The distinction between infected and non-infected is one of the most obvious descriptive features of sputum that is relevant in clinical medicine. Non-infected mucoid sputum is variously described as clear, white, or like jelly. Viscid mucoid sputum is sometimes seen in asthma, and the patient may report seeing pellets or even branching plugs of mucus that are presumed to be casts of small bronchi. In bronchopulmonary aspergillosis, similar pellets or casts have a dark brown colour. In city dwellers, and those in dusty occupations, mucoid sputum can be various shades of grey. Coal miners may produce jet-black sputum (melanoptysis) if an area of fibrosis breaks down and is expectorated.

In most lower respiratory tract infections pus is admixed with mucus to produce mucopurulent sputum. Pure pus can be expectorated from a lung abscess or from stagnant bronchiectatic cavities. An offensive smell to the sputum, particularly in these last two conditions, often comes from infection with anaerobic organisms. A rarely seen but distinctive brown discoloration ('anchovy sauce') is seen with pus from an amoebic lung abscess, usually secondary to hepatic amoebiasis.

Apart from its appearance, the only other macroscopic attribute to sputum is its quantity. Excessively large quantities of sputum are found in bronchiectasis, particularly where this is widespread, as in cystic fibrosis, and in alveolar-cell carcinoma where large quantities of watery mucus can occasionally be produced. The amount of sputum in both chronic bronchitis and asthma is very variable, but can be excessive. Briefly, severe pulmonary oedema leads to the production of a large quantity of frothy sputum.

Haemoptysis

Patients rightly regard the presence of blood in the sputum as sinister. Despite this, a definite cause of haemoptysis is only found in about half of cases in most series. In the assessment of haemoptysis it is important to establish first that the blood-stained material has come from the chest and not from the gastrointestinal tract. Some patients find this difficult. Haemoptysis is produced with a 'cough' not a 'retch'. Accompanying features of an appropriate disease are usually present, but it is worth remembering that in haemoptysis there is usually froth due to admixed air, and the blood is bright red, not dark brown. Gastric contents should be acid; bronchial contents should be alkaline. Another trap for the unwary is contamination with blood from the nose or upper respiratory tract.

It is unwise to attribute haemoptysis simply to 'bronchitis' or infection. In bronchiectasis, however, haemoptysis not uncommonly mixes with mucopurulent sputum. In the early stages of pneumococcal pneumonia a 'rusty' staining of mucoid sputum is quite characteristic. In tuberculosis, frank blood in otherwise mucoid sputum is well recognized. Sudden haemoptysis is a hallmark of pulmonary embolism with infarction. In bronchial neoplasia there may be streaking of the sputum with blood or more substantial bleeding with clots, often observed daily. Recurrent blood-staining of the sputum is seen in idiopathic pulmonary haemosiderosis and also, although usually over a shorter time span, in Goodpasture's syndrome, which are both uncommon conditions. Cardiac conditions associated with blood in the sputum are pulmonary oedema, with pink frothy sputum, and mitral stenosis. The recurrent haemoptyses of the latter condition are infrequently seen today. In a general context, it may be necessary to consider thoracic trauma, endometriosis, or a blood coagulation disorder as causes of haemoptysis.

In the investigation of haemoptysis the chest radiograph will often indicate a probable diagnosis, for example an apical tuberculous infiltrate or a neoplastic hilar mass, but this must be backed up by appropriate microbiological or cytological examination of the sputum. Old, presumably healed and calcified, tuberculous lesions may be reactivated and may be a sufficient cause for haemoptysis simply due to local bronchiectasis, and invasion by mycetoma must be considered. Bronchiectasis and pulmonary infarction may not be evident on a plain radiograph, but both should give a suggestive history. High-resolution computed tomography (HRCT) will diagnose bronchiectasis, and ventilation–perfusion scanning or spiral CT will diagnose a pulmonary embolism.

If examination of the sputum and radiology (plain or specialized) yields no obvious cause for haemoptysis, then bronchoscopy must be considered. After a single haemoptysis in a young person with a normal chest radiograph, this can be deferred for a month. A recurrence of haemoptysis or a single episode in an older person, particularly a smoker, are indications for early bronchoscopy.

Laboratory examination of sputum

Expectorated sputum should be subjected to microscopic and microbiological investigation as appropriate (see Chapter 17.3.3). Sputum eosinophilia is a good guide to airway allergy. The cytological examination of sputum for malignant cells can only be done by an expert, but in skilled hands it is invaluable and time-saving.

Investigating cough

The cause of a cough of recent onset will usually be obvious enough. Infection tops the list. Carcinoma must be excluded in the smoker and radiology will detect parenchymal disease. In the case of persistent cough without apparent cause in a non-smoker, occult asthma should first be eliminated. Assessment of airflow variability using either diurnal peak flows or a histamine reactivity test are first-line investigations (see Chapter 17.4.1.1). It is worth looking for a chronic sinonasal infection or allergy and then for gastro-oesophageal reflux before proceeding to bronchoscopy, which statistically is not very rewarding in the context of cough as a lone symptom.

Treatment

Once diagnosed, the cause may well be treatable, even if the only appropriate advice is to stop smoking. If the condition is not treatable or if no cause can be found, symptomatic measures need to be considered. Two lines of approach are open: to suppress the cough or, accepting the cough as inevitable, to make expectoration easier.

All cough suppressants in common use act centrally. Most are opiate derivatives. Codeine and pholcodine have a weak antitussive action, but when made into a

sweet syrup they seem to have a soothing effect. Methadone and the stronger opiates are more powerful in suppressing cough, but they depress respiration and also cause constipation. In terminal bronchial carcinoma they are invaluable. Attempts to suppress cough by a peripheral action on bronchial afferent receptors have not been successful. Inhaled local anaesthetic can be helpful, and its effect on cough may long outlast its anaesthetic action. Drugs that act on the production of bronchial mucus will lessen cough if its purpose is the expectoration of that mucus. Atropine is used to this end preoperatively, but rarely in disease. Corticosteroids can diminish mucus production in asthma and in alveolar-cell carcinoma.

Agents claimed to increase sputum quantity or accelerate expectoration include the volatile oils such as menthol and inorganic salts such as potassium iodide. The movement of particles up the mucociliary escalator of the bronchial tree has been charted using radioisotope techniques and shown to increase under the influence of ingested guaifenesin (present in several 'cough medicines'), inhaled beta-adrenergic agonists, and hypertonic (1.2 M) saline.

Attempts to decrease the viscosity of sputum using mucolytic agents have been clinically disappointing, despite definite *in vitro* evidence of activity. Inhaled acetylcysteine works more convincingly as a mucolytic but has the great disadvantage of inducing bronchoconstriction. In cystic fibrosis, DNase has been used with modest success.

Most patients with haemoptysis require no more than treatment appropriate to their underlying condition, but occasionally haemoptysis is massive and life-threatening. The recorded mortality of 50 per cent with haemoptysis of 200 ml or more includes patients with initially poor respiratory reserve, as well as those who asphyxiate. At bronchoscopy it may be difficult to locate the source of bleeding, but local endoscopic measures may be applicable (topical epinephrine (adrenaline) application, balloon tamponade, and cold saline lavage). An open surgical approach (lobectomy or pneumonectomy) carries a mortality of up to one-third, and if operative intervention is contemplated, bronchial arteriography should be considered. The source of bleeding is from the bronchial arteries, so that embolization of the appropriate bronchial artery has successfully been used to control massive haemoptysis in a high proportion of patients who are actively bleeding.

Breathlessness

This major symptom of pulmonary, cardiovascular, and other systemic diseases suffers much because it is so frequently referred to by physicians as dyspnoea. Whilst patients sometimes speak of difficulty in breathing, they more frequently use the terms 'breathlessness', 'short of breath', or 'out of breath'. It is usually only on direct questioning that specific features reveal clues that are likely to be useful clinically. Despite the often quoted statement of Comroe that dyspnoea is not tachypnoea, hyperpnoea, or hyperventilation, but difficult, laboured, or uncomfortable breathing, patients are quite unaware of these fine distinctions. Rapid breathing, the necessary increase in ventilation in response to exercise, and ventilation in excess of metabolic requirements are all at times described by patients as breathlessness. Just what degree or quality of awareness of respiratory movement deserves to be called breathlessness is probably indefinable; awareness undoubtedly varies from patient to patient and even within the same subject from time to time. However, the implication of most terms used by patients to describe this type of pulmonary sensation is that in some way the performance of the respiratory apparatus ('breath-') is not meeting ('-less') a demand placed on it.

Pathophysiology

The respiratory muscles are supplied by motor nerve fibres from cervical and thoracic anterior horn cells, from C3 to T12. Like all other anterior horn cells, the respiratory motor nerve cells are served by pyramidal fibres from the motor cortex in the precentral gyrus. Directives from the cortex enable respiratory movement to be modulated to serve such functions as talking, holding the breath, voluntary hyperventilation, and the performance of lung function tests. This pathway will also be responsible for the conscious, and perhaps unconscious, transmission of anxiety or a calming influence on respiratory performance. However, to an extent that is unparalleled in other mammalian skeletal muscle, the respiratory motor neurones are under dual control, the second component being the motor output from the brainstem respiratory centre responsible for involuntary or automatic respiratory movement. This is the movement necessary to satisfy metabolic requirements for oxygen supply and carbon dioxide removal.

For the purposes of understanding breathlessness, respiratory centre activity can be seen as being under the influence of chemical and neurogenic stimuli. The chemical stimuli of hypoxia and acidaemia are relevant to the breathlessness of high altitude and diabetic coma. The general traffic of neurogenic stimuli impinging on the reticular formation from all sources maintains a certain level of activity in the medullary respiratory neurones irrespective of more specific stimuli. The modest quietening of this activity in sleep is associated with a small drop in minute ventilation, and the dramatic curtailment of spinal ascending information that sometimes occurs following high spinal tractotomy (usually for intractable pain) can completely abolish automatic medullary respiratory activity. There is no clear-cut association between increased reticular formation activity causing hyperventilation and states of breathlessness, but the increase in ventilation at the very onset of exercise is thought to be neurogenic in origin, possibly originating from the exercising muscles.

The respiratory centre receives information from the lungs through the vagus nerve. This originates in bronchial epithelial irritant receptors, stretch receptors, and interstitial J receptors within the alveolar/capillary interface. Stimulation of all these receptors will produce reflex effects, amongst which (for example) tachypnoea will make up a component of breathlessness in an appropriate setting. Whether the afferent information travelling up the vagus itself reaches the sensorium, or whether it merely modulates some other afferent pathway, is not clear. Afferent information that undoubtedly reaches consciousness is that concerning the rate and degree of thoracic cage movement and, quite accurately, a sense of lung volume (degree of lung inflation/deflation). This information comes from joint, tendon, and muscle receptors in the chest wall, and for sense of movement (of air) perhaps also from the oropharyngeal mucosa. It seems evident that information from these latter sources is part of natural and healthy sensation; it also seems likely that the same channels will signal an increased rate or depth of movement which, if excessive, will be described as breathlessness. In exercise the description 'breathless' often comes at the point where the smooth linear relation between ventilation and oxygen consumption is disturbed. Ventilation becomes excessive for metabolic requirements. How this becomes described as a shortness or loss of breath is not clear.

Two 'unnatural' respiratory sensations that can only be inadequately mimicked in a healthy individual are those associated with abnormal lung mechanics (for example in airways narrowing) and muscle paralysis. An obvious parallel for the first is breathing through an external resistance, and this technique has been widely used by those investigating dyspnoea. The useful finding that may have some bearing on the clinical situation is that in resistance breathing the ability to detect an increased load depends not on the absolute magnitude of the load, but on the ratio of that load to pre-existing loading of the system. Thus, a given absolute increase in airways resistance will be much more obvious to an individual with near-normal airways function than to one already suffering from pathological airways narrowing. The sensations of those few normal individuals who have undergone muscle paralysis for experimental purposes include phrases such as 'choking' and 'I would give anything to be able to take one deep breath'. These are similar to the reported symptoms of patients with paralytic diseases affecting the respiratory muscles. The element of inadequate performance is stressed. Whether this sensation can be simulated by the voluntary withholding of respiratory movement, as in breath-holding, is very doubtful. This much studied experimental model undoubtedly gives sensations, most of which probably arise from the diaphragm twitching ineffectually, and it is difficult to see where this fits into a clinical setting.

If any common thread can be drawn between these examples, it is at the level of an interaction between the drive to breathing and achievement—a drive that fails to achieve because of poor performance or mechanical loading of the respiratory system. The neurophysiological implications of this hypothesis are that there should be monitoring systems for both drive and performance. It is obviously feasible for the brain to assess and summate the various drives to breathing, and so monitor motor output. The muscle spindle has been proposed as the probable detector of achievement, but several objections exist to this proposal, not least that there are relatively few muscle spindles in the diaphragm, which is the most important muscle of respiration.

When it comes to the application of these principles to disease, some parallels are obvious, but an example from one common condition—acute bronchial asthma—will illustrate that the situation is not straightforward, and frequently multifactorial. In acute asthma there may be excessive drive from bronchial irritant receptors, and often cortical drive expressing itself in anxiety, even panic, as well as hyperventilation. There is clearly poor performance because of the increased resistance of narrowed airways, but in addition it seems likely that the respiratory muscles will act at a mechanical disadvantage because of lung hyperinflation.

The clinical analysis of breathlessness

Whilst bearing these neurophysiological points in mind, when it comes to devising symptomatic measures for the relief of breathlessness the clinician must still largely rely on an empirical approach to the analysis of this symptom. Such an analysis will rely on four characteristics of breathlessness: its quality, its timing, its severity, and the circumstances that precipitate or relieve it.

Quality

Breathlessness is difficult to describe. Most patients can go no further than saying that they are 'short of breath'. The asthmatic will generally recognize the quality of

wheeze and, contrary to the opinion of physiologists, usually finds it more difficult to breathe in than out. An asthmatic who develops more persistent breathlessness between attacks often recognizes this as 'different from my asthma'. A sense of suffocation is a feature of massive pleural effusions and of pulmonary oedema. Phrases such as 'I can't fill my lungs properly' and 'I need to take a big breath' suggest the possibility of psychogenic breathlessness, but muscle weakness must be carefully excluded.

Timing

Of the greatest value in separating out conditions likely to be associated with breathlessness is noting its rate of onset. There are five categories. Breathlessness may be of dramatic onset (over minutes), acute onset (over hours), subacute onset (over weeks), or chronic onset (over months or years), or it may be intermittent. Table 1 gives a guide to conditions falling into these categories. The subdivisions are not rigid. Asthma again provides an example. About half of all acute attacks of asthma build up in less than 24 h, but some asthmatics slowly deteriorate over a week or so and, occasionally, they can be transformed from being asymptomatic to having desperate breathlessness and unconsciousness within 15 min; in addition, asthma is also intermittent. Likewise, left ventricular failure, although usually developing over hours, may be dramatic in, for example, aortic valve rupture, or more persistent in long-standing hypertension. Pulmonary embolism can also present in a very variable manner, ranging from the dramatically sudden to the chronic.

The pattern of breathlessness in certain disorders depends on the stage of the disease and the structural or functional changes that it causes. Thus in early sarcoidosis, diffuse infiltration of the lungs can cause the quite rapid development of breathlessness over a week or so; by contrast, the late fibrotic stage of sarcoid will be associated with relentlessly progressive breathlessness as pulmonary reserve diminishes. Breathlessness in a condition such as carcinoma of the lung will be determined by the pattern of structural change—whether there is, for example, bronchial stenosis, collapse, or pleural effusion.

Severity

The severity of breathlessness is traditionally gauged on scales relating to activity. Many scales have been devised. All have two faults. The first is that there is a temptation to assume that the grading system with which one is familiar is universally known. It is not. Thus it is preferable to describe the amount of exercise limitation on an individual patient basis. Second, no scale suggests a convention for dealing with variable breathlessness. Very few patients have a consistent level of severity of breathlessness, but any attempt to introduce a range of severity will have to be accompanied by some assessment of the time extent of each grade, which is an almost impossible task.

A refinement of the scaling technique can be used to record the degree of breathlessness during exercise. During a standard exercise test a record is made of breathlessness on a visual analogue scale concurrently with minute ventilation. The sort of data produced can be used to assess the benefits of therapeutic intervention. The Borg scale (Table 2) can be similarly adapted and has been used with simple exercise tests. Tests such as the distance walked in a specified time (for example, a 6- or 12-min walk), are influenced by training and motivation. Patients may differ in their approach to a treatment benefit. One might walk no further and be relieved to achieve the same distance with less breathlessness, whereas another might extend the walking distance by being prepared to become just as breathless as before.

Occurrence

The circumstances under which breathlessness is experienced can give important diagnostic clues. Only psychogenic breathlessness bears no relation to exertion or is experienced only at rest. Many patients with organic diseases are breathless at rest as well as on exertion, this being an expression of severity. Breathlessness made worse by lying flat (orthopnoea) is characteristic of left ventricular failure and is also experienced by patients with diaphragmatic paralysis. Nocturnal awakening with suffocating breathlessness and frothy sputum production (paroxysmal nocturnal dyspnoea) is a more serious manifestation of left ventricular failure and can be relieved by sitting or standing up. The asthmatic also awakens in the small hours of the night with breathlessness accompanied by coughing and wheezing, or these symptoms may be delayed until the normal waking hours. Any sputum produced by the asthmatic under these circumstances is likely to be sticky and mucoid. Postexertional breathlessness and the immediate triggering of an episode of wheezing breathlessness by non-specific irritants (dust and fumes) or specific allergic stimuli (pollen, animal danders, etc.) also characterize the asthmatic. In occupational asthmas, breathlessness will bear a temporal and circumstantial relation to the working environment. In byssinosis the first day at work is characteristically troublesome (Monday morning tightness). Patients with type III hypersensitivity reactions such as bronchopulmonary aspergillosis or extrinsic allergic alveolitis (Chapter 17.11.11) will notice breathlessness 4 to 6 h after exposure. An intercurrent respiratory tract infection will worsen breathlessness in patients with any form of diffuse airway or parenchymatous lung disease.

Spontaneous improvement occurs in most breathless patients with rest or the removal of trigger factors. The postexertional breathlessness of the asthmatic is an important, though temporary, exception. Patients with pulmonary hypertension, even with severe exertional breathlessness, improve dramatically quickly as soon as they sit down.

The investigation of the breathless patient

The clinical history may immediately suggest a probable cause. Beyond this the two most helpful pointers are simple lung function tests and chest radiology. Spirometric testing will define three groups: normal, an obstructive pattern, and a restrictive pattern (see Chapter 17.3.2). The chest radiograph will be of most value in furthering the diagnosis in conditions giving a restrictive pattern. The further investigation of the patient with airflow obstruction is dealt with in Section 17.4.

Breathlessness in a patient with normal spirometric testing and a clear chest radiograph presents special problems. In this situation four categories should be considered. Is there intermittent disease? Are the tests being used too crude to pick up significant abnormalities? Is there extrathoracic disease? Is this psychogenic breathlessness?

Many asthmatics reviewed in a clinic will have normal lung function. The value of serial recordings of lung function over several days in these patients cannot be overemphasized. Conditions affecting the heart and pulmonary circulation can also be intermittent, but more often the problem is that conventional tests of lung function do not seem to demonstrate significant abnormalities when there is quite considerable dyspnoea. Pulmonary embolism is a good example of this: imaging to assess the integrity of the pulmonary vascular bed is required. Tests of muscle power will pick up neuromuscular conditions weakening respiratory movement. The hyperventilation of acidosis, as in uraemia or diabetic coma, is not often described by patients as breathlessness and is otherwise easily diagnosed. However, hyperthyroidism and anaemia should not be forgotten as causes of breathlessness. Some 60 per cent of patients with a haemoglobin level of less than 8 g/dl will have this symptom.

Psychogenic breathlessness is diagnosed by exclusion, although there may be clues in the history and examination. The quality of the breathlessness has been described above. The sighing and irregular breathing will be readily noticeable to a keen observer. Associated complaints directly related to the hyperventilation are paraesthesiae in the hands and perhaps feet, dizziness, and collapse. Apparently non-specific features such as fatigue, insomnia, weakness, or chest pains may all be part of the syndrome. Depression and anxiety may both be aspects of the underlying psychiatric state. By definition, in pure psychogenic breathlessness, the chest radiograph and lung function are normal. However, some patients may develop breathlessness because they have been told they have a 'shadow on the lung' or through anxiety exhibit a degree of breathlessness disproportionate to a mild functional abnormality. The latter patients tend to have an obsessional personality or may be looking for compensation for supposed 'lung damage' due to injury or occupation.

Treatment

The relief of breathlessness is best achieved by treating the underlying condition. This may mean the removal of 'mass' lesions (pneumothorax, pleural effusion), or the treatment of pneumonia, airflow obstruction, or alveolitis. Loss of muscle power is occasionally treatable, as in myasthenia gravis, or may recover spontaneously. An attempt to relieve breathlessness should not be neglected, even when the underlying condition is untreatable (pleural effusion in carcinoma of the bronchus, or a reversible steroid-responsive component in a patient with chronic airflow obstruction).

The symptomatic treatment of breathlessness is far from satisfactory, but can usefully be considered in terms of the physiological disorder(s) that can be responsible for the symptom. Excessive respiratory drive may be dampened, for example by oxygen for the hypoxic. A direct approach to the vagal afferent system has met with little success: local anaesthetic to the airways gives a short-lived effect but may itself be irritant. In a select few with intense breathlessness due to diffuse infiltrative disease, vagotomy in the thorax has given some relief. Psychogenic breathlessness may be helped with b-blockers (but asthma must be excluded with absolute certainty). Dihydrocodeine reduces breathlessness in chronic obstructive lung disease but is very constipating and, like the more powerful opiate sedatives, can

dangerously depress respiration. There has been a sad failure to find opiate derivatives with more selective action on breathlessness. Diazepam and promethazine have given subjective relief to some patients disabled by breathlessness from severe emphysema. The use of rehabilitation measures is considered elsewhere (Chapter 17.7).

