorinate water than to change human sexual behaviour. The difficulty of changing human behaviour has also provided a major obstacle to the implementation of the critically important safety measure in preventing person-to-person spread and in food safety—hand washing.

The classification of pathogens

Many different bacteria and viruses cause disease in humans. Biodiversity is their hallmark. The modern classification of bacteria is based on DNA sequence data. So far, only a few genomes have been completely sequenced and relationships have been worked out using data from limited regions of the genome, particularly those coding for 16S ribosomal RNA—a relatively stable molecule from an evolutionary standpoint (Fig. 1). Viruses are classified according to schemes which take account of the nature of the nucleic acid in the virus particle—DNA or RNA—and its size and dispositions, particle structure—particularly crystallographic symmetry, size, and the presence or absence of a lipid envelope—and the pathways of virus messenger RNA synthesis (Fig. 2). Only a few general rules emerge from these groupings. Thus, the ability to form spores (which drives the need for autoclaves) only occurs in two medically important Gram-positive genera, *Clostridium* and *Bacillus.* Gram-negative and Gram-positive bacteria have different cell wall structures which play an important role in determining the different antibiotic sensitivities of organisms in these categories. Endotoxin, a major virulence factor, is the lipopolysaccharide component of the Gram-negative cell wall.

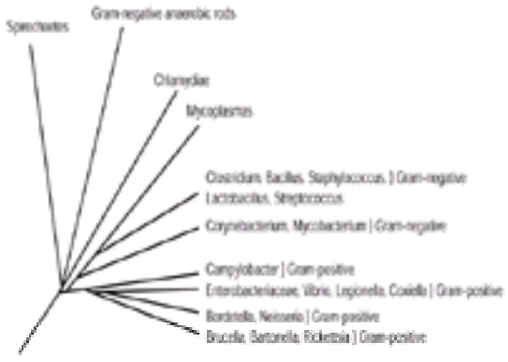

Fig. 1 Phylogenetic tree of medically important bacteria based on 16S rRNA sequence comparisons.

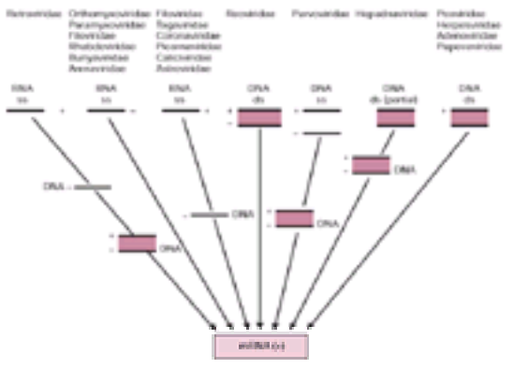

Fig. 2 Grouping of viruses by genome composition and pathway of mRNA synthesis.

Only viruses with DNA genomes (such as herpesviruses) or with RNA genomes that are copied into DNA as part of the infection cycle (such as retroviruses) set up long-term or permanent residence in the host; sometimes this is associated with the formation of malignant tumours. Genome size is inversely proportional to the rate of evolution of natural populations. A small genome, coupled with high mutation and replication rates and high yields, explains why the evolution of some viruses proceeds millions of times faster than that of the human host. In one or two cases, notably HIV, the evolution rate is so great that the virus population in a patient comprises a 'quasispecies' made up of a 'cloud' of variants a few mutational steps away from a master sequence—the sequence of highest fitness—and the master sequence itself. For the influenza viruses a high evolution rate is facilitated by a high recombination rate (strictly speaking a reassortment of segments of its naturally fragmented genome). Other RNA viruses, such as measles virus and poliovirus, show much less genetic variation during natural infections—one reason why their empirically developed vaccines continue to be successful many years after their development.

The fact that they have not been designed, but have evolved, explains why pathogens are so diverse and why so few general principles can be drawn from the groupings that emerge from their classification. Nevertheless, important guides to practice do emerge from evolutionary considerations. Thus the use of antibiotics, antiviral drugs, and vaccines exert strong selection pressures on pathogens and so should only be used in the context of evolutionary thinking. Evolutionary theory also generates explanations as to why virulence has evolved to certain levels; these may in turn generate hypotheses about how to reduce it.

Virulence determinants

Just as pathogens show enormous biodiversity, so many different mechanisms—virulence determinants—are involved in the causation of disease by them. The coincidental operation of multiple factors is nearly always needed to cause disease. A classical and notable exception is botulism, where the ingestion of preformed exotoxin in food is sufficient.

For most pathogens our knowledge of which virulence factors they possess and how they work together is significantly incomplete. The practical impact of this on clinical work is that it often limits the help that laboratory tests can provide in assessing the virulence of organisms isolated from patients. Indeed, tests for the production, or capability of producing, exotoxins, as in the cases of *Corynebacterium diphtheriae* and enterohaemorrhagic *E. coli* (such as *E. coli* 0157 H7), provide about the only examples where routine laboratory testing for virulence factors is used to distinguish between virulent and avirulent strains of the same species. Lack of knowledge about virulence factors and how they work in concert is a particularly important deficiency in the area of emerging and rapidly evolving pathogens such as influenza virus, and antibiotic resistant bacteria such as MRSA (methicillin-resistant *Staphylococcus aureus*). Thus it is still not possible, confidently, to predict from the details of its genetic structure whether an influenza virus will be more or less virulent—despite the very great depth of knowledge accumulated over many years about the sequence, function, and variation of the genes of the virus, and its structure, replication, and natural history in general. Likewise, laboratory tests have not helped to resolve the debate about whether—drug resistance apart—MRSA have added clinical importance because they are more virulent than other *Staphylococcus aureus* strains.

Adhesion and cell entry

To cause disease after being transmitted to its host, a pathogen must adhere to cells or other structures such as connective tissue or foreign bodies. Some bacteria produce clinically apparent effects when growing extracellularly; for others, entry into cells is an essential part of the disease process. Obligate intracellular parasites such as viruses and some bacteria must go through this step in order to replicate. The rates and extent of subsequent local or distant growth are usually important determinants of disease outcomes. Specialized structures, molecules, and processes are used to carry out these steps. For bacteria, surface structures and molecules important for adhesion include fimbriae (pili)—hair-like structures synthesized by Gram-negative bacteria—, flagella (in *Vibrio cholerae* and *Campylobacter jejuni*), outer membrane proteins (particularly in *Neisseria gonorrhoeae*), exopolysaccharides (in cariogenic streptococci and some staphylococci), and collagen, fibronectin, and fibrinogen binding proteins (as in *Staphylococcus aureus*). Many important pathogens employ molecular mimicry. In some, their adhesion molecules may mimic natural ligands, such as the *Bordetella pertussis* haemagglutin which mimics integrins. In others, the organism binds to host ligands which then bind to their natural receptors, as with *Legionella pneumophila* which becomes coated with complement components which then bind to complement receptors.

One of the main functions of a virus particle is to optimize the likelihood of infection by providing structures that interact with molecules on the surface of host cells and prepare the way for virus entry into them. All animal viruses carry multiple attachment proteins or sites on their surface. In some, these are discrete structures, such as the glycoprotein spikes on the surface of influenza virus. In others, such as picornaviruses, receptor binding sites are created at the interfaces between different viral polypeptides. In some large viruses, such as *Herpes simplex*, an initial low-affinity interaction with one receptor is followed by a slower, tighter, binding to another. Viruses enter cells either by fusing their envelopes with the cell membrane and internalizing the nucleocapsid, or by receptor-mediated endocytosis into endosomes, subsequent fusion of the virus with the endosome membrane, and entry of its genome into the cytoplasm.

The bacterial species that enter cells when infecting humans are all important pathogens. They include *Mycobacterium* species, *Salmonella*, *Shigella*, pathogenic *E. coli, Yersinia, Legionella*, and *Listeria.* For *Yersinia* and *Listeria* internalization correlates with a strong adhesion of bacteria to the cell surface (mediated in *Yersinia* by interactions between bacterial invasion and multiple integrins, and in *Listeria* by its internalin interacting with cellular E-cadherin). Cellular pseudopods extend around the bacterium and engulf it in a tight phagosome. *Shigella* and some pathogenic *E. coli* inject proteins into cells which cause rearrangements which promote and lead to entry. The *Shigella* Ipa protein enters the cell and associates with vinculin. A major rearrangement of the host cytoskeleton follows in which actin linked to the cell membrane causes the formation of projections which engulf the bacterium, cell entry occurring by micropinocytosis. Other pathogens, as taxonomically diverse as *Listeria* and vaccinia virus, also associate with the cytoskeleton. They use actin cables to move about the cell during the intracytoplasmic part of their life cycles.

Spread of pathogens within the body

Local, restricted spread is sufficient for some pathogens to cause common and self-limiting or, with a few bacterial species, lethal conditions. The commonest clinically apparent staphylococcal infections—boils—fall into the first category, as do rhinovirus infections of the upper respiratory tract. Localized infections may be life threatening because of the productions of exotoxins that act at a distance, as with *Clostridium tetani*, or exotoxins that act locally as well, as with *Corynebacterium diphtheriae*, *Clostridium perfringens* when causing gas gangrene, and *Streptococcus pyogenes* when causing necrotizing fasciitis. A few bacterial pathogens, such as *Salmonella typhi* or *Treponema pallidum*, invade and grow in organs such as the brain, bones, and skin as a matter of course. For the majority of common bacterial pathogens such outcomes occur in only a small minority of infected individuals. Thus the number of individuals that develop meningitis or septic arthritis is much smaller than the number who carry *Neisseria meningitidis* in their throats or suffer from gonorrhoea. Nevertheless, all these pathogens must possess mechanisms—many of which are poorly understood at present— that allow them to reach blood vessels, traverse the endothelial lining, and use the circulation to travel to distant organs. Similar considerations apply to viruses. While some remain localized, others spread widely. The circulation is the most important route. Viruses enter either via lymphatics or are shed from infected endothelial cells or circulating mononuclear leucocytes. Then they circulate free in the plasma or associated with formed elements. During this process some replicate in monocytes, T or B lymphocytes, or, occasionally, erythrocytes. A particularly important example is HIV, which infects CD4+ T lymphocytes and monocytes in the blood, particularly the former. Some viruses are disseminated in the body by spreading along peripheral nerves, an essential route for rabies and certain herpesviruses, and a supplementary one (to viraemia) for polio- and reoviruses.

Factors that neutralize host defences

Many pathogens employ mechanisms which optimize their chances of establishing themselves and growing in a host. Some bacteria that live in the respiratory tract, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*, produce a protease that selectively destroys host secretory IgA. Bacterial polysaccharide capsules protect against phagocytosis— unless opsonized by the attachment of specific antibody—and against the activity of the alternative complement pathway. Some bacteria evade the host immune response by taking up an intracellular location; it is considered that *Mycobacterium tuberculosis* can survive inside macrophages for long periods, setting up a latent infection which can reactivate and cause disease many years after the initial infection. Large DNA viruses code for proteins that interfere with host mechanisms that respond to infection. A major herpes simplex glycoprotein binds the C3b and iC3b components of the complement cascade protecting against complement-mediated virus neutralization and lysis of infected cells; likewise the vaccinia virus complement control protein binds to C4b—mutations in this gene result in reduced virulence. Poxviruses also induce the synthesis of many other proteins that interfere with host cytokine functions, including soluble receptors for interleukin-1b (IL-1b), interferon g, and tumour necrosis factor (TNF), serpins that inhibit cytokine activation, and proteins that inhibit the expression of MHC-1 antigens at the cell surface.

Factors that damage the host

Bacterial infections damage hosts in three different ways. Bacterial cell components are directly toxic; some bacterial species produce exotoxins which damage cells, cell function, or physiological processes; and the host response to infection may itself contribute to pathology.

The lipopolysaccharide component of the cell walls of Gram-negative bacteria, particularly its core region lipid A, is an important virulence factor. Lipid A stimulates the production of cytokines such as IL-1 and TNF by macrophages. Gram-positive cell wall and other surface structures components may also be toxic. A diversity of bacterial species produce exotoxins. They are important because their toxicity can be very great and because medical measures can be targeted against them by developing toxoids for prevention, and antitoxins for treatment. The former have been much more successful in practice than the latter. Exotoxins are nearly all medium sized to large proteins. Multicomponent ones, such as cholera toxin with one A subunit and five B subunits, are the exception. Some are inactive when produced and need to be cleaved by proteolysis, such as cholera toxin, the *Clostridium botulinum* toxins, and diphtheria toxin. The B region of the latter molecule, for example, binds to cells and is proteolytically nicked to release another part, the A region, which enters the cell and exerts its toxic effect. Some exotoxins cause very different diseases but have similar actions at the molecular level. Thus both the cholera toxin and a pertussis toxin activate adenylate cyclase by enzymatically ribosylating its GTP-binding regulator, and diphtheria toxin causes the ADP ribosylation of elongation factor 2. The end result of these actions on individuals is, of course, quite different. Activation of adenylate cyclase by pertussis toxin damage inhibits the functions of immune effector cells, while in cholera it stimulates chloride secretion and the inhibition of sodium uptake in villus and crypt gut cells causing profuse, watery diarrhoea. In diphtheria, cell protein synthesis is turned off. Some toxins are highly organ specific, such as the neurotoxins of *Clostridium botulinum* which cause flaccid paralysis by acting presynaptically at neuromuscular junctions where they inhibit the exocytosis of vesicles containing acetylcholine. Others have a more widespread effect, such as the staphylococcal toxins that act directly on cell membranes, the a toxin causing cytotoxic damage by creating transmembrane channels, and the b toxin, a phospholipase active on sphingomyelin, being cytolytic for red cells, platelets, and macrophages.

Viruses do not produce exotoxins, neither do their virions contain toxic components such as endotoxins. They produce disease by killing cells (directly or indirectly), by altering patterns of cell growth, and by immunopathological mechanisms. The irreversible inhibition of host cell protein synthesis is a common consequence of infection. A variety of mechanisms selectively turn off cell protein synthesis. They include host mRNA degradation and the inactivation and subversion of components involved in the translation of capped mRNAs. The induction of apoptotic cell death by virus infection has been clearly shown in experimental models. Its role in the causation of human disease is not clear. The induction of benign or malignant tumours by viruses is not uncommon. Representatives of all the major subdivisions of viruses with double-stranded DNA have been implicated in neoplasia, and it has been estimated that up to 20 per cent of human tumours have a viral risk factor. Oncogenes occur in retroviruses and some DNA viruses; the association of other virus infections with tumour formation is indirect and usually associated with cofactors such as malaria in the case of Epstein–Barr virus and Burkitt's lymphoma. The mechanisms responsible for virus-induce immunopathology are exemplified by hepatitis B, where the destruction of virus-infected hepatocytes can follow attack by CD8 T cells, and rashes, glomerulonephritis, and polyarteritis nodosa can be caused by immune complexes.

Why do pathogens cause disease in particular patients?

The possession of virulence factors by a pathogen are necessary, but not usually sufficient, for it to cause disease. In other words, infections with most pathogens are asymptomatic in at least a minority of patients. Factors which may increase the probability of host damage include pathogen dose and route of transmission, particularly if the latter by-passes host defences. In individual patients, it is hardly ever possible to measure pathogen dose and prognostic attention usually focuses on host factors. Many are important, including the efficiency of non-specific and immunological host defences in neutralizing virulence factors and inhibiting pathogen growth. Previous infections can play roles through immunosuppressive effects, as in HIV and AIDS, or by causing tissue damage, as in the bacterial pneumonia that sometimes follows influenza. Genetically determined host susceptibilities to infection include various immunodeficiencies, and conditions which enhance the ability of pathogens to cause tissue damage. Human B19 parvovirus infections provide a good example. The much shortened red cell survival times in sickle-cell disease and hereditary spherocytosis combine with the preferential replication of this virus in erythroid precursor cells to lead to complete red cell aplasia in individuals with these conditions, in contrast to the transient reduction in reticulocyte count seen in normal individuals.

Age is also an important factor in determining the outcome of infection. Although as a general rule disease severity is more severe in the very young and the very old, pathogen-specific features such as the severe organ damage produced by rubella in the first trimester of pregnancy are also important. The biological basis of age-determined susceptibility is not known for most pathogens, even when the effect is consistent and marked. In untreated typhus, for example, mortality rates increase steadily with age, being negligible in children, about 5 per cent in young people under 20, 50 per cent in 50-year olds, and 100 per cent in those over 60.

All the factors discussed in this chapter are the result of evolution. Evolutionary studies on pathogenicity have only just started but they are beginning to provide explanations about how organisms evolve towards virulence. Bacteria reproduce asexually and so have clonal population structures. Horizontal gene exchange is not infrequent, however, and genomes have mosaic structures built up of a basic clonal framework peppered with DNA regions derived from other organisms. These include 'pathogenicity islands'—stretches of DNA containing many virulence genes. Toxin genes also move around on bacteriophages and plasmids. Viruses have incorporated virulence genes, such as oncogenes, from their hosts. Why organisms become pathogens is much less certain.

7.4 The host response to infection

Leszek K. Borysiewicz

Introduction

The expansion in our knowledge of the pathogenesis of infectious diseases over the last two decades is principally a consequence of the development of analytical techniques for investigating biological molecules. Our greater understanding of the biology of infectious agents, including complete genomic sequences of pathogens, as well as the nature of the host response, provides new opportunities for therapeutic research. The interdependence of host and parasite shows the importance of selective pressure from microbes on the evolution of human immune responses. None the less, the central and perplexing question confronting clinicians remains unanswered—what are the principal determinants of disease in an individual patient? This chapter cannot answer this question, but it does describe developments in the field and how they may impact on our understanding of infectious diseases.

The nature of the host–pathogen interaction

Although the parasite–host interaction is often portrayed as a balance of host and parasite factors (Fig. 1), the full range of interactions is large and complex. Symbiosis occurs in the gastrointestinal tract even though factors involved in pathogenesis, such as bacterial adherence and colonization, also operate—but usually with benefit to the host. True pathogenic effects are seen when the host–parasite interaction is modified, such as antibiotic-associated colitis. The survival advantage to a pathogen of host damage is variable and often the best-adapted parasites find an ecological niche and disseminate with minimal disturbance to the host.

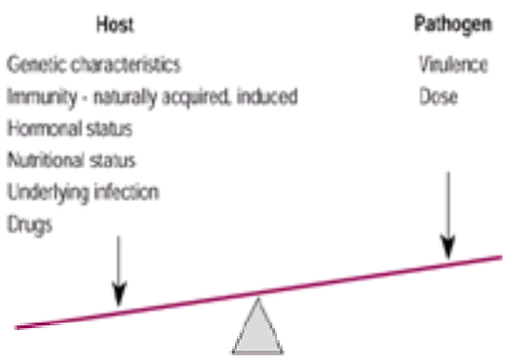

Fig. 1 Factors affecting the host/parasite balance.

Pathogen factors

The molecular basis of microbial pathogenicity has advanced significantly through a genomic approach. Since the sequence of *Haemophilus influenzae* was reported in 1995, more than 50 complete bacterial genomes have now been sequenced. They range from 0.58 Mbp for *Mycoplasma genitalium* to 4.4 and 4.6 Mbp for *M. tuberculosis* and *Escherichia coli*, respectively. Analysis of these genome sequences supports earlier work suggesting that bacterial populations are derived from clonal lineages. This concept implies that genetic exchange (through recombination or horizontal exchange using mobile genetic elements) occurs at low frequency, otherwise a greater heterogeneity of bacterial populations would be observed. However, horizontal transfer is an important source of diversity in bacterial genomes (~18 per cent in *E. coli*). Some pathogenic bacteria are remarkably homogeneous; there are few clonal populations of *Shigella sonnei* and *Bordetella pertussis* in which a single clonal type represents the whole species. Other species such as *Neisseria gonorrhoeae* and *N. meningitidis* show random chromosomal rearrangement, although, during outbreaks of meningitis, a few clonal types dominate the bacterial isolates. Multiple clones of *E. coli* are present during colonization but pathogenic clones persist, suggesting a process of selection within the host environment.

Virulence factors

Observations based on genome analysis combined with information on pathogenic factors, suggest that three mechanisms, each operating on a different time-scale, permit the acquisition of pathogenicity within a clonal subpopulation of bacteria:

- Transfer of virulence genes on mobile genetic elements, such as bacteriophages and plasmids, is rapid, and in the clinical context that allows the acquisition of antibiotic resistance in a population of bacteria during a single episode of infection. Other virulence factors are similarly transferred: for example, cholera toxin is encoded by a vibriophage, which integrates into the *Vibrio cholerae* chromosome.
- Random chromosomal transfer and bacterial transformation allows the acquisition of factors by *N. gonorrhoeae* to replicate in a host.
- The above mechanisms may be coupled with chromosomal relocation of genes in pathogenic bacteria to create 'pathogenicity islands'. These are segments of the bacterial genome (up to 200 kbp) that are flanked by repeat or insertion elements. The segments encode clusters of virulence genes including adhesion molecules, toxins, and secretory and regulatory proteins.

Bacterial virulence factors are regulated such that they are expressed in particular environmental circumstances. Common factors triggering expression include: changes in ionic concentration, pH, iron concentration, and temperature: for example, induction of K-88 and K-99 and pyelonephritis-associated fimbriae in uropathogenic *E. coli*. The factors regulating transcription of these genes are often aggregated into 'regulons' as exemplified by *Bordetella pertussis*. The bacterium expresses a number of virulence factors, such as pertussis toxin, haemagglutinin, fimbrial protein, and pertactin, regulated in a co-ordinated manner by the *bvgAS* chromosomal locus. The locus encodes a BvgS protein that spans the periplasmic membrane. At 37 °C, BvgS autophosphorylates with later transfer of the phosphorylation signal to BvgA, a bacterial regulator that can bind to specific regions of *Bordetella* DNA, thereby promoting the specific transcription of virulence factors as well as amplifying its own signal and repressing other genes. Thus a single signalling cascade can induce a variety of changes responding to several environmental stimuli in a co-ordinated manner.

Although many virulence factors are secreted, others are surface molecules that promote adhesion and bacterial entry by intracellular pathogens as well as interfering with specific host immunity. Intermittent expression of such factors on bacterial pili in *N. gonorrhoeae* reduces the ability of the host to mount a neutralizing antibody response. The mechanisms regulating antigenic variation at this locus and the correct orientation of such factors in pili are the consequence of gene rearrangements in chromosomal DNA and are essential for immune evasion by *N. gonorrhoeae*. Similar mechanisms operate in larger parasites such as *Trypanosoma brucei*.

Route of entry

Invasion of the host to access its environmental niche requires a pathogen to overcome physical barriers, as well as specific defence mechanisms, to establish itself. Many organisms have more than one phase in their lifecycle, either in another host (for example, malaria) or persisting outside a host by an alteration of its lifecycle (for example, encystment in *Amoeba* spp. or spore formation in *Clostridia* spp.). The skin is a relatively impermeable barrier which the pathogen must bypass. This can be achieved for some pathogens by insect vectors or direct trauma with penetrating wounds: for example, a needlestick injury for transmission of the human immunodeficiency virus (**HIV**) and hepatitis C. Even those organisms that produce local skin infections have to either penetrate the skin at sites of injury to gain access to susceptible cells in the basal layers of the epithelium (for example, human papillomaviruses) or infect adnexal structures (for exam-ple, staphylococcal folliculitis).

Alternatively, pathogens enter at mucosal surfaces; but here again physical barriers limit the ability of the pathogen to be retained, let alone replicate at such sites. Many pathogenic factors encoded by bacteria are adhesion molecules that interact with specific host receptors, for example to enable the pathogen to avoid the mucociliary carpet of the respiratory tract or the urothelial/gastrointestinal tract. However, such interactions are not inert because receptor–ligand binding may trigger cellular activation, which itself can be utilized to promote pathogenicity.

For intracellular parasites such as viruses, host interactions also provide the mechanism of entry to the intracellular environment. One of the best-studied mechanisms for the initiation of infection is the interaction of the haemagglutinin of orthomyxoviruses, such as influenza A, with sialic acid. The influenza haemagglutinin (**HA**) is present in the viral envelope as homotrimers of 550 amino-acid chains attached to a membrane-spanning and a short cytoplasmic domain. The molecule has a globular head that includes a conserved receptor pocket in the HA_1 globular region and a long stalk that incorporates an HA_2 domain. Depending on minor variations in HA_1, there are preferences between influenza strains for the optimum configuration of the presented sialyl residues that are bound. After the virus has bound to the cell surface, it is endocytosed and transferred to the endosomal compartment where the pH is reduced to between 5 and 6. Acidification results in an irreversible conformational change, which exposes a hydrophobic domain of amino acids in HA_2, normally concealed in the stalk of the intact molecule. The hydrophobic domain interacts with the lipid bilayers to result in membrane fusion and release of the viral genome into the intracellular environment to initiate virus replication. This mechanism of entry is blocked by amantadine, which can inhibit virus replication by raising the pH within cellular endosomes thus preventing haemagglutinin cleavage and exposure of the hydrophobic domain. Influenza mutants resistant to amantadine have been identified, these are characterized by changes in the hydrophobic region to initiate membrane fusion at higher pH, thereby bypassing the action of this drug.

The molecular structure of the binding domain for the host cell receptor is central to the process of infectivity and the establishment of virus infection. It is a common structural feature of viruses that this domain is often shielded by numerous loops—giving rise to the concept of a receptor 'canyon', first promulgated in the context of rhinovirus infection and its interaction with the intercellular adhesion molecule, **ICAM-1**. Such loops can enhance the specificity of a receptor–ligand interaction, but they also deflect the generation of antibodies from the receptor-binding site itself. This is an important virus evasion mechanism, since greater variation in these loops can be accommodated than in the sterically sensitive receptor site.

Adhesion is essential for bacterial pathogenesis. This is usually achieved through fimbriae or pili, present as 100 to 1000 2- to 7-nm rod-like structures often identified as virulence factors. Uropathogenic *E. coli*, express so-called P-fimbriae in up to 90 per cent of patients with pyelonephritis. These *E. coli* bind to uroepithelial cells through glycolipids expressing a galactose–galactose (**Gal–Gal**) carbohydrate moiety. P-fimbriae genes are expressed from the *pap* gene operon in *E. coli*—*papA* gene products form the core of the fimbrial rod, attached to the membrane through *papH*, and this assembly is protected by two-pap operon-encoded chaperones. The ends of the P-fimbriae consist of fibril-associated proteins, with the *papG* product at the tip acting as the Gal–Gal binding unit. There are at least three 'alleles' of *papG* with slightly different affinities for Gal–Gal, which in turn affect disease association in the urinary tract. However, there is added complexity, in that the whole P-fimbriae complex is regulated, possibly by the *papI* and *papB* units of the operon, enabling the detachment and migration of bacteria to new sites. Therefore local pathogenicity and transmission in a single host may be regulated in response to environmental change.

The ability to interfere with bacterial–host cell binding is attractive for prophylaxis or therapy. The presence of excess soluble Gal–Gal subunits blocks bacterial adhesion, and immunization with *E. coli* bearing class-II PapG protects primates against pyelonephritis by the development of P-fimbrial antibodies. However, protection is limited to a specific allele on the P-fimbriae and little cross-protection against other strains of *E. coli* is observed.

The adhesion of *E. coli*, in particular enteropathogenic types, alters epithelial-cell morphology to facilitate bacterial colonization. Binding of the bacterial adhesin intimin to a membrane receptor (**Tir**, translocated intimal receptor), results in the host membrane developing pseudopodia or 'pedestals', via a cytoskeletal modification process, to aid bacterial attachment but not cell invasion. This is regulated through a bacterial pathogenicity island—'locus for enterocyte effacement'. However, this effacement is unusual in that the 'cell' receptor is also of bacterial origin. Tir is secreted from the bacterial cell through a specialized secretory pathway along with other molecules that cause the epithelial cell to phosphorylate Tir, as well as producing other changes in the activation state of the epithelial cell. Other gastrointestinal pathogens induce similar epithelial-cell adaptations such as the epithelial ruffling associated with *Salmonella* spp., in this instance facilitating bacterial uptake into the optional intracellular environment.

Bacteria also colonize surfaces as 'biofilms'—arrangements of populations of bacteria, which coexist on an inert surface surrounded by a matrix that contains microchannels which facilitate the circulation of micronutrients required for colony survival. Microfilms have evolved to promote bacterial survival in adverse environmental conditions; they occur naturally in dental plaque. Microfilms have assumed great importance because of the bacterial biofilm contamination of indwelling devices including intravenous catheters, peritoneal dialysis tubing, urinary catheters, mechanical valves, and orthopaedic prostheses. The formation of biofilms is associated with a 500-fold enhanced antibiotic resistance related to the presence of the matrix encapsulating the micro-organisms. *Staphylococcus epidermidis*, a common skin commensal, is often associated with the development of such films on indwelling devices. The initial adherence to plastic is through fimbrial adhesion proteins SSP-1 and SSP-2, which is followed by bacterial replication. Secretion of a polymer of b1–6-linked, 2-deoxy-2-amino-glucopyranosyl residues, in a structure that resembles cellulose, is regulated by a bacterial operon, and this allows the formation of bacterial colonies in the biofilm.

Pathogen dose

One important pathogenicity factor, frequently forgotten, is the dose of pathogen that is delivered at the portal of entry. The numbers of organisms required for the development of clinical syndromes are dependent on the site of entry as well as on the nature of the pathogen. Conclusions are often drawn from experimental infections that use inappropriate routes of infection, and excessive pathogen doses. It is difficult to establish the infectious dose needed to produce disease through natural routes in humans. Studies rely entirely on volunteers, which in some instances have been held as unethical. The infectious doses for respiratory virus based on direct inoculation studies suggest that 1 $TCID_{50}$ is sufficient to produce infection via the nasal cavity but that a higher dose is required at the posterior pharyngeal wall.

Large doses (>10^8 bacteria) of water-borne pathogens such as *Vibrio cholerae* are needed to produce a gastrointestinal infection, this is because many bacteria are inactivated by gastric acidity—the infectious dose administered with bicarbonate is reduced to 10^4 bacteria. About 10^5 salmonellae are required for infection, while only 10 to 100 shigellae are needed because of their resistance to gastric acid.

Encysted forms of organisms are particularly resistant to gastric acid—mathematical modelling of a water-borne outbreak of cryptosporidiosis in Milwaukee suggested that ingesting a single oocyst may have been sufficient to produce disease.

Host factors

The susceptibility of the host to infection is dependent on the ability of a pathogen to break down or bypass host barriers, physical and non-specific defence mechanisms which developed early in phylogeny.

Mechanical and local barriers to infection

Skin and epithelial surfaces

Provided the morphological integrity of local epithelial surfaces is maintained, epithelia represent a harsh environment for micro-organisms. Skin is dry and slightly acidic (pH 5–6) due to fatty acids, which are often produced by the local bacterial microflora from the hydrolysis of triglycerides. In addition, secretions such as sebum may be protective, while physical desquamation itself prevents effective colonization by adherent pathogenic species.

Mucosal barriers are more inviting to micro-organisms because of humidity, but this is offset by an established microflora and secretions with antimicrobial properties: for example, lysozyme and *N*-acetyl muramyl-L-alanine amides which cleave the amino-acid backbone of the peptidoglycans found in Gram-positive organisms. Each anatomical site has specific antimicrobial barriers, as discussed below.

Respiratory epithelium

- Air filtration provided by the upper respiratory tract and large bronchi ensures that larger particles are deposited on bronchial mucus and that penetration to the bronchioles and alveoli only occurs with particles smaller than 5 µm in diameter. The large numbers of suspended bacteria in air (approximately 400–900 organisms/m^3 in buildings, resulting in 10^4–10^5 organisms inhaled and cleared each day) emphasizes the efficiency of this barrier.
- A mucociliary blanket clears 90 per cent of surface-deposited material in less than 1 h
- Secretion of defensins and collectins in alveoli help in the opsonization of organisms for clearance by alveolar macrophages.

Intestinal epithelium

- Gastric acidity provides a direct barrier—bacteria penetrate more readily to intestinal sites in the presence of achlorhydria.
- Pancreatic, biliary, and intestinal secretions contain antimicrobial agents, including enzymes and defensins.
- Peristalsis—use of atropine-like agents can prolong the duration of infection with *Shigella* spp.
- Normal bowel flora

Genitourinary epithelium

- Urinary pH and osmolarity is inhibitory to bacterial growth.
- Tamm–Horsfall protein may compete for bacterial binding to the epithelium.
- Urinary voiding—bacterial urinary tract infection is more common where there is a genitourinary obstruction.
- Lactobacilli, present at 10^8/ml in the vaginal microflora, degrade glycogen to lactic acid thereby producing an acidic environment.

The role of commensal microflora at epithelial surfaces

This important barrier to pathogenic micro-organisms is acquired from the environment after birth and is modified throughout life. Although the bacterial interactions in this environment are poorly understood, perturbations caused by the therapeutic use of antibiotics that bring about the establishment of an inappropriate flora readily exemplify its importance. The precise mechanisms of protection are unknown, but commensal bacteria may:

- compete for adhesion sites with pathogenic organisms;
- produce antibacterial compounds to limit bacterial expansion from outside the ecosystem;
- compete with pathogens for nutrients;
- produce metabolic products that limit the growth of other species: for example, lactobacilli in vaginal secretions;
- induce generation of 'natural' antibodies.

Non-specific protective immunity

This involves several defensive mechanisms mediated through cellular and humoral mechanisms.

Complement

Complement is an evolutionary conserved cascade of proteins that not only provides direct protection against invading micro-organisms but also augments the effector functions of specific immune responses (Chapter 5.4). These include:

- *Complement-mediated lysis* is largely dependent on the presence of antibody; polysaccharide-coated bacteria can directly activate this alternative pathway, as can certain virus-infected cells (for example, measles), but this is seldom enough to mediate direct damage. There is little direct evidence that complement lysis in isolation is protective, although deficiency of the terminal pore-forming C8/9 components predisposes to neisserial infection.
- *Opsonization and neutralization*.
- *Induction of inflammation.*

Febrile response

Although body temperature is tightly regulated, no single 'temperature centre' has been identified in the central nervous system. A series of structures in the reticular formation, limbic system, and lower brainstem, including the hypothalamic preoptic region with thermosensitive neurones, can initiate behavioural thermoregulatory responses. These regions become responsive by increasing the rate of neuronal firing to a variety of interactive cytokines, either by direct receptor interactions or through intermediary mediators, such as prostaglandins. Micro-organisms induce the release of pyrogenic cytokines from macrophages, including interleukin (**IL**)-1a and -1b, IL-6, tumour necrosis factor-a (**TNF-a**), and interferon-g (**IFN-g**). Unfortunately, because of their complex interaction and involvement of intermediaries, it is difficult to dissect individual roles. Although cytokines may not cross the blood–brain barrier, they can alter the thermo-regulatory setpoint either by inducing phospholipase A_2 to release prostaglandin E_2 or using a common pathway involving IL-6.

Acute-phase response

Similar stimuli generating a febrile response also induce acute-phase proteins, which may modulate inflammation and tissue repair: for example, the C-reactive protein (**CRP**) binding of phospholipids on damaged cells or micro-organisms. It may also activate the complement cascade and promote anti-inflammatory products. Serum amyloid A may potentiate the inflammatory response by improving adhesion between effector cells and lipid uptake. Complement components and proteins, such as haptoglobin, with antioxidant activity are increased alongside a number of protease inhibitors (for example, a $_1$-antichymotrypsin).

Acute inflammatory responses and the role of the polymorphonuclear leucocyte

Polymorphonuclear neutrophils are produced at the rate of 10^{11} cells daily, with a marrow reserve allowing a 10-fold increase in the presence of infection. Neutrophils circulate in rapid flow as a marginated population of cells through transient endothelial interactions. Following establishment of an infection, polymorphs are recruited to the site by their interaction with specific endothelial and chemokine receptors. There are four distinct phases of migration recognized—rolling adhesion, integrin activation, firm adhesion, and transmigration—mediated, respectively, by selectins, integrins, immunoglobulin-like proteins, and mucin-like selectin ligands. The process is active both in the endothelial cell and neutrophil, necessitating the differential expression of receptors as well as an altered affinity of receptors. This is regulated by multiple interacting signals requiring accessory molecules and signalling through chemokines such as IL-8.

Phagocytosis of microbes is enhanced by receptor-mediated entry, especially if the microbe is opsonized by antibody or complement components. Once the microbe is ingested, the changes in the cytoskeletal architecture adjacent to the vacuole allow the orderly fusion of cellular proteins to ensure a sequential transfer to the phagosome and, ultimately, fusion with neutrophil granules. The pH in the granules falls to 3.5, and enzymes aiding the breakdown of bacteria are released. A distinct microbicidal mechanism is the generation of a respiratory burst enabling the production of reactive oxygen species that are toxic to bacteria. In addition, non-oxygen-dependent killing also occurs through a variety of mediators, including pH, enzymes, defensins, bactericidal/permeability-increasing protein (BPI), lactoferrin, and a range of cationic proteins. This complex interaction has resulted in the identification of numerous clinical syndromes associated with a failure of neutrophil function, all of which enhance susceptibility to infection.