Chest pain

The greater part of the lower respiratory tract is insensitive to pain and most parenchymal lung disorders proceed to an advanced state without becoming painful. However, the parietal pleura is exquisitely sensitive to painful stimuli and unpleasant sensations can arise from the tracheobronchial tree.

Pleurisy

Typical pleural pain has a sharp, stabbing, and knife-like character; is aggravated by respiration and coughing; and leads to rapid, shallow breathing and a suppressed cough. The pain is likely to be due to stretching of the inflamed parietal pleura and can be relieved by splinting the chest wall.

Afferent pain fibres from the parietal pleura pass through the intercostal nerves. Those from the central portion of the diaphragm run in the phrenic nerve to the cervical cord (C3/4). Central diaphragmatic pleurisy is thus referred to the lateral side of the neck and shoulder tip; indeed, local anaesthesia to the shoulder trigger area can relieve diaphragmatic pleurisy. The outer portions of the diaphragm are served by intercostal nerves (T7–12), causing referred pain to be felt in the lower thorax, lumbar region, and upper abdomen.

Most conditions giving rise to pleuritic pain are acute and inflammatory, either infective (usually pneumonia) or infarctive, as in pulmonary embolism. The immunologically based pleurisies (as in systemic lupus erythematosus or rheumatoid disease) give pain less frequently. Recurrent pleurisy at the same site should suggest bronchiectasis; at different sites it suggests embolism or bronchopulmonary aspergillosis. Sudden chest pain occurs at the onset of a pneumothorax. It is pleural in origin, due to the inrush of air from the lungs and, sometimes, the tearing of adhesions.

If pleurisy progresses to pleural effusion, the sharp pain largely disappears and is replaced by a dull and more constant ache or heaviness. Pleural fibrotic disease is rarely painful, but pleural neoplasia frequently is. The severity and quality of pain depends on the extent of the tumour, and particularly on spread into the chest wall. A superior sulcus tumour of bronchial origin (Pancoast's tumour) infiltrating the brachial plexus gives very severe and persistent pain in the shoulder and in the distribution of C8, T1, and T2.

Pain from the chest wall

Chest-wall pain can mimic pleurisy, and conditions in the chest wall provide its most important differentials. Pain due to strain or tearing of thoracic muscles can be quite sharp, and since it is likely to be caused or exacerbated by coughing and lead to shallow respiration, it can easily be confused with pleurisy. However, there is always local tenderness over the affected muscle and none of the ancillary investigations for pleurisy prove positive. Patients with persistent cough or distressing breathlessness, particularly due to asthma, may complain of muscular pain around the lower rib cage.

Epidemic myalgia or Bornholm's disease is a bothersome manifestation of Coxsackie B infection giving fever and recurrent muscle pain. If the intercostal muscles are involved (pleurodynia), the associated breathlessness and tachypnoea can exactly mimic pleurisy, as can the pre-eruptive stage of thoracic herpes zoster, which gives a stabbing pain in the distribution of the affected nerve. Costal cartilage pain is generally not inflammatory. In Tietze's disease there is a painful protuberance of one or more costal cartilages, usually the second to fourth, probably due to asymmetrical growth of the rib cage. Osteoarthritis and dislocation of the costosternal joints can give chronic pain. Rib fractures rarely present diagnostic problems, but cough fracture in osteoporotic bone should not be forgotten. Thrombophlebitis of chest-wall vessels after surgery or trauma gives anterior chest pain and a tender palpable vascular cord. Most primary chest-wall tumours are not painful, but the more common metastatic disease of bone frequently is, and may be symptomatic before radiological change is evident.

Fleeting transient chest pains are often part of chronic somatized anxiety states, and when this is the case tend to be accompanied by tachycardia, palpitations, and features indicating hyperventilation. Perhaps the commonest chest pain of all is left inframammary pain. This is a transitory sharp but quite severe pain, felt over the apex of the heart at rest or on mild activity. It lasts up to a few minutes and may cause a catching of the breath or shallow breathing. Its cause is unknown but it seems to be totally benign.

Central chest pain

Sensations arising from the tracheobronchial tree are less easy to characterize as painful, although some are exceedingly unpleasant. Instrumentation of the trachea causes pain referred to the anterior chest wall. This is usually abolished by vagotomy and is most likely to be perceived from irritant receptor discharge. Tracheal inflammation, as in infective tracheobronchitis or following the inhalation of toxic vapours, causes a raw painful retrosternal sensation. It is difficult to say how much or how often sensations arising from the main airways are describable as pain. There is often a component described as tightness, and this is a common complaint of patients with generalized airflow obstruction, although it is probably naïve to think that the sensation is a direct appreciation of airways narrowing. Further complicating the interpretation of sensation in these conditions is the almost universal association with coughing which, if persistent, can itself lead to soreness in the upper airways and trachea.

Finally, the mediastinal structures of the thorax are responsible for a multitude of pains, the majority of which are dealt with elsewhere in the chapters on cardiology and gastrointestinal disease. Few central pulmonary lesions give mediastinal pain. Only neoplasia is a common culprit. A central bronchial carcinoma or hilar nodes associated with it can be responsible for a deep dull aching pain in the centre of the chest. Similar pain can sometimes occur in the early stages of sarcoidosis with hilar lymphadenopathy and in lymphoma.

Other symptoms in pulmonary diseases

Patients or their relatives on their behalf may complain of noisy breathing, generally using the word 'wheeze'. A harsh inspiratory wheezing sound arising from obstruction in the larynx or major airways is termed stridor. There may be accompanying hoarseness or features of intrathoracic disease. Wheeze is the externally audible counterpart of the sounds heard with the stethoscope in asthma and obstructive bronchitis. It is a term frequently used by asthmatic patients to describe their respiratory symptoms.

When airflow obstruction is suspected, specific enquiries should be made for the features of bronchial irritability. In response to changes in atmospheric conditions (particularly temperature) or to the inhalation of dusts, fumes, or vapours, the patient with irritable bronchi will respond with a variety of symptoms: cough, tightness in the chest, wheeze, or breathlessness.

Rarely, patients may complain that they are blue (cyanosed), although their carers may do so more often. This and finger clubbing are more often elicited as physical signs (see below).

General history

A full history is essential, emphasizing the following features:

1. cardiac disease as a cause or aggravating factor in breathlessness;
2. the legs for ankle oedema as a result of lung disease or deep venous thrombosis;
3. the upper respiratory tract for infectious, allergic, or vasculitic disorders;
4. the skin for eczema, urticaria, erythema nodosum, or vasculitis;
5. features of rheumatoid or collagen-vascular disease;
6. the nervous system for disease that might impair ventilatory control; and
7. pointers to metastatic spread or the non-metastatic manifestations of malignant disease.

The past history may reveal atopy, tuberculosis, or other serious infectious disease, particularly in childhood. It is always worth asking about previous chest radiographs which may be obtainable for comparison.

A full smoking history is essential. A detailed drug history is essential because of potential toxic effects on the lungs (see Chapter 17.11.19).

A complete occupational and environmental history is of the utmost importance. Whilst the mining industries will be obvious, many other occupations that create dusts of both inorganic and organic materials are now recognized as presenting hazards to the chest (see Chapter 17.11.7). Certain working environments may lead to exposure to organisms likely to cause pulmonary infection: *Chlamydia psittaci* from contact with domestic or wild birds, *Coxiella burnetti* in slaughterhouses, and tuberculosis through working with susceptible groups.

Finally, certain disorders have a familial predisposition. These include asthma and other atopic diseases (see Chapter 17.4.1), cystic fibrosis (see Chapter 17.10), Kartagener's syndrome, familial fibrocystic pulmonary dysplasia (a form of fibrosing alveolitis) (see Chapter 17.11.2), pulmonary lymphangiomyomatosis (see Chapter 17.11.10), and alveolar microlithiasis (see Chapter 17.11.16). A family or personal contact history of tuberculosis should be noted, as should any record of previous tuberculin testing or bacille Calmette–Guérin (**BCG**) vaccination.

Physical signs in pulmonary disease

Inspection of the chest

The pattern of breathing and the configuration of the chest must be observed. The normal respiratory rate when the subject believes him or herself to be unobserved is around 10 to 14 per min. Higher rates than this are commonly recorded in the healthy, but a rate above 20 per min is abnormal. Pneumonia, many interstitial lung disorders, and abnormal drives to breathing, including anxiety, will increase the rate. If the chest is free to move, the tidal volume will also increase, but this is not the case with restrictive disease or painful conditions of the thoracic cage or upper abdomen. An abrupt stop to inspiration when there is pain can be seen. The frequency of deep sighs, normally 8 to 10 per hour in quiet breathing, is greatly increased in psychogenic breathlessness, when there may be an irregular pattern including phases of rapid breathing and relative apnoea. A regular alternation of apnoeic periods of 5 to 30 s with a period of increasing and then decreasing ventilation characterizes Cheyne–Stokes respiration. This and several other irregular breathing patterns are usually associated with brainstem or cerebral lesions, but they can also be a feature of severe heart failure.

In observing respiratory movement, particular attention must be paid to expansion. Poor movement of the chest on one side only always indicates pathology on that side. Generally poor expansion is seen in the hyperinflated chest of the patient with severe airflow obstruction and in the fixed thoracic cage of advanced ankylosing spondylitis. In airflow obstruction two other features may be observed: an indrawing of intercostal spaces during inspiration (reflecting the negative intrapleural pressure necessary to draw air into the lungs) and abnormal movement of the lower chest. Normally, the lower chest moves outwards during inspiration, but in gross hyperinflation the diaphragm is flat and its contraction merely causes the lower thoracic cage to move inwards. In the same patients the anterior abdominal wall may also move inwards during inspiration instead of outwards, and this asynchrony of movement carries a poor prognosis.

Abnormalities of the shape of the chest are well recognized. An increased anteroposterior diameter to give a 'barrel chest' is as often a sign of the kyphosis that accompanies senile osteoporosis as it is of the hyperinflation of emphysema and chronic airflow obstruction. Pectus carinatum (pigeon chest), an outward protuberance of the sternum, may reflect severe attacks of asthma in childhood when it may be accompanied by bilateral indrawing of the anterior portions of the lower ribs (Harrison's sulci); it is now rarely due to rickets. The opposite, pectus excavatum (depressed sternum), is a congenital anomaly. Scoliosis is important because of the severe impairment of respiratory movement that it causes, and it can lead to respiratory failure (see Chapter 17.13). Localized collapse and fibrosis may draw in the adjacent rib cage (which will also move poorly) and, if severe, unilateral fibrosis of the whole lung can cause a scoliosis with its curvature towards the affected lung.

Palpation of the chest

Palpation is used to confirm the observed patterns of chest expansion and to identify the position of the trachea and apex beat. The trachea should be localized in the suprasternal notch with the index finger. With the patient looking directly forwards, any deviation of the trachea from the mid-line should be assessed using a combination of touch and vision. Aside from tension pneumothorax, deviation of the trachea to one side is due to either apical fibrosis pulling it to the affected side or a mass in the neck (for example, goitre) or upper mediastinum pushing it to the opposite side. As with the trachea, the position of the apex beat can reflect pressure against or traction on mediastinal structures, but due consideration must be given to displacement of the apex beat due to intrinsic cardiac disease.

The detection of the transmission of vocal sounds by the placing the palm of the hand on the chest (vocal fremitus) should be abandoned in favour of vocal resonance (listening with the stethoscope for voice sounds), except for a simultaneous comparison of the two sides of the chest.

Percussion of the chest

In properly performed percussion, the examiner listens for the pitch and loudness of the percussed note, and both listens and feels for the postpercussive vibrations that give the note its resonance. The sides of the chest must be compared from identical sites. A dull note lacks resonance and is higher in pitch and softer than a normal percussion note; it signifies the presence of solid tissue or fluid underneath the percussed area. 'Stony' dullness with a complete lack of any vibrations coming back from the lung is heard and felt over pleural effusions. It is important to delineate the surface markings of any dullness: pneumonic consolidation and collapse will follow the distribution of the affected lobe, whereas the upper limit of a pleural effusion will be determined by the effects of gravity. It requires a fine ear to pick up Ellis's S-shaped line—a slightly higher level of dullness in the axilla when the patient is in the sitting position. Large effusions which displace mediastinal contents may produce an area of dullness at the opposite base close to the mid-line (Grocco's sign).

A hyper-resonant note is lower in pitch and louder than normal, and occurs over hyperinflated lung as in emphysema or an air-filled space, that is to say a large bulla or a pneumothorax. It is more difficult to be certain about hyper-resonance than dullness, particularly in thin subjects.

Auscultation of the chest

There are three types of sound that can be heard coming from the lung: breath sounds, adventitious sounds, and voice sounds.

Breath sounds

Normal breath sounds are better termed 'normal' rather than 'vesicular'. They are certainly not generated in the vesicles or alveoli of the lung where air flow is too low, but probably reflect turbulent flow in major bronchi. The pattern and intensity of breath sounds reflects regional ventilation. Thus, in the normal upright lung, breath sounds are loudest at the apex in early inspiration and at the bases in mid-inspiration. Breath sounds are quietened over areas of atelectasis. During expiration normal breath sounds rapidly fade out, probably due to the decreasing air-flow rate.

Bronchial breathing is heard over airless lung as in consolidation, atelectasis, or dense fibrosis. There is some resemblance to the sounds heard over the normal trachea, but, by comparison with normal breath sounds, bronchial breathing is higher in pitch and more blowing in quality. It does not have to be loud. Bronchial breath sounds are classically heard throughout both inspiration and expiration. Very quiet breath sounds are heard over hyperinflated lungs as in emphysema or when breath sounds are prevented from reaching the chest wall by a layer of air, fluid, or fibrosis.

Adventitious sounds

The terminology of adventitious sounds is confused. This arises because, whereas Laennec originally used the term rales (rattle) to embrace all added sounds, Latham, introducing the classification dry and moist sounds in 1876, applied rale exclusively to the former and rhonchi to the latter. Until recently the established convention in the United Kingdom was to drop rale altogether and to call interrupted non-musical sounds crepitations and continuous musical sounds rhonchi. The move to replace the term crepitations with crackles and the term rhonchi with wheezes has now gained widespread acceptance. Crackles may be coarse or moist

when they are due to the movement of sputum in large airways, or fine when they are probably created by small airways snapping open as pressure equalizes in the distal lung compartment. Coarse early inspiratory and expiratory crackles are often heard in respiratory tract infection, particularly in patients with chronic obstructive lung disease, whilst fine late inspiratory crackles are characteristic of pulmonary oedema and fibrosing alveolitis. Occasionally a single mid to late inspiratory 'squawk' is heard in patients with a variety of pulmonary fibroses.

Wheezes signify obstruction in airways. A sound of single pitch (monophonic) in inspiration and/or expiration, which cannot be altered by coughing to shift mucus, signifies a localized obstruction in a major airway. Several sounds of varying pitch (polyphonic) heard randomly in inspiration and expiration are typical of the widespread airways obstruction of asthma and chronic obstructive bronchitis. A polyphonic wheeze on forced expiration signifies diffuse airflow obstruction and can be a useful sign when tidal breathing is free of added sounds.

A pleural rub is the diagnostic added sound of pleurisy. It is a superficial grating or rasping sound synchronous with late inspiration and early expiration, best heard at the bases and rarely at the apices. A soft friction rub may be mistaken for crepitations, but is not altered by coughing and can be made louder by pressure with the stethoscope. Inflammation of the pleura close to the heart can give a friction rub that synchronizes with the heart beat but will cease if the breath is held.

Voice sounds

A long sound such as 'ninety-nine' is favoured for detecting voice sounds that are transmitted by normal lung, but not by air space or fluid, and pass through solid lung with undue clarity, even allowing whispered sounds to be heard (whispering pectoriloquy). Certain physical characteristics of a solid lung allow low frequency sounds to be filtered out, leaving a sound of bleating or nasal quality (aegophony); this is particularly noticeable over a collapsed lung adjacent to a pleural effusion.

The relevance of the general examination in respiratory disease

Clues to the diagnosis of respiratory disease and critical extrathoracic manifestations of primary lung conditions must be sought in the general examination.

Overall appearance

Obesity places an added burden on the respiratory system, sometimes sufficient in itself to cause a degree of exertional breathlessness and potentially a cause of obstructive sleep apnoea (see Chapter 17.8.2). Truncal obesity with moon facies and skin bruising is an unfortunate complication of oral corticosteroid therapy which may have to be given for several pulmonary diseases.

Weight loss is a feature of emphysematous obstructive lung disease and, of course, malignancy, with the late stages of bronchial carcinoma and pleural mesothelioma often being characterized by a distressing cachexia. Malabsorption can result in weight loss in cystic fibrosis if inadequately managed.

Body habitus can alert to possible respiratory complications, particularly the more severe degrees of kyphoscoliosis, which can lead to hypoventilation, and also rarer disorders such as Marfan's syndrome (associated with pneumothorax) or ankylosing spondylitis.

Cyanosis

Cyanosis is the blue discoloration imparted to the nailbeds, lips, and tongue by hypoxaemic blood. Peripheral cyanosis due to a sluggish peripheral circulation, as in cold weather, will leave the tongue still pink, whereas in central cyanosis the tongue will be blue and the peripheries blue yet often warm. The frequently repeated statement that 5 g of reduced haemoglobin is required before cyanosis can be detected is false. Most patients with a saturation of 90 per cent or less will appear cyanosed. This represents just 1.5 g of reduced haemoglobin if the total haemoglobin is 15 g. Cyanosis is less marked in severe anaemia and more obvious in polycythaemia. The curious phenomenon of orthocyanosis (hypoxia occurring only in the upright position) is generally associated with pulmonary arteriovenous malformations.

Clubbing of the fingers

Loss of the natural angle between the nail and the nailbed in a properly manicured finger, and a boggy fluctuation of the nailbed are cardinal signs of clubbing (Fig. 1). An increased curvature of the nail and enlargement of the end of the finger develop later. The toes may also be affected. The differential diagnosis of clubbing of the fingers includes many extrathoracic conditions but, as far as the lungs are concerned, three categories deserve consideration: (1) suppurative disease, particularly bronchiectasis of long-standing but also acute lung abscess and empyema, but not uncomplicated bronchitis; (2) fibrosing alveolitis and asbestosis, but rarely other diffuse fibrotic diseases; (3) malignant disease, particularly carcinoma of the bronchus and also pleural malignancy. If finger clubbing is associated with hypertrophic pulmonary osteoarthropathy, a painful osteitis of the distal ends of the long bones of the lower arms and legs, malignancy is associated in 95 per cent of cases.

Fig. 1 Clubbing of the fingers.

There is no satisfactory explanation for clubbing and hypertrophic pulmonary osteoarthropathy. Pathologically, there is abnormal vascularity and new bone formation in the peripheries, and evidence of abnormal bronchopulmonary anastomoses in the lungs. The latter may be under vagal control since vagotomy has sometimes abolished clubbing in lung cancer patients. These intrathoracic channels may allow substances normally detoxified by the lungs, which could be responsible for the peripheral changes, to enter the systemic circulation.

The skin and eyes

Eczema and urticaria point to an atopic diathesis and hence possible asthma. Erythema multiforme can accompany mycoplasma pneumonia, rarely other pneumonias, and pulmonary blastomycosis. Erythema nodosum, tender nodules fading to a bruised purple on the shins and occasionally the forearms, is a classical presentation of sarcoidosis, frequently associated with hilar lymphadenopathy and less often with pulmonary infiltrates. It may also be found in primary tuberculosis and rarely in other chest infections.

Several other dermatological, ocular, arthritic, and internal manifestations may also alert to the diagnosis of sarcoid. Skin and eyes are also the site of lesions in Wegener's granulomatosis, systemic lupus erythematosus, systemic sclerosis, and dermatomyositis, each of which has potential pulmonary manifestations.

Patients with diffuse neurofibromatosis and tuberous sclerosis can both develop a severe pulmonary fibrosis with late-stage destructive emphysema. Rarely, hereditary haemorrhagic telangiectasia, with its characteristic lesions on the lips, face, and mouth, can extend to the lungs with pulmonary haemangiomas which give haemoptysis as well as the more commonly found gastrointestinal lesions. The latter give anaemia, and this, whatever its cause, can cause breathlessness and so

must be checked for, as must jaundice by looking at the eyes.

The skin is the site of secondary deposits from carcinoma of the lung in a small percentage of cases, although usually late in the disease when the diagnosis is all too obvious. Other carcinomas may spread to skin and lungs, and Kaposi's sarcoma is a cutaneous manifestation of disseminated HIV infection (see Chapter 7.10.21).

Head and neck

Signs of upper respiratory tract disease are relevant in pointing to a site and source of infection that could track down to the lungs, and for the ways in which they signify allergy. Furthermore, neurological disease of the pharynx or structural abnormalities of the larynx encourage aspiration and repeated respiratory tract infection. A short thick neck, retrognathia, and a large uvula can all predispose to sleep apnoea. A goitre may be large enough to compress the trachea and cause stridor. It could be associated with hyperthyroidism and so breathlessness; or hypothyroidism and hence hypoventilation; or even be a source of a carcinoma that could metastasize to the lungs. Even more important are signs in the neck that represent primary intrathoracic malignancy. Hard enlarged cervical lymph nodes are a well-recognized metastatic site for carcinoma of the lung, but can signify lymphoma or primary cancer from elsewhere (stomach, breast). The local extension of central bronchogenic carcinoma gives superior vena caval thrombosis. There is fixed elevation of jugular venous pressure, a large neck, a congested face and head, and, in severe cases, exophthalmos and impaired vision.

Cardiovascular system

The pulse is of poor volume in pulmonary hypertension, bounding and full in hypercapnic respiratory failure, and waxes and wanes in acute severe airflow obstruction (pulsus paradoxus). In the last of these the pulse can actually disappear at the height of the negative intrapleural pressure swing (mid to late inspiration).

The pulmonary hypertension that accompanies severe hypoxic cor pulmonale is manifested on physical examination by a raised jugular venous pressure with a prominent A wave, peripheral pitting oedema, and cardiac signs of right ventricular heave, a loud P2 wave, and, in failure, a gallop rhythm. Oedema alone should add differential diagnoses such as liver or renal disease, both of which can have pulmonary manifestations.

17.3.1Thoracic imaging

Susan Copley and David M. Hansell

Despite recent technological advances, chest radiography remains the cornerstone of thoracic imaging. The chest radiograph is justifiably regarded as an integral part of the examination of the patient in respiratory medicine. Because of the wealth of information available from chest radio-graphy, careful interpretation of the chest radiograph remains a necessary clinical skill. Advances in cross-sectional imaging have had a great impact in improving the diagnosis of thoracic pathology, not only for the assessment of mediastinal disease but also in the evaluation of patients with suspected diffuse lung disease. Nevertheless, a chest radiograph should always be obtained and looked at carefully before submitting a patient to more sophisticated imaging techniques. The expense and radiation burden, in the case of computed tomography, is an important consideration.

Techniques in thoracic imaging

Chest radiography

The first chest radiograph was taken over 100 years ago and chest radiography is now the most frequently requested radiological investigation worldwide. The technique has changed surprisingly little over the years, although digital technology has recently been used to overcome some of the shortcomings of conventional film-based radiography.

Technical considerations

An ideal chest radiograph is taken with the patient standing erect, suspending respiration at total lung capacity, and with the X-ray beam traversing the thorax from back to front (the posteroanterior (**PA**) or frontal view). Because of the wide range of densities within the chest (soft tissues of the mediastinum through to aerated lung), perfect exposure of every part of the chest radiograph is impossible. The resulting suboptimal exposure of the denser part of the chest can be partially overcome with a high-kilovoltage technique (120 to 150 kVp). With this technique there is greater penetration of the mediastinum, which improves visualization of the trachea and main bronchi. A disadvantage of high-kilovoltage radiography is the relatively poor demonstration of calcified structures so that rib fractures and calcified pulmonary nodules or pleural plaques are less conspicuous. Even with an optimal technique, nearly a third of the lungs are partially obscured by overlying mediastinum, diaphragm, and ribs.

Automatic exposure devices have been developed to expose accurately the various parts of the chest. One of these, the Advanced Multiple Beam Equalisation Radiography (**AMBER**) system, produces chest radiographs which greatly improve the demonstration of both mediastinal anatomy and pulmonary abnormalities (see Fig. 16). Another approach to this problem is phosphor-plate computed radiography, which uses digital technology. This is ultimately expected to replace conventional film radiography, and has already done so in some centres. A phosphor plate is handled in a conventional cassette (which does not contain film) and is exposed in the normal way. The energy of the incident X-ray beam is stored as a latent image. The phosphor plate is then scanned with a laser beam and the light emitted from the excited latent image is detected by a photomultiplier. Thereafter this signal is processed in digital form, and the image may either be viewed on a television monitor or laser-printed on to film. The advantage of phosphor-plate computed radiography is that it can retrieve an image of diagnostic quality from an imperfect exposure, which would otherwise result in a non-diagnostic conventional film radiograph. Manipulation or processing of the digital image data can enhance certain features of the radiograph to improve diagnosis.

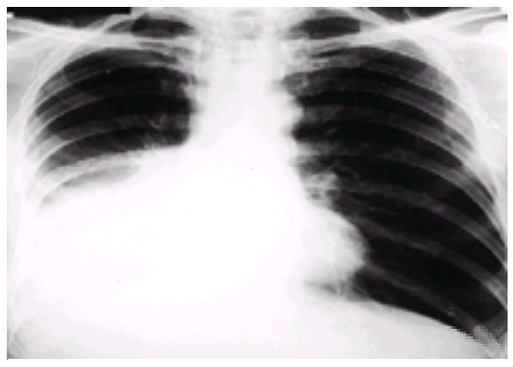

Fig. 16 Right lower lobe collapse.

Standard radiographic views of the chest

The posteroanterior projection is the standard view (see Fig. 11(a)). The patient is positioned with his anterior chest wall against the film cassette and his arms are abducted to rotate the scapulas away from the posterior chest. Chest films taken in the anteroposterior (**AP**) projection are usually taken when the patient is too ill to stand for a formal PA radiograph. A consequence of this view is that the heart is magnified because it lies further from the film. Moreover, the shorter X-ray tube-to-film distance, which is inevitable when a portable AP radiograph is taken, causes further magnification that must be taken into account when assessing the

heart size on an AP chest radiograph.

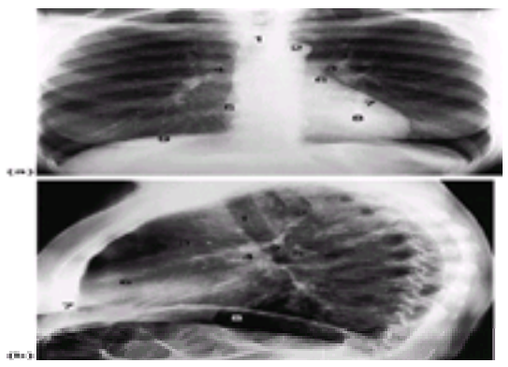

Fig. 11 Normal radiographic anatomy on (a) PA and (b) lateral chest radiographs. (a) 1, Trachea; 2 aortic arch; 3, left main pulmonary artery; 4, right main pulmonary artery; 5, right atrial border; 6, left atrial appendage; 7, left ventricular border; 8, right ventricle; 9, right dome of the diaphragm. (b) 1, Trachea; 2, scapulas; 3, anterior aortic arch; 4, right pulmonary artery; 5, left pulmonary artery; 6, right ventricle; 7, breast shadows; 8, gastric bubble under the left hemidiaphragm; 9, left main bronchus.

The lateral radiograph is obtained by placing the patient at right angles to the film cassette (see Fig. 11(b)). The lateral projection provides the third dimension and helps to determine the site of a lesion identified on the PA projection (although it is surprising how often an opacity clearly seen on the PA radiograph is invisible on the lateral radiograph). As well as allowing accurate localization of lesions, the lateral radiograph may reveal concealed abnormalities that lie behind the heart or diaphragm. Furthermore, with some experience, evaluation of the hilar structures and major airways is aided by the lateral radiograph (see later section on the anatomy on the lateral chest radiograph).

Over the years, a number of supplementary projections have been developed to provide information about areas that are not easily seen on the standard PA and lateral radiograph. With the advent of cross-sectional imaging, notably computed tomography (**CT**), many of these extra views have become obsolete. However, even with access to CT, some of these views supply extra anatomical detail readily and inexpensively and these will be considered briefly.

The lateral decubitus projection is sometimes useful for the demonstration of small pleural effusions. For this view the patient lies on his side, with the side in question downwards; the film is positioned behind the patient and the X-ray beam traverses the patient horizontally. Small quantities of pleural fluid (50 to 100 ml), which are not detectable on a PA chest radiograph, can be demonstrated tracking up the lateral chest wall, but ultrasonography is increasingly being used as a reliable technique for demonstrating small pleural effusions. Other supplementary projections, for example apical and lordotic views, improve visualization of the lung at the extreme apices. These are now rarely performed, CT being much more effective at showing pathology in these difficult areas.

The technique of screening the patient with fluoroscopy has the advantage of allowing 'real time' radiographic examination. It allows localization of lesions by the use of unusual oblique projections, for example to distinguish a small pleural plaque from an intrapulmonary nodule. Fluoroscopy is also the quickest method of evaluating diaphragmatic movement and diagnosing air-trapping in a child who is suspected of inhaling a foreign body.

Ultrasonography

High-frequency sound waves do not traverse air and are completely reflected at interfaces between soft tissue and air. The use of this technique in the chest is therefore limited by normally aerated lung. However, fluid can be readily detected and the main use of ultrasound is for the localization of small or loculated pleural effusions. Furthermore, ultrasound can differentiate between pleural fluid and pleural thickening in cases in which radiography cannot make this distinction. Ultrasonography is an extremely useful technique for guiding percutaneous needle biopsy of masses arising from the chest wall or pleura, or peripheral pulmonary masses or consolidation, and for aiding the accurate placement of a chest drain within a pleural collection. Ultrasonography may show numerous septations within an exudative pleural effusion (Fig. 1), but thoracocentesis may be required to distinguish between a parapneumonic effusion and an empyema.

Fig. 1 Ultrasonography showing a pleural effusion. Fibrinous septations traverse the pleural space.

Computed tomography

Computed tomography (CT) depends on the same basic principle as conventional radiography, namely the differential absorption of X-rays by tissues of disparate densities. However, CT is much more sensitive to differences in attenuation of X-rays by various tissues. A CT machine consists of an X-ray source and an array of detectors which surround the patient. The X-ray source rotates around the patient and the resulting attenuated beam is measured by the detectors. The signals from the detectors are used to construct an image by a mathematical technique. The reconstructed images are transverse (axial) cross-sections of the patient and are viewed as if from the patient's feet (i.e. on the image, the patient's right side is to the viewer's left). Each CT section is a matrix of three-dimensional elements (voxels) containing a measurement of X-ray attenuation, arbitrarily expressed as Hounsfield Units (**HU**): water measures 0 HU, air –1000 HU (so that lung parenchyma is approximately –600 HU), fat –80 HU, soft tissue 40–80 HU, and bone 800 HU. If a voxel is completely occupied by a tissue of uniform density (most frequently the case with narrow sections) then the HU will be truly representative of that tissue. If the section contains tissues of two different densities (more likely with thicker sections), for example half lung and half dome of diaphragm, then the attenuation value will be a weighted average of the two components: the so-called 'partial volume' effect.

Because of the cross-sectional nature of CT it can accurately localize lesions seen on only one view on chest radiography. The superior contrast resolution of CT gives exquisite detail of the various components of mediastinal anatomy (for example, lymph nodes and vessels) and density differences (for example, calcifications within a pulmonary nodule). Different image settings are needed to view the soft tissue structures of the mediastinum and the aerated lung parenchyma (Fig. 2).

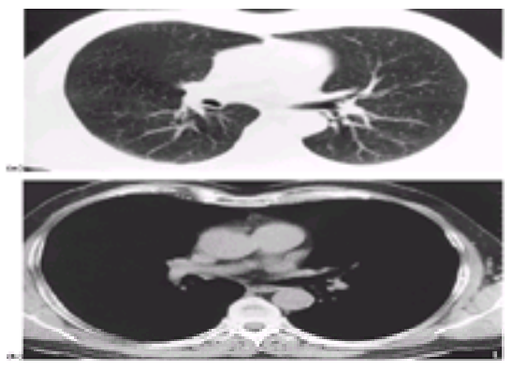

Fig. 2 Computed tomography section through the mid-thorax. The window settings have been adjusted to show details of (a) the lungs and (b) the soft tissues of the mediastinum.

Spiral (helical) CT

The principle of spiral CT involves the continuous rotation of the X-ray beam and detectors around the patient while the table moves into the gantry. Markedly reduced scan times are possible with the introduction of spiral CT, allowing the entire thorax to be imaged in a single breath-hold. An examination of sufficient diagnostic quality can be obtained in dyspnoeic patients and young children during quiet respiration. It also allows an intravenous injection of contrast medium to be accurately timed to give the optimum opacification of, for example, the pulmonary arteries, thus enabling the detection of pulmonary emboli (Fig. 3). In many centres, spiral CT has supplanted ventilation–perfusion radionuclide imaging in the investigation of patients with suspected pulmonary embolism and, with optimum technique, the accuracy approaches that of pulmonary arteriography for the diagnosis of central, lobar, and segmental pulmonary emboli. However, radiation dose and availability are important considerations. The technique is most useful in patients with coexisting lung disease which would result in an inconclusive ventilation–perfusion radionuclide study.

Fig. 3 Computed tomography of a patient with acute bilateral pulmonary emboli. Filling defects in contrast media opacification are seen within the right main pulmonary artery and the left interlobar pulmonary artery (arrows). Note the right-sided pleural effusion.

Computer software can perform multiplanar two- and three-dimensional image reconstructions of spiral CT images, which provide novel views of the bronchial tree that can aid interventional techniques such as bronchial stent placement (Fig. 4).

Fig. 4 Reconstructed three-dimensional image from spiral CT showing the carina and the right and left main bronchi viewed from above.

High-resolution computed tomography

High-resolution computed tomography (**HRCT**) uses very thin sections (1–3 mm) and a high spatial frequency reconstruction algorithm to produce highly detailed sections of the lung parenchyma. Both conventional and spiral CT scanners can produce thin sections, and the terms 'spiral CT' and 'high-resolution CT' should not be confused. Submillimetre structures can be resolved with this technique, and the subtle and sometimes complex morphology of interstitial lung diseases can be shown with great clarity (Fig. 5). Since the mid-1980s, the development of high-resolution computed tomography has changed the radiological approach to the diagnosis of diffuse lung disease. High-resolution CT images of the lung correlate closely with the macroscopic appearances of pathological specimens, so that HRCT represents a substantial improvement over chest radiography in terms of sensitivity, specificity, and diagnostic accuracy. Furthermore, CT samples a far greater volume of lung than even the most generous lung biopsy, making it less prone to sampling errors.

Fig. 5 High-resolution computed tomography of a patient with lymphangioleiomyomatosis showing thin-walled cysts throughout the lungs. These cysts were not apparent on chest radiography.

High-resolution CT has also been shown to provide useful information regarding prognosis and response to treatment in some diffuse lung diseases. Nevertheless, despite the increased confidence with which a specific diagnosis of diffuse lung disease can be made with HRCT, open lung biopsy is still required to achieve a definitive histological diagnosis in difficult cases. The extent of diffuse lung disease can be estimated precisely on HRCT and, when a biopsy is indicated, the distribution of disease will indicate whether a transbronchial biopsy or an open lung biopsy is more likely to obtain a representative specimen.

The disadvantages of CT are its relatively high cost and increased radiation exposure to the patient, particularly in comparison with chest radiography. For these reasons, CT should not be regarded as a routine investigation and examinations should always be tailored to solve questions not answered by less sophisticated investigations. The commonest indications for thoracic CT are summarized in Table 1.

Magnetic resonance imaging

The physical principles of magnetic resonance imaging (**MRI**) are very different to those governing CT scanning. An MR image is obtained by placing an individual in a strong magnetic field which polarizes some of the ubiquitous hydrogen protons (which can be thought of as behaving like randomly oriented bar magnets) in the body so that they have the same alignment. The application of radiofrequency wave pulses of specified lengths and repetition (pulse sequences) displace the protons and some of this transmitted energy is absorbed by them. With the cessation of the radiofrequency pulse, the protons return to their initial alignment and in so doing they emit, as a weak signal, some of the energy they have absorbed; this signal is received and then amplified and handled in digital form, and is subsequently reconstructed into an image.

The advantages of MRI include its ability to obtain sections in any plane (Fig. 6), the improved contrast resolution between different soft tissues compared with CT scanning, and the use of special sequences which give functional information, for instance the velocity of blood flow. Another important advantage of MRI is the lack of any known hazard to the patient, in contrast to CT scanning with its small attendant risk from ionizing radiation. Disadvantages of MRI include the long scan time (although this is continually being shortened), reduced spatial resolution compared with CT, the inability to image calcium, its reduced acceptability to patients because of the claustrophobic bore of the magnet, and important contraindications such as permanent cardiac pacemaker devices and ferromagnetic intraocular foreign bodies.

Fig. 6 Magnetic resonance image (coronal section) showing the relationship of an apical bronchial carcinoma to the chest wall and adjacent mediastinum. There are enlarged subcarinal lymph nodes and a metastatic deposit in the right adrenal gland.

In many respects the imaging of the mediastinum by CT scanning and MRI are comparable. However, MR images of the lungs are currently markedly inferior to CT scanning. This is because of the very low water (and therefore proton) content of the lungs: the signal produced by a normal lung is therefore small and not visualized by conventional sequences.

Radionuclide imaging

Ventilation–perfusion radionuclide scanning is an effective non-invasive method of providing both anatomical and physiological information about the lung. It is the commonest radionuclide study of the lungs, and is most frequently used to confirm or exclude the diagnosis of suspected pulmonary embolism.

Regional pulmonary capillary perfusion can be assessed following the intravenous injection of a bolus of particles which have been labelled with technetium-99m. The minute particles are microspheres or macroaggregates of human albumin (between 15 μm to 70 μm in diameter). These particles are evenly dispersed by the time they reach the pulmonary circulation and become temporarily lodged in a very small fraction (less than 0.5 per cent) of the precapillary arterioles and capillaries of the lungs. There is a small theoretical risk of compromising the pulmonary vascular bed in patients with severe pulmonary hypertension, but this is not an absolute contraindication to the examination. The distribution of gamma-ray emission from the technetium-labelled particles is directly proportional to the regional pulmonary flow, and a significant defect in perfusion is usually readily detected. It is important to appreciate that such defects may be due to a variety of conditions other than a pulmonary embolism, including any cause of hypoxic vasoconstriction such as an area of subsegmental collapse or space-occupying lesions not supplied by the pulmonary circulation. However, in these cases the affected area of lung will be neither ventilated nor perfused, in contrast to acute pulmonary embolism in which there is no corresponding defect of ventilation. Thus, to improve the specificity of the diagnosis of a pulmonary embolism, ventilation scintigraphy is usually performed at the same time as perfusion scanning.

Evaluation of ventilation of the lungs depends on filling the distal air spaces with a gamma-ray emitting radionuclide. The radionuclides suitable for inhalation are the inert gases xenon-133 and krypton-81m or a technetium-99m aerosol (Technegas). While krypton-81m gives the highest quality images, Technegas is being increasingly used because of its ready availability. The characteristic abnormality of pulmonary embolism is the so-called mismatched defect in which a regional defect in perfusion is not matched by a defect in ventilation (Fig. 7(a) and Fig. 7(b)). However, the picture in pulmonary embolism may not always be clear-cut, particularly when pulmonary infarction has occurred, when there will be a matched defect of both ventilation and perfusion. Because of the importance of establishing a correct diagnosis of pulmonary embolism, ventilation–perfusion scans should always be interpreted in the light of current chest radiographs and clinical information. Even then a proportion of ventilation–perfusion scans remain indeterminate, hence the increasing use of CT angiography in the management of these patients. Due to the decreased radiation burden, V/Q scanning remains a reasonable first-line investigation in young patients with no pre-existing lung disease and a low pretest probability for pulmonary embolism.

Fig. 7 A ventilation–perfusion radionuclide study (oblique views). The perfusion scan (a) shows a defect in the left mid-zone which is not matched on the corresponding view of the ventilation scan (b). The so-called mismatched defect is characteristic of a pulmonary embolus.

Positron emission tomography

Positron emission tomography (**PET**) relies on the tissue uptake of radioisotopes which decay by positron emission. Detectors located around the patient map the site of origin of the two resultant photons emitted at 180 degrees from each other. The most widely used isotope for the detection of pulmonary malignancy is [^{18}F]fluorodeoxyglucose (**FDG**), a D-glucose analogue. The increased uptake and retention of glucose by malignant cells allows differentiation of benign from malignant pulmonary masses, detection of lymph node involvement by tumour, and identification of distant metastases (Fig. 8). Limitations of the technique include false-positive results caused by granulomatous infection or acute inflammation, and false-negative results with certain tumours (e.g. bronchioloalveolar carcinomas and carcinoid tumours). The technique is not widely available at present.

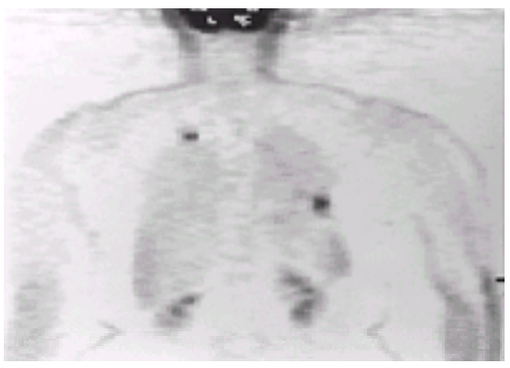

Fig. 8 Positron emission tomography image showing increased uptake of [^{18}F]fluorodeoxyglucose (FDG) in the left lower zone corresponding to a primary bronchial carcinoma. Note the pulmonary metastasis at the right apex.

Pulmonary and bronchial arteriography; superior vena cavography

The 'gold standard' for identifying emboli within the pulmonary arteries has traditionally been pulmonary arteriography (Fig. 9). This requires the puncture of an antecubital, jugular, or femoral vein, with the catheter guided through the right heart under fluoroscopic control. While the complication rate is low, it is a time-consuming procedure requiring an experienced angiographer.

Fig. 9 A digital subtraction pulmonary arteriogram showing abrupt termination of the vessels supplying the right upper lobe caused by a pulmonary embolus.

The bronchial arteries which supply the airways become hypertrophied in chronic inflammatory pulmonary disease, notably in bronchiectasis. Rupture of these vessels can cause severe and life-threatening haemoptysis. The bronchial arteries can be selectively catheterized by the passage of a catheter via the femoral artery and aorta. Having identified the abnormally hypertrophied bronchial arteries (Fig. 10), they can be therapeutically embolized. This technique is usually successful in abating massive haemoptysis in patients unable to undergo immediate surgical treatment.

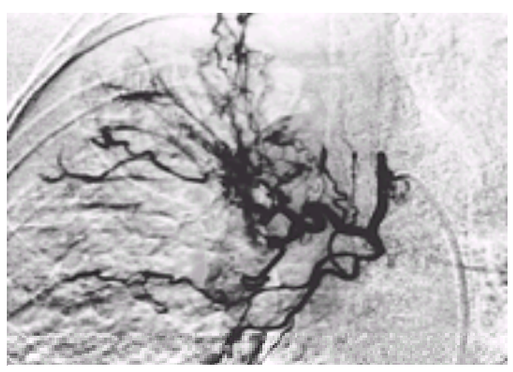

Fig. 10 Abnormally hypertrophied bronchial arteries supplying the right upper lobe shown on a selective digital subtraction bronchial arteriogram. The patient had cystic fibrosis and had had a massive haemoptysis; these bronchial arteries were subsequently embolized.