A neutropenia of less than 1000 cells/mm^3, regardless of its clinical cause, carries a significant risk of Gram-positive and Gram-negative bacterial sepsis. More specifically, defects in intracellular killing as found in chronic granulomatous disease caused by different mutations in the NADPH-dependent oxidase complex, can have multiple effects, often depending on the severity of the impairment of the oxidative burst. In its most severe form, there is increased susceptibility to staphylococcal with Gram-negative bacterial infections which normally would be low-grade pathogens for example, *E. coli*, *Klebsiella*; failure to clear the pathogen often results in granuloma formation with viable pathogens in the presence of accumulated polymorphs and macrophages. The selective nature of the defect is illustrated by the observation that most neutropenic patients have minor problems with streptococcal infection. A mild counterpart in the family of neutrophil deficits is myeloperoxidase deficiency. Previously thought to be rare, this disorder is now identified as one of the most common gene defects (1 in 2–4000 of the population), but as yet has not been associated with susceptibility to infections, except perhaps an increased frequency of candidiasis.

While identification of these defects underlines the importance of the polymorph in host protection, their cellular nature does not render them easily accessible to passive replacement therapy—thus antibiotic prophylaxis is the mainstay of treatment. However, in the future, gene therapy-based approaches may offer the best option for cure.

Natural killer (NK) cells

These cells have long been recognized by their ability to kill both virus-infected and tumour cells *in vitro* without the requirement of MHC restriction. This activity is markedly enhanced by the presence of cytokines such as IFN-g during infection *in vivo*. The capacity of NK cells to recognize transformed or infected target cells does not depend on conventional antigen presentation. NK cells carry receptors which are C- type lectins that bind diverse carbohydrates or inhibitory receptors interacting with MHC molecules, that is to say killing occurs when MHC is downregulated. The specificity of the three immunoglobulin-like receptors is being defined, but their role in protective immunity may be broader. Human NK-cell defects are rare, but in one that was identified, the deficit was only identified as a result of an enhanced susceptibility to herpesvirus infections. Therefore, although the direct protective role may be limited, recent studies suggest that the initial NK response at sites of infection may be important for initiating local-early specific responses to the pathogen. Such initiation may represent a fundamental link between innate and specific immunity.

Specific immune responses

Vertebrates, and especially mammals, have evolved specific immunity, probably in response to the selective pressure of exposure to intra- and extracellular pathogens. Although originally protective, enhanced immunity may render some responses detrimental (for example, atopy and asthma) or occasionally augment the effect of an infection by immune-mediated injury. Each effector mechanism is tightly regulated to minimize this possibility and immune responses show unique properties of: specificity for antigens; the ability to turn off the response once an exposure is cleared; and memory with augmentation, such that repeated exposure results in a more rapid and augmented response. These detailed aspects and associated pathology are discussed elsewhere (Section 5), and only mechanisms associated with protective antimicrobial immunity are considered here.

Antibody-mediated protection

Antibodies consist of glycoprotein immunoglobulin molecules secreted in response to infection by T-cell regulated B cells. Antigenic specificity is provided by the primary protein structure at one end of the heavy and light chains that make up the molecule. These specificities are produced by a recombination to bring one of a large number of variable gene segments alongside constant-region genes before transcription and translation of the resultant complex. The biological properties of antibodies are a property of the heavy chains, and immunoglobulins are divided into classes based on the genes that encode the heavy-chain polypeptides. The molecules are invested with unique protective properties against microbial pathogens:

- *Neutralization of toxins and viruses*. One of the earliest observations of the clinical role of antibodies was the recognition that a soluble factor could block both bacterial toxins as well as pathogen entry, especially with viruses. This has led to the use of passive immunotherapy where antibodies can be administered postexposure in toxin-mediated disease (for example, tetanus) or in susceptible patients to block infection (for example, varicella-zoster virus infection in immunocompromised children). However, a wider utility of this approach with the development of monoclonal-antibody technology has not proved successful, for example the use of anti-J5 antibody in *E. coli* bacteraemia. Neutralization is often viewed as steric hindrance consequent on an antibody binding close to a receptor/ligand domain. But, particularly in the context of virus neutralization, this view is simplistic. Titration analysis of picornaviruses has shown that one or two antibody molecules may neutralize poliovirus infectivity despite the presence of 60 potential receptor-binding sites. The exact mechanism of inactivation is unknown, but it could be due to antibody-induced changes in the virion capsid or an inability of the virus to uncoat on entry into the cell.
- *Agglutination*. This may be considered another form of neutralization but is a result of polyvalent antibodies of IgM, IgA, and IgG classes crosslinking particles, thereby blocking adherence and infectivity—as well as enhancing susceptibility to phagocytosis.
- *Complement activation*. IgM and IgG are able to bind complement through the classical pathway via C1q, particularly when there is aggregation of IgG on the surface of the microbe. Binding of complement augments local inflammation and enhances phagocytosis consequent on opsonization.
- *Opsonization and phagocytosis*. Antibodies together with any bound complement components enhance phagocytosis by promoting receptor-mediated entry into phagocytes. Such interactions may also trigger cytokine release, as well as promoting enhanced bactericidal activity in the phagocyte by direct activation of the oxidative burst in these cells.
- *Antibody-dependent cellular cytotoxicity*. Binding through the Fc receptor on leucocytes can kill the target cell, which has been well described with NK cells and the low-affinity FcgRIII. However, the relative importance of this mechanism in host protection is unknown.

Perhaps the best measure of the importance of antibody-mediated protection against microbes is from naturally occurring deficiency diseases. These include X-linked agammaglobulinaemia, common variable immunodeficiency, and the X-linked hyper-IgM syndrome (Chapter 5.6). These diseases present with common clinical features of early-onset recurrent pulmonary infections with *S. pneumoniae* and *H. influenzae* often complicated by chronic sinusitis and middle-ear infections, with gastrointestinal infections caused by common pathogens, such as *Salmonella* spp., *Shigella* spp., and *Campylobacter* spp., as well as more chronic infection with *Giardia* spp. Increased susceptibility to viral infection is limited to rotavirus and enteroviral infection. The latter are unusual in that they can induce a chronic viral meningitis in the face of immunoglobulin-replacement therapy. Enteroviruses are also associated with an unusual polymyositis syndrome.

Cell-mediated immunity

Specific cell-mediated immunity to infection is mediated by T cells of thymic origin, which recirculate to specific sites because of specific cell-surface receptors. Naïve T cells first encounter antigen that has been processed by professional antigen-presenting cells such as dendritic cells. As has been shown by cannulation of lymphatic vessels draining to and from local lymph nodes following local visna virus infection, these cells pick up antigen locally, are activated, and then migrate to the lymph nodes. Here the cells mature and express the processed antigen in the context of MHC class I and II molecules, as well as numerous accessory molecules (for example, CD40 and B7) required for efficient maturation of specific T cells. Specific T cells leave the lymph node after 4 to 5 days and aggregate at sites of infection and/or inflammation. Here the T cells encounter processed antigen either in infected cells or in local antigen-presenting cells. CD8 T cells may act by directly killing infected cells through perforin or the FAS–FASL (FAS ligand) interaction, with the consequential activation of apoptotic pathways. CD4 and, to a lesser extent, CD8 T

cells release a range of cytokines such as the interleukins, IFN-g, TNF-a and -b, granulocyte–macrophage colony-stimulating factor (**GM-CSF**), etc., which may have a direct anti-infective action but that also allow the development of delayed-type hypersensitivity, particularly important for the control of intracellular bacteria. Cytokines and their specific functions are discussed in Chapter 4.4.

One feature of the specific cell-mediated response is the development of memory T cells. These cells are characterized by the expression of specific cell-surface proteins and their ability to recognize antigen without the need for priming through professional antigen presentation. It has been shown for a number of specific cell-mediated immune responses, notably CD8 T-cell responses to the lymphocytic choriomeningitis virus (**LCMV**), that a circulating pool of memory T cells is established following the first *in vivo* encounter with antigen. Subsequent encounter with the virus results in the more rapid activation from this pool of memory T cells, which are often retained for the lifetime of the host. Numerous studies are currently focusing on the nature of the memory T-cell pool: whether it can be augmented; whether antigen is required to sustain this T-cell population; and whether continuous exposure can result in specific depletion. These issues are of particular importance to the development of effective subunit vaccines, as well as to the development of optimum methods of vaccination for maximum protection especially against weaker antigens.

Mucosal immunity

Since the primary encounter with antigen occurs at mucosal surfaces, the nature of the local response can often determine whether infection is initially established. Various elements of the innate immune response are active at surfaces, including cytokines, complement, lysozyme, lactoferrin, NK cells, and phagocytes, as well as specific immune responses such as secretory IgA (**sIgA**). IgA is secreted at most surfaces (including in colostrum) by the addition of a 'secretory piece' to dimeric IgA. Its secretion follows initial encounter of antigen by a mucosal B cell, which circulates to localize at distant mucosal sites, such as salivary glands. Their mucosal localization is determined by specific receptors to endothelial cells at these locations. This has given rise to the concept of a mucosal, as distinct from a systemic, immune system. This system permits the use of active vaccines to block the entry of pathogens at mucosal sites.

Evasion of the host immune response

To establish effective parasitism, it is essential to bypass the immune response in the host. Several strategies are used, such as the speed of replication—the organism replicates rapidly and spreads to infect the next host before an effective specific immune response can be generated (for example, picornaviruses). If a specific locally active antibody response is generated, then some organisms can bypass it by destroying the antibody through IgA proteases. Alternatively, the antibody may be deflected to components of a pathogen that are irrelevant: for example, failure to develop neutralizing antibodies or even antibodies that may facilitate the entry of the micro-organism to optimum sites of replication as in dengue infection. Some viruses may coat themselves with antibody by expressing Fc receptors to block the development of neutralizing activity.

Similarly, the infected cell can be 'masked' by pathogens so that it becomes invisible to the immune response; for example, DNA viruses, especially herpesviruses, downregulate the expression of MHC class I molecules and block antigen processing/presentation so that specific CD8 cytotoxic T cells cannot recognize the infected cell. Inhibition of cytokine action is similarly employed by viruses, notably vaccines that interfere with cytokine action by virally encoded inhibitors and decoy cytokine receptors (for example, for IL-1, IL-8, TNF).

Alternatively, many pathogens such as *Trypanosoma brucei* vary their antigenicity. The parasite is surrounded by a surface coat of carbohydrate and a 67-kDa glycoprotein. The trypanosome genome consists of a large number of chromosomes, including around 150 mini-chromosomes. The coat glycoprotein is encoded by basic copy genes lying near telomeric sites and also internally within chromosomes, so that more than 200 copies of these genes exist. In humans, trypanosomes express one copy of the protein which is transcribed from a telomeric site. Variation occurs by gene conversion, replacing the gene at the active transcription site by a silent copy from elsewhere in the genome, although additional novel sequences may be created. During infection, changes in the basic copy gene expressed occur spontaneously once in 10 000 organisms, resulting in an antigenic change that can always bypass the host immune response generated. Although the organism commits approximately 10 per cent of its genome to this evasion mechanism, it ensures its long-term survival in the host in the presence of an otherwise effective immune response.

Antigenic variation also occurs outside the host to ensure pathogen survival within the population. This is exemplified by influenza whose mode of entry via haemagglutinin and sialic acid interaction has been described. During virus replication in the host, point mutations are introduced into haemagglutinin which result in the virus bypassing the prevalent immune response to the original infecting virus type. Hence, a small number of hosts will always be susceptible to such changes. As the immune response in the population naturally wanes, the population again becomes susceptible to the parental strain every 4 years, resulting in local outbreaks of influenza. This phenomenon is termed 'antigenic drift'. However, influenza A also demonstrates 'antigenic shift', which is the consequence of the genetic recombination of large segments of the genome in an intermediary host such as birds. If such recombination involves the haemagglutinin gene, against which most neutralizing antibodies are directed, then the host population is severely exposed and global pandemics of influenza A as occurred during 1918, 1957 (Asian 'flu), and 1968 (Hong Kong 'flu) can result.

The ability to maintain a reservoir of pathogen in the face of an active immune response, either in the host or the population, is a prerequisite for the effective survival of many pathogens. Each of the mechanisms briefly considered requires elaborate genomic mechanisms or the utilization of a considerable part of the genome to be committed to this end—for example, a trypanosome utilizes approximately 10 per cent of its genome by encoding multiple copies of the surface glycoprotein, while human cytomegalovirus, in the more restricted genome of viruses, utilizes at least six open-reading frames for genes that interfere with MHC class I antigen presentation in the infected cell. Such genomic commitment, of itself, recognizes the importance of evading immunity for parasite survival.

Pathogen persistence and latency

Pathogens, especially DNA herpesviruses, have evolved a virus cycle that enables them to remain dormant at anatomical sites with little virus gene expression, thereby minimizing the potential for immune activation. Following primary infection with herpes simplex, multiple cutaneous lesions develop and virus is shed. An effective immune response develops that clears most of the infectious virus, and the skin lesions heal. However, virus passes to nerve ganglia where it enters a latent state. Periodically it can be triggered to reactivate; infectious particles track down axons with epithelial reinfection and temporary shedding until the immune response again clears the cutaneous site. Therefore a virus–host equilibrium is established, although the relationship is never symbiotic. Not only can activation of the virus by non-specific triggers alter the equilibrium, but immunosuppression can result in the more widespread peripheral dissemination of reactivation. The virus gains two major advantages from this virus cycle: evasion of the immune response and a host reservoir that enables it to bypass a host generation for horizontal transmission, thereby sustaining itself in small isolated populations in the face of an active immune response.

Immune-mediated injury

In most instances the development of an active immune response is beneficial to the host and results in pathogen clearance or the establishment of persistent or latent infection, in which a host–parasite equilibrium is established that minimizes damage to the host. Occasionally, the infectious agent may not itself be as damaging to the host as the immune response that is generated against it.

Immunopathology

At the simplest level, many clinical features of infection are the result of the host's response to the infectious agent; fever is caused by the release of cytokines to the infectious agent. However, in some circumstances the phenotype of clinical disease is altered depending on the nature of the immune response. *Mycobacterium leprae* infection results in a spectrum of disease phenotype with lepromatous and tuberculoid leprosy at either extreme. In the former, the host is relatively 'anergic' to the infectious agent or products of *M. leprae*, with the result that the clinical lesions are less physically destructive but contain high levels of viable organisms, allowing easier spread of infection. In the tuberculoid form, the cell-mediated response to *M. leprae* is strong, with local mononuclear infiltrates at sites of infection and few organisms but more intense tissue destruction and local injury.

Similarly, respiratory syncytial virus infection can result in bronchiolitis in young infants. An immunopathological explanation for this condition was suggested following a failed vaccination campaign using an alum-precipitated killed virus, which resulted in vaccinated children suffering worse disease. The mechanism was thought to be a failure to induce neutralizing antibody, but a T_H2 response capable of releasing IL-3, IL-4, and IL-5 was generated. On infection, release of these cytokines resulted in bronchospasm and local inflammation with eosinophil infiltration. Similar changes can be observed in experimental murine infection.

Autoimmunity

If immunopathology can be induced by an infecting agent through the generation of an aberrant or misdirected immune response, the question arises of whether such a response could be sustained and result in end-organ damage as in autoimmune disease. While attractive as a hypothesis, the 'hit and run' nature of infectious triggers for common autoimmune disorders is difficult to establish. However, in the experimental setting autoimmunity is induced using bacterially derived adjuvants in genetically susceptible hosts. In such circumstances the infectious agent may break tolerance, although direct evidence for this mechanism in humans is lacking.

Alternative mechanisms have been proposed that include molecular mimicry, in which an immune response is generated against an antigen from an infectious agent to trigger a crossreactive response to a host-cell protein, due to its structural similarity. Experimentally transgenic mice expressing the LCMV nuclear protein under an insulin promoter (such that it is expressed only in b cells in the Islets of Langerhans) do not generate a response against the protein and do not develop diabetes. However, if the mouse is infected with the virus then the CD8 T cells generated will destroy the islets and render the mouse diabetic. Evidence for this phenomenon in humans is lacking; infection with *Streptococcus* spp. elicits crossreactive antibodies resulting in rheumatic fever, but even in this case there is little evidence that the response can be sustained. Similarly, the demonstration of prior chlamydial infection in the identification of a specific MHC type and late Reiter's syndrome with reactive arthritis is suggestive but not conclusive.

Host susceptibility to infection

In addition to specific and non-specific immune mechanisms, there are several other host factors that mediate susceptibility to infection.

Genetic factors

The overall impact of genetic factors in host susceptibility to infection is difficult to estimate. Perhaps the best evidence comes from twin studies—susceptibility to infections ranging from malaria to *Helicobacter pylori* are inconclusive, with associations being established for disease severity rather than a global susceptibility to an infectious agent. However, a Swedish study of adoptees reported a sixfold increased risk of an infectious cause of death where a biological, as opposed to an adoptive, parent had also died from an infectious illness. Alternatively, the role of candidate genes in specific infections has been suggested.

MHC and infection

The central position of the MHC in regulating specific immunity make this locus an obvious candidate. However, studies have required large numbers of subjects because this locus is highly variable. Perhaps the best known association is the linkage of HLA-B*5301 with resistance to severe malaria in children in The Gambia. This study was given additional impetus with the identification of a malaria-derived peptide that shows variability and can be presented by HLA-B*5301. An MHC class II locus *HLA-DRB1*1302* was also associated with disease resistance. Taken together with the observation that the HLA-B53 association did not pertain in East African populations, this suggests that the association is complex and that there could be geographical variation in the pathogen which could influence susceptibility to infection by affecting the presentation of microbial peptides by different MHC molecules.

Other associations have been described including: HLA-DQ with cervical cancer associated with human papillomavirus infection (**HPV**); and HLA-DRB1 with the clearance of hepatitis B infection. Numerous studies have been performed to try to establish an association of resistance or disease progression with HIV infection but none are conclusive to date. The subtleties of such associations are exemplified by the association of HPV infection and cervical cancer. While an MHC class II association has been recognized, differences in the survival of patients with invasive cervical cancer have been linked to HLA-B7. This is not evident when all patients with HLA-B7 who have the disease are studied. However, in cervical cancer, there is selective loss of expression of individual MHC class I alleles on the surface of tumour cells. In this instance, patients who lost only HLA-B7 expression on tumour cells had a reduced survival rate. This could be the result of tumour-specific MHC class I-restricted immune responses, but whether the restriction affects the initial infection with HPV or the maintenance of the oncogenic process, is unknown.