Superior vena cavography is usually performed to evaluate the exact site of narrowing in patients with symptoms of obstruction of the superior vena cava: it is not generally required to confirm the diagnosis, which is usually evident from the clinical signs alone. Patients with symptoms of superior vena cava obstruction, most frequently due to neoplastic involvement of mediastinal lymph nodes, can be successfully palliated by radiotherapy or the insertion of an expandable metallic wire stent at the site of the narrowing.

Percutaneous lung biopsy

Percutaneous needle biopsy of a pulmonary lesion or mediastinal mass is usually performed in patients in whom a bronchoscopic biopsy has failed to produce a histological specimen, or if a thoracotomy to resect the lesion is deemed inappropriate. It should not be regarded as a routine procedure in the investigation of all solitary pulmonary nodules, and should only be performed after considering the risks to the patient and whether the information forthcoming from the procedure will direct management.

Many different types of needles have been developed, and the frequency of complications, mainly pneumothorax and haemoptysis, is partly related to the diameter of the needle and the depth of the lesion. Percutaneous biopsy is performed under local anaesthesia with CT guidance: ultrasound guidance can be used if the mass

abuts the pleura. Contraindications to the procedure include any patient with poor respiratory reserve who would be unable to withstand a pneumothorax, and pulmonary arterial hypertension.

Normal radiographic anatomy

The mediastinum

On a PA chest radiograph (Fig. 11(a)) the mediastinal structures are superimposed on one another and thus cannot be distinguished individually. The mediastinum is conventionally divided into superior, anterior, middle, and posterior compartments. The practical use of these arbitrary divisions is that specific mediastinal pathologies show a definite predilection for individual compartments (for example, a superior mediastinal mass is most frequently due to intrathoracic extension of the thyroid gland, a middle mediastinal mass is usually due to enlarged lymph nodes). However, it should be borne in mind that the position of a mass within one of these compartments is no guarantee of a specific diagnosis, nor do these boundaries preclude disease from spreading from one compartment to the next.

Because only the outline of the mediastinum and the air-containing trachea and bronchi are clearly seen on a PA chest radiograph, the mediastinal anatomy will be considered in more detail in the description of CT anatomy. On a chest radiograph, the right superior mediastinal border is formed by the right brachiocephalic vein and superior vena cava. The mediastinal border to the left of the trachea above the aortic arch represents the sum of the left carotid and left subclavian arteries together with the left brachiocephalic and jugular veins. The left cardiac border comprises the left atrial appendage which merges inferiorly with the left ventricle. The cardiac silhouette is always sharply outlined: any blurring of the border denotes replacement of the aerated lung immediately adjacent to the heart, usually by collapse or consolidation (see Silhouette sign in Common radiological signs of disease).

The density of the cardiac shadow to the left and right of the vertebral column should be identical, and any difference signals pulmonary pathology (for example, consolidation in a lower lobe). A density with a convex lateral border is often seen through the right heart border on a well-penetrated film: this apparent mass is due to the confluence of the pulmonary veins as they enter the left atrium and is of no pathological significance.

The trachea and main bronchi are visible through the upper and middle mediastinum. The trachea is rarely straight and is often to the right of the mid-line at its mid-point. In elderly patients, the trachea may appear dramatically displaced by a dilated aortic arch. The angle of the carina is usually somewhat less than 80 degrees. Splaying of the carina is a sign of gross disease, either in the form of massive subcarinal lymphadenopathy, or a markedly enlarged left atrium. A more sensitive sign of a subcarinal mass is obliteration of the azygo-oesophageal line which is usually visible on a well-penetrated chest radiograph. The origins of the lobar bronchi, where they are projected over the mediastinal shadow, can usually be made out, but the segmental bronchi within the lungs are not generally seen on plain radiography.

The hilar structures

The hilar shadows on a chest radiograph are a complex summation of the pulmonary arteries and veins, with virtually no contribution from the overlying bronchial walls or normal-sized lymph nodes. The hila are approximately the same size, with the left hilum always lying between 0.5 cm and 1.5 cm above the level of the right hilum. The size and shape of the hila in normal individuals show remarkable variation so that subtle abnormalities are difficult to detect. In detecting a mass at the hilum, at least as important as an abnormal contour is a discrepancy in density between the two hila. Both hilar shadows, at equivalent points, will be of equal density, and a mass at the hilum (or an intrapulmonary mass projected over the hilum) will be evident as increased density of that hilum.

The pulmonary fissures, vessels, and bronchi

The lobes of each lung are surrounded by visceral pleura: the upper and lower lobes of the left lung are separated by the major (or oblique) fissure. The upper, middle, and lower lobes of the right lung are separated by the major (or oblique) and minor (horizontal or transverse) fissures. The minor fissure is visible in about 60 per cent of normal PA chest radiographs. In normal individuals, this fissure runs horizontally and any deviation from this course represents a loss of volume of a lobe. The major fissures are inconstantly identifiable on lateral radiographs. Other fissures are occasionally seen, for example in the left lung a minor fissure can occur which separates the lingula from the remainder of the upper lobe.

All the branching structures seen within the lungs on a chest radiograph represent either pulmonary arteries or veins. The larger pulmonary vessels can be traced back to the hila and mediastinum. The pulmonary veins can sometimes be differentiated from the pulmonary arteries: the superior pulmonary veins have a distinctly vertical course, but in practice it is often impossible to distinguish arteries from veins in the outer two-thirds of the lung. On a chest radiograph taken in the erect position, there is a gradual increase in the diameter of the vessels, at equidistant points from the hilum, travelling from lung apex to base: this is a gravity-dependent effect and is abolished if the patient is supine or in cardiac failure.

The lobes of the lung are divided into segments, each of which is supplied by its own segmental bronchi. The walls of the segmental bronchi are rarely seen on the chest radiograph, except when lying parallel with the X-ray beam when they are seen end-on as ring shadows measuring up to 8 mm in diameter.

The diaphragm and thoracic cage

The interface between aerated lung and the domes of the diaphragm is sharp, and in general the highest point of each dome is medial to the mid-clavicular line. The right dome of the diaphragm is higher than the left by up to 2 cm in the erect position, unless the left dome is temporarily elevated by air in the stomach. Laterally, the diaphragm dips steeply downwards to form an acute angle with the chest wall. Filling in or blunting of these costophrenic angles usually represents pleural disease, either pleural thickening or an effusion.

Localized humps on the dome of the diaphragm are common and represent minor weaknesses or defects. Similarly, interposition of the colon in front of the right lobe of the liver is a frequently seen normal variant.

Deformities of the thoracic cage may cause distortion of the normal mediastinum and so simulate disease. One of the commonest deformities is pectus excavatum, which, by compressing the heart between the depressed sternum and vertebral column, causes displacement of the apparently enlarged heart to the left and causes blurring of the right heart border.

High-kilovoltage chest radiographs often allow the vertebral bodies to be seen through the cardiac shadow. However, the ribs, particularly their posterior parts, are often rendered invisible by this technique.

Anatomy on the lateral chest radiograph

It is useful to get accustomed to viewing a lateral film (Fig. 11(b)) in the same orientation, whether it is a right or left lateral projection. Familiarity with the same orientation improves the viewer's ability to detect deviations from normal.

The trachea is angled slightly posteriorly as it runs towards the carina and the posterior wall of the trachea is always visible as a fine stripe. Furthermore, the posterior walls of the right main bronchus and the right intermediate bronchus are outlined by air and are also seen as a continuous stripe on the lateral radiograph. The spines of the scapulas are invariably seen running almost vertically in the upper part of the lateral radiograph and they should not be confused with intrathoracic structures. Further spurious shadows are formed by the soft tissues of the outstretched arms which are projected over the anterior and superior mediastinum. Although the carina is not visible on the lateral radiograph, the two transradiancies projected over the lower trachea represent the right main bronchus (superiorly) and the left main bronchus (inferiorly).

More lung is obscured by overlying structures on a lateral radiograph than on the PA view. The unobscured lung in the retrosternal and retrocardiac regions should be of the same transradiancy. Furthermore, as the eye travels down the dorsal spine, the viewer should be aware of a gradual increase in transradiancy. The loss of this phenomenon suggests the presence of disease in the posterobasal segments of the lower lobes (sometimes not visible on the frontal radiograph).

The two major fissures are seen as diagonal lines, often incomplete and of a hair's breadth, running from the upper dorsal spine to the anterior surface of the

diaphragm. Care must be taken not to confuse the obliquely running edges of ribs with fissures. The minor fissure extends horizontally from the mid right major fissure. It is often impossible to distinguish the right from the left major fissures with confidence. Similarly, although the two hemidiaphragms may be identified individually (especially if the gastric bubble is visible under the left dome of the diaphragm), the distinction between the right and the left is often impossible. A helpful sign is the relative heights of the two domes: the dome furthest from the film is usually higher because of magnification.

The summation of both hila on the lateral radiograph generates a complex shadow. However, there are some generalizations which aid the interpretation of this difficult area. The right pulmonary artery lies anterior to the trachea and right main bronchus, whereas the left pulmonary artery hooks over the left main bronchus so that a large part of it lies posterior to the major bronchi. As a result, any mass identified on a PA and lateral radiograph that lies anterior to the left hilum or posterior to the right hilum is not vascular in origin and is most likely to represent enlarged hilar lymph nodes.

A band-like opacity is often seen along the lower third of the anterior chest wall behind the sternum. This represents a normal density and occurs because there is less aerated lung in contact with the chest wall because the space is occupied by the heart: it should not be confused with pleural disease.

Normal CT anatomy of the mediastinum

As computed tomography provides unique information about the anatomy of the mediastinum, it is often used to provide further information about abnormalities which are seen merely as a deformity of the mediastinal contour on chest radiography. The normal structures that are always identified on a CT of the mediastinum are the blood vessels (which make up the bulk of the superior mediastinum), the major airways, the oesophagus, and mediastinal fat. An appreciation of the relationship of these structures to each other is crucial for the correct interpretation of CT scans: four important levels are shown in Fig. 12(a), Fig. 12(b), Fig. 12(c) and Fig. 12(d)).

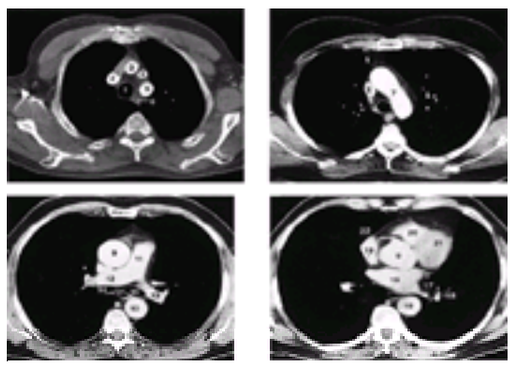

Fig. 12 (a–d) Computed tomography with contrast enhancement to show the normal anatomy at four levels through the mediastinum. 1, Trachea; 2, superior vena cava; 3, brachiocephalic artery; 4, left common carotid artery; 5, left subclavian artery; 6, oesophagus; 7, aortic arch; 8, azygos vein; 9, ascending aorta; 10, descending aorta; 11, main pulmonary artery; 12, right pulmonary artery; 13, left pulmonary artery; 14, right main bronchus; 15, left main bronchus; 16, left atrium; 17, left inferior pulmonary vein; 18, segmental bronchi of the left lower lobe; 19, right atrium; 20, right ventricular outflow; 21, left ventricle.

Normal lymph nodes surrounded by fat may be identified throughout the mediastinum. Many schemes have been devised to map their precise locations, but they can be broadly divided into: (1) anterior mediastinal; (2) posterior mediastinal; and (3) tracheobronchial. The latter can be further subdivided into the following regions: (a) right and left paratracheal; (b) subaortic; (c) pretracheal; (d) subcarinal. It is important to appreciate that the absolute size of lymph nodes identified on CT (or by direct inspection at mediastinoscopy) should not be regarded as a foolproof criterion for significant disease, particularly in the context of lung cancer. Although markedly enlarged lymph nodes, greater than 2 cm in diameter, almost invariably signify important pathology, moderate enlargement of mediastinal lymph nodes may represent reactive hyperplasia of little clinical significance. Conversely, small-volume lymph nodes or lymph nodes not identified by CT may sometimes contain micrometastases from a distant primary neoplasm.

The thymus gland occupies a large part of the anterior mediastinum in children. In adult life the remnants of the normal thymus are normally inconspicuous on CT.

Points in the interpretation of a chest radiograph

Even when there is an obvious radiographic abnormality, there is much to recommend a careful and systematic method in reviewing a chest radiograph. Such an approach will allow an appreciation of normal variations of anatomy to be built up with time. With increasing experience an appreciation of a deviation from normal appearances becomes more rapid, which leads quickly to a directed search for related abnormalities.

Before interpreting a chest radiograph, it is vital to establish whether there are any previous radiographs for comparison: the sequence and pattern of change is often as important as the identification of a radiographic abnormality. Information gained from preceding radiographs, particularly the lack of serial change, will often prevent needless further investigation. Demographic details, particularly the age and racial origin of the patient, should be noted, since this information may increase the probability of a differential diagnosis which is based on the radiographic findings alone.

A quick check that the radiograph is of satisfactory quality includes an estimation of the radiographic exposure, depth of inspiration, and position of the patient. As a general rule, the intervertebral disc spaces of the entire dorsal spine should be visible on a correctly exposed radiograph, with the mid-point of the right hemidiaphragm lying at the level of the anterior end of the sixth rib if the patient has taken a satisfactory breath in. The patient is axially rotated if the medial ends of the clavicles are not equidistant from the spinous process of the thoracic vertebral body at that level.

The order in which the structures on a chest radiograph are analysed is unimportant. A suggested sequence is to start with a scrutiny of the position of the trachea, mediastinal contour (which should be sharply outlined in its entirety), and then the position, outline, and density of the hilar shadows. Only then are the lungs examined, taking into account their size, the relative transradiancy of each zone, and the position of the horizontal fissure (and any other indirect signs of volume loss—see later section on lobar collapse). Pulmonary vessels are seen as far as the outer third of the lung and the number of vessels should be roughly symmetrical on the two sides. Next, the position and clarity of the hemidiaphragms should be noted, followed by an assessment of the ribs and soft tissues of the chest wall. Special care should be taken to look for pleural thickening along the lateral chest walls which can easily be overlooked.

Before saying that a chest radiograph is normal, it is worth reviewing areas which are either poorly demonstrated or often misinterpreted. These include: (1) the central mediastinum, where even a large mass may be barely visible on the PA view; (2) the areas behind the heart and hemidiaphragms; (3) the lung apices, often obscured by overlying clavicle and ribs; and (4) the lung and pleura just inside the chest wall.

Once a radiographic abnormality has been detected it should be considered in terms of gross pathology. Both the site and the radiographic characteristics of the lesion will allow the observer to proceed to, at the very least, a generic diagnosis. A precise (unique) diagnosis can only rarely be achieved from the radiographic appearances alone without knowledge of the clinical context.

Common radiological signs of disease

Pulmonary consolidation

Consolidation is a pathological description of the state of the lungs when the normal air-filled spaces, distal to the bronchi, are occupied by the products of disease (for example, water, pus, or blood). The most important radiographic signs of pulmonary consolidation are: (1) an area of increased opacification in the lungs which obscures the underlying blood vessels and has a poorly defined margin—unless it is bounded by a fissure; (2) an 'air bronchogram'; and (3) the 'silhouette sign' (Fig. 13). The air bronchogram is a distinctive and certain sign of intrapulmonary pathology and is seen as a radiolucent (grey) branching structure of the bronchi against a more opaque (white) background of an air-less lung. Although an air bronchogram is seen almost invariably in consolidation, a lung which has become collapsed and

air-less, for example due to a large surrounding pleural effusion, may also show an air bronchogram. The silhouette sign is seen when the normally clear border of a structure is lost because the air-filled lung outlining the border is replaced by fluid or a mass. Recognition of this sign can help to localize the area of abnormality within the lungs, for example consolidation in the lingula will make the left heart border indistinct. As with the air bronchogram sign, the silhouette sign may be seen in either pulmonary consolidation or collapse, for example loss of a clear right heart border may be due to right middle lobe consolidation with or without lobar collapse: the common feature is loss of normal aeration of the affected lung. The causes of widespread pulmonary consolidation are numerous but may be broadly divided into five categories shown in Table 2.

Fig. 13 Widespread pulmonary consolidation in a patient with alveolar proteinosis. The right heart border is obscured, confirming that a large part of the consolidation is in the right middle lobe (the silhouette sign).

Pulmonary collapse

This is the term used to describe the loss of aeration and therefore inflation in part or all of a lung. Depending on the cause, collapse may occur at any level from small, subsegmental areas of lung through to an entire lung. Small areas of subsegmental collapse occur very commonly in debilitated and postoperative patients, where they are seen as linear, usually horizontal, opacities. At the other end of the spectrum, collapse of an entire lung, usually due to an endobronchial lesion or inhaled foreign body, has a dramatic radiographic appearance with complete opacification of the affected lung and loss of volume of that hemithorax. At the lobar level, the signs of collapse of an individual lobe are characteristic, but, depending on the lobe, may be very subtle. Recognition of the collapse of individual lobes is important and these are described in detail.

Collapse of individual lobes

- *Right upper lobe*: on the frontal radiograph there is elevation of the minor fissure and of the right hilum. If the collapse is complete the non-aerated lobe is seen as a density alongside the superior mediastinum (Fig. 14). On the lateral view the minor fissure moves upwards and the major fissure moves forwards. The retrosternal area becomes progressively more opaque and the anterior margin of the ascending aorta becomes obscured.

Fig. 14 Right upper lobe collapse.

- *Right middle lobe*: on the frontal radiograph the lateral part of the minor fissure moves down. There is blurring of the normally sharp right heart border, which may be a subtle abnormality that is easily overlooked (Fig. 15). On the lateral view the minor fissure moves downwards and the lower half of the major fissure moves forwards, giving rise to a triangular shadow with its apex at the hilum and its base behind the lower sternum.

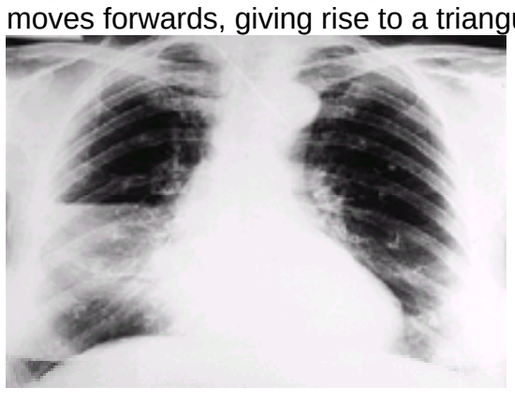

Fig. 15 Right middle lobe collapse.

- *Right lower lobe*: there is an increase in density overlying and obscuring the medial portion of the right hemidiaphragm, and the right hilum is displaced inferiorly on the frontal radiograph (Fig. 16). By contrast to right middle lobe collapse, the right heart border usually remains sharply defined since this is in contact with the aerated right middle lobe. On the lateral view the major fissure moves backwards and downwards; with increasing collapse there is a loss of definition of the posterior part of the right hemidiaphragm as well as increased density overlying the lower dorsal vertebral column.
- *Left upper lobe*: the main finding on the frontal radiograph is a veil-like increase in density, without a sharp margin (quite unlike right upper lobe collapse), spreading outwards and upwards from the elevated left hilum (Fig. 17). The outlines of the aortic knuckle, left hilum, and left heart border become ill-defined. As the collapse increases, the lobe moves centrally and the apical segment of the left lower lobe expands to fill the space left by the collapsed upper lobe: this is the cause of the relatively transradiant lung apex. With complete left upper lobe collapse, a sharp border may return to the aortic arch because it is surrounded by the hyperinflated apical segment of the lower lobe. On the lateral view the major fissure moves superiorly and anteriorly while remaining relatively vertical and roughly parallel to the anterior chest wall.

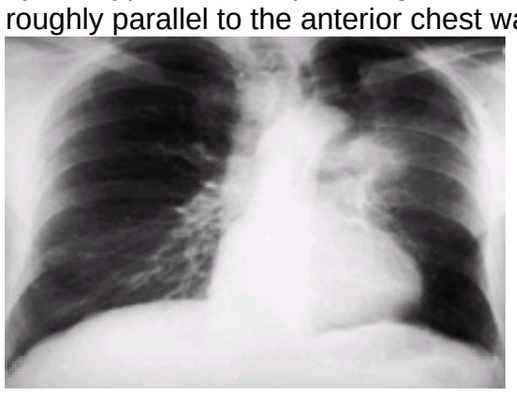

Fig. 17 Left upper lobe collapse.

- *Left lower lobe*: on the frontal radiograph there is a triangular density behind the heart with loss of the medial part of the left hemidiaphragm (Fig. 18). Even on a properly exposed radiograph it may be difficult to appreciate the collapsed lobe behind the heart. Supplementary signs include inferior displacement of the left hilum, loss of volume and increased transradiancy of the left hemithorax. On the lateral view there is posterior displacement of the major fissure. As with right lower lobe collapse, there is increased density over the lower dorsal vertebral column and the posterior part of the left hemidiaphragm is effaced.

Fig. 18 Left lower lobe collapse (an AMBER chest radiograph which improves exposure in the mediastinal region).

Complete opacification (or a white-out) of a hemithorax is generally due to either collapse of a lung or a large pleural effusion or tumour. Shift of the mediastinum to the affected side implies that volume loss, that is to say collapse of the lung, has occurred. By contrast, a pleural effusion or soft tissue mass which is large enough to cause complete opacification of a hemithorax will almost invariably displace the mediastinum away from the side that is opacified. An important exception is an advanced mesothelioma which may encase one lung and 'freeze' the mediastinum and prevent a contralateral mediastinal shift. Occasionally, when there is no obvious shift of the mediastinum, it is surprisingly difficult to differentiate between these two completely different causes of an opacified hemithorax. In these instances, ultrasonography and computed tomography allow the distinction to be made with confidence and may give further information about the underlying disease.