The recognition that infections are associated with specific antigens in the host's MHC is important. With improved knowledge of the regulation of cellular immunity and an ability to generate specific immunity with peptides that bind to appropriate MHC molecules, it is possible to develop a new range of vaccines for the treatment and prevention of a range of infectious diseases. However, the vaccine-based approach must take into account possible protective and adverse associations to ensure that the real risk of immunopathology is minimized.

Other genetic factors

A range of other candidate genes have been identified that predispose to specific susceptibility. Blood groups are well described; peptic ulceration is associated with blood-group secretor status, which may confer susceptibility to *H. pylori* infection. Mutations in haemoglobin, particularly in heterozygotes, results in resistance to malaria, which may allow the persistence in the population of what would otherwise be a detrimental defect. Several authors have reported alterations in receptor and chemokine and cytokine genes and susceptibility to infection: elevated TNF concentrations consequent on a mutation in the promoter of TNF-a have been associated with cerebral malaria in Africa, mucocutaneous leishmaniasis in South America, and lepromatous leprosy in India. Mutations in chemokine CCR5 receptors are associated with a reduced susceptibility to HIV infection. Other molecules that may be linked to immune or inflammatory responses are also associated with susceptibility to infection, for example mannose-binding lectin may be associated with invasive disease by encapsulated bacteria, although enhanced susceptibility to individual pathogens has not been demonstrated. The natural resistance-associated macrophage protein type 1 (**NRAMP1**) protein is found on macrophages. The gene encoding NRAMP1 is homologous to a murine gene that has been associated with a susceptibility to leishmania and salmonella infection in defined strains, but mutations in the human gene product are associated with severe pulmonary tuberculosis. Mutations in the human vitamin D receptor also appear to be associated with severe *Mycobacterium tuberculosis* infections.

Conclusions

Despite a number of interesting associations with widely disparate molecules, it is difficult to draw conclusions with respect to pathogenesis at this stage. As the most intriguing associations are with the MHC complex, it is tempting to infer that microbial infections are a powerful evolutionary driver to polymorphism at these loci. Although the specific examples described here are intriguing, it is likely that the factors that determine susceptibility and resistance to individual pathogens in the general population are highly polygenic.

Environmental and intercurrent susceptibility to infection

Several additional factors that operate in a patient have to be considered as influencing susceptibility, severity, and the likelihood of recovery from infection.

Age

Common infectious diseases occur more frequently in older patients: for example, pneumonia (twofold), bacteraemia (threefold), urinary tract infections (fivefold), reactivation of varicella-zoster virus (**VZV**), and tuberculosis (**TB**). The explanation is frequently given that cell-mediated immunity declines with age and that this is reflected in the increased incidence. While this may be the case with VZV and TB, it is difficult to reconcile this alongside other common physical problems of ageing, such as urinary obstruction due to prostatic hypertrophy, and confounding variables such as relative malnutrition, social isolation, and socioeconomic deprivation.

Hormonal influences

Hormones can affect immunity and impact on infections. 'Stress' is often cited as an important factor in the severity of infection. Chronic stress and 'life events' are strongly associated with the increased duration of virus shedding and the intensity of symptoms in upper respiratory tract infections. Pregnancy is associated with an increased severity of poliomyelitis and influenza (among other viral infections) during the third trimester.

Malnutrition

Worldwide, calorie malnutrition is the most common cause of increased susceptibility to infections such as bacterial septicaemia, middle-ear infection, dental caries,

and perioral infection. Enhanced severity of measles has been widely reported, although the effect of overcrowding, which frequently accompanies malnutrition in developing countries, may also contribute. However, improvement in diet has historically been associated with reduced mortality from several infectious diseases. Specific nutrients are difficult to identify, although the best evidence supports a role for vitamin A; deficiency of this vitamin in pregnancy has been associated with enhanced vaginal HIV shedding and increased perinatal transmission.

Intercurrent illness and infections

Many severe illnesses, including other infections, can impair host immunity. Although the obvious example is HIV infection, impairment can also be associated with many conditions such as alcoholism, liver failure, renal failure, and late-stage cancer. Some specific examples are also well documented: measles infection is associated with the loss of delayed-type hypersensitivity in the Mantoux response, with the possibility that tuberculosis may be exacerbated.

Therapy

There are obvious examples of immunosuppressive drugs that render the host susceptible to numerous opportunistic infections.

Altering the host response to prevent and treat infection

Vaccination

The decline in common infectious diseases throughout the last 150 years can be attributed to improved public health measures (sanitation and hygiene) and the development of cheap and effective vaccines. The success of mass vaccination was highlighted by the eradication of smallpox in 1980, and may soon be followed by the eradication of poliomyelitis. However, the vaccination programme has also controlled important childhood infections such as measles, mumps, rubella, diphtheria, haemophilus meningitis, etc. The development of these vaccines has relied primarily on empiricism based on the principle of producing a mild form of the illness, either by using a low infecting dose or an attenuated live agent. Killed vaccines are effective where the appropriate immunity can be generated to a pathogenic toxin, for example antitetanus toxoid.

With a greater understanding of the nature of immunity induced by vaccination, a rational basis exists to pursue the more difficult pathogens that remain major targets for vaccine development, including: malaria, schistosomiasis, hookworm, tuberculosis, infantile diarrhoea, pneumonia, and HIV infection.

A successful vaccine not only has to induce effective immunity, but it must also be acceptable to the public. Such acceptability is difficult to gauge and varies from one community to another. Public acceptance may be partly based on a relative-risk perception between the hazards of vaccination and the burden of morbidity and mortality. There are several examples of difficulties in implementing vaccination programmes such as the *Bordetella pertussis* vaccine and the recent difficulties of sustaining high levels of immunity against measles due to a suggested link between autism and the triple vaccine. Failure to sustain high levels of herd immunity result in resurgent epidemics of diseases previously held under control, for example the diphtheria outbreaks in the former Soviet Union. In addition, for worldwide use a vaccine has to be stable, cheap, and easy to administer. Thus the development of a theoretically effective immunogen may not necessarily translate directly to a successful vaccine for clinical use.

None the less, improvements in technology utilizing the nature of T- and B-cell interaction have seen the development of cellular conjugate vaccines such those undergoing trial against *S. pneumoniae*. Adjuvant technology is also improving to enhance immune responsiveness, and cytokines have been shown to enable vaccine non-responders to generate effective immunity to hepatitis B. Furthermore, DNA vaccines are being produced and undergoing efficacy testing alongside appropriate delivery systems; such as prime–boost immunization—where two different vaccines are administered in sequence: for instance DNA vaccination followed by a booster of the same agent in another recombinant form or the pure cognate protein. Similarly, specific antigens are being delivered to different anatomical sites to enhance mucosal immunity utilizing isolated properties of pathogens, for example the fimbrial proteins of *S. typhimurium*.

This expansion in the utilization of new methods for vaccine development has raised our expectations of tackling difficult pathogens—especially those where a persistent or latent state can be established in the host. There is also the possibility that vaccines may be able to alter the immune response against established infections to control clinical disease. In infections such as leprosy, leishmaniasis, and schistosomiasis, cytokine therapy may modify the effects of the infection, especially where the disease itself is mediated by immune events. Some viruses that persist or even transform cells may continue to express a range of proteins in the transformed state; these products too may serve as appropriate targets for eliminating the infected or transformed cell.

Passive immunotherapy

Perhaps one area that has still not seen the full exploitation of its potential is passive immunotherapy. Passive antibody is used to prevent disseminated varicella in immunocompromised subjects and in the treatment of tetanus; it is also used as an adjunct to the postexposure prophylaxis of rabies. The ability to modify heterologous antibodies to render them less immunogenic, alongside the ability to select the antibody repertoire *in vitro*, makes passive immunotherapy an attractive option for the control of established infection or for modifying immunopathology. In addition, the adoptive transfer of specific cell-mediated immunity in specific circumstances, such as following bone marrow transplantation to prevent human cytomegalovirus pneumonia, may be coupled with the modification of cellular responses including the repertoire of T-cell receptors. Currently, these approaches are still experimental but they may soon be explored in clinical trials.

Conclusions

Although there have striking advances have been made in the control of infectious disease by modifying host responses, many challenges remain. Common childhood infections pose major difficulties for healthcare in many parts of the world, and here the availability of effective prophylaxis must engender greater international effort for its effective implementation. Finally, a greater understanding of the nature of the host–parasite relationship will, coupled with increased knowledge of immune mechanisms, be required to develop new methods to prevent and treat the more intractable common infections.

All of us are exposed to potentially lethal infectious agents from shortly after birth until we die. And while there are viral, bacterial, fungal, and parasitic infections, there is no doubt that the most dangerous organisms are bacteria. Bacteria in logarithmic phase divide every 15 to 20 min: no eukaryotic cell can match that rate, nor can any virus, fungus, or parasite. The immune system evolved primarily to deal efficiently with bacterial infections. It is true that the immune system has minor effects on some tumours, but if mice with severe inherited immune defects are maintained in a sterile environment they have a normal lifespan and do not have an unusual incidence of cancer. Out of the plastic bag, they last a week or two before dying of overwhelming infection.

The immune system is divided into the natural immune system and the acquired immune system. The natural immune system is a series of defences against bacteria and other infections which is present from birth. None of its mechanisms depend on previous experience with the organism, and they do not improve with experience. It is so efficient that the overwhelming majority of bacteria are destroyed shortly after entry into tissue without eliciting any noticeable host response. There are responses, but they function at a microscopic, sometimes a molecular, level. The only infectious diseases of which we become aware are those in which the natural immune system has failed, the population of invading organisms has become large, and inflammatory reactions become sufficiently pronounced to cause symptoms that we can feel and signs that we can see. A healthy adult may go months or years between clinically apparent infections.

Acquired immunity is called on when the initial battle has gone badly and bacterial populations have become large. Initiating an immune response of any kind usually requires antigen concentrations in the microgram range. Since a bacterium weighs about a picogram, specific acquired immune responses are only likely to occur when bacterial populations are measured in millions or billions. Organisms which can multiply to these levels in healthy people generally have some feature, such as a capsule, which enables them partially to evade the natural immune response. Small numbers of B and T lymphocytes which can respond to essentially any immunodeterminant exist in everyone. Uncontrolled infection leads to rapid clonal expansion of specific B and T cells which mediate immunity to the pathogen, most usually by antibody formation. Antigen is maintained in tissue depots so that antibody secretion is prolonged long after the initiating infection has resolved. Both B and T cells generate long-lived memory cells which can initiate secondary immune responses if the organism is encountered again. Secondary immune responses require ten to a hundred times less antigen to elicit them, and occur faster than do primary immune responses. The increased efficiency means that many clinical infections occur only once. Lifelong immunity is often, but not always, maintained by periodic asymptomatic rechallenge with virulent organisms.

Bacteria and fungi are recognized as foreign by the natural immune system. Both classes of organism have thick cell walls which have no counterpart in mammalian cells. The recognition molecule is C3; one important foreign structure is a hydroxyl group on each of two adjacent carbon atoms, which is found in most sugar residues. C3 has a very low but finite rate of spontaneous activation to C3a and nascent C3b. Nascent C3b has an unstable thioether bond which has about 60 μs to find a carbohydrate before it reacts with water and is inactivated. Binding to carbohydrate results in covalent attachment of a molecule of C3b to the bacterial or fungal surface. This is the primary activator of the alternative pathway of complement fixation, which causes fixation of C3b to the foreign surface in amounts which are opsonic for phagocytic cells. Mammalian glycoproteins have carbohydrate groups but many of the hydroxyl residues on terminal sugars are oxidized to carbonyl groups which do not react with C3b.

There are whole families of proteins, both soluble and cell bound, which recognize specific sugar residues such as mannose. Since many fungi have cell walls which are largely polymannose, some of these are likely to be important for antifungal defence.

Bacteria are prokaryotic and present many more foreign labels than do fungi. Probably most important are the major cell wall constituents, endotoxin in Gram-negative organisms and peptidoglycan in Gram-positive organisms. These are recognized as foreign by many systems, both soluble proteins such as lysozyme and cell bound proteins. The key cell in initial defence against organisms is clearly the macrophage. Every tissue contains macrophages which are often organized anatomically in ways which facilitate defence against infection. Alveolar macrophages patrol the alveoli, Kupffer cells have processes which stretch across hepatic sinusoids, and splenic macrophages inspect the blood which filters past them in the red pulp. Most normal tissues contain few or no polymorphonuclear leucocytes. CD14 protein is exposed on macrophage membranes. It contains two high-affinity binding sites, one for endotoxin and one for peptidoglycan. These sites are not identical, but they are so close together that monoclonal antibodies exist which can block binding of both ligands. This single protein is a bacteria detector, and binding of its ligand activates the macrophage to secrete interleukins IL-8 and IL-1 and tumour necrosis factor. IL-1 and tumour necrosis factor act on capillary endothelium to initiate the cascades which result in increased permeability and display of receptors for polymorphonuclear leucocytes. IL-8 is powerfully chemotactic for polymorphonuclear leucocytes. Thus recognition of bacteria by the CD14 protein initiates the natural immune response.

Additional properties of bacteria which initiate inflammation are their ability to fix complement and the fact that bacterial proteins start with an *N*-formyl methionine residue rather than the methionine employed by eukaryotic cells. Almost all bacteria fix complement in the cell wall, though pathogenic species may fix complement in deep layers which are not accessible to polymorphonuclear leucocytes. The soluble complement component C5a is strongly chemotactic for polymorphonuclear leucocytes and even though the bacteria are not opsonized, if polymorphonuclear leucocytes are attracted to their vicinity the bacteria may be destroyed by surface phagocytosis. Similarly, there is a high-affinity receptor for *N*-formyl methionyl peptides in the membranes of polymorphonuclear leucocytes; binding to this receptor initiates a chemotactic response which may be useful in the same way.

Some bacteria, such as mycobacteria, and some fungi, such as *Histoplasma capsulatum*, can evade the natural immune response and the antibody mediated arm of the acquired immune response. These infections tend to be chronic, asymptomatic at first, but progress to extensive destructive reactions such as caseous necrotic cavitation and scarring. The destructive reactions are mediated by macrophages highly activated by parasite-specific T cells.

In general, viruses do not contain components which are directly inflammatory, but typically produce inflammation by killing cells. Some viral infections are not cytolytic; symptoms occur only when the acquired immune response is activated and large populations of virus-specific T cells have been generated. When these T cells kill cells infected by virus, inflammation is induced. In measles, cells can be replaced and the rash signals the end of the disease. If the cells are not replaceable (for example neurones) the immune response may be lethal.

Parasites which live in tissue are almost never directly inflammatory, and they invariably have some mechanism for suppressing or evading the acquired immune response.

A few organisms have specific properties which determine most of the features of the illness. Sore throat due to diphtheria bacilli would be inconsequential if it were not for the toxin which binds to cardiac muscle cells, stops protein synthesis, and leads to heart failure. Many diarrhoeal syndromes are mediated by bacterial toxins, and the absence of toxin means absence of disease. However, even where there are distinctive features some symptoms are shared with other infections—there is almost always fever and inflamed areas hurt.

The general characteristics of infections are explained by the features discussed above. The vast majority of infections are dealt with at a microscopic level by the natural immune system and never give rise to any clinical symptoms. The relative importance of natural and acquired immunity is given by observations on untreated individuals born with congenital defects of one or other system. A child born with no B cells will generally die of infection at about the age of 6, a child born with no T cells will generally die at 2 or 3. A child born with no neutrophils will last a few weeks, and no child with congenital absence of macrophages has ever been described. Admittedly, that may have more to do with the role of macrophages in remodelling tissues during fetal development than with resistance to infection.

Bacterial infections are characterized by acute onset, intense local general inflammation, rapid progression to severe local and general symptoms, and resolution towards death or recovery in a week or two. Infections by slowly dividing organisms like mycobacteria are characterized by less initial inflammation but deterioration over months or years. Fungal infections are far less inflammatory than bacterial ones, though there may be intense inflammation in the later course due to acquired immunity. Viral infections are not usually serious unless, as in poliomyelitis, the virus grows in a population of cells which cannot be replaced. Patients with fungal and viral infections may be highly febrile, but are-notably less generally ill than those with bacterial infections, because the infecting organisms are less inflammatory.

Whether or not an infection becomes established depends on the balance between the host's ability to mobilize an adequate inflammatory response and the parasite's ability to evade that response. Numbers are crucial: it is highly improbable that one organism by itself can initiate a serious or lethal infection. There is good evidence that many infections begin with the survival of a single organism from the initial inoculum, and that all the myriad of organisms which eventually overwhelm the patient are descendants of that one bacterium. However, the probability of that happening is so low that it is almost never observed. As a practical matter, most experimental infections in small groups of animals are initiated by inocula of many millions of organisms so that the individual tiny probabilities are multiplied to a level which can be observed. Spontaneous infections in people are ordinarily initiated by small inocula, but there are hundreds of millions of people. Even though serious infection is improbable, the number of people at risk is so huge that some serious infections are observed.

If there is a defect in host defences, the probability of a serious infection initiating from a small inoculum is greatly increased. Worldwide, the most common cause of poor immune performance is malnutrition, especially lack of adequate protein. Every component of the natural and acquired immune system depends on proteins, and if the building blocks are not available these components cannot be made. Premature infants and elderly patients have serious defects of T-cell function; in one case the system has not completely developed and in the other it has atrophied. There are also numerous acquired immune defects in people who have had transplants, been given chemotherapy for malignancy or immunosuppressive treatment for diseases such as lupus erythematosus and rheumatoid arthritis, and infected with HIV. All these people frequently develop infections with organisms which rarely or never trouble normal people because they cannot control bacterial populations at a low level.

Large numbers of bacteria are inherently inflammatory. If bacterial populations reach hundreds of millions, inflammation will occur whether the bacteria are alive or dead. It makes no difference whether or not the species is 'pathogenic'; the response is to the cell wall components which are found in all bacteria. Pathogenic species possess some attribute such as a capsule or a leucocidin which enables them to evade the initial natural immune response and to multiply in tissue. Multiplication to large numbers does several things. Local inflammation is induced wherever the organisms are, and one sees a clinical sore throat, a boil, pneumonia, or a urinary tract infection. Initially mediators of inflammation leak out of the inflamed area into the circulation and induce a systemic inflammatory response. The systemic inflammatory response includes new aspects of protection by the natural immune response. Generally speaking, bacteria in numbers which induce a systemic inflammatory response also initiate acquired immune responses. Bacteria may invade the bloodstream from the local lesion; they may be able to grow in the bloodstream (sepsis), or they may set up distant foci of infection such as endocarditis, a septic joint, or a splenic abscess. Finally, certain aspects of the systemic inflammatory response are deleterious and may progress to circulatory failure (septic shock) or multiple organ failure.