Increased transradiancy of a hemithorax

There are many causes of an increased transradiancy (darkening) of one lung, ranging from a loss of soft tissues of the chest wall (for example, a mastectomy) through to reduced perfusion of one lung due to hypoxic vasoconstriction resulting from underventilation of the lung because of an inhaled foreign body, or a tumour in a main bronchus. It is surprisingly easy to overlook this important radiographic abnormality, especially when the density difference between the two lungs is slight. A subtle discrepancy in density between the two hemithoraces is more readily appreciated by viewing the radiograph from a distance of at least 1.5 metres. The commonest causes of a relatively transradiant hemithorax are shown in Table 3. Close scrutiny of the chest radiograph will usually indicate which one of the categories of causes is responsible for this radiographic sign. If there is any clinical suggestion that the cause of the increased transradiancy is due to an obstructing lesion in a central airway, a chest radiograph taken in full expiration will accentuate the increased transradiancy and will show that the lung fails to empty.

Once it has been established that the difference in density of the lungs is not due to a technical problem, for example rotation of the patient, points to look for are: (1) loss of symmetry of the soft tissues of the chest wall; (2) discrepancy in the volumes and vascular pattern between the two lungs; (3) a visceral pleural edge (denoting a pneumothorax). The identification of a pneumothorax on an erect chest radiograph is usually straightforward because of the appearance of the collapsed lung which is clearly demarcated by the fine edge of the visceral pleura. However, in the supine patient, such an edge is often not seen because air in the pleural space drifts anteriorly to the least dependent part of the chest. In this situation, a pneumothorax is only seen as a vague area of increased transradiancy over the lower zone of the chest. It is vital to recognize when the pressure of the air trapped in the pleural space exceeds alveolar pressure, a so-called tension pneumothorax. The typical signs are of a contralateral mediastinal shift with straightening and flattening of the ipsilateral dome of the diaphragm (Fig. 19).

Fig. 19 A left-sided tension pneumothorax in a patient with cystic fibrosis. Note the mediastinal shift and straightening f the left hemidiaphragm.

The pulmonary mass

Many pulmonary masses are discovered incidentally on a chest radiograph. Whenever possible, previous films should be obtained so that the growth rate of the lesion can be estimated. The growth rate is a more reliable indicator of the likely nature of a pulmonary mass than any one of its radiographic features: if a lesion doubles in volume (increases in diameter by approximately 25 per cent on serial chest radiographs) in less than 1 week or more than 18 months, it is very unlikely to be malignant. The doubling time of most malignant lesions is between 1 and 6 months.

Over the years much importance has been attached to the radiological characteristics of a solitary pulmonary mass in an attempt to make the crucial distinction between benign and malignant lesions. With the possible exception of heavy calcification within the lesion (most commonly seen in ancient granulomas), no radiological appearance will reliably differentiate a benign from a malignant mass. Although generalizations can be made (for example, that bronchial carcinomas have irregular and spiculated margins, whereas benign lesions are more likely to have smooth outlines), in the individual patient it is not safe to rely on these radiographic features alone to make the distinction between a benign and malignant lesion.

After the discovery of a pulmonary mass on chest radiography, further imaging and other investigations of a patient will depend on the symptomatology, age, and smoking history of the patient. Computed tomography is valuable in evaluating extension of a central mass into the mediastinum (Fig. 20); for demonstrating the presence or absence of enlarged mediastinal lymph nodes, which may (but not invariably) indicate local tumour spread; and also for the detection of distant metastases, for example to the contralateral lung, adrenal glands, and liver. It is usually the overall pattern and extent of disease on a staging CT examination, rather than any single abnormality, which indicates whether a patient with bronchial carcinoma, who is otherwise fit, is likely to be suitable for surgical resection. Local invasion of the chest wall by an adjacent bronchial carcinoma is not always demonstrated by CT: MRI, because of its ability to image in different planes, may be useful. When surgery is not indicated and a histological diagnosis is needed, percutaneous needle biopsy of central lesions can be performed safely under CT guidance. Similarly, smaller peripheral lesions that are not accessible by bronchoscopy may be biopsied under CT or, if abutting the pleura, ultrasound guidance.

Fig. 20 Computed tomography of a central cavitating bronchial carcinoma showing direct extension of the tumour into the subcarinal region of the mediastinum.

Cavitating pulmonary lesions

The radiological definition of cavitation is a lucency, representing air, within a mass or area of consolidation. The cavity may or may not contain a fluid level or an intracavitary body, and is surrounded by a wall of variable thickness. The two most likely diagnoses in an adult presenting with a cavitating pulmonary mass on chest radiography are bronchial carcinoma (central, large, and often squamous in type) (Fig. 21) or a lung abscess (usually peripheral and sometimes multiple). Cavitation is recognized in a variety of bacterial pneumonias, particularly those due to tuberculosis, staphylococcus, anaerobes, and klebsiella infections. Less commonly, cavitation is seen within pulmonary infarcts and in areas of pulmonary contusion due to trauma. Long-standing cavities in lungs scarred by previous tuberculosis infection predispose to the formation of mycetomas; once these fungus balls occupy most of the cavity, a characteristic translucent 'air-crescent sign' may be seen between the upper surface of the fungus ball and the margin of the cavity on chest radiography (Fig. 22).

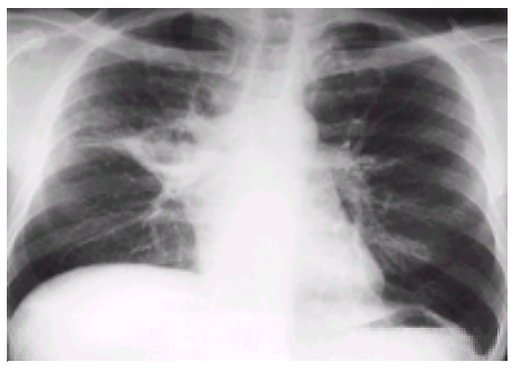

Fig. 21 Chest radiograph of a large cavitating squamous-cell bronchial carcinoma adjacent to the right hilum. The right hemidiaphragm is raised because of phrenic nerve invasion by the tumour.

Fig. 22 An air crescent (arrow) around a fungus ball at the left apex. This had developed in a tuberculous fibrotic cavity.

Multiple pulmonary nodules

Many conditions are characterized by multiple small pulmonary nodules (Fig. 23). Only by combining the relevant clinical information with a precise description of the size and distribution of the nodules can the differential diagnosis be narrowed. In the United Kingdom, metastatic deposits are by far the commonest cause of multiple pulmonary nodules of varying sizes in an adult. In some parts of the southern United States, histoplasmosis is endemic and multiple granulomatous nodules are commoner than those due to disseminated malignancy. In the absence of a known malignancy and when clinical findings and laboratory investigations are inconclusive, biopsy of one of the nodules may be the only means of establishing a diagnosis.

Fig. 23 Multiple pulmonary nodules of varying sizes typical of metastatic disease.

A myriad of small nodules, less than 5 mm in diameter, produces a pattern which is often described as miliary. A list of causes of miliary shadowing is given in Table 4. An important diagnosis to consider in any patient with this radiographic pattern is miliary tuberculosis. Other differential diagnoses in an asymptomatic patient with numerous pulmonary nodules include sarcoidosis, metastatic disease, or, if there is a relevant occupational history, a pneumoconiosis. As always, comparison with previous radiographs will give invaluable information about the rate of progression and thus the likely nature of the pulmonary nodules. To a lesser extent the distribution of nodules is a consideration in refining the differential diagnosis of multiple pulmonary nodules: for example, the small nodules of pulmonary sarcoidosis

tend to be mid-zone and perihilar, whereas haematogenous metastases are generally of varying sizes and have a predilection for the lower lobes (probably because of increased blood flow to these regions).

The density of nodules sometimes provides conclusive evidence that the nodules are of benign aetiology, for example the heavily calcified nodules which are seen following histoplasmosis or chickenpox (varicella) pneumonia. The majority of multiple pulmonary nodules are of soft tissue density, and it may be extremely difficult to judge whether small nodules are of calcific or soft tissue density because their apparent density depends so critically on the radiographic technique used.

Numerous poorly defined nodules of low density of approximately 8 mm in diameter may be seen around areas of pulmonary consolidation. In other areas they may be confluent and so make up a larger poorly defined opacity; occasionally these nodules will be uniformly distributed through out the lungs. At a pathological level these nodules correspond to individual acini which are full of the products of disease, such as pulmonary oedema, an inflammatory exudate, or haemorrhage.

17.3.2 Respiratory function tests

G. J. Gibson

Scope of respiratory function tests

The clinical roles of respiratory function tests include diagnosis, assessment of severity, monitoring the effects of treatment, and assessing prognosis of various respiratory conditions. In the diagnosis of specific diseases, respiratory function tests, like functional tests of other organs, inevitably have limitations. Their use as a diagnostic tool is in recongizing that different patterns of abnormality characterize particular types of disease. More often they are used to quantify the severity of functional disturbance or to locate the likely anatomical site(s) of disease, such as airways, alveoli, or chest wall. The results should be compared with reference values obtained in healthy populations (see Appendix) and should always be evaluated in the light of clinical and radiographic information. The commonly applied tests are most conveniently classified as tests of (1) respiratory mechanics, (2) pulmonary gas exchange (and acid–base balance), and (3) exercise. Measurements made during sleep are described elsewhere (see Chapter 17.8.2).

Tests of respiratory mechanics

The volume of air in the lungs at the end of tidal expiration (functional residual capacity— **FRC**) represents the 'neutral' volume of the thorax, that is, the volume pertaining when the respiratory muscles are inactive (as during anaesthesia with muscle paralysis). Expansion of the lungs above FRC is achieved by contraction of the inspiratory muscles (predominantly the diaphragm), which results in a negative (subatmospheric) alveolar pressure. Normal resting tidal expiration is essentially passive with the driving force provided by elastic recoil of the lungs. The main expiratory muscles are those of the abdominal wall, contraction of which increases abdominal pressure which in turn is transmitted to the thorax. In health these muscles become active when ventilation is increased markedly, as on exercise, or during coughing, when a high intrathoracic pressure aids the clearance of airway secretions.

Measurements of tidal breathing (tidal volume, respiratory frequency) are rarely made in the resting awake subject, other than conventional recording of respiratory rate, which is part of clinical examination. Measurement of ventilation is of more importance in patients receiving ventilatory support (such as in intensive care units), during detailed exercise testing, and during sleep investigations. During exercise testing, ventilation is usually obtained by electrical integration of airflow measured at the mouth, but this approach is impracticable for prolonged monitoring (such as during sleep) and the application of a mouthpiece and nose clip may itself disturb the pattern of resting breathing. An alternative, less intrusive method is to measure external movement of the chest wall (rib cage and abdomen), but the estimates of ventilation obtained are at best semiquantitative.

In principle, the mechanical function of the respiratory system can be characterized by the compliance of the lungs and chest wall and the resistance of the airway. In practice, however, neither of these is commonly measured directly in clinical testing. Measurement of pulmonary compliance (an index of the 'stiffness' of the lungs) requires measurement of oesophageal pressure, which equates to pleural pressure and allows calculation of the pressure required to distend the lungs. In clinical investigation, the elastic properties of the lungs are usually inferred from measurements of lung volumes, because lungs which are unusually stiff and poorly compliant (as in pulmonary fibrosis) are usually shrunken and reduced in volume, while lungs with abnormally high compliance are easily distensible and are associated with increased total lung capacity (as in emphysema). The traditional subdivisions of lung volume are illustrated in Fig. 1.

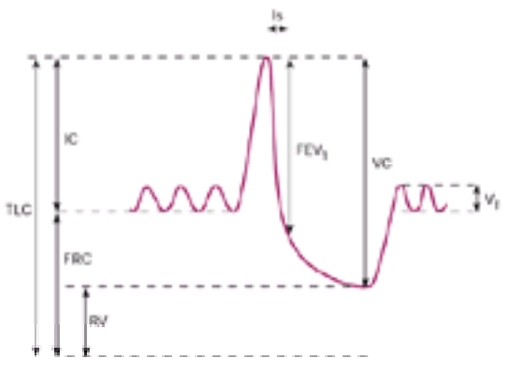

Fig. 1 Subdivisions of lung volume illustrated by spirometric recording of volume against time during tidal breathing for three breaths, followed my maximal inspiration and then maximal forced expiration, before returning to tidal breathing in a normal subject. RV, residual volume; FRC, functional residual capacity; IC, inspiratory capacity; TLC, total lung capacity; FEV_1, forced expiratory volume in 1 s; VC, vital capacity; V_T, tidal volume. Note that TLC = FRC + IC = VC + RV.

Measurement of airway resistance requires estimation of the pressure difference along the airway—between the alveoli and mouth. The various techniques available for obtaining alveolar pressure include oesophageal pressure monitoring, body plethysmography, and transient interruption of airflow, with mouth pressure during occlusion taken to equal alveolar pressure. None of these is widely used in clinical testing. An alternative method, which has recently gained popularity, involves superimposition of a small oscillating pressure at the mouth during tidal breathing; the resulting pressure and flow information is used to calculate airway resistance. In practice, however, airway function is most commonly assessed by tests based on forced expiration.

Measurements of lung volume

A spirometer measures only the air which can be displaced from the lungs and does not give an indication of their absolute volume because the unmeasured residual volume (**RV**) remains in the lungs after full expiration. The vital capacity (**VC**) is the maximum volume expired after a full inspiration (or inspired after a full expiration) and the total lung capacity (**TLC**) represents the volume of air in the lungs after full inspiration— the sum of VC and RV (Fig. 1).

Two main clinical methods are used for measurement of absolute lung volume: inert gas dilution and whole body plethysmography. With the former, the subject breathes from a closed circuit a gas mixture containing an inert marker gas, usually helium. The helium equilibrates gradually with the gas in the lungs so that its concentration falls progressively and stabilizes once mixing is complete. In a healthy individual this occurs in 5 to 10 min, but in patients with diffuse airway disease such as asthma or chronic obstructive pulmonary disease (**COPD**), equilibration is much slower due to unequal ventilation, and the end point may be much less definite. The lung volume measured is that in the lungs when the subject was connected to the circuit (usually FRC). After disconnection from the rebreathing circuit

the subject inspires fully and the volume inspired (inspiratory capacity, **IC**) added to FRC gives TLC (Fig. 1). With moderate or severe airway disease the uneven distribution of the inspired gas and poor mixing in the lungs results in underestimation of lung volumes.

In the alternative plethysmographic technique, the subject sits within a large air-tight chamber and makes gentle breathing efforts against a shutter, which closes the airway at the mouth. Since the pressure within the rigid plethysmograph changes as lung volume changes according to Boyle's law (pressure × volume = a constant), this allows calculation of thoracic gas volume, from which total lung capacity and residual volume are derived by full inspiration and expiration immediately on opening the shutter. This method measures the volume of any air spaces within or without the lung which share pressure changes during breathing efforts, so that poorly ventilated (or even totally unventilated, such as a bulla) areas of lung are included.

Some increase in TLC occurs in most patients with symptomatic diffuse airway obstruction. A large increase is characteristic of emphysema but is not specific for this condition. Increases are seen in asthma, even when the condition is in relative remission. A pathological reduction in TLC occurs in several conditions (Table 1), not only lung diseases such as pulmonary fibrosis, but also extrapulmonary diseases affecting the pleura, thoracic skeleton, or respiratory muscles, conditions which all potentially impede full lung expansion.

Tests of forced expiration

The strengths of tests of forced expiration include the simplicity of both the manoeuvre and equipment required, and also the relative independence of the measurements on the effort applied by the patient. Forced expiratory tests are effort dependent to the extent that a preceding full inspiration is required, but during forced expiration the larger intrathoracic airways are subject to dynamic compression by the surrounding pleural pressure. The net result is that, provided a modest effort is applied, increasing the effort merely compresses the airway further and produces no increase in flow. This effort independence is more marked as forced expiration proceeds and is also more marked in patients with airway obstruction than in healthy subjects. At higher lung volumes (i.e. closer to full inflation), maximum expiratory flow is more dependent on effort. Since peak expiratory flow (**PEF**) is attained very rapidly at the start of forced expiration, it is more effort dependent than the forced expiratory volume in 1 s (**FEV1**), which effectively integrates flow over a large proportion of the volume range. PEF is measurable with a very simple peak flow meter which has the advantage of portability and is used routinely, particularly in asthma, to monitor respiratory function at home. Although more effort dependent, PEF is reproducible by most patients after a few practice efforts.

The most commonly used index of mechanical function of the lungs in hospital is the 1 s forced expiratory volume (FEV_1)—the volume expired forcefully in 1 s following complete inspiration (Fig. 1). This is usually obtained together with the forced vital capacity (**FVC**). In healthy subjects the FVC is effectively the same as VC, but in patients with airway disease the FVC is often appreciably less than the true ('relaxed') VC obtained when the subject is encouraged to expire completely without excessive initial effort.

The characteristic feature of diffuse airway obstruction is slowing of the rate of expiration so that the ratio of FEV_1 to FVC (or FEV_1 to VC) is reduced. This defines an 'obstructive' ventilatory defect as opposed to the 'restrictive' pattern in which both FEV_1 and FVC are reduced in approximate proportion. Although in patients with diffuse airway obstruction the FVC and VC are reduced, at least in patients with symptomatic disease, the reduction is proportionally less than the reduction in FEV_1. The ratio of FEV_1 to FVC indicates the presence of airway obstruction but is a poor guide to severity, which is better assessed by comparing the FEV_1 alone with its predicted value. An obstructive spirometric pattern is seen in asthma, COPD, and bronchiectasis, while a restrictive spirometric pattern is seen in all those conditions which are also associated with a reduced TLC (Table 1). A further feature of diffuse airway obstruction is an increase in RV and in the ratio RV/TLC, but this is less specific than the spirometric pattern as it also occurs in some patients with cardiac disease or with respiratory muscle weakness. With dual pathology, combined obstructive (low FEV_1/VC) and restrictive (low TLC) defects are seen. Sometimes in this situation total lung capacity may be within the normal range due to opposing influences with, for example, lung fibrosis tending to shrink the lungs and airway obstruction tending to produce hyperinflation.

Spirometric measurements such as FEV_1 are less sensitive to localized narrowing of the central airway than to the diffuse airway narrowing of COPD or asthma. If upper airway obstruction is suspected, it is helpful to visualize the information obtained during forced expiration (and also inspiration) in a different manner as the maximum flow–volume curves, which relate instantaneous flow to volume expired and inspired (Fig. 2). The expiratory curve has a characteristic shape with an early peak (equivalent to the PEF obtained with a peak flow meter). Maximum expiratory flow then declines progressively as volume is expired. In young healthy subjects (Fig. 2(a)), the descending limb of the curve approximates a straight line, whilst in older normal subjects (Fig. 2(b)), maximum expiratory flow decreases, particularly at lower lung volumes so that the curve appears concave. In patients with diffuse intrathoracic airway obstruction (such as COPD or asthma) this ageing appearance is greatly exaggerated so that expiratory flow is reduced more markedly as lung volume declines (Fig. 2(d)). The shape of the flow–volume curve does not distinguish between different causes of diffuse airway narrowing, that is, it does not allow the distinction of asthma from COPD or emphysema.

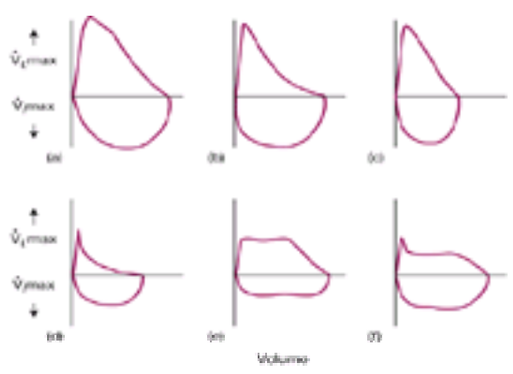

Fig. 2 Schematic maximum expiratory and inspiratory flow–volume curves in: (a) normal young adult; (b) normal older adult; (c) patient with fibrosing alveolitis and reduced FVC; (d) patient with moderately severe COPD showing markedly reduced $_E$max, particularly at lower lung volumes; (e) patient with subglottic (extrathoracic) tracheal stenosis showing markedly reduced $_I$max at all volumes and reduced $_E$max at higher volumes; (f) patient with central intrathoracic (carinal) tracheal narrowing showing similar plateaus of flow to (e) but greater reduction of $_E$max than of $_I$max.

The maximum inspiratory flow–volume curve has a more symmetrical appearance than the expiratory curve. In patients with diffuse airway narrowing there is an overall reduction in inspiratory flow, but little change in shape (Fig. 2(d)). In patients with a restrictive ventilatory defect caused, for example, by pulmonary fibrosis, the volume displaced (FVC) is reduced but absolute flows are little affected (Fig. 2(c)).

Characteristic flow–volume curves are seen in patients with localized narrowing of the proximal airway, with the pattern depending on whether the narrowing is extra- or intrathoracic. Extrathoracic narrowing (Fig. 2(e)), such as occurs with subglottic tracheal stenosis or tracheal tumours, has a relatively greater effect on inspiratory than expiratory flow (which corresponds to the predominantly inspiratory timing of the stridor of upper airway narrowing). It also affects maximum expiratory flow but (unlike COPD or asthma) the effects are most marked at higher lung volumes, often producing a virtual 'plateau' of expiratory flow in the first part of forced expiration. If, on the other hand, the central airway is narrowed within the thorax (for example the lower trachea, carina) a similar plateau of expiratory flow, often with a small initial peak, may be seen, but maximum inspiratory flow is less affected than with narrowing of the extrathoracic airway (Fig. 2(f)). These patterns of abnormality of maximum flow can be quantified in terms of various ratios, such as the ratio of maximum expiratory to inspiratory flow at 50 per cent VC, or the ratio of PEF (markedly reduced with upper airway obstruction) to FEV_1 (proportionally less reduced). Usually, however, it is essential to visualize the curves and interpret such derived indices in the light of the overall contour.

The 'plateau' of maximum expiratory flow over a significant proportion of the FVC which occurs with upper airway obstruction has implications for the shape of the more commonly recorded forced expiratory spirogram in this situation. Since flow on the spirogram (relation of volume to time) is given by the instantaneous gradient of the curve, a plateau on the flow–volume curve implies a 'straight' (rectilinear) spirogram over the same volume range. This appearance should therefore alert the investigator to the likelihood of narrowing of the central airway rather than the more common diffuse airway obstruction seen with asthma and COPD (Fig. 3).

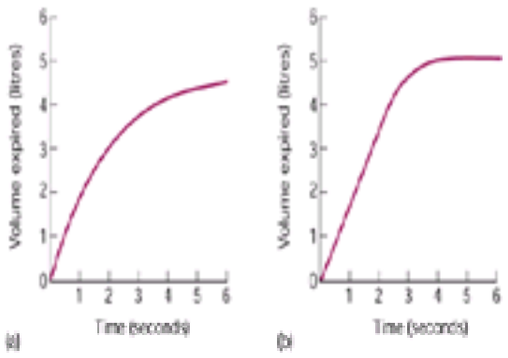

Fig. 3 Spirograms of two patients with airway obstruction and similar FEV_1. (a) Diffuse intrathoracic airway narrowing (COPD or asthma). Note that forced expiration is continuing after 6 s. (b) Upper airway narrowing with 'straight' spirogram which corresponds to plateau of flow in earlier part of expiration.

Respiratory muscle function

The simplest method of measuring respiratory muscle strength is for the subject to perform forcible static inspiratory and expiratory efforts against a closed airway. This provides values of maximum expiratory and inspiratory pressures (***P*Emax**, ***P*Imax**). In general the expiratory (predominantly abdominal) muscles perform most effectively at high lung volumes and the inspiratory muscles (predominantly the diaphragm) at lower volumes. $P_E$max is therefore usually measured after full inspiration and $P_I$max at either FRC or RV. Unfortunately the normal ranges for these tests are wide and some subjects find difficulty in performing the manoeuvres (which are, of course, by definition completely effort dependent). An alternative method for assessing inspiratory muscle strength is by making the measurement during a forceful sniff, with the pressure measured in the nose via an occluded nostril (sniff nasal inspiratory pressure—SNIP). Many patients find this easier than performing maximum static manoeuvres so that the sniff technique tends to give more reproducible results.

These measurements all assess the global strength of the inspiratory or expiratory muscles. More specific information on diaphragmatic function requires measurement of transdiaphragmatic pressure using pressure sensing devices in both oesophagus and stomach, a specialized investigation available in only a few centres. A simple indirect index of disproportionate diaphragmatic weakness or paralysis is a large (more than 25 per cent) reduction in VC in the supine compared with the erect posture. However, isolated bilateral diaphragmatic paralysis or severe weakness is very unusual and most patients with respiratory muscle weakness have disease affecting all the muscles. The causes include not only primary neuromuscular diseases such as myopathies, muscular dystrophy, motor neurone disease, and myasthenia gravis, but also drug treatment (corticosteroids), several endocrine and connective tissue disorders, and cachexia from whatever cause. Respiratory muscle weakness is often an important factor preventing weaning from assisted ventilation.

Measurements of respiratory muscle function are indicated in evaluation of patients with various neuromuscular diseases. They are also helpful in confirming or excluding muscle problems in those with otherwise unexplained dyspnoea and in patients with a restrictive ventilatory defect in whom the cause of the lung volume reduction is not apparent on clinical and radiographic grounds. Interpretation of results may be complicated in patients with airway obstruction (such as COPD or asthma) because the associated hyperinflation of the lungs (increased FRC) itself impairs inspiratory muscle function simply because of the distorted thoracic mechanics. Consequently an apparently impaired maximum inspiratory pressure in such patients may not necessarily reflect true muscle weakness. Maximum expiratory pressure is not significantly affected by hyperinflation, however, and can be used as a guide to the presence of true muscle weakness in this situation.

Tests of pulmonary gas exchange

Carbon monoxide uptake

Carbon monoxide (CO) diffusing capacity or transfer factor (*TL*CO) is used widely as a simple test of the integrity of the alveolar capillary membrane and of the overall gas exchanging function of the lungs. It has good sensitivity but poor specificity, as impairment can result from a variety of pathological processes (Table 2). The subject takes a full inspiration of a gas mixture containing a very low concentration of CO and the rate of uptake of gas is measured during breath holding for 10 s. The test was introduced originally as a method of assessing diffusion of gas across the alveolar capillary membrane, but thickening of the diffusion pathway for carbon monoxide in disease is quantitatively less important than other mechanisms, the most important factor being the effective surface area of alveoli available for gas exchange. Consequently *TL*CO is reduced when this area is diminished, for example after resection of lung or with widespread emphysema, in which normal alveoli are replaced by much larger air spaces. *TL*CO is also reduced when there is loss of the 'effective' alveolar volume (V_A). The latter is measured simultaneously from the dilution of helium which is also included in the test breath. The 'effective' V_A is reduced if there is maldistribution of ventilation as this causes some alveoli to receive little or none of the inspired gas. Other factors affecting the *TL*CO include the availability of haemoglobin and disease of the pulmonary capillaries.

The transfer coefficient (*K*CO), which is obtained along with the *TL*CO, represents the uptake of CO per litre of 'effective' alveolar volume, that is, $K\text{CO} = TL\text{CO} / V_A$. To a large extent, *K*CO allows correction for any real or effective reduction of alveolar volume, tending to be normal after lung resection, when both *TL*CO and V_A are reduced approximately to the same degree. *K*CO is usually normal (or even mildly increased) in asthma, where any reduction in *TL*CO is due only to maldistribution of ventilation secondary to airway narrowing. By contrast, in widespread emphysema, *TL*CO is reduced due not only to maldistribution of inspired gas, but also because the gas exchanging surface area is diminished even in the relatively better ventilated parts of the lung. Consequently, there is an associated reduction in *K*CO. Diseases associated with reductions in *TL*CO and *K*CO are listed in Table 2.

In some conditions *K*CO and, less commonly, *TL*CO may increase (Table 3). The latter usually results from an increase in red blood cells in the lungs due to greater blood flow, haemorrhage, or polycythaemia. *K*CO is similarly increased in these conditions, as it is if, at full inflation, the density of pulmonary capillaries per unit alveolar volume is greater than normal. This occurs most commonly in patients with extrapulmonary volume restriction, when the density of pulmonary capillaries is unusually high in relation to the (restricted) lung volume at which the measurement is made.

Arterial blood gases

The primary measurements made by modern blood gas analysers are the arterial partial pressures of oxygen ($P\text{aO}_2$) and carbon dioxide ($P\text{aCO}_2$), and pH. The alternative commonly used method of assessing oxygenation is by pulse oximetry, which estimates arterial oxygen saturation ($S\text{aO}_2$). An oximeter has the advantage of allowing continuous monitoring but it provides no information on $P\text{CO}_2$. The general relation between oxygen pressure and saturation is defined by the oxygen–haemoglobin dissociation curve (Fig. 4). The position of this curve is influenced by the prevailing pH, temperature, and $P\text{CO}_2$. In addition, several rare abnormal variants of the haemoglobin molecule cause the curve to shift either to the right (reduced oxygen affinity) or the left (increased affinity). Approximate values for normal arterial and resting mixed venous $P\text{O}_2$ and saturation are shown in Fig. 4. Another clinically useful 'landmark' is a saturation of 90 per cent which, with a normally positioned curve, represents a $P\text{O}_2$ of approximately 8 kPa (60 mmHg). Also shown in Fig. 4 is the P_{50}, that is, the $P\text{O}_2$ at a saturation of 50 per cent, which for normal adult haemoglobin is approximately 3.5 kPa (27 mmHg). This is essentially an *in vitro* measurement which is used to characterize abnormal haemoglobin molecules associated with increased (low P_{50}) or decreased (high P_{50}) affinity for oxygen.

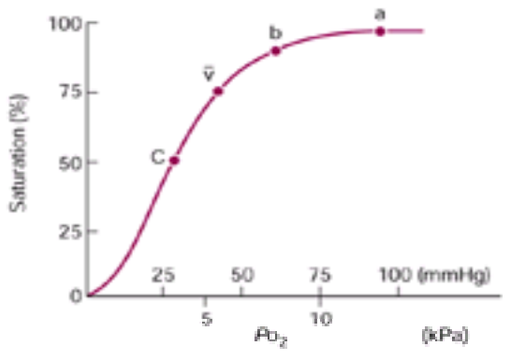

Fig. 4 Normal haemoglobin–oxygen dissociation curve relating saturation to PO_2. Point a represents normal arterial values (PO_2 90 mmHg, 12 kPa; SaO_2 98 per cent) and v normal resting mixed venous values (PvO_2 40 mmHg, 5.3 kPa; SaO_2 75 per cent). Also shown are the PO_2 (~ 60 mmHg, 8 kPa) corresponding to 90 per cent saturation (point b) and the P_{50} (point c), i.e. PO_2 corresponding to 50 per cent saturation (~ 27 mmHg, 3.5 kPa).

A reduction in PaO_2 can occur by various mechanisms (Table 4). In disease, the commonest is mismatching of alveolar ventilation ($_A$) and perfusion (). Even in healthy lungs, distribution of both ventilation and perfusion is uneven. In normal subjects this results mainly from the effects of gravity. In the upright posture, both ventilation and perfusion increase towards the lung bases, but the effects on perfusion are relatively greater, so that the ratio of ventilation to perfusion ($_A$/) is higher towards the apices and lower towards the bases. In disease, these relatively small gravitational effects are outweighed by unevenly distributed pathological changes affecting the distribution of ventilation or perfusion or both. Alveoli with greater than average $_A$/ have higher than average local PO_2 and lower PCO_2, that is, closer to those of inspired air. Conversely, those with lower than average $_A$/ have lower PO_2 and higher PCO_2, that is, closer to the values in mixed venous (pulmonary arterial) blood. The gas tensions in the draining pulmonary capillaries essentially reflect those of the alveoli which they subtend as, within a single alveolus, complete equilibration of local gas tensions usually occurs. For CO_2 the effects of high $_A$/ and low $_A$/ areas on the final arterial value approximately cancel each other out, that is, the $PaCO_2$ is close to the average value in all the capillaries draining the alveoli with a variety of local PCO_2 values. However, for oxygen the situation is different as blood draining alveoli with high $_A$/ (and relatively high local PO_2) cannot compensate for the areas with low $_A$/ (and low PO_2) because of the shape of the oxygen dissociation curve. The relatively flat upper part of the curve means that increasing PO_2 adds very little to oxygen saturation and therefore to oxygen concentration. Consequently, mixed pulmonary venous (and therefore systemic arterial) blood has an appreciably lower PO_2 than would be found in mixed alveolar air.

An approximate assessment of the overall effects of $_A$/ mismatching on arterial oxygenation and PaO_2 is given by calculation of the alveolar to arterial oxygen pressure gradient ($P(A\text{-}a)O_2 = PAo_2 - PaO_2$). This requires estimation of the average alveolar PO_2 (PAO_2) which is determined by the inspired PO_2 (PIO_2) and the average alveolar PCO_2 ($PACO_2$). For the reasons discussed above, alveolar and arterial PCO_2 (unlike PO_2) are virtually the same and the alveolar PO_2 is given simply by:

$$PAO_2 = PIO_2 - PaCO_2/0.8$$

The PIO_2 breathing room air at sea level is 20 kPa (150 mmHg). In normal young subjects the upper limit for $P(A\text{-}a)O_2$ is 2.5 kPa. It rises with age and in healthy subjects aged 60 to 70 years may be up to 4.7 kPa (35 mmHg). Unfortunately interpretation of the $P(A\text{-}a)O_2$ is complicated by the fact that its relation to the severity of $_A$/ mismatching is not constant. For a given degree of $_A$/ mismatching, the $P(A\text{-}a)O_2$ increases as the alveolar PO_2 increases. It therefore increases if the inspired oxygen is increased or if $PaCO_2$ falls (see Equation 1).

Alternative indices which relate more predictably to the degree of $_A$/ mismatching are the ratios of arterial to alveolar PO_2 (a/A PO_2) and of arterial PO_2 to the inspired oxygen fraction (PaO_2/FIO_2). The former is normally greater than 0.75 and changes little as FIO_2 increases, whereas the more traditional $P(A\text{-}a)O_2$ difference increases. The ratio of PaO_2/FIO_2 is widely used in assessment of patients with severe problems of oxygenation. For example, in acute lung injury a value greater than 300 (PaO_2 in mmHg, FIO_2 as a fraction) indicates relatively mild hypoxaemia, whilst a value of less than 100 represents very severe disturbance of gas exchange.

The dependence of $P(A\text{-}a)O_2$ on inspired oxygen is exemplified by the effects of breathing pure oxygen. This is used as a test for the presence of anatomical right to left shunting, since the effects of $_A$/ mismatching on PaO_2 are effectively eliminated by breathing pure oxygen. Even in diseased lungs, nitrogen is gradually 'washed out' of all the alveoli and the only remaining cause of arterial hypoxaemia is the anatomical shunt via channels which bypass the lungs, or through the capillaries supplying any alveoli which are totally unventilated. Although prolonged breathing of 100 per cent oxygen may itself encourage alveolar atelectasis which would exaggerate the shunt, in practice the technique is useful in investigation of causes of hypoxaemia. The usually quoted normal upper limit for the 'anatomical' shunt measured in this way is 5 per cent of the cardiac output. In terms of the PaO_2, a value greater than 500 mmHg (more than 73 kPa) is usually achieved, representing a $P(A\text{-}a)O_2$ of more than 100 mmHg, which greatly exceeds the normal upper limit when breathing room air. At these levels of PaO_2 haemoglobin is virtually fully saturated with oxygen and increasing the PaO_2 above 200 to 300 mmHg results in greater oxygen carriage by simple solution only. Consequently, increases in oxygen content and PO_2 become linearly related on the 'flat' part of the dissociation curve. As a rule of thumb, with a PaO_2 greater than 300 mmHg, each 20 mmHg of $P(A\text{-}a)O_2$ represents an anatomical shunt of 1 per cent.

Respiratory failure

Respiratory failure is defined conventionally in terms of the arterial blood gas tensions as a reduction in PaO_2 below 8 kPa (60 mmHg) at sea level, either without ('type I') or with ('type II') CO_2 retention. Hypercapnic (type II) respiratory failure is also known as ventilatory failure. The causes of type I respiratory failure are legion and include virtually all diseases which can affect the alveoli or the airways, either primarily or secondarily (as in cardiac failure). Hypercapnic (type II) respiratory failure is most commonly due to severe chronic airway disease and less often to reduced ventilation as, for example, with severe respiratory muscle weakness or scoliosis. The mechanisms of elevation of $PaCO_2$ in type II respiratory failure are twofold. Sustained 'pure' hypoventilation, that is, a reduction in overall ventilation resulting in hypercapnia, is rare. It is seen with inadequate performance of the respiratory 'bellows', for example in neuromuscular disease or because of reduced drive to breathe in the unconscious subject. Much more commonly in chronic airway disease, the 'effective' alveolar ventilation is reduced as a consequence of mismatching of ventilation and perfusion. In this situation there is often a considerable amount of ineffectual or wasted ventilation ('physiological dead space') and consequently in such patients the total ventilation is often greater than normal, even in the presence of hypercapnia.

Acid–base balance

The carriage of CO_2 by the blood and its excretion by the lungs constitute one of the two homeostatic mechanisms for regulating the acid–base status of the body. Because of the ease with which CO_2 excretion can normally be increased, the lungs are able to adjust acid–base balance much more rapidly than the kidneys.

The concentrations of hydrogen ions, bicarbonate, and carbonic acid in the blood are linked inevitably by the carbonic acid association/dissociation equation:

$$CO_2 + H_2O \text{ ?2; } H_2CO_3 \text{ ?2; } H^+ + HCO_3^-$$

This defines the chemical relation between the three variables, pH, PCO_2, and $[HCO_3^-]$ and if two are measured, the third is readily calculated. Abnormal acid–base disturbances are classified in terms of these variables as one of four classic types (Table 5 and Fig. 5), but combined disturbances are frequently seen. The commoner causes of acid–base disturbance are given in Table 6.

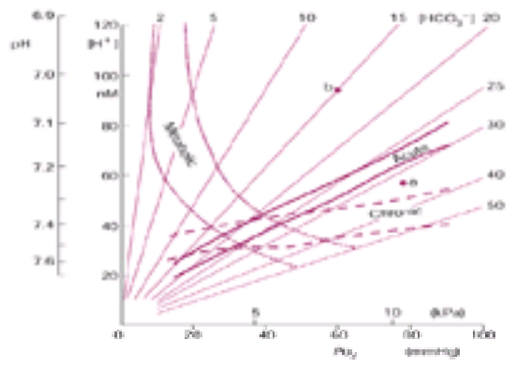

Fig. 5 Relations of pH and [H^+] to PCO_2 in acid–base disorders. Bands indicate the expected ranges in uncomplicated respiratory disorders (acute and chronic) and in metabolic acidosis and alkalosis. Isopleths represent corresponding estimates of arterial [HCO_3^-] (mmol/l). Values outside these bands indicate intermediate or combined disturbances. For example: patient a with an acute exacerbation of COPD has an 'acute on chronic' respiratory acidosis ($PaCO_2$ 10.6 kPa, pH 7.24, [HCO_3^-] 34 mmol); patient b with both respiratory and circulatory failure has a combined respiratory and metabolic acidosis ($PaCO_2$ 8 kPa, pH 7.04, [HCO_3^-] 15 mmol).

Respiratory acidosis and alkalosis

In respiratory acidosis the prime event is accumulation of CO_2 due to inadequate or ineffective ventilation. This causes the equilibrium of Equation 2 to shift to the right, generating both hydrogen and bicarbonate ions. The immediate increase in bicarbonate concentration is dictated by this chemical relationship and not by the physiological response, which occurs later. The vast majority of hydrogen ions produced are buffered by proteins with the result that the measured rise in [HCO_3^-] is actually very much greater than the measured increase in hydrogen ion concentration. (The logarithmic pH scale is deceptive in that both the hydrogen ion concentration in the blood and the changes which occur in disease are extremely small. For example, a normal pH of 7.4 represents a [H^+] of 40×10^{-9} mol, whereas [HCO_3^-] is measured to 10^{-3} mol, i.e. the hydrogen ion concentration is approximately 1 millionth of the concentration of bicarbonate). Conventionally the effects of acute respiratory acidosis are distinguished from the 'chronic' respiratory acidosis which results after several hours or days. This follows renal retention of even more bicarbonate, which in turn tends to correct the pH towards normal (Fig. 5).

In respiratory alkalosis the primary event is an increase in CO_2 excretion resulting from increased ventilation, so that both [HCO_3^-] and hydrogen ion concentrations fall (pH rises). Again, most of the reduction in hydrogen ion concentration is buffered. It is less useful to distinguish acute and chronic respiratory alkalosis than it is to distinguish acute and chronic forms of respiratory acidosis.

Metabolic acidosis and alkalosis

In metabolic acidosis, [H^+] rises (pH falls) and [HCO_3^-] falls. The physiological response is so rapid that acute and chronic phases are not distinguishable. Any tendency for $PaCO_2$ to rise (equilibrium of Equation 2 shifted to the left) is more than offset by the increased drive to breathe resulting from production of acid, and the measured effect is a reduction in $PaCO_2$.

In metabolic alkalosis there is an increase in [HCO_3^-] and a reduction in [H^+] (pH increases). The measured result is somewhat variable as opposing influences are involved; any increase in $PaCO_2$ tends to stimulate breathing but the reduced acidity tends to inhibit it. In subjects with healthy lungs, the net effect is often maintenance of $PaCO_2$ in the high normal range, unless the alkalosis is profound (as, for example, is seen with pyloric stenosis and severe depletion of acid). However, in patients with chronic airway disease and either pre-existing or incipient hypercapnia, a more marked increase in $PaCO_2$ is frequently seen. This is particularly relevant to patients with COPD receiving treatment with diuretics and corticosteroids, both of which tend to produce a metabolic alkalosis.

Several other indices of acid–base status have their advocates. Standard bicarbonate, base excess and deficit, and total buffer base are often derived when blood gases are measured by automated equipment. They are obtained by titration of the blood *in vitro* to specified standard values of pH and/or PCO_2. As such, they are open to the very real objection that the results differ from those which would be obtained if the same titration could be performed *in vivo*, where the extracellular fluid, and not just the blood, participates in buffering. Indices such as standard bicarbonate and base excess are used mainly to distinguish 'respiratory' and 'metabolic' components of an acid–base disturbance, but in this context the 'metabolic' component includes renal compensation for a primary respiratory disturbance. Consequently, in a respiratory acidosis an increased standard bicarbonate indicates some degree of chronicity.

One further frequently available index of acid–base status is the venous 'bicarbonate' (strictly total CO_2 content) which is often obtained routinely when electrolytes are measured. A raised value is seen with primary metabolic alkalosis, but in patients with respiratory disease it may be a useful clue to unsuspected ventilatory failure.

Exercise testing

Exercise tests allow observation of patients and their performance at a time when symptoms are present. This can be useful in assessing breathlessness as the meaning of the term varies among patients: to some it means excessive ventilation, to others difficulty in breathing because of airway narrowing, while some interpret the sensation of myocardial ischaemia as breathlessness. Formal quantification of exercise performance also provides objective assessment of disability and an exercise test may give useful information on the likely factors limiting exercise in that individual.

In healthy subjects, ventilation and cardiac output increase progressively with oxygen consumption. Oxygen uptake (O_2) increases with work rate, but at high levels of exercise anaerobic respiration increases with generation of lactate. Initially, CO_2 output increases in proportion to oxygen consumption until increasing anaerobic metabolism results in disproportionate production of CO_2. Measurement of an 'anaerobic threshold' is favoured by some investigators, but the criteria used for its identification are not universally agreed.

The maximum oxygen consumption or maximum aerobic capacity of a healthy subject is determined by the ability of the circulation to supply oxygen to exercising muscle, rather than by the maximum ventilation which can be achieved. In patients with pulmonary disease, particularly airway disease, the maximum attainable ventilation is reduced, approximately in proportion to the abnormality of pulmonary mechanics. This may then determine exercise capacity, although circulatory factors and deconditioning also contribute in many patients and dominate in some.