The concept that large numbers of essentially any bacterium in tissue will cause serious or fatal inflammatory reactions explains a number of clinical situations: aspiration of saliva containing 10^8 bacteria/ml causes pneumonia; a burst appendix causes peritonitis. Infusion of infected fluids intravenously has caused fatal shock in otherwise healthy people. Most of the fatal cases have been due to Gram-negative species; if the organism is Gram positive high fever is common but death is rare. This corresponds to the fact that endotoxin is more inflammatory than peptidoglycan by a factor of 10 to 1000, depending on the test used. In all these cases, most of the bacteria are of species which are ordinarily not pathogenic, This is particularly clear with infected blood transfusions, where the selective factor is the ability to grow in a refrigerator at 4 °C, not the ability to evade the immune response.

It is possible to explain, at least in general terms, almost all the changes which we see in infected patients. The most common reaction to infection in normal people is to develop no clinical symptoms. However, a great deal is going on unobserved. The natural immune system controls and eliminates most invading pathogens. However, the natural immune system has as its key cell the macrophage, which is also a key cell for the acquired immune response. Macrophages display pieces of dismembered bacteria on their cell membranes, in the context of major histocompatibility determinant and IL-1. This is recognized by T cells, which help B cells to make antibodies. Only about 1 per cent of healthy people can remember an attack of pneumococcal pneumonia, but every healthy adult has serum antibodies to 30 or 40 pneumococci, as well as antibodies to common bacteria of most other species. Most infections result in symptomless seroconversion.

If the infection is not controlled at a low population, local inflammation will develop. The classical signs of local inflammation are redness, warmth, swelling, pain, and loss of function. As mentioned above, inflammation is initiated by macrophages which secrete tumour necrosis factor-a, IL-1, IL-6, and IL-8 in response to sensing bacteria through the CD14 protein. Macrophages secrete a powerful thromboplastin which initiates thrombosis and fibrinolysis. Local vasodilatation (redness) is caused by many molecules: in no particular order some of them are histamine from local mast cells, several arachidonic acid derivatives from the membrane phospholipids of activated cells of many types, kinins from serum kininogens activated by Hageman factor exposed to endotoxin, and nitric oxide generated by capillary endothelial cells. There are two distinct waves of nitric oxide synthesis, both induced by IL-1 and tumour necrosis factor acting synergistically. In the first few hours preformed enzyme is activated. After about 12 h newly synthesized enzyme becomes most important.

Local warmth (heat) occurs because of increased blood flow, which raises the temperature of the skin closer to aortic blood temperature. In the fingers this is very obvious because the temperature of the skin of the hand is normally about 30 °C. However, even shoulder skin normally has a temperature of about 35 °C and covered skin such as that on the stomach is still a degree or so below central temperature. The increased rate of local metabolism must contribute something to local warmth, but the effect is thought to be trivial.

Swelling occurs because of local accumulation of extravascular fluid. Normally the amount of albumin in blood is just sufficient to pull back into the low-pressure venous end of the capillaries almost all the fluid which passes into the extracellular space under the higher pressure of the arterial end of the capillary. The rate of lymph flow from a resting non-inflamed tissue is almost zero, and the albumin content is less than 0.5 per cent. Inflamed capillary endothelium is leaky; initially IL-1 and tumour necrosis factor synergize to cause retraction of the cell edges so that gaps develop between adjacent cells. Later, polymorphonuclear leucocytes bound to integrins and palisaded along the endothelial cells may degranulate directly onto the endothelial cell surface and may cause further endothelial cell damage due to lipid peroxidation by generation of reactive oxygen derivatives such as superoxide and hydroxyl radicals. Eventually, there is widespread death of endothelial cells, some of which seems to be due to apoptosis. The increased capillary permeability is of extraordinarily rapid onset—1 h after injecting Gram-negative bacteria into the veins of a dog, pulmonary lymph flow had quadrupled, and the albumin content of pulmonary lymph was over 2 per cent.

Pain appears to be relatively simple. In experiments in which various inflammatory mediators were dropped onto denuded blisters in people, bradykinin was by far the most effective at eliciting pain.

Pus forms when so many polymorphonuclear leucocytes accumulate locally that their secreted proteases are able to overwhelm the local concentrations of antiprotease control proteins such as a_1-antitrypsin. Pus has a thick consistency because it contains large amounts of DNA from the nuclei of broken down polymorphonuclear leucocytes, and it is sometimes greenish because of the presence of large quantities of myeloperoxidase. Pus formation causes local tissue destruction, and, although bacteria do not grow well in it, spontaneous or surgical evacuation of pus often brings an infection to an end.

In serious infections, cytokines such as IL-1, IL-6, and tumour necrosis factor leak out of the local lesion and cause a generalized inflammatory response. This is characterized by fever, polymorphonuclear leucocyte lecocytosis, a striking lowering of serum iron and zinc, and major changes in hepatic protein synthesis. All these changes are adaptive, systemic aspects of the natural immune response which often enable survival in serious infections for long enough to allow production of specific antibody so that the host can recover. A most striking example of this was sometimes found in untreated pneumococcal pneumonia, in which the patient was desperately ill for 6 or 7 days and then, if lucky, had an almost miraculous recovery in a 24-h period. This crisis corresponded to the appearance of free antipneumococcal antibody in the serum, indicating that enough antibody had been made to opsonize all the pneumococci and leave some unbound antibody in the serum.

Fever is due to resetting of the anterior hypothalamic thermostat by IL-1, IL-6, and tumour necrosis factor. The body temperature is controlled just as precisely as it is in health, but the set point is higher. These three cytokines probably work by inducing hypothalamic synthesis of prostaglandin E_2 or a similar compound; aspirin and other non-steroidal anti-inflammatory drugs are antipyretic because they inhibit prostaglandin synthesis. The adaptive value of fever in infectious illness appears to be that it potentiates the immune response.

Polymorphonuclear leucocyte leucocytosis is largely induced by IL-1; initially they are mobilized from the reserve pool of mature polymorphonuclear leucocytes in bone marrow. In a healthy person, this reserve contains about 100 times more polymorphonuclear leucocytes than there are in the blood. Blood smears show more polymorphonuclear leucocytes than average with an increased proportion of band forms. In serious infections, the mature pool of polymorphonuclear leucocytes in the bone marrow is exhausted, and production of polymorphonuclear leucocytes is stimulated from earlier levels. Development is hurried and polymorphonuclear leucocytes are allowed into blood with markers of rushed development. 'Toxic granules' are large, blue perfectly normal polymorphonuclear leucocyte tysosomal granules; the cell did not have time to make the specific granules which would ordinarily have covered them up. 'Dohle bodies' are bluish patches in the cytoplasm of a polymorphonuclear leucocyte; they are pieces of endoplasmic reticulum which the cell did not have time to discard. Vacuoles are not markers of immaturity:

polymorphonuclear leucocytes with vacuoles are cells which have had a 'near miss' with bacteria and have partially degranulated into their own cytoplasm. Vacuoles are highly correlated with the presence of bacteraemia. The adaptive value of mobilization of polymorphonuclear leucocytes is obvious.

The specific granules of polymorphonuclear leucocytes contain lactoferrin an iron binding protein which has a dissociation constant two orders of magnitude less than that of transferrin, the normal serum iron transport protein. Polymorphonuclear leucocytes exposed to bacteria are 'messy feeders' and much of their lactoferrin is released into the surrounding fluid. Lactoferrin finds its way into the circulation, strips iron off transferrin, and the lactoferrin–iron complex is taken up and stored in the reticuloendothelial system. Iron is not available for haemoglobin synthesis, and so the 'anaemia of chronic disease' develops in prolonged infections. More important, iron is not available for bacterial growth. There are many organisms which become highly virulent in iron-overloaded individuals. An example is *Vibrio vulnificus* septicaemia, which is very rare. More than half of the published cases have occurred in people with haemochromatosis.

Normally, the liver makes mostly albumin. It also makes smaller amounts of plasma proteins such as complement components and coagulation cascade proteins, both participating proteins such as fibrinogen and control proteins such as protein C. During serious infections, there is a switch. Little or no albumin is made, and the production of complement and coagulation proteins is increased. Serious infections in individuals with extensive atherosclerosis are often punctuated or terminated by thrombotic events such as strokes and myocardial infarctions. The increased erythrocyte sedimentation rate found in acute infections is mostly due to increased plasma fibrinogen. The adaptive significance of increased levels of complement is obvious; the adaptive significance of faster blood clotting is not so obvious. In addition, the liver makes huge quantities of two proteins, C reactive protein and serum amyloid associated protein, which are not found at all in normal serum. C reactive protein is a phosphoryl choline binding protein which binds to the cell walls of many bacteria. Once bound, it fixes complement, and the bacterium becomes opsonized. Serum amyloid associated protein behaves in a similar way. These proteins act in a non-specific and low-affinity manner, and the protection they provide against any one organism is far inferior to that provided by specific antibody. But their non-specificity is their virtue: they provide low-grade protection against a wide variety of bacteria, and they are available in quantity early in infection. In 24 h, the liver can synthesize 15 g of C reactive protein. The main inducer of changes in liver protein synthesis is IL-6, with assistance from IL-1.

If infection becomes overwhelming, especially if bacteraemia is present, a generalized inflammation of capillaries occurs which is clearly maladaptive. The inducers of the sepsis syndrome are the same as those which induce local inflammatory changes; sepsis is simply inflammation writ large and affecting every tissue in the body. The shock of sepsis is due to peripheral circulatory failure—there is generalized vasodilation in all the vascular beds of the body. Patients with normal hearts attempt to compensate by tachycardia and increased left ventricular stroke volume, The cardiac output in a young man may be 15 to 20 litre/min, with a blood pressure of 80/50 and a systemic vascular resistance of about 4×10^{7} N s/m^{-5}. This pattern is completely different from either shock due to left ventricular failure or shock due to major blood or fluid loss. In both of these, the blood pressure may be identical, but the cardiac output is very low, and the peripheral resistance is high. The circulatory pattern is so reliable that the diagnosis of sepsis can be made with virtual certainty if it is present. The only real differential diagnosis is anaphylaxis, which can generally be ruled out on the history.

The capillaries become leaky, and there is a steady loss of fluid and albumin from the blood into the extravascular space ('third spacing'). Unless fluid is replaced, the contracting intravascular volume exaggerates the shock state because the heart cannot maintain a high cardiac output and cardiac output eventually falls below normal. By this time the patient is well into multiple organ failure—the lungs are heavy and waterlogged and PO_2 plunges to levels which require supplemental oxygen. Eventually, the lungs become so stiff that the patient cannot sustain the work of breathing and needs intubation. Even then very high inflation pressures, high positive end expiratory pressure, and high concentrations of inspired oxygen may be necessary. This is full-blown adult respiratory distress syndrome and carries a 50 per cent mortality because the measures required to keep the patient alive themselves induce progressive pulmonary damage.

Other organs react to the anoxia in their own ways. Delirium is an early sign of sepsis: neurones are adapted to a lower pH and slightly different electrolyte concentrations from those found in serum. When the blood–brain barrier becomes leaky, the concentrations of constituents of the cerebrospinal fluid approach those in serum and there is clouding of consciousness. Initially, septic patients are lethargic and inattentive, but can be roused. Late in sepsis patients are usually stuporous. The kidney stops making urine, the liver may stop conjugating bilirubin, and the intestine may become permeable to the endotoxins and bacteria in its lumen. There is lactic acidosis, probably because of glycolysis in ischaemic tissues. Eventually the heart stops beating.

Sepsis has for 40 years carried a mortality of about 30 per cent. If there is adult respiratory distress syndrome the mortality is 50 per cent, and if three or more organs fail the mortality is 85 per cent. For most of this time the treatment has been with antibiotics to eliminate bacteria, fluid replacement to restore intravascular volume, vasoconstrictors if necessary to get the mean arterial pressure above 70, provision for oxygenation by whatever means necessary, correction of obvious electrolyte disorders, hypoglycaemia, and perhaps extreme acidosis, and support for organ failure. In 28 clinical trials, attempts have been made to lower the mortality of sepsis using antagonists of known septic mediators such as tumour necrosis factor, IL-1, platelet activating factor, etc. And it has not worked: the mortality of sepsis has not changed over that 40-year period.

Recently some progress may have occurred. First, experiments in animals have made it clear that the high flow rates in early sepsis are deceptive: much of the bloodflow is bypassing the tissues, and from the outset there is tissue ischaemia. The most convincing demonstration of this was in septic rats: their livers showed strong fluorescence when illuminated with ultraviolet light, indicating that most of the cellular NAD was in the reduced state, and therefore that the hepatocytes were anoxic. Livers of normal rats had low fluorescence. Second it was realized that at least some of the progressive capillary obliteration, which underlies multiple organ failure, is due to exhaustion of clotting control proteins and widespread thrombosis.

Septic patients were shown to have very low or zero levels of activated protein C, and the lower the level the worse the outlook. Replacement with human recombinant activated protein C was shown to reverse some of the circulatory disorder. A placebo controlled double blind multicentre trial of the efficacy of human recombinant activated protein C in 1000 septic patients with at least one organ failing has just been published. For the first time in 40 years, a significant change in mortality was demonstrated. Mortality fell from 30 per cent to 25 per cent—not much, but significant in this number of patients. Where this will lead is difficult to say, but a way has been found to start attacking the capillary dysfunction which is the main problem in septic people.

7.6 Antimicrobial chemotherapy

R. G. Finch

Introduction

The discovery and clinical application of antibiotics and antimicrobial chemotherapeutic agents is one of the major achievements in medicine. Life-threatening infections such as meningitis, endocarditis and typhoid fever are now treatable, whereas before they were generally fatal. Likewise, the morbidity associated with many infectious diseases of a less life-threatening nature, such as urinary tract infections, skin and soft tissue infections, and bone and joint sepsis, has been substantially reduced. Perioperative prophylactic use of antibiotics has reduced the risk of infections complicating surgical procedures, such as large bowel and gall bladder surgery, vaginal hysterectomy, and implant surgery, such as the insertion of prosthetic heart valves, joints, and neurosurgical shunting devices.

Antimicrobial chemotherapy is the use of antibiotics and chemotherapeutic substances to control infectious disease. The term 'antibiotic' was coined by Waksman to describe a substance derived from naturally occurring micro-organisms and possessing antimicrobial activity in high dilution. The latter characteristic is essential in defining its selective toxicity to other micro-organisms. True antibiotics include penicillin, derived from the mould *Penicillium notatum*; streptomycin from *Streptomyces griseus,* and the cephalosporins from *Cephalosporium* spp. Many chemotherapeutic substances with antimicrobial activity have been artificially synthesized, such as the sulfonamides, quinolones, and isoniazid. However, the term 'antibiotic' is loosely applied to both the true antibiotics and other antimicrobial agents.

Antibiotics are among the most widely prescribed drugs, accounting for an international expenditure of $25b. In the United Kingdom, some 80 per cent of all prescribing is in the community where the emphasis is largely on oral agents; the remainder are used in hospitals where there is a greater emphasis on injectable drugs. More than 125 different antibiotics are available, but a relatively small number is necessary to deal with most prescribing needs. It is important that clinicians who prescribe are familiar with the principles of antimicrobial chemotherapy and that they adopt a continuous learning approach throughout their professional lives to ensure safe and effective prescribing. Table 1 summarizes the agents available for the treatment of bacterial, mycobacterial, fungal, viral, protozoal, and helminthic infections. More agents have been developed for the treatment of bacterial infections, but globally viral, fungal, and parasitic infections predominate. In recent years, there have been major advances in the availability of antiviral drugs particularly for the treatment of the herpesviruses and HIV. Likewise, safe and effective systemic antifungal agents have resulted from the discovery of azoles and triazoles.

The very success of antimicrobial chemotherapy has led to widespread and often excessive use, particularly in community practice where prescribing is largely empirical and clinical distinction between viral and bacterial infections is difficult. Antibiotics are used extensively in animal husbandry both for the treatment and prevention of infectious disease and, more controversially, as growth-enhancing agents among commercially raised poultry and swine. This has raised concerns about the emergence and spread of antibiotic resistance which affects many classes of antibiotic, may be intrinsic to a particular pathogen, or may result from genetic mutation. Resistance may be caused by enzymatic inactivation (b-lactamase), failure of drug penetration into the bacterial cell (porin mutation), alteration of the target binding site (e.g. penicillin-binding protein alteration in penicillin-resistant *Streptococcus pneumoniae*), or from efflux resistance whereby the drug is extruded from the bacterial cell (e.g. chloroquine-resistant *Plasmodium falciparum*). Organisms can also develop alternative metabolic pathways which by-pass drug inactivation. Resistance may be transferable between the same species or genera but may also spread between genera. Coding for multiple antibiotic resistance has been increasingly observed and results from a number of mechanisms, in particular plasmid transfer.

Despite the advances in antimicrobial chemotherapy, fresh challenges remain. These include the treatment and prevention of viral causes of enteric infection, meningitis, and hepatitis which are still without effective chemotherapy. Tuberculosis and malaria are among the world's major infectious disease killers and here problems of antibiotic resistance and, in the case of tuberculosis, the continuing need for long and complex regimens continue to frustrate disease management.

Among the more worrying trends in antibiotic resistance is the emergence within hospitals of methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci (VRE). Among community pathogens, *Strep. pneumoniae* has rapidly become less sensitive to penicillin causing clinical failures in the treatment of meningitis and otitis media. Internationally, multidrug resistant tuberculosis and multidrug resistant salmonellae, including *Salmonella typhi,* are of major concern.

Resistance is not confined to bacteria. Fungal resistance is increasing (e.g. of *Candida albicans* and *C. krusei*. to fluconazole). Resistance by the human immunodeficiency virus (HIV) to the nucleoside, non-nucleoside, and protease inhibitors is rapidly emerging. Within a decade of the introduction of antiviral agents, failure of chemotherapy may become a major factor responsible for progression of HIV disease.

Pharmacology

Mode of action

Knowledge of the pharmacological mode of action of an antimicrobial agents permits an understanding of the diverse mechanisms of microbial inhibition and the

opportunities for drug resistance. This is best established for antibacterial and antiviral agents. In the case of antifungal, and especially antiparasitic agents, the modes of action are less well defined. This reflects the process of drug discovery whereby an understanding of the biochemical and molecular action of agents derived from natural or chemical sources has not always been a priority in establishing efficacy and safety.

Antibacterial drugs

Antibacterial agents may affect cell wall or protein synthesis, nucleic acid formation, or may act on critical metabolic pathways (Table 2).

The b-lactams (penicillins, cephalosporins, and monobactams (aztreonam)) and the glycopeptides (vancomycin and teicoplanin), inhibit cell wall synthesis. The b-lactams, which share the common b-lactam ring, act on cell wall transpeptidases to inhibit cross-linking of peptidoglycan. The glycopeptide antibiotics act at an earlier stage of cell wall synthesis by binding to acyl- D-alanyl-D-alanine. Despite their similar mode of action, they are less efficient bactericides than the b-lactams.

Inhibitors of protein synthesis

Antibacterial agents that inhibit protein synthesis act on the 30S ribosomal subunit responsible for binding mRNA, or the 50S subunit which binds aminoacyl tRNA. The aminoglycosides, tetracyclines, and macrolide antibiotics are the most widely used inhibitors of protein synthesis. Chloramphenicol, clindamycin, and the recently introduced agent quinupristin/dalfopristin (Synercid) also act at this site.

Inhibitors of nucleic acid

Nucleic acid synthesis is targeted by quinolones, metronidazole, and rifampicin. The bacterial DNA gyrase is essential for the supercoiling of bacterial DNA. This, together with the enzyme topoisomerase IV, are the major targets for the quinolones. These enzymes are absent in humans, explaining the selective activity of these drugs. Rifampicin and other rifamycins interfere with DNA-dependent RNA polymerase, preventing chain initiation.

Metabolic inhibitors

The best known metabolic inhibitors are the sulfonamides and trimethoprim which interfere with folic acid synthesis by sequentially inhibiting the enzymes pteroic acid synthetase and dihydrofolate reductase. By acting sequentially, a combined bactericidal effect results. The selective activity of these compounds is dependent upon the fact that humans are unable to synthesise folic acid and require preformed folic acid in their diet.

Antiviral agents

Viruses live and replicate within the host cell. Antiviral chemotherapy therefore presents a particular challenge if it is to be selectively toxic. The cycle of viral replication provides a number of opportunities for therapeutic intervention. Most available antiviral agents are nucleoside analogues, largely used in the treatment of HIV or herpesvirus infections (Table 3). The recent growth in numbers of antiviral agents has benefited greatly from HIV related research through the identification of new drug targets (Fig. 1). Interference with cell surface attachment through ligand blockade of surface receptors provides a theoretical, as yet unfulfilled, target. Penetration into the host cell may be through a process of translocation or direct fusion between the outer lipid membrane of the virus and the cell membrane, before uncoating and release of viral nucleic acid. Replication differs among viruses, thereby providing a number of therapeutic options. Viral mRNA becomes translated into multiple copies of viral proteins encoded by the viral genome either as a result of virus-specific enzymes or by co-opting host-derived protein. HIV, for example, employs its own reverse transcriptase to convert RNA to DNA before integration into the host cell chromosome. Transcription and translation follow. Before the virus can be released, new viral particles must be assembled for which host cell proteins and mechanisms of phosphorylation and glycosylation may be recruited. The protease inhibitors act at this stage and have been particularly successful. Virus release is either the result of transportation and budding, or host cell lysis.

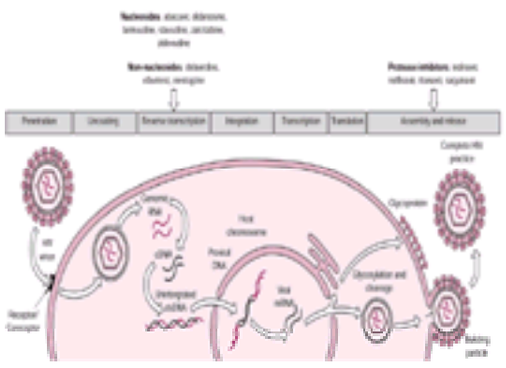

Fig. 1 Sites of inhibition of HIV replication by current antiretroviral drugs.

Antifungal agents

The polyene antifungals (amphotericin B and nystatin) act on ergosterol within the fungal cell membrane. Ergosterol is largely absent from bacteria and humans, explaining the selective toxicity of these agents. The azole antifungals include the imidazoles (e.g. clotrimazole, miconazole, ketoconazole) and the triazoles (fluconazole and itraconazole) which bind preferentially to fungal cytochrome P450 to inhibit 14-a-methylsterol demethy-lation to ergosterol.

Antiparasitic agents

The mechanism of action of many antiparasitic drugs is only partially known. Among the antimalarials, chloroquine interferes with the digestion of haemoglobin taken up by *Plasmodia*. Quinine is thought to act in a similar manner. Metronidazole is active against a number of protozoa such as *Entamoeba histolytica* as well as anaerobic bacteria. It acts as an electron sink, by reducing of its 5-nitro group and activated by nitroreductase within the target pathogen, thus interrupting DNA synthesis.

Among the antihelminthic drugs, piperazine and paraziquantel act by selectively inducing muscle paralysis in the target helminth. Others, such as thiabendazole, inhibit parasitic ATP synthesis and energy production.

Antimicrobial spectrum of activity

The antimicrobial spectrum of an agent is dependent upon target site susceptibility among pathogenic organisms at clinically achievable drug concentrations. Some micro-organisms are intrinsically resistant to certain antibiotics. For example the aminoglycosides are inactive against anaerobic bacteria because cell entry is an energy dependent process relying on respiratory quinones, which are absent in anaerobic bacteria. Certain strains of *Pseudomonas aeruginosa* are resistant to the aminoglycosides as a result of altered protein porin channels which inhibit antibiotic penetration.

The antimicrobial spectrum of a drug in part dictates its clinical indications. While information on this spectrum is more easily determined *in vitro*, *in vivo* efficacy can only be confirmed through clinical use, which can be supported by animal model data during drug development. For example *in vitro Salmonella typhi* is susceptible to gentamicin, but the drug is not effective clinically.

Narrow spectrum and broad spectrum agents

There are few truly narrow spectrum agents. Fusidic acid, mupirocin, and the glycopeptides (vancomycin and teicoplanin) target specific pathogens and are mainly

used to treat microbiologically confirmed infections.

Broad spectrum agents, such as the quinolone antibiotics and the parenteral cephalosporins, such as cefotaxime and ceftriaxone, are active against many Gram-positive and Gram-negative pathogens. Metronidazole has activity against a large number of anaerobic bacteria and, because of this restricted activity, is considered to have a narrow spectrum. The aminoglycosides, although active against staphylococci and aerobic Gram-negative bacilli are inactive against streptococci and anaerobes and are therefore frequently prescribed in combination. The carbapenems (imipenem and meropenem) possess the broadest spectrum of activity which includes most aerobic and anaerobic bacterial pathogens. Broad spectrum agents are often used empirically in the initial management of severe infection. However, they frequently affect the normal flora so that super-infection with *Clostridium difficile* and yeasts are more likely to arise.

Susceptibility testing

Antibiotic susceptibility testing of clinical isolates is important for appropriate prescribing and for gathering epidemiological data. It is determined *in vitro* by using either broth- or agar-based methods. Pathogens are exposed to known concentrations of an antibiotic and their degree of inhibition compared to a standard control. Disk susceptibility testing is the most widely used method. Zones of inhibition around the antibiotic-containing disk are measured, compared to a standard, and the pathogen designated sensitive, resistant, or of intermediate susceptibility to the drug. Currently, such methods require the isolate to be tested in pure culture. It is therefore difficult to obtain information on the susceptibility of a pathogen in less than 36 to 48 h from sample collection.

The minimal inhibitory concentration (MIC) in mg/l provides more precise *in vitro* information on the activity of a drug against bacterial pathogen. It is more time consuming and costly to determine although automated systems and commercial strip tests are available (Fig. 2). Defining susceptibility by MIC determination permits greater predictive benefit in the treatment of certain infections such as gonorrhoea, bacterial endocarditis, and pneumococcal meningitis. Knowledge of the *in vitro* susceptibility of common pathogens to antimicrobial agents (Fig. 3) is helpful in selecting drug therapy but is only relevant to the achievable drug concentrations, which is important in predicting performance as discussed below.

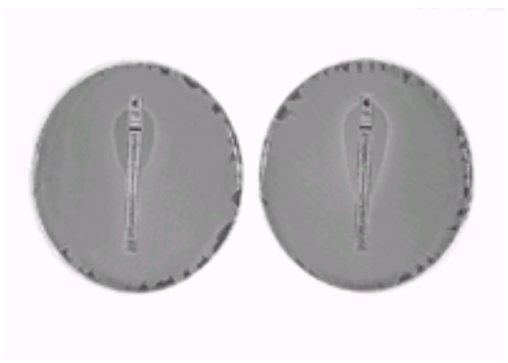

Fig. 2 *Staphylococcul aureus* resistant to penicillin (minimum inhibitory concentration 8 mg/l) on the left and sensitive to vancomycin (minimum inhibitory concentration 1.0 mg/l) on the right as demonstrated by a commercial strip test.

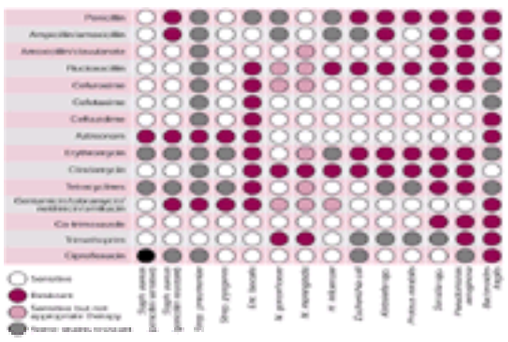

Fig. 3 Sensitivity of selected pathogenic bacteria to some common antibacterial agents.

Combined drug therapy

In hospital practice, it is common to combine agents when dealing with mixed infections or where initial broad spectrum empirical therapy is required. Another important reason for combining drugs is to prevent the emergence of antibiotic resistance, such as in the treatment of tuberculosis and HIV infections. Antituberculosis regimens have been developed to ensure that naturally occurring minority populations of *Mycobacterium tuberculosis* resistant to isoniazid or rifampicin do not emerge during therapy. By combining isoniazid and rifampicin with pyrazinamide and ethambutol for the initial phase of therapy (2 months), resistance is usually avoided. Therapy can be restricted to isoniazid and rifampicin for the continuation phase (4 months). The regimen is extended in those patients unable to tolerate pyrazinamide and in the treatment of tuberculous meningitis (Table 4).

HIV infection is treated with multidrug regimens. The success of highly active antiretroviral therapy, in which nucleoside analogues and protease inhibitors are combined in a three-drug regimen, is not only based on greater potency of the combined regimen but also on its ability to slow the emergence of drug-resistant mutants. The more recently introduced non-nucleoside reverse transcriptase inhibitors, such as efavirenz, appear to be equally potent in combination with nucleoside analogues and can delay the need for using protease inhibitors. This may increase the period of time in which antiretroviral therapy remains effective in an individual. The options for treating HIV infection are summarized in Table 5 (see also Chapter 7.10.21).

Occasionally, drugs are combined for the purpose of achieving a synergistic effect based on evidence that the *in vitro* activity of the combination is shown to be greater than the sum of the activity of the individual agents. Most drugs in combination will simply be additive in effect. One of the more frequently prescribed synergistic combinations is that of penicillin (or ampicillin) and streptomycin (or gentamicin) in the treatment of endocarditis caused by *Enterococcus* spp. The aminoglycoside alone is generally inactive against enterococci but in combination with ampicillin achieves synergistic killing (Fig. 4). A similar effect is employed in the treatment of viridans streptococcal endocarditis with this combination.

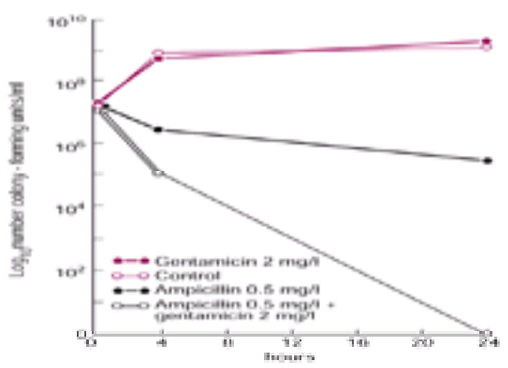

Fig. 4 Effects of ampicillin (0.5 mg/l) and gentamicin (2 mg/l) alone and in combination on a strain of *Enterococus faecalis* from a patient with infective endocarditis. A

synergestic effect is observed with the combined agents.

Another widely used example of synergistic inhibition is the combined effects of an antipseudomonal b-lactam, such as ceftazidime or piperacillin, and an aminoglycoside, such as gentamicin, tobramycin, or amikacin. This combination is used to treat documented or suspected *Pseudomonas aeruginosa* infections occurring in neutropenic states complicating bone marrow transplantation, cytotoxic chemotherapy, and burn wound infections.

Antibiotic resistance

General considerations

Antibiotic resistance has been recognized since the introduction of effective antibiotics. For example penicillin-resistant strains of *Staphylococcus aureus* became widespread shortly after the introduction of this agent; penicillin sensitive strains are now uncommon. Resistant strains of Gram-negative bacteria, such as *Klebsiella, Enterobacter, Acinetobacter,* and *Pseudomonas* spp. are commonly found in high dependency units where they may cause epidemics. The international emergence of epidemic MRSA infections, primarily within hospitals and nursing homes, is very worrying. Conventional approaches to controlling these infections have been largely unsuccessful. The emergence of MRSA together with multiple-antibiotic-resistant coagulase-negative staphylococci has rapidly increased the use of vancomycin. Vancomycin-resistant enterococci has emerged in specialist hospital facilities such as dialysis and haematology units; therapeutic options are limited. Other problems include the emergence of penicillin-resistant pneumococci and b-lactamase producing *Haemophilus influenzae*.

At present, there is great international concern among professionals, politicians, and, increasingly, the public about antibiotic resistance. In the United Kingdom, the House of Lords published an influential document in 1998 reviewing the issues surrounding this problem. This has led to a number of initiatives: reducing the use of antibiotics, particularly in the treatment of minor upper respiratory tract infections in the community; education strategies for prescribers and the public; and better enforcement of infection control policies. Within the European Union, similar measures have been proposed together with a ban on the use of antibiotics as growth promoters in livestock animals. However, antibiotic resistance is a global problem. An increasing number of multidrug resistant infections caused by *Salmonella* spp. and *Mycobacterium tuberculosis* are being imported from developing countries where the availability or prescribing of antibiotics is less controlled.

Antibiotic resistance drives changes in patterns of prescribing and is a major impetus to the pharmaceutical industry in its search for new therapies. Micro-organisms differ in their ability to develop resistance, which may affect a particular drug, a class, or multiple classes of antibiotics. Genetic mutations select for antibiotic resistance which frequently occur under the influence of antibiotic pressure. The major mechanisms of resistance are summarized in Table 6. Resistance to single or multiple antibiotics may be either chromosomally, or plasmid mediated, or both. In turn, genes may code for resistance to a single or multiple antibiotics. In addition to plasmid-mediated resistance, other transposable genetic elements (transposons), and insertion sequences incapable of self-replication, may exist within a chromosome, plasmid, or bacteriophage.

Resistance genes are most frequently transferred between organisms by conjugation. This occurs between the same or different species of bacteria and also between different genera. Other mechanisms of transferring resistance include transduction via a bacteriophage, and less commonly transformation in which naked DNA released during cell lysis is taken up by other bacteria.

Transposon-mediated resistance reflects transfer of discreet sequences of DNA between chromosomes or plasmids whereby individual or groups of genes can be inserted into the host bacterial cell. More recently, molecular structures known as integrons have been identified which facilitate new combinations of resistance genes within the bacterial chromosome, plasmid, or transposons. The antibiotic resistance genes are bound on each side by conserved segments of DNA. These individual resistance genes can be inserted or removed between the conserved structures and act as an expression vector for antibiotic resistance genes.

While the molecular mechanisms of antibiotic resistance are legion, the ability of drug-resistant micro-organisms to survive, disseminate, and cause disease varies widely. In many instances, antibiotic resistance may give a survival advantage only in the presence of continued antibiotic exposure to such agents. This is reflected in the occurrence of epidemic disease in high-dependency units such as intensive care facilities where antibiotic usage is often high. However, it is also clear that once the genetic mechanism for evading antimicrobial activity has been acquired, it is rarely lost and adds to the continuously expanding genetic memory that has steadily eroded the efficacy of many antimicrobial drugs.

Enzymatic inactivation

Aminoglycoside-modifying enzymes include adenylating, acetylating, and phosphorylating enzymes. Gentamicin is the most susceptible and amikacin the least susceptible to such inactivation. However, the largest group of inactivating enzymes are the b-lactamases which hydrolyse the b-lactam ring common to all penicillins and cephalosporins. Penicillinase was the first b-lactamase to be identified and is the reason why most strains of *Staphylococcus aureus* are resistant to this drug. Another important b-lactamase is that known as TEM-1 which is responsible for resistance to ampicillin by *Haemophilus influenzae*. The major impetus to the development of the penicillins and cephalosporins was to extend their spectrum of activity by resisting inactivation by b-lactamases present in many aerobic Gram-negative bacilli. However, new inactivating enzymes continue to emerge, including the extended spectrum b-lactamases, which are now limiting the clinical utility of third-generation cephalosporins, and the carbapenemases which hydrolyse imipenem.

Impermeability resistance

Drug uptake of antibiotics such as the penicillins, tetracyclines, and quinolone antibiotics by bacteria is through protein channels (porins) which cross the outer membrane. Alterations in the permeability of the outer membrane of Gram-negative bacteria is an increasingly important mechanism of drug resistance. Mutations in porin structure are responsible for resistance among pathogens such as *P. aeruginosa* and *Serratia marcescens.*

Alterations in target site

Another important mechanism of resistance is mutational modification of drug binding sites. This affects susceptibility to b-lactams, erythromycin, chloramphenicol, and rifampicin. Erythromycin and chloramphenicol bind to the bacterial 50S ribosomal subunit which is subject to genetic mutation. In contrast, the quinolones target DNA gyrase which is subject to subunit structure alteration resulting in one variety of resistance to drugs such as ciprofloxacin. The increasing resistance to penicillin among *Streptococcus pneumoniae* is the result of reduced binding of penicillin to several binding proteins (PBP-2a and PBP-2x). *Staph. aureus* resistance to methicillin is due to the presence of penicillin binding protein (PBP-2a) which has reduced affinity for methicillin and other b-lactams and is encoded by the *mecA* gene.