Exercise tests vary considerably in complexity and in the number and types of measurements made. Simple self-paced tests of walking distance, most commonly in 6 min, aim to mimic the real life situation and are widely used for global assessment of disability. However, such tests are insensitive to mild disease and there is a significant learning effect, as well as dependence on motivation and encouragement. In the shuttle walk test the subject increases his walking speed each minute, giving results which are more reproducible and closer to laboratory-based tests of maximum performance. More formal testing involves exercise on a bicycle ergometer or treadmill. Usually the workload is increased by a constant amount, with periods of 1 to 3 min at each level. Measurements include heart rate, ventilation, and gas exchange (O_2 and CO_2) and oxygen saturation by pulse oximetry. The subject exercises at increasing loads until no longer able to continue because of discomfort, or until stopped by the investigator. The maximum oxygen consumption (symptom limited O_2max) is a useful indicator of overall exercise capacity. Comparison of the maximum ventilation and heart rate at the end of progressive exercise with those predicted from spirometric measurements and age, respectively, gives some indication of the likely factor(s) limiting performance. The level of breathlessness at each workload in an incremental test can also be usefully assessed using simple self-rating scales (visual analogue scale or Borg scale). Arterial oxygen desaturation is seen particularly in interstitial lung disease and pulmonary vascular disease and this may be helpful in predicting which patients are likely to benefit from use of ambulatory oxygen.

A common reason for performing an exercise test is to evaluate the main cause of breathlessness and, in particular, to determine whether this is due predominantly to

cardiac or ventilatory abnormalities. If a patient achieves the predicted maximum heart rate during a progressive test (as is seen in normal subjects), it is reasonable to conclude that the limit to further exercise is set by the cardiovascular system. In most respiratory diseases, patients cease exercise with a lower heart rate as more often the limit is set by the maximum ventilation achievable.

The identification of exercise-induced asthma has rather different requirements. During exercise, most subjects with asthma show some degree of bronchodilatation, and in those who develop exercise-induced asthma, bronchoconstriction develops after exercise. Many patients with asthma, of course, become breathless during exercise, but this is not necessarily due to bronchoconstriction. The intensity of exercise necessary to provoke asthma is relatively high and for this reason exercise-induced asthma is relevant mainly to children and young adults. Optimally it is demonstrated after exercise for at least 5 min at a constant rate, chosen to increase ventilation to around 50 per cent maximal or to increase heart rate to around 80 per cent maximal. FEV_1 or peak flow should be measured beforehand and for up to 30 min afterwards.

Miscellaneous tests

Analysis of expired air has traditionally been limited to oxygen and carbon dioxide, but recently attention has turned to other gases which are present in very low concentrations. The concentration of exhaled carbon monoxide has been used for some years as a guide to its inhalation and as a valuable method for confirming non-smoking claims. The measurement can now be made very simply with a portable analyser. Breath carbon monoxide is also increased in non-smoking subjects with asthma, where it appears to be released as a result of airway inflammation. In similar fashion, expired nitric oxide concentration is increased as a consequence of airway inflammation and it has been proposed as a non-invasive way of assessing airway inflammation and its treatment, particularly in those with asthma. Care needs to be taken to avoid contamination of expired air from the bronchial tree with that from the nose and nasal sinuses, which contain higher concentrations.

17.3.3Microbiological methods

*Robert Wilson**

Microbiological investigations in clinical practice

Microbiological investigations are an important part of the management of infected patients, since few aetiological agents produce diagnostic clinical features and other investigations are not specific. However, treatment of a severe infection should not be delayed while awaiting the results of laboratory tests because this can be fatal. Clinicians need to know the types of respiratory infection that are prevalent and the likelihood of antibiotic resistance to enable them to select appropriate empirical treatment. However, the level of microbiological investigation needed to provide this information for surveillance purposes usually exceeds that required in clinical practice.

Once the clinical diagnosis of a respiratory infection has been made the physician must decide whether to perform any investigations before starting treatment. The type of patient and the severity of the illness will guide this decision. However, even with extensive testing, it is recognized that the causal pathogen may not be identified in over 50 per cent of patients with community-acquired pneumonia, a condition in which a bacterial aetiology is most likely. The proportion of negative results rises steeply if the patient has received an antibiotic before the microbiological samples are taken. Other explanations for negative bacteriology results include a viral infection being the cause, the presence of non-infectious conditions mimicking pneumonia, the presence of unusual pathogens that go unrecognized (for example, fungi), and the presence of pathogens that are currently not identified or recognized.

This chapter describes the available microbiological methods, and Table 1 indicates the clinical conditions for which they should be used. Some patients should receive more intensive investigation. These include those patients with more serious illness; those with underlying medical problems that put them at higher risk of serious illness (for example, those who are immunocompromised); those at risk of exposure to more unusual pathogens (for instance, nursing-home residents), or of nosocomial infections; and those not responding to treatment. Decisions regarding more invasive investigations, which might have a greater likelihood of giving a positive result, need to be balanced against the risks of any procedure.

Interpretation of results

The interpretation of positive microbiological results may call for fine judgement, and careful consultation between the clinician and medical microbiologist. There are two situations that commonly cause difficulty: the isolation of a species which is part of the commensal flora, and the isolation of an opportunistic pathogen. In these circumstances particularly, but true always, the microbiological results should be considered together with the clinical information and the results of non-microbiological investigations.

The mucosal surfaces of the mouth, nose, pharynx, larynx, and trachea are colonized by a complex variety of bacterial species that make up the commensal flora, whereas the middle ear cavity, the paranasal sinuses, and the lower airways distal to the first bronchial division are usually sterile. The commensal flora confer a level of protection against infection by occupying a niche within the body that might otherwise be colonized by species with greater pathogenicity, and by providing non-specific and specific (via crossreactive antigens) stimulation to the immune system. Some of the commensal species, for example *Streptococcus pneumoniae* and unencapsulated non-typable *Haemophilus influenzae*, may, under permissive conditions, be pathogenic and are amongst the most common causes of respiratory infection.

Many respiratory samples are obtained via routes that are naturally colonized by commensal flora (for example, expectorated sputum), so there is always some uncertainty whether the bacterium has been cultured from the putative site of infection in the bronchial tree or has contaminated the sample during its passage through the oropharynx. A significant proportion of exacerbations of chronic bronchitis have a non-bacterial aetiology, but clinical information can be used as a guide, since patients who have an increased sputum volume which is purulent and increased breathlessness are more likely to have a bacterial infection.

Opportunistic pathogens do not infect patients with intact normal host defences, but do so if the host defences are impaired, either by a humoral or cellular defect, or when the defences are breached artificially, for example by an endotracheal tube. Opportunistic pathogens, for example *Pseudomonas aeruginosa*, have relatively low pathogenicity. However, chronic infection commonly occurs for many years in conditions such as cystic fibrosis and other forms of bronchiectasis. Patients have acute exacerbations intermittently when their symptoms increase and the level of lung inflammation is greater. The sputum bacteriology during these exacerbations is usually the same as when the patient is in a stable state, although bacterial numbers may be greater. Other features, such as the white cell count and C-reactive protein level are helpful in differentiating an acute exacerbation. *P. aeruginosa* can also colonize the bronchial tree of patients who are being ventilated, without causing a significant deterioration in their condition, but this bacterium is also a major cause of ventilator-associated pneumonia, a condition with high mortality. An increase in temperature and the appearance of a new infiltrate on the chest radiograph, as well as a rise in the inflammatory markers, signal the onset of pneumonia.

Direct investigations

Non-invasive tests

Upper respiratory tract samples

Nose and throat swabs provide no useful information about the likely pathogen in patients with sinusitis and otitis media. Throat swabs should be performed during investigation of suspected complications of group A b-haemolytic streptococcal pharyngitis (acute rheumatic fever or glomerulonephritis). Virus isolation is dependent on the presence of an adequate number of infected epithelial cells and high-quality samples are imperative; nasopharyngeal washes or aspirates may provide a better sample than swabs in paediatric cases.

Sputum culture

The information gained from this frequently performed test is limited, unless careful steps are taken to improve specificity. Often, the patient cannot produce a sample to order, which limits its usefulness for outpatients or when empirical treatment is to be commenced quickly. The sample should be transported to the laboratory within 2 h to avoid overgrowth by rapidly growing species. The yield of positive cultures is higher if the sample is purulent; a good sample should have fewer than 10 squamous epithelial cells, indicating the lack of significant contamination from the upper respiratory tract, and more than 25 neutrophils per low-power field (at 100 × magnification). As bacteria are unevenly distributed in sputum, the sample is first homogenized by vigorous agitation in Ringer's solution or by the addition of a commercially available digestion agent, and then is diluted so that a quantitative assessment can be made of the bacteria present.

Gram stain of sputum has been advocated as a rapid diagnostic test, such as when Gram-positive diplococci are seen indicating a pneumococcal pneumonia. However, interpretation of the stain can be subjective and this test should not be performed by an inexperienced observer. In addition, it has to be kept in mind that respiratory infections can be mixed, so focused therapy based on the result of a Gram stain might not cover co-infection with an atypical pathogen such as *Mycoplasma pneumoniae*.

Sputum culture is an important non-invasive investigation in patients with pneumonia of sufficient severity to lead to hospital admission. However, it is rarely useful in the community; nor is it usually helpful in chronic bronchitis, when the results are predictable and unlikely to influence the choice of antibiotic. It might be considered if

a patient fails empirical therapy, when culture may reveal a b-lactamase-producing strain, or occasionally in severe chronic obstructive pulmonary disease an unexpected pathogen such as *P. aeruginosa*. Results of routine sputum culture performed in a cystic fibrosis outpatient clinic (and in other patients with chronic infection, for example bronchiectasis) may be used to guide empirical treatment when the patient presents with an acute exacerbation; sensitivity testing is also useful in these situations to monitor the development of resistance. A new pathogen that would alter management, for example *Burkholderia cepacia*, might also be identified by routine screening of this type of patient.

A range of culture media are inoculated: blood agar, chocolate (heated blood) agar to aid the isolation of *Haemophilus* species, and MacConkey's agar for some Gram-negative bacilli and coliforms. Special culture medium can be used for other bacteria, for example *Legionella* species, various fungi, and acid-fast bacilli. Although many species can be identified to guide the choice of antibiotic after overnight culture, full identification and determination of antibiotic sensitivities take a further 24 h. For some patients (for example, cystic fibrosis with mixed infections), a range of selective media can be used to encourage the growth of some species whilst suppressing others. Additional special staining techniques can be used in appropriate clinical circumstances, for example for acid-fast bacilli and *Pneumocystis carinii*. Culture of *Mycobacterium tuberculosis* on standard media such as Lowenstein–Jensen used to take 6 to 8 weeks before antibiotic sensitivities were available, but nowadays more rapid automated liquid cultures, for example BACTEC®, provide a result in 2 to 4 weeks.

A considerable proportion of patients cannot produce a sample of sputum even with the help of a physiotherapist. This difficulty led to the development of a technique to induce sputum, which has been particularly useful in human immunodeficiency virus (**HIV**)-infected patients with suspected *P. carinii* or mycobacterial infection. The patients brush their teeth and gums, gargle with water, and hydrate themselves with a couple of glasses of water. They then inhale nebulized 3 per cent saline for 20 min, and every 5 min are encouraged to cough. A b2-agonist can be given before the procedure, but the technique has been limited in its application because of the severity of coughing and bronchospasm that may be produced. The procedure should not be performed in an open ward or an area where there are other immunocompromised patients, because of the danger of spreading pathogens.

Several new diagnostic tools have been developed or are in development to examine sputum and other specimens. Broadly speaking, these detect antigens or other products of micro-organisms directly by immunological techniques based on monoclonal antibodies; or they use molecular techniques to identify the organism's DNA or RNA, either directly using a probe or following amplification by the polymerase chain reaction (**PCR**). At the present time, molecular techniques are most commonly used in selected patients to identify *M. tuberculosis*, and in particular isolates carrying the antibiotic-resistance gene for rifampicin. Probes for other resistance genes will follow in time and provide a powerful tool in the diagnosis of multidrug-resistant tuberculosis. Molecular techniques are also being introduced for the detection of cytomegalovirus from cases of pneumonia in immunodeficient patients. It is in this area that new microbiological methods in the diagnosis of respiratory infections are likely to appear, and they will be particularly useful if problems of sensitivity and specificity can be solved so that they can be applied to readily obtained samples such as sputum.

Other non-invasive investigations

In patients with pneumonia two sets of blood cultures should be taken before antibiotics are started. Bacteraemia is intermittent, so ideally samples for culture should be taken at least 1 h apart using the inoculum volume recommended by the supplier, but treatment should not be delayed unless the patient's condition allows it. The presence of bacteraemia increases the risk of complications from pneumonia, so a positive result has prognostic as well as diagnostic implications. However, the sensitivity of the investigation is only 10 to 20 per cent overall, with *S. pneumoniae* being the most common pathogen identified by this method.

A significant pleural effusion should always be aspirated and the following investigations requested: white cell count and differential; measurement of protein, glucose, lactate dehydrogenase, and pH; Gram stain and staining for acid-fast bacilli; culture for bacteria, mycobacteria, and fungi.

Pneumococcal antigen detected in the urine by counter-immunoelectrophoresis has an acceptable sensitivity, which is even higher in pleural fluid, but this is a cumbersome test to perform in the laboratory and is rarely used. *L. pneumophila* antigen in the urine is now used routinely and identifies serotype-1 infection, which is the most common serotype causing pneumonia.

The isolation of respiratory viruses requires sensitive cell-culture systems. Incubation time is very variable from 24 h with herpes simplex to 14 days for cytomegalovirus, but in most cases it is too long for the test to be clinically useful. Viral infection of exfoliated cells can be diagnosed rapidly using immunofluorescent techniques incorporating monoclonal antibodies. Conjugated monoclonal antibodies are available for a range of viruses including respiratory syncytial, influenza, parainfluenza, adeno- and cytomegaloviruses, as well as other microbes (for example *L. pneumophila* and *P. carinii*). Other viruses may require an indirect method using unlabelled mouse antibody and a second step with anti-mouse conjugated antibody.

Invasive tests

A number of invasive diagnostic techniques have been developed to obtain specimens directly from the lower airways that are relatively uncontaminated by oropharyngeal flora. In all cases, the yield is greater if antibiotics have not been commenced prior to the procedure; if the patient is already receiving antibiotics they should not have been changed for several days before the test is performed.

Transtracheal aspiration

Although still performed in some centres this approach is not recommended due to poor patient tolerance and low specificity.

Bronchoscopic protected brush catheter (PBC)

This technique employs a double-catheter brush system which is inserted via the bronchoscope. A distal wax plug in the catheter is dislodged by advancing the inner catheter only when the bronchoscope is in the correct position to take a sample from the identified area. The brush is advanced to take the specimen and then retracted before withdrawing the whole catheter from the bronchoscope. The brush is aseptically cut into a vial containing Ringer's solution, or its equivalent, and agitated to ensure all bacteria are removed, then quickly transported to the laboratory where quantitative cultures are performed. Care should be taken when interpreting the results obtained from patients with chronic obstructive pulmonary disease who can have lower airway bacterial colonization without parenchymal infection.

Bronchoscopic bronchoalveolar lavage (BAL)

This technique also uses the bronchoscope to obtain samples from distal airways and the alveolar space, but it is more likely to be contaminated by nasopharyngeal commensals during insertion of the bronchoscope in the non-ventilated patient. The bronchoscope is wedged into a distal segment of the identified area and sterile normal saline (about 50 to 100 ml) is instilled and aspirated to provide about 10 ml for investigation. The fluid from an initial aliquot may be discarded to try to reduce any contamination with bacteria from the upper airways. Squamous epithelial cells signify upper airway contamination, while the presence of intracellular organisms in phagocytic cells indicates true bacterial infection. Quantitative cultures are again recommended. A certain level of bacterial growth is required to be regarded as significant in both PBC and BAL, usually 10^3 colony-forming units/ml for the former and 10^4 colony-forming units/ml for the latter. However, detection of some microbial species should be considered significant whatever their concentration—for example, *P. carinii*, *Toxoplasma gondii*, *Legionella* species, *M. tuberculosis*, respiratory syncytial virus—whereas isolation of fungi and environmental *Mycobacteria* species need to be correlated with clinical and radiographic findings.

Percutaneous fine-needle aspiration

This may be guided by computed tomography (**CT**) scanning. Complications are infrequent in centres experienced in this technique.

These invasive procedures are rarely used in patients with community-acquired pneumonia, particularly since retrospective data has shown that outcome is not improved by establishing a specific aetiology in those patients with a severe illness. However, bronchoscopy is useful in patients who have failed empirical therapy. This may reveal resistant or unusual pathogens or a mechanical factor delaying resolution, for example an obstructing endobronchial lesion.

Invasive procedures are used more commonly in the immunocompromised patient with pneumonia, when the range of pathogens is much larger, and consequently the choice of empirical therapy much more difficult. In addition, the likelihood of a non-infectious cause of 'pneumonia' is greater. The bronchoscopic techniques have reasonable sensitivity and specificity when performed correctly, carry less risk of complications, and are usually more acceptable to patients. A transbronchial biopsy

can be taken during the bronchoscopy to obtain lung tissue for histology and culture. Direct histological examination of the lung or pleura is important in several situations: detection of herpes simplex virus or cytomegalovirus is not an accurate indicator of pneumonitis without histological confirmation; cytomegalovirus pneumonitis is clinically very similar to acute rejection in transplant patients; granulomas suggest mycobacterial or fungal infection and acid-fast bacilli or fungi with characteristic features may be seen.

In ventilated patients there is less agreement about the role of invasive tests. Culture of endotracheal aspirates should be performed routinely. Failure to culture bacteria from a patient not being given antibiotics has a high negative predictive value for ventilator-associated pneumonia. There may be a higher percentage of false-positive results compared to bronchoscopic techniques, due to bacterial colonization; but quantitative cultures taken together with clinical information and the results of other investigations usually indicate the significance of a positive culture. In ventilator-associated pneumonia this approach is simpler than bronchoscopy; moreover, studies have failed to demonstrate that the information obtained from invasive techniques reduces mortality. Also, bronchoscopy may not be readily available in some hospitals, and by sampling a limited area of the lung it may be less sensitive.

Indirect investigations

Respiratory infections caused by a range of pathogens can be detected late in the infection or retrospectively by serological tests. The delay required until the antibody response occurs means that the results are rarely clinically relevant and these investigations therefore do not need to be performed routinely.

Serological methods are commonly used for viral infections and the atypical bacterial pathogens that are difficult to culture: *L. pneumophila*, *M. pneumoniae*, and *Chlamydia pneumoniae*. Seroconversion takes 3 to 6 weeks, but in elderly patients legionella can take up to 14 weeks. In several rarer infections (for example, histoplasmosis, coccidiomycosis, filariasis), a positive antibody result suggests the presence of active infection. Several serologic methods are available. For many years the most widely used, because of its flexibility, was the complement fixation assay. This detects primarily IgG antibody and, therefore, requires a fourfold rise in antibody levels between acute and convalescent serum samples to demonstrate a new infection. The complement fixation assay has now been replaced for some species by enzyme-linked immunosorbent assays (**ELISA**) that detect specific IgM, which is predictive of a recent or active infection in a sample collected 10 days or more after the onset of symptoms.

*I thank Maureen Chadwick and Paul Taylor from the Microbiology Department at Royal Brompton Hospital for their helpful comments on the manuscript.

17.3.4 Diagnostic bronchoscopy, thoracoscopy, and tissue biopsy

M. F. Muers

Introduction

Diagnostic bronchoscopy, thoracoscopy, and tissue biopsy are an integral part of the investigation of respiratory disease. They should be regarded as complementary to, rather than substitutes for, simpler and cheaper tests.

The introduction of the flexible fibreoptic bronchoscope by Ikeda in 1974 and the subsequent improvements in instrumentation, together with a widening number of applications, have revolutionized the practice of respiratory medicine worldwide. By contrast, rigid bronchoscopy—although essential in some circumstances—has become much less common. Thoracoscopy, the examination of the pleural cavity by a percutaneously introduced instrument, was first performed in 1913 by the Swedish physician, Jacobaeus. The technique has remained similar ever since, but has in recent years been substantially improved with the introduction of video-assisted equipment—the **VATS** (video-assisted thoracoscopic surgery) approach. With respect to other methods of tissue sampling, the major change in recent years has been the improved accuracy and safety of percutaneous needle-biopsy techniques by the simultaneous use of cross-sectional imaging or ultrasound.

Bronchoscopy

Indications (Table 1)

Bronchoscopy is mainly used to investigate or confirm the possibility of carcinoma, and/or to obtain histological and cytological confirmation of a clinical diagnosis, and to provide evidence about operability. A diagnosis at bronchoscopy does not just depend on tissue sampling as many abnormal appearances are characteristic. It is particularly useful in excluding endobronchial abnormalities as a cause for persistent symptoms in the presence of a normal radiograph. The use at bronchoscopy of imaging and flexible instruments allows sampling of distal bronchi or lung parenchyma that cannot be seen directly.

Techniques

Fibreoptic bronchoscopy

Fibreoptic bronchoscopy is usually an outpatient procedure, done with local anaesthesia and sedation. The list of preoperative requirements is shown in Table 2. The procedure causes a fall in PaO_2 of about 2.5 kPa. For this reason, and particularly because many patients have impaired lung function, oxygen supplementation by nasal cannulation to maintain the SaO_2 at 90 per cent or greater is recommended, with oxygen saturation monitored by pulse oximetry and oxygen supplementation continued postoperatively.

The bronchoscope is best inserted through the nose, but if the nasal passages are too narrow, the instrument can be inserted through the mouth with an appropriate guard. The nose, oropharynx, vocal cords, and bronchial tree are anaesthetized with lidocaine (lignocaine) aerosol or gel. Care must be taken not to over use lidocaine: a maximum total dose <7 mg/kg should be ensured.