The recently recognized problem of vancomycin resistant enterococci, which largely affects *Enterococcus faecium,* is the result of the production of enzymes (ligases) which permit continued cell wall synthesis despite the presence of vancomycin. To date, five different genes have been found responsible for this phenomenon (Van A-E) which result in different phenotypic patterns of resistance to the glycopeptides vancomycin and teicoplanin.

Metabolic bypass resistance

Bacteria must synthesize folic acid from the precursor *p*-aminobenzoic acid. The sulfonamide antibiotics competitively inhibit the enzyme dihydropteroate synthetase. Trimethoprim acts on the same metabolic pathway by inhibiting dihydrofolate reductase. The sequential inhibitory effects of trimethoprim and sulfamethoxazole (co-trimoxazole) result in synergistic bactericidal activity against many pathogens. Resistant organisms are able to synthesize their own enzymes thereby evading such competitive inhibition.

Surveillance of antibiotic resistance

Information on the susceptibility of pathogenic micro-organisms is important. Such data can provide information on the relative frequency of pathogens and the pattern of susceptibility to prescribed agents. Surveillance, therefore, has a role in guiding prescribing, in developing prescribing policies and in identifying and monitoring

organisms which are subject to infection control measures. On a broader front, surveillance is also of value in alerting industry and health-care planners to the need for new drug and vaccine strategies for disease control.

To be of maximum benefit, surveillance needs to be sensitive to a defined geographical base which may simply reflect the catchment area of specimens submitted to a particular laboratory, providing information on the trends in community and hospital isolates. Within hospitals, more specific information can be provided about susceptibility patterns in high dependency units, where antibiotic consumption is often greater, and more resistant pathogens, such as *Klebsiella, Serratia, Enterobacter, Acinetobacter spp.,* and *Pseudomonas aeruginosa* are found. Among Gram-positive pathogens, *Staphylococcus aureus* and enterococci present an increasing challenge to prescribing and infection control practice.

National networks of surveillance often vary in their focus and include data on enteric pathogens, *Staphylococcus aureus*, penicillin resistance among pneumococci, and, more recently, vancomycin resistant enterococci. There are important international networks which collect information on such pathogens as *Legionella pneumophila* and *Mycobacterium tuberculosis*. Drug resistant tuberculosis is increasingly prevalent in the United Kingdom and overseas.

Surveillance of resistance to antiviral agents is rudimentary. Patient-specific data is increasingly sought in those with HIV infection, to assess drug failure, guide change in management, and direct primary therapy in selected cases of person-to-person and mother-to-infant transmission. Determination of phenotypic resistance is still costly and time consuming and most data relate to genotypic patterns of resistance to antiretroviral drugs among HIV isolates.

Pharmacokinetics

To be effective, antimicrobial agents must achieve therapeutic concentrations at the site of the target infection. This may be localized to a single anatomical site, such as the bladder or the cerebrospinal fluid, or involve a major organs such as the lung. Infections may also be generalized and affect many body sites. Drug selection must take into consideration the fact that pathogens such as *M. tuberculosis, Legionella pneumophila,* and *S. typhi* replicate intracellularly. Antimicrobial drugs may be administered arenterally, orally, or topically to the skin, external auditory meatus, conjunctiva, and by intraocular application. In the case of systemically active agents, the effective drug concentrations are determined by the standard pharmacokinetic parameters of absorption, distribution, metabolism, and elimination. Since selective toxicity is crucial to safe prescribing, the dose regimen for each agent aims to avoid concentrations toxic to the host but inhibitory to the micro-organism. This 'therapeutic window' varies by drug.

Bioavailability

The rate and degree of absorption from the gastrointestinal tract is not only important for plasma concentrations reflected in the pharmacokinetic parameters of C_{max} and T_{max} of a drug, but also for potential adverse effects on the bowel (Table 7). For example ampicillin, the first of the aminopenicillins, commonly caused gastrointestinal side-effects, most notably diarrhoea. These effects have been reduced by increasing the bioavailability of the active drug through the introduction of hydroxy-ampicillin (amoxicillin) and various esters and prodrugs of ampicillin.

Some agents such as cefalexin, doxycycline, and a number of the quinolone antibiotics are extremely well absorbed, achieving 80 to 100 per cent bioavailability. In the case of some recent quinolones, the excellent bioavailability has raised the possibility of treating with oral antibiotics some severely ill patients who might normally require parenteral therapy. In contrast, drugs which are poorly bioavailable, such as cefixime and cefuroxime axetil, not only have a higher incidence of gastrointestinal side-effects but are also more likely to select for *Clostridium difficile* associated large bowel disease.

Distribution

Most drugs are distributed in the blood via the plasma before gaining access to the extracellular fluid. Tissue concentrations of a particular agent are affected by pH, drug ionizability, lipid solubility, and the presence of an inflammatory reaction whereby the capillary fenestrations are increased in size. In the case of agents administered intravenously by infusion or by bolus injection, the distribution phase is rapid in comparison with orally, rectally, or intramuscularly administered drugs. Drugs which are poorly lipophilic, such as the b-lactams and aminoglycosides, achieve low concentrations in tissues such as the brain. However, the b-lactams achieve therapeutic concentrations in the cerebrospinal fluid as a result of the inflammatory reaction which accompanies meningitis.

Drugs may also be taken up intracellularly, as in the case of macrolides and quinolones, resulting in a large volume of distribution compared to drugs confined to the extracellular space, such as the b-lactams and aminoglycosides. This is important in relation to the treatment of intracellular pathogens such as *Mycoplasma pneumoniae*, *Legionella pneumophila,* and *Mycobacterium tuberculosis* which can only be effectively treated by drugs which are concentrated and remain biologically active intracellularly.

The plasma half-life (T½), which is the time required for the concentration of a drug in the plasma to fall by half, is affected by drug distribution and, in particular, its rate of elimination as a result of metabolism and excretion. This in turn affects the time taken to reach steady state. In the treatment of life-threatening infections, it is important that steady state kinetics are achieved rapidly. This may require the administration of a loading dose. This applies to the use of agents such as gentamicin for the treatment of serious Gram-negative infections and intravenous quinine in the case of life-threatening malaria where the pharmacokinetic behaviour can be altered by the severity of the disease in comparison with healthy subjects (Fig. 5).

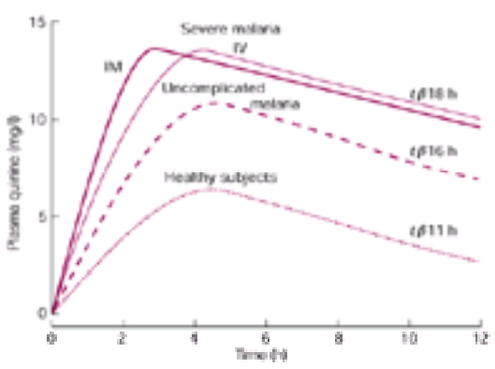

Fig. 5 Average plasma quinine concentrations following administration of a loading dose of 20 mg (salt)/kg to patients with severe and uncomplicated malaria, compared with those predicted to occur in normal subjects. (Reproduced from White (1992), with permission.)

Drugs are commonly distributed in the blood and tissues bound to plasma proteins, largely albumin. Drugs vary in their degree of protein binding. With agents such as flucloxacillin and ceftazidime it exceeds 95 per cent. The importance of protein binding lies in the fact that the active moiety is the unbound drug. Dissociation from the bound to the unbound state is usually rapid but this equilibrium may affect drug performance at certain sites such as the joints. The relationship between protein binding and drug performance has been emphasized in recent studies of the pharmacodynamics of drug activity (see below).

Metabolism

Antibiotics, like other drugs, are degraded at various sites in the body but, predominantly within the liver. Degradation involves conjugation, hydrolysis, oxidation, glucuronidation, or dealkylation, according to the particular drug. Members of the hepatic cytochrome P450 group of enzymes play a dominant role in this process. Drug metabolites are usually but not always biologically inactive. For example cefotaxime is degraded to desacetyl-cefotaxime and clarithromycin to hydroxy-clarithromycin, both of which are biologically active and contribute to the overall antibacterial activity of these agents.

Excretion

Most drugs are excreted in the urine by glomerular filtration, tubular secretion, or a combination of these mechanisms. Thus high concentrations of drug will often be present in the urine; this has therapeutic importance in the treatment of urinary tract infections. Urinary pH affects the biological activity of many drugs; for example the activity of ciprofloxacin is markedly reduced at pH 5.5. Tubular excretion can be blocked by probenecid. This was formerly used to ensure higher plasma concentrations of penicillin and is still recommended in the treatment of gonorrhoea with single doses of amoxicillin, ampicillin, or intramuscular procaine penicillin. It is also important to note that any reduction in glomerular filtration rate will not only affect urinary concentrations of drug but also the plasma half-life and, in turn, serum concentrations of drugs which are primarily excreted by this route. In the case of antibiotics such as the aminoglycosides and vancomycin, the dose must be reduced in renal failure.

Biliary excretion is another important route for drug elimination either as the active compound or as a microbiologically active or inactive metabolite. Reabsorption from the gastrointestinal tract can result in enterohepatic recirculation, which in turn may affect plasma half-life. Drugs which achieve high concentrations in the bile are effective in the treatment of infections at this site such as cholecystitis. However, biliary obstruction or hepatic impairment may reduce therapeutic efficacy and require dose reduction to avoid toxic effects. Examples include clindamycin, efavirenz, mefloquine, and tetracyclines.

Therapeutic drug monitoring of some antibiotics is essential in order to ensure therapeutic yet non-toxic concentrations. This applies particularly to aminoglycosides which have a relatively narrow therapeutic index. Trough concentrations of gentamicin in excess of 2 mg/l, if sustained, can result in nephrotoxicity and ototoxicity. The target cells for such toxicities are the renal tubular lining cells and the cochlear hair cells of the inner ear respectively. Vancomycin is also frequently monitored, particularly in patients with impaired renal function.

Pharmacodynamics

The inter-relationship between drug, micro-organism, and the infected host creates an important pharmacological dynamic. Antibiotics are unique in therapeutics in that they are targeted at an invading micro-organism which may be present at a particular site or be more widely distributed in the body. The host's response to infection may modify the pharmacokinetic handling of a drug. Many antibiotics have a measurable effect on a variety of bacterial and host cell functions, even at subinhibitory concentrations. It is difficult to establish the exact role that these factors play clinically, but they are likely to contribute to the overall effect of an antibiotic. Macrolides, such as erythromycin, illustrate this point since they affect a variety of virulence characteristics (Table 8) as well as affecting the host's response to infection.

Exposure of micro-organisms to sublethal concentrations of an antibiotic may temporarily inhibit growth which recommences following removal of the drug. The time to recovery is known as the postantibiotic effect. This varies with the drug and the micro-organism; for example the quinolones have a longer postantibiotic effect than b-lactams (Table 9). The relevance of this observation to the *in vivo* situation, where plasma drug concentrations are often well above the inhibitory concentration and are sustained through repeat dosaging, remains uncertain. It may have greater relevance to tissue concentrations which tend to be lower than plasma concentrations. Postantibiotic effect certainly contributes to the effects of agents that are administered once daily, such as gentamicin.

The relationship between the pharmacokinetic characteristics of a drug and bacterial inhibition is critical to therapeutic outcome (Table 10). In the case of agents such as penicillins and cephalosporins, the time that drug concentrations are maintained above the minimum inhibitory concentration (MIC) predicts the response. This contrasts with agents such as the quinolones and aminoglycosides, where it is more important to achieve high C_{max} to MIC ratios. Modelling the MIC of a particular organism against the dose response curve for a drug (Fig. 6) has established a number of important pharmacodynamic parameters which have been supported by studies in animal models and man. For example dosage regimens of quinolones, such as ciprofloxacin and levofloxacin, have been based on pharmacodynamic data. The ratio of C_{max}:MIC has been refined in the parameter, area under the inhibitory concentration, which is the ratio of the area under the time curve (AUC):MIC. This is more predictive of outcome. The importance of protein binding for drug performance has also emerged as an important modifying factor in this modelling. The AUC:MIC of the free drug is the most sensitive predictor of response. The manner in which these ratios differ for selected quinolones is shown in Table 11.

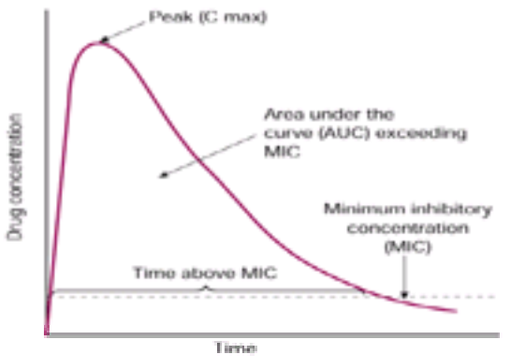

Fig. 6 Relationship between the MIC of a drug and its pharmacokinetic profile.

Principles of use

In comparison with many other classes of drugs, antimicrobial agents are usually prescribed in short courses ranging from a single dose to a few days. Prolonged therapy is required for certain infections such as tuberculosis and bone and joint sepsis, and for HIV infection, treatment is usually life-long.

Most antibiotic prescribing, especially within community practice, is empirical. Even among patients in hospital, where there are greater opportunities for diagnostic precision based on laboratory investigations, the exact nature of the infection is established in only a minority of cases. Most therapeutic prescribing requires a presumptive clinical diagnosis which, in turn, is linked to a presumptive microbiological diagnosis based on knowledge of the usual microbial causes of such infections. Among the most widely treated infections are those affecting the upper and lower respiratory tracts, the urinary tract and skin and soft tissues for which the likely microbial aetiology is restricted. For example urinary tract infections arising in the community are usually caused by *Escherichia coli* and other Gram-negative enteric pathogens and, less commonly, by enterococci or *Staphylococcus saprophyticus*. Local knowledge of the susceptibility of these pathogens to commonly used agents such as trimethoprim, ampicillin, and a quinolone such as norfloxacin is helpful in recommending initial empirical antibiotic management.

In more severe infections, such as community-acquired pneumonia, prompt empirical therapy is essential. Although the range of possible pathogens is more extensive (Table 12) *Streptococcus pneumoniae* predominates and must always be targeted. Assessment of severity, based on validated criteria, assists in defining the initial empirical antibiotic regimen. This is illustrated by the British Thoracic Society's recommendations for the initial empirical antibiotic management of community acquired pneumonia (Table 13).

The use of empirical therapy depends on the ease with which a clinical diagnosis can be made, disease severity, and toxicity. In the case of herpesvirus infections, the empirical use of aciclovir for the treatment of mucocutaneous herpes simplex infections or of shingles in the elderly is now common. However, it would be inappropriate to start treatment for HIV or CMV infections without laboratory support for these diagnoses in view of the toxicity and cost of the antiviral agents used to treat these infections.

Antibiotic prophylaxis

Antibiotics are used widely in the prevention of infection, in association with surgery and in a range of medical conditions (see above). Antibiotic prophylaxis is used for selected surgical procedures where the risk of infection, although relatively low, is of serious import should it occur. Examples include prosthetic joint implantation and cardiac surgery in which prosthetic valves and intracardiac patches are inserted.

The principles of antibiotic prophylaxis are based on the selection of an agent active against the known potential target pathogen(s). The drug should be present in

high concentrations at the site and time of surgery and be relatively free from adverse reactions. One or two doses are generally effective depending on the length of the procedure. No regimen can be effective against all potential pathogens hence the importance of postoperative follow-up.

An important medical indication for the use of prophylactic antibiotics is the prevention of bacterial endocarditis in those with established valvular heart disease undergoing selected dental, urinary tract, or gastrointestinal procedures during which transient bacteraemia carries the risk of endocardial infection. Here again, the principles governing the selection of the regimen are based on the recognition of the likely target pathogens, their pattern of susceptibility, and the necessity to ensure high bactericidal concentrations of drug at the time of the procedure. In community dental practice, single-dose oral therapy with high-dose amoxicillin/clavulanate (co-amoxiclav) or in those allergic to this agent, clindamycin, are currently recommended. Another example of effective prophylaxis is the use of low-dose suppressive therapy to prevent *Pneumocystic carinii* pneumonia in those with advanced HIV infection. Co-trimoxazole is the preferred agent. Dapsone and inhaled pentamidine are also used.

Anatomical or functional asplenia is associated with a 12.6-fold increased incidence of severe sepsis compared with the general population. This risk is related to the patient's age and, in those splenectomized, the reason for surgery and the period of time that has elapsed. Young children are particularly at risk but this declines substantially after the age of 16 years. Hence the recommendation for prophylactic oral penicillin (erythromycin for the intolerant) to prevent fulminant pneumococcal sepsis which predominates. It will not offer protection against other pathogens such as *Escherichia coli* and *Pseudomonas aeruginosa.* Apart from good evidence for the benefit of prophylaxis in children with sickle cell disease, there is poor support for efficacy in splenectomized patients.

There remain, therefore, differences of opinion about the recommendation for the continued use of chemoprophylaxis in adults. Issues of cost, compliance, and drug resistant pathogens add further fuel to the debate. What is clear is that the patient or legal guardian(s) should be educated concerning this risk.

Dose selection

Few antibacterial drugs are specific to a single pathogen, hence the dosage regimen must capture a range of susceptibilities of the various target micro-organisms to ensure a successful response. The dosage regimen is determined initially by pharmacokinetic studies in healthy volunteers. This is supplemented by information from standardized animal models which simulate infections such as peritonitis, endocarditis, meningitis, thigh abscess, otitis media, pneumonia, and sepsis complicating neutropenia. In man, information on drug penetration into CSF, bile, joint fluid, and cutaneous blisters can be supplemented by data from biopsy specimens from sites such as tonsils, bronchus, and prostate. The role of pharmacodynamic assessment is of increasing importance in defining dose and predicting outcome as discussed earlier. Despite all this information, the definitive dosage regimen still requires support from large clinical trials in which the endpoints of response are precisely determined.

Bactericidal versus bacteristatic agents

In the treatment of many common community infections which are usually of mild or moderate severity, the choice of either a bacteristatic or bactericidal antibiotic is of limited importance. However, in patients with severe infection, particularly when complicating an immunocompromised state, a bactericidal agent must be used. This applies particularly to those with severe granulocytopenia which is a common accompaniment of cytotoxic chemotherapy, especially in the treatment of haematological malignancies and following bone marrow transplantation. Another important indication for selecting a bactericidal regimen is in the treatment of infective endocarditis; although the infected vegetations are in the bloodstream, they are relatively protected from host phagocytic control. Effective penetration into the fibrin–platelet mass requires high concentrations of a bactericidal drug to sterilize the infected vegetations.

Duration of treatment

The duration of therapy for many common infections has not been rigorously determined. The treatment of many common conditions is based on custom and practice and often varies internationally. The duration of treatment has been more thoroughly determined in the following cases:

- Gonococcal urethritis responds promptly to single dose treatment with agents such as ceftriaxone, spectinomycin, or a quinolone antibiotic such as ciprofloxacin or ofloxacin.
- Uncomplicated urinary tract infection, particularly when affecting women of child bearing years, responds promptly to single dose and 3-day treatment regimens with selected agents such as trimethoprim and norfloxacin, although bacteriuria can be eliminated with a single dose, the symptoms of dysuria and frequency take longer to subside, hence a 3-day course is preferred.
- Pharyngitis caused by *Streptococcus pyogenes* improves symptomatically within a few days of antibiotics such as penicillin but eradication of the infecting organism from the throat often takes up to 10 days. It is acknowledged that this presents major difficulties with regard to drug compliance.
- Pulmonary tuberculosis—the current recommendation of 6-months treatment with rifampicin, isoniazid, pyrazinamide, and ethambutol, reducing to isoniazid and rifampicin for a further 4 months provided the isolate is confirmed to be susceptible, is based on extensive clinical trials (Table 4).
- Bacterial endocarditis—knowledge of the *in vitro* susceptibility of the infecting organism is crucial in determining dose, duration, and outcome of therapy. Highly penicillin-sensitive strains (MIC < 0.1 mg/l) of viridans streptococci are treated effectively with a 2-week regimen of parenteral penicillin which may be supplemented with sequential high-dose oral amoxicillin for a further 2 weeks. Less sensitive strains should be treated with parenteral penicillin and gentamicin for a total of 4 weeks, which is essential if the infecting organism is an enterococcus.

Infections caused by *Staph. aureus* are a particular challenge since the severity is highly variable and yet the potential for metastatic infection and chronicity as in the case of osteomyelitis must be kept in mind. The isoxazolyl penicillins, such as flucloxacillin are preferred with, or without, the addition of fusidic acid. Clindamycin is a useful alternative agent. Many *S. aureus* of the skin and soft tissues respond promptly to 7 to 14 days oral therapy. Where there is a severe systemic response to infection, parenteral therapy is appropriate initially. Where there is evidence of dissemination, treatment should be extended for periods up to 4 weeks.

In the case of septic arthritis, antibiotics should be given promptly and joint aspiration carried out, sometimes repeatedly, to avoid damage to the articular cartilage. The duration of therapy has not been rigorously determined. Most infections will resolve in 2 to 3 weeks. One of the most challenging infections is staphylococcal osteomyelitis. To avoid chronicity, it is customary to treat for 4 to 6 weeks. Treatment is generally administered parenterally. In centres where skill, experience, and administrative support exist, patients are increasingly being managed in the community by parenteral administration through peripherally inserted venous catheters. Under these circumstances, a glycopeptide such as teicoplanin is convenient since it is administered once daily.

For most infections, the duration of therapy remains uncertain. However, many mild to moderate uncomplicated infections will defervesce within a 3 to 5-day period suggesting that 5 to 7-days treatment is usually adequate. There is little evidence to suggest that treatment periods of 7 to 14 days, or longer, are any more effective and are likely to be associated with an increased risk of side-effects, superinfection, and the selection of antibiotic resistant organisms, apart from being more costly.

The parenteral administration of antibiotics is appropriate in the management of severe life-threatening infections and when oral therapy is contraindicated, such as in the postoperative period, if the patient is vomiting, or where gastrointestinal absorption cannot be relied upon. However, the need for continued parenteral therapy should be reviewed regularly. In the treatment of many common infections, the acute features of infection such as temperature, tachycardia, and an elevated circulating neutrophil count usually improve within a period of 48 to 72 h. Provided there is no contraindication to oral therapy, this should be considered early in the course of patient management. The advantages are not just in the reduced cost of medication. The risk of intravenous line associated complications, such as infection, is also eliminated and discharge from hospital may be hastened.

Adverse drug reactions

Overall, antimicrobial agents have an outstanding record of safety. Nonetheless, no drug is without the potential for side-effects. The risk varies by agent, sometimes dose, while host genetic factors and pathophysiological status can also be important.

Oral antibiotics are largely used in the community where they are generally well tolerated and used in the treatment of minor infections in large populations. Injectable agents selected for short course perioperative prophylaxis have a well established safety record. However, agents such as the antiretroviral drugs and amphotericin B carry a higher risk of more serious adverse drug reactions which must be balanced against the life-threatening nature of their target infections.

While drug safety is assessed during drug development, the full repertoire of adverse reactions becomes apparent only during widespread clinical use, hence, the importance of adverse drug reaction reporting systems. In the United Kingdom, the 'yellow card' system has been very successful and relies on voluntary reporting of

possible adverse drug events to the Medicines Control Agency by physicians and, more recently, pharmacists. It is important to distinguish between adverse event reporting and adverse drug reaction reporting. The latter is more difficult to establish with certainty and may require rechallenge which raises medical and ethical concerns.

It is essential to enquire about previous drug reactions as well as other forms of drug toxicities before prescribing. The relationship to a previously prescribed drug requires careful assessment. Hypersensitivity is among the more common of drug reactions and, in the case of b-lactam drugs, appears to be more a function of the five-membered thiazolidine ring (Fig. 7) of the penicillin molecule since hypersensitivity reactions are less common with the cephalosporins which have a six-membered dihydrothiazine ring. The monobactam, aztreonam, has neither ring structure and hypersensitivity reactions appear to be rare. However, it is important to note that accelerated systemic hypersensitivity reactions (anaphylaxis) can be life-threatening such that any previous association with a b-lactam drug is an absolute contraindication to the use of all b-lactams.

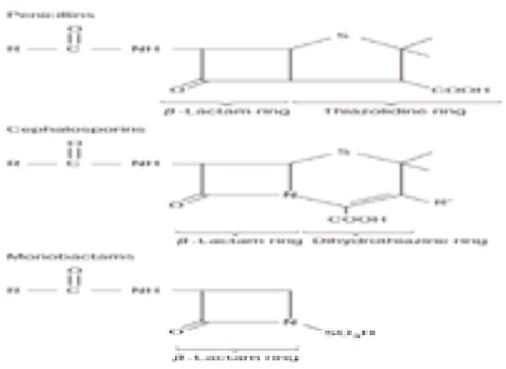

Fig. 7 Chemical structure of the b-lactam antibiotics (penicillins, cephalosporins, and monobactams) identifying the common b-lactam ring component which is subject to hydrolysis by b-lactamases.

Some drug toxicities are genetically determined. For example people who are genetically slow acetylators of isoniazid are more at risk of side-effects such as peripheral neuropathy. Those genetically deficient in the enzyme glucose-6-phosphate dehydrogenase are at risk of drug-induced haemolysis. This risk is more common in those of African, Mediterranean, or Far Eastern descent. Hence, it is important to screen for this red cell enzyme deficiency before the administration of oxidant drugs such as primaquine.

Adverse drug reactions may not always be acute in their presentation but reveal themselves after prolonged drug exposure. Oral flucloxacillin and co-amoxiclav when administered for several weeks, particularly in the elderly, are more likely to induce drug-associated hepatotoxicity. Likewise, parenteral formulations of selected drugs may be more toxic than their oral formulation, as is the case with a fusidic acid where prolonged parenteral administration frequently gives rise to hepatotoxicity.

Concentration-dependent adverse reactions (Table 14) are more likely to occur in the presence of organ system failure. Aminoglycoside toxicity is more common in the elderly, in those with pre-existing renal failure, and after repeated aminoglycoside doses or other nephrotoxic drugs. Concentration-dependent bone marrow suppression characterizes the use of chloramphenicol whereby pancytopenia arises when plasma concentrations are in excess of 25 mg/l. This is to be distinguished from the idiopathic aplastic anaemia that is a rare accompaniment of chloramphenicol use, but unfortunately is rarely reversible.

Much has been learned about the structure activity determinants of drug toxicity. For example the quinolone antibiotics as a class have the potential to induce phototoxicity, arthrotoxicity, CNS toxicity, cardiotoxicity, and interact with agents such as caffeine, theophylline, and non-steroidal anti-inflammatory drugs (Fig. 8). Knowledge of such predictors has lead to the selection of agents with safer structural profiles. Despite this, adverse drug reactions have led to the withdrawal or modification of the licensed indications for several quinolones, notably temafloxacin, trovafloxacin, sparfloxacin, and grepafloxacin, emphasizing the importance of clinical recognition and reporting of adverse events.

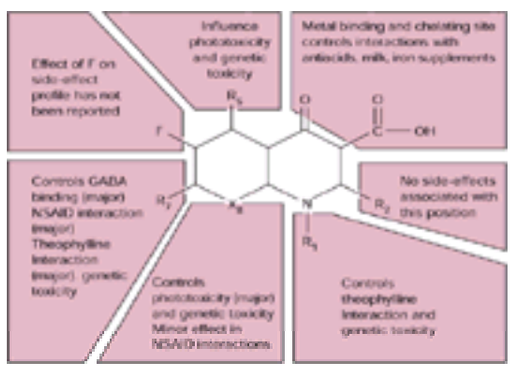

Fig. 8 Structure:activity side-effect relationships of the fluoroquinolone antibacterial drugs (redrawn after Domagala 1994).

Few infectious conditions require life-long therapy. The management of HIV infection has challenged this tenet. To date, drugs directed at the causative viruses or complicating opportunistic infections are suppressive rather than achieving eradication. It is also important to note that the drugs used in the treatment of HIV and AIDS are often licensed with limited information concerning their long-term safety. The potential for adverse reactions and especially interactions is considerable and requires careful attention to their detection and management. This has become an increasingly important challenge as life expectancy for those with HIV infection improves. It is important to balance drug safety while encouraging compliance and the maintenance of a reasonable state of health.

Failure of antibiotic therapy

Antimicrobial therapy may fail for a number of reasons. The agent selected may be inappropriate for the particular infection and fail to inhibit the target organism, or fail to reach the site of infection in sufficient concentration. For example drugs such as nitrofurantoin and norfloxacin, while achieving high urinary concentrations, fail to deal adequately with parenchymatous infection of the kidney or bacteraemia which may complicate acute pyelonephritis.

The prostate also presents a chemotherapeutic challenge owing to the relatively low pH, of about 6.4, in chronic bacterial prostatis. Drugs which are weak bases, such as trimethoprim either alone or in combination with sulfamethoxazole (co-trimoxazole), are preferred, especially since they are also lipid soluble. Ciprofloxacin has similar characteristics and has also produced favourable results. However, treatment of acute bacterial prostatitis sometimes needs to be prolonged (4–6 weeks and occasionally for longer duration), especially if there is a history of chronic relapsing infection.

The drug may be appropriate, but the dose selected may be inadequate. This may apply to such conditions as unsuspected bacterial endocarditis where high-dose parenteral antibiotic is required. Likewise, the concentration of penicillin required to deal with pneumococcal meningitis greatly exceeds that effective in the treatment of pneumococcal pneumonia; occasionally the two diseases may coexist. Infections caused by *Legionella pneumophila* and *Chlamydia* spp. require drugs that achieve high intracellular concentrations such as the macrolides, tetracyclines, or quinolones.

Resistance emerging during treatment is an uncommon cause of clinical failure but should be considered. Drug resistant *Mycobacterium tuberculosis* can develop on therapy as a result of the emergence of minority populations of organisms resistant to such first-line drugs as rifampicin and isoniazid. The current multidrug regimens are, in part, designed to avoid this occurrence. Likewise, in those with HIV infection, drug resistant virus is an increasingly important cause of treatment failure and

requires good compliance with multidrug regimens to slow its rate of emergence.

Mixed infections are commonly associated with intrabdominal sepsis and occasionally with infections of the lung. They may fail to respond to treatment unless the regimen covers the full range of bacterial pathogens. In the case of intrabdominal sepsis, the regimen should be active against anaerobic as well as aerobic bacterial pathogens.

Another important cause of antibiotic failure is the continued presence of a focus of infection. This may be an abscess which requires surgical drainage or the removal of an implanted medical device such as an intravascular catheter. Much more serious is infection of a prosthetic heart valve, hip joint, or CNS shunt where revision surgery carries significant risks. Many antibiotics fail to achieve therapeutic concentrations within abscess cavities, or are pH sensitive. Implant-associated infections present a similar challenge since bacteria often replicate slowly within a biofilm that is protective against normal host defences.

Finally, it should be remembered that a persistently elevated temperature in the presence of what appears to be adequate antibiotic treatment can reflect drug fever or indeed fever complicating a non-microbial diagnosis. This emphasizes the importance of monitoring the response to treatment and repeated patient assessment.

Practice guidelines and formularies

The plethora of therapeutic agents currently available presents a considerable challenge to the prescriber. Guidance on the choice of agent and the management of disease is becoming increasingly important. This is not only to ensure that the selection of treatment is appropriate for the target infection and consistent with current patterns of antimicrobial susceptibility but that it reflects an acceptable safety profile as well as being sensitive to the appropriate use of health-care resources. Such guidance is increasingly provided within formularies designed for local use, either within a hospital or community practice. These frequently offer information on preferred and alternative regimens for particular infections. Formularies should include drugs currently tested by the diagnostic laboratory since changing patterns of susceptibility may require modification of recommended drugs.

Within hospital practice, it is common for such formularies to identify drugs which may be prescribed freely according to specific indications, and those for which expert advice from a clinical microbiologist or infectious disease specialist should be sought. The latter applies particularly to drugs that require specific skill and experience in their use, need drug levels to be monitored, or are expensive. For example the treatment of deep-seated fungal infections with amphotericin B requires careful clinical assessment and guidance on dosage and monitoring. Likewise, the treatment of HIV infection is increasingly a specialist area. Antibiotics which are expensive to prescribe such as parenteral quinolones, third generation cephalosporins, and the carbapenems may be restricted. The policy may also have recommendations for the timing of transfer from parenteral to oral therapy in order to minimize the use of injectable agents.

Formularies are educational and allow the prescriber to become familiar with indications and safety of the most commonly used agents. Their use should be supported by educational activities both at undergraduate and postgraduate level.

Ideally, the selection of agents for inclusion in the formulary should be based on sound evidence of efficacy, safety, and economic benefit. However, such evidence-based medicine is often lacking or incomplete for commonly treated infections, since clinical trials of antibiotics, although increasingly robust in their design, are largely conducted to support licensing requirements rather than to address clinical use. They generally demonstrate the equivalence of a new agent in comparison with existing therapies. As a result, the recommendations of formularies and practice guidelines are based on a matrix of information derived from knowledge of the *in vitro* profile of an agent, its pharmacokinetic parameters, its clinical and microbiological efficacy, and safety profile. This in turn is modified by custom and practice which explains why there is local and, sometimes, national and international variation in recommendations for some common indications such as community-acquired pneumonia and bacterial meningitis.

In developing countries where medical resources are much more limited, greater reliance is placed on low-cost agents. The World Health Organization regularly updates its list of recommended essential drugs which includes anti-infective agents (Table 15). Despite the emphasis on low cost agents, the drugs offered cover the majority of infections and prescribing needs of developing countries. The agents available in individual countries often vary according to local interpretation of the needs for these 'essential' drugs.

Recent developments in economically advanced countries have included an assessment of health-care technologies for current management, national need, and the resources available. In the United Kingdom, the National Institute of Clinical Excellence (NICE) was established in 1999 to assess a variety of health-care technologies including procedures as well as new therapies. At the ime of its initial assessment by NICE, zanamavir, a recently licensed drug effective in the treatment of influenza virus infection, lacked sufficient evidence of efficacy in people known to be at higher risk of complicated influenza virus infection. Such assessments place greater emphasis on ensuring that new technologies are evaluated in a manner that more closely resembles clinical practice as well as demonstrating economic benefit, in contrast to drug licensing which addresses the quality, safety, and efficacy of new therapies. This new emphasis is likely to require a greater partnership between health-care systems and pharmaceutical companies to ensure that the place of new technologies is not only rapidly assessed but that they are consistent with health-care strategies.

7.7 Immunization

D. Goldblatt and M. Ramsay

Introduction

Infectious diseases remain a major cause of mortality and morbidity worldwide. The prevention of certain infectious diseases by effective immunization programmes represented one of the major triumphs of twentieth-century medicine. Most of this was achieved in the final third of that century during which rapid strides in the understanding of the biology and causality of infectious agents and improved techniques for the purification of infectious agents or their components led to the development of safe and effective vaccines. The greatest triumph in the field of immunization was the eradication of smallpox. In 1959 the World Health Organization (**WHO**) declared its intention to eradicate smallpox, and in 1966 began to allocate sufficient resources to accomplish this ambitious goal. Thirteen years later, in 1979, the global eradication of smallpox was officially declared. Effective vaccines can eliminate infectious diseases, but to do this they must be implemented and used appropriately. Over 12 million children under the age of 5 years die annually. Two million of these deaths are from diseases that could be prevented by vaccines already available through the WHO's Expanded Programme of Immunization (**EPI**). While rapid advances in vaccine science have introduced new techniques such as DNA vaccines, delivering vaccines to those most at risk must remain a priority.

Immunology of active immunization

Both non-specific (innate) and specific adaptive immune systems are responsible for protecting humans against infectious diseases. The ability of the adaptive immune system to refine its antigen recognition domains and establish immunological memory is the basis of successful active immunization. The specific immune system contains both cellular and humoral elements whose relative importance differs depending on the nature of the infecting organism. Cell-mediated immune responses depend on T lymphocytes and their secreted factors derived from the thymus, while humoral responses involve B lymphocytes derived from the bone marrow which produce antibodies (immunoglobulins IgG, IgM, IgA, IgD, or IgE).

Cellular responses are induced when antigen-presenting cells, such as dendritic cells, present antigens to T cells. T cells do not respond to soluble, unmodified antigens but only recognize peptide antigens in association with self major histocompatability complex (**MHC**) molecules. Two major forms of MHC molecules exist. The majority of nucleated cells express MHC class I molecules, which stimulate a subset of T cells expressing the CD8 differentiation antigen. These T cells recognize and lyse infected target cells, hence their designation as cytotoxic T lymphocytes. In contrast, MHC class II molecules are expressed on cells that participate in the immune response, and are recognized via a subset of T cells expressing the CD4 differentiation antigen. A major role of such T cells is to augment the immune response and so they are known as T helper cells. At least two subsets of T helper cells have been described: T helper 1 cells are involved in cytotoxic and delayed hypersensitivity type responses, while T helper 2 cells support antibody production.