There have been four large retrospective studies of the safety of fibreoptic bronchoscopy involving between 4000 and 48 000 patients. Reported mortality rates have ranged between 0 and 0.04 per cent and major complication rates between 0.08 per cent and 0.5 per cent. It is accepted that the risk of complications is greater when transbronchial biopsy is performed, in the presence of coagulopathies, and in patients who are frail or very ill.

Postprocedure infection is very rare, occurring in one in 2500 procedures in a large study. There have been no reported cases of the human immunodeficiency virus (**HIV**) being transmitted by bronchoscopy. However, contamination of bronchoscopes is important for another reason, namely that organisms introduced into the lungs and sampled may give a false impression of infection. This is a particular difficulty with non-tuberculous mycobacteria, which can grow in contaminated rinse water and be resistant to some disinfectants. The most common disinfecting agent is gluteraldehyde. This has to be handled with care: it is a potent sensitizer of the respiratory tract and aerosol contamination of the working environment can put staff at risk of contracting occupational asthma.

Rigid bronchoscopy

Rigid bronchoscopy is performed under general anaesthesia with oxygen Venturi ventilation. The procedure is indicated if previous fibreoptic bronchoscopy has failed to make a diagnosis and there is still a suspicion of pathology, if there is anxiety about uncontrolled bleeding, or when foreign body removal is being contemplated. Most surgeons will re-inspect the bronchial tree before a planned resection to reassess operability, and rigid bronchoscopy offers better conditions for some difficult therapeutic procedures such as laser therapy and the insertion of stents—although both of these can be performed with the fibreoptic instrument. Rigid bronchoscopy

is preferable for children.

Diagnosis at bronchoscopy

The standard 5-mm diameter fibreoptic bronchoscope allows inspection of all the lobes to subsegmental level; smaller 3-mm diameter paediatric bronchoscopes extend this range of vision but cannot be used for biopsies. Approximately 70 per cent of bronchial carcinomas are within visible and sampling range. Many diagnoses can be made without biopsy: for example, paralysis of the left recurrent laryngeal nerve causing vocal cord paresis; endobronchial pus from infected segments; distortion due to lung collapse or metastatic carcinoma; or a large endobronchial tumour (Fig. 1 and Plate 1). Although the appearance of many tumours is quite characteristic, it must be borne in mind that the differential diagnosis of primary lung cancer at bronchoscopy includes adenomas, endobronchial metastatic deposits, for example from breast cancer, or more rarely endobronchial tuberculosis or sarcoidosis.

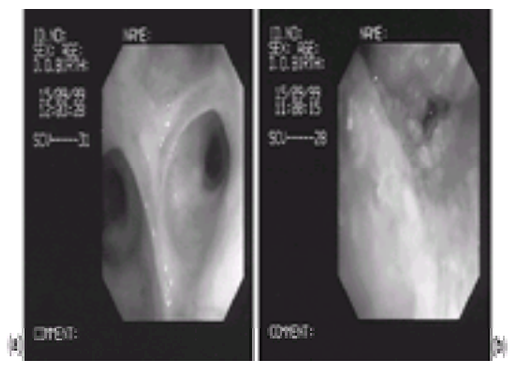

Fig. 1 Appearances at bronchoscopy. The normal thin mucosa and sharp interlobar carinae of the normal left side (a) are in contrast to the irregular exophytic appearance of an advanced non-small cell tumour of the right main bronchus (b) in the same 73-year-old patient. (See also Plate 1.)

Endobronchial brushing, biopsy, and 'washing'

The majority of endobronchial lesions are carcinomas and best sampled by a combination of brushing of the surface for cytology, forceps biopsy for histology, and (where sampling has been difficult) bronchial 'wash' for cytology. Sheathed disposable nylon brushes can safely be applied to most tumours and the resulting specimens rubbed on to slides and air- or ethanol-fixed for cytology. Flexible biopsy forceps provide adequate samples from most endobronchial tumours, but it is advisable to take up to four or five biopsies of each lesion. For a diagnostic bronchial wash, 20 to 40 ml of normal saline is injected over the endobronchial lesion into the peripheral lung and the residual fluid rapidly aspirated in to a trap. A combination of brushing, biopsy, and washing gives the highest yield for malignancy, and this should be well over 80 per cent. If the tumour appears vascular, it is wise to brush first, and proceed to biopsy if significant bleeding does not occur.

A bronchial wash is also useful for microbiological tests particularly for mycobacteria or fungi—for example, if there is a suspicion of tuberculosis in an upper lobe, but no sputum.

Bronchoalveolar lavage

This technique provides a sample of cells from the peripheral airways and alveoli of a lung segment or lobe. It is occasionally useful for the diagnosis of diffuse lung disease, and has been used extensively as a research tool. A bronchoscope is wedged into a segment of lung, either guided by a radiographic abnormality or if not, usually the right middle lobe. Between 150 and 300 ml of buffered normal saline at 37 °C are instilled by syringe pressure in 50 to 60 ml aliquots. Low-pressure suction is continuously applied after each aliquot and the aspirated fluid collected in a trap, the average return being approximately 60 per cent of the injected volume. Particular care has to be taken when the procedure is undertaken in patients with an FEV_1 of less than 1.5 litres (**FEV_1**, forced expiratory volume in 1 second). Supplementary oxygen is nearly always necessary, and after 10 per cent of lavages there is transient pyrexia lasting for between 4 and 8 h.

The lavage specimen is centrifuged down and subjected to cytological examination, when absolute yields and differential cell counts as well as functional studies can be made (Table 3). Lavage in normal non-smoking subjects shows a preponderance of alveolar macrophages with less than 20 per cent of the cells being lymphocytes, polymorphonuclear neutrophils, and eosinophils. Cell counts are increased approximately threefold in smokers and altered in many diffuse lung diseases, particularly sarcoidosis and allergic alveolitis. Although characteristic profiles can be recognized, lack of specificity is a major problem, and in routine clinical practice they provide only supportive evidence for most diagnoses. There are, however, a few pathognomonic appearances (see Table 3). Lavage specimens are particularly useful in the investigation of diffuse lung shadowing in patients who are immunocompromised (see below).

Transbronchial biopsy

This technique enables specimens of lung parenchyma (namely small bronchi, bronchioles, alveoli, and their associated vessels) to be examined. It may be useful in the diagnosis of diffuse parenchymal lung disease (**DPLD**) and occasionally in the diagnosis of localized lesions, for example persistent consolidation.

Closed, flexible, bronchial biopsy forceps are advanced to within about 1 cm of the pleura and then opened, next they are moved gently backwards and forwards two or three times to ensure full opening, before being firmly advanced more peripherally, whilst the patient is asked to breathe out (Fig. 2). The forceps are then closed and withdrawn, usually with a perceptible 'tug'. The bronchoscope is left in position to check there is no appreciable bleeding. The specimens, which are approximately 1 to 2 mm^3, are put in formal saline for histology, or in normal saline for microbiological culture. The diagnosis of diffuse lung disease needs two or three specimens, and more are required for the accurate diagnosis of focal lesions. The diagnostic rate depends very much on the lung pathology being sampled. In fibrosing alveolitis biopsies are often unsatisfactory, but in a condition such as lymphangitis carcinomatosa or sarcoidosis, diagnostic rates may approach 80 per cent or more. For peripheral tumours, the diagnostic rate depends upon the size, but it is characteristically about 50 per cent. An alternative procedure here is a percutaneous lung biopsy.

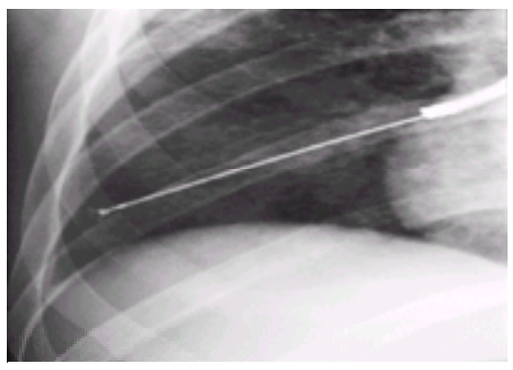

Fig. 2 Transbronchial biopsy through the fibreoptic bronchoscope. The bronchoscope is wedged in the right lower lobe bronchus. Flexible biopsy forceps have been advanced to within 1 cm of the chest wall under screening. The diagnosis: miliary tuberculosis in a renal transplant recipient.

Complications are more common in immunocompromised patients or in the presence of coagulopathies. Mild haemorrhage occurs in 5 to 10 per cent of patients, and pneumothorax in 1 to 5 per cent, with a mortality rate of approximately 0.1 per cent. Bleeding can be reduced by the bronchoscopic injection of 1 to 5 ml of 1:10 000

epinephrine (adrenaline). Because of the risk of pneumothorax, transbronchial biopsy is usually restricted to one lung, although bilateral samples are taken in cases of heart lung transplantation for the surveillance of transplant rejection. A postprocedure radiograph is usual: if pneumothorax is not present 1 h afterwards, it is very unlikely to develop later. There is debate as to whether fluoroscopic screening is required routinely: it is certainly an advantage when the technique is being learned, but in skilled hands the yield and complication rate is similar whether or not screening is used. It is possible to take transbronchial biopsies from patients on intermittent positive-pressure ventilation, but under these circumstances bronchoalveolar lavage alone or an open lung biopsy is probably safer and the latter has a far higher chance, usually, of achieving an accurate diagnosis.

Transbronchial needle aspiration

This technique can be used to sample abnormal bronchial mucosa, peripheral lesions, and occasionally peribronchial lymph nodes. A sampling needle, in a flexible sheath, is passed through the bronchoscope and the needle advanced into lung tissue. Suction is applied to obtain a cell sample.

The technique can be used in addition to, but not usually as a substitute for, the assessment of endobronchial tumours by forceps biopsy, brush, and wash. It is likely to be more useful if a carcinoma has spread submucosally, when bronchial biopsies are often difficult. In this instance the needle is inserted at an angle to the bronchial wall.

Transbronchial needle aspiration is an alternative to transbronchial forceps biopsy for the assessment of peripheral lesions under fluoroscopic guidance. For small peripheral lesions less than 2 cm in diameter, the sensitivity is similar to that of forceps biopsy, about 35 per cent, but may be up to 75 per cent for larger lesions.

Transbronchial needle aspiration can be used to stage lung cancer by obtaining samples from peribronchial nodes. The technique used is similar to that for submucosal sampling, but the needle has to be inserted more perpendicular to the bronchial wall, between bronchial cartilage rings. There is good evidence that directing sampling in the light of a previous thoracic computed tomography (**CT**) scan improves the yield. Under these circumstances about 65 per cent of true-positive nodes may be sampled. The technique is relatively easy when subcarinal nodes are sampled but is much more difficult if the nodes are paratracheal. Probably for this reason, most centres still prefer mediastinoscopy or mediastinotomy.

Bronchoscopic bronchography

High-resolution CT (**HRCT**) is now the diagnostic methods of choice for the investigation of possible bronchiectasis. Bronchography is reserved for the uncommon indication of a focal lung lesion in which HRCT has given equivocal results.

Percutaneous needle biopsy

In 1883 Leyden made a diagnosis of pneumonia by needle aspiration, and in 1886 it was used by Menetier to diagnose lung cancer. The development of fine-bore needles and screening techniques means that this is a very widely used method of obtaining lung tissue. The indications for needle biopsy are usually to confirm a diagnosis of lung cancer, particularly where there is a peripheral lesion not easily accessible to bronchoscopy; occasionally to prove that a lesion is benign; to obtain micro-organisms from an area of consolidation or abscess; and to diagnose a mediastinal mass.

Percutaneous fine-needle aspiration biopsy (FNAB)

This produces samples for cytological examination, but lung architecture is not preserved. Screening is required: fluoroscopic, CT, or (if the lesion abuts the pleura) real-time ultrasonography. A fine spinal 22- to 25-gauge needle is advanced perpendicular to the skin under local anaesthesia until the tip lies within the lesion (Fig. 3). Suction is applied and the needle tip is moved slightly to increase the tissue yield. Aspirated material is expressed on to slides for cytology, or sent for culture. The procedure can be repeated, but multiple passes increase the chance of a pneumothorax. A postprocedure radiograph is mandatory.

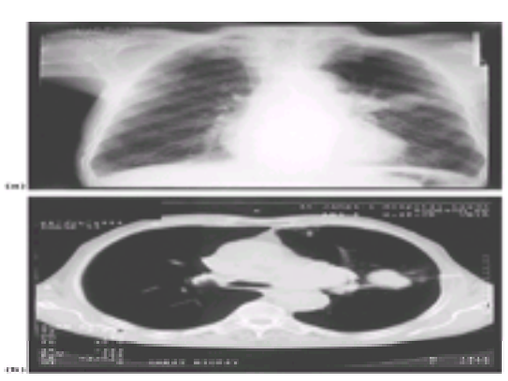

Fig. 3 Chest radiograph (a) showing a mass in the left upper lobe with hilar node enlargement; (b) fine-needle aspiration biopsy under CT guidance. The diagnosis: squamous-cell lung cancer.

There are no absolute contraindications to needle biopsy, but an uncooperative patient, severe emphysema or pulmonary hypertension, a coagulopathy, or a contralateral pneumonectomy can substantially increase the risk. A positive diagnosis can be obtained in patients with cancer in about 90 per cent of cases. The rate is influenced by the size and depth of the lesion and the experience of the operator. False-positive rates (namely a diagnosis of cancer where none is present) are extremely low at well under 2 per cent, but the false-negative rate is much higher, probably 30 per cent to 40 per cent. This means that it is wiser to attempt a specific histological diagnosis of a benign lesion rather than rely on the reported absence of malignant cells. Cell typing of a carcinoma is more difficult from needle aspirates than from histological specimens. The most common complications of FNAB are pneumothorax and minor haemoptysis (about 10 per cent). A large haemoptysis, haemothorax, and implantation of tumour in to the needle track are rarer complications.

Percutaneous cutting-needle biopsy

This technique uses larger gauge needles to obtain a specimen suitable for histology. A 20-gauge or more Trucut biopsy needle or a spring-loaded instrument such as the Biopty are used. The sampling technique is similar to FNAB, but multiple biopsies are accompanied by a much higher complication rate. The indications for using a cutting needle are usually when there is an area of pleural thickening or mass, or when an accessible lesion is thought, prebiopsy, to be benign and requires a specific diagnosis. Theoretically cutting needles can sample diffuse lung disease, but because of the high complication rate transbronchial biopsy or a thoracoscopic biopsy are probably safer.

Pleura and pleural fluid sampling

Most unilateral and some bilateral pleural effusions need samples to be taken for diagnosis. Larger effusions can be sampled by needle aspiration using the physical signs on the chest radiograph to direct the needle into the intercostal space above the area of maximum dullness to percussion. Smaller effusions require fluoroscopic or ultrasound guidance. A 21-gauge venepuncture needle fitted to a 20 to 50 ml syringe can be used in the clinic or on the ward, usually without local anaesthesia. Diagnostic information is obtained from the appearance of the fluid, for example whether it is blood-stained, pus, or chylous, and from various microbiological, cytological, and biochemical tests, as indicated in Table 4. Measurement of pleural fluid atrial natriuretic factor (ANF) is very occasionally helpful in making the diagnosis of systemic lupus erythematosus (SLE). For malignancy, simple aspiration cytology has a diagnostic sensitivity of about 60 per cent, rising to about 75 per cent after repeated aspirations.

Pleural biopsy

Percutaneous pleural biopsy using an Abram's needle is usually done at the same time as a first or repeat aspiration of pleural fluid, when local pleural disease (as opposed to organ failure) is suspected as the cause, and when the diagnosis has not been obtained by simple aspiration. It is necessary to use an aseptic technique, to give adequate local anaesthesia down to the pleural surface (commonly 20 ml of 2 per cent lidocaine (lignocaine)), and to verify the presence of an effusion by prebiopsy aspiration of fluid. A deep incision is made above a rib so that the puncture biopsy needle can be introduced without undue effort in to the pleural space. Multiple samples should be taken, avoiding the inferior surface of the rib above. These should be sent for histological examination and for microbiological culture, particularly if tuberculosis is suspected. The technique is not easy, although samples are highly specific for tuberculosis and malignancy. Routine biopsy after repeatedly negative fluid cytology increases the diagnostic yield for neoplasia by about 10 per cent. False-negative biopsies are common, particularly in mesothelioma. If there is a prebiopsy suspicion of localized pleural tumour, particularly mesothelioma, cutting-needle biopsy under screening is a preferred technique.

Thoracosopy and diagnostic thoracotomy

Thoracoscopy allows direct inspection and biopsy of the pleural cavity. The use of video-assisted equipment in recent years has allowed the expansion of this technique to include more complex procedures (Table 5).

Thoracoscopy

This is indicated if a pleural effusion remains undiagnosed after percutaneous aspiration and needle biopsy. It can be done under sedation and local anaesthesia, but more commonly a general anaesthetic is employed. The patient lies on the contralateral side, a small stab wound is made in the mid-axillary line in the 6th or 7th interspace, and after blunt dissection a rigid 9-mm thoracoscope is used to enter the pleural space. A flexible fibreoptic thoracoscope has been developed, but its use is not widespread.

Pleural fluid is drained, then 200 ml of air is introduced to collapse the lung and allow the pleural surface to separate. The thoracoscope is manipulated to allow inspection of the whole of the pleural surface, and biopsies of abnormal pleura can then be done under direct vision. Adhesions can be broken down, and, if needed, a pleurodesis can be achieved either by using talc powder or a slurry of talc in saline. A chest drain is placed postoperatively. Complications are rare and death from the procedure extremely uncommon. The sensitivity of thoracoscopy for the diagnosis of malignant pleural effusion or tuberculosis is more than 90 per cent.

Video-assisted thoracic surgery (VATS)

In recent years the technique of video-assisted minimally invasive surgery has been applied to the thorax. This avoids the postoperative pain and morbidity associated with many thoracotomies. It allows lung biopsy or resection in patients who might be at high risk because of poor lung function for an open procedure, but the technique is difficult and adequate training is mandatory. Under general anaesthesia the ipsilateral lung is collapsed with the use of a standard double-lumen endotracheal tube, and a stab incision with adjacent instrumentation ports is made in the 6th or 7th intercostal space in the mid-axillary line (Fig. 4). In other respects the technique is similar to standard thoracoscopy, and postprocedure pulmonary tube drainage is required. Patients require a shorter hospital stay than after a standard thoracotomy.

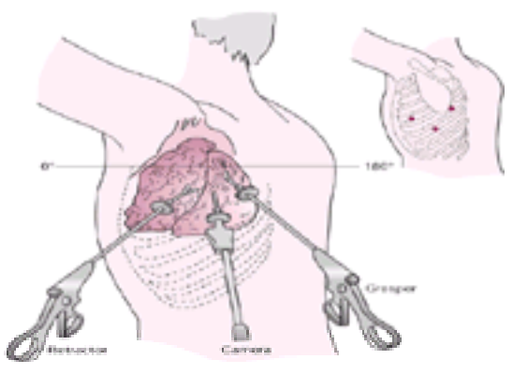

Fig. 4 The arrangement of ports for video-assisted thoracic surgery (VATS). Note the principal access is in the mid-axillary line. (Taken with permission from Landreneau RJ, *et al*. (1992). *Annals of Thoracic Surgery* **54**, 425.)

VATS can be used for diagnosis and treatment. Control of malignant pleural effusions can be achieved by simple talc pleurodesis, providing the lung remains flexible and the visceral and pleural surfaces can be apposed. Alternatives are mechanical pleurodesis by abrading the visceral pleural surface, or total or partial pleurectomy. However, effusions accompanied by contraction and trapping of the lung by tumour or fibrous tissue cannot be effectively pleurodesed. Although small peripheral lesions up to 3 cm in diameter and in the outer third of the lung parenchyma can be relatively easily removed at VATS, greater skill is needed to achieve lobectomy. VATS is an excellent technique for the treatment of persistent pneumothorax, since peripheral bullae can be recognized and excised and a pleurodesis undertaken. Rarer indications include mediastinal sampling—an alternative to percutaneous techniques—and the treatment of malignant or benign pericardial disease by pericardiectomy.

Open lung biopsy

Introduced by Klassen in 1949, the sampling of lung tissue under direct vision through a small 7- to 10-cm thoracotomy under general anaesthesia was the final arbiter in difficult cases, particularly of diffuse lung disease. It has largely been superseded by VATS biopsy. Bilateral diffuse lung disease is best sampled by a right submammary incision allowing samples to be taken from the right upper, middle, and lower lobe. Sampling from an upper lobe lesion, particularly the apical segments, requires a much larger incision. Surgeons are advised not to simply sample the most visibly affected areas, but also the less abnormal, where active pathology rather than fibrosis is more often to be found. As with VATS it is important that CT scanning is obtained to direct the biopsy.

Adequate material for histology is nearly always obtained and a specific diagnosis achieved in more than 90 per cent of cases. However, indications for open lung biopsy, particularly for the confirmation of fibrosing alveolitis, are decreasing due to the combination of high-resolution CT scanning and transbronchial biopsy.

Mediastinal sampling

Mediastinal sampling is required when the clinical problem is either the diagnosis of a mediastinal mass or the assessment of operability of lung cancer.

Needle biopsy of the mediastinum

Mediastinal masses can be diagnosed by percutaneous needle biopsy. The techniques used are similar to those described above for pulmonary sampling by a cutting needle. Biopsy under fluoroscopy was introduced in the late 1970s but has now been largely superseded by real-time ultrasound, which allows sampling of anterior and posterior mediastinal masses that abut the chest wall, or CT scanning which allows anterior middle and posterior mediastinal compartment masses to be sampled.

As with pulmonary lesions, fine-needle aspiration biopsy is both sensitive and highly specific for a diagnosis of cancer, but much less satisfactory if the prebiopsy diagnosis is considered likely to be a benign lesion, a cyst, lymphoma, or a thymic tumour. If this is the case, a cutting-needle biopsy is required. Thus, fine-needle aspiration biopsy has a sensitivity of approximately 85 per cent for any malignancy, but allows an accurate histological diagnosis in only about 60 per cent of cases. Diagnostic sensitivity of a cutting-needle biopsy approaches 90 per cent.

Complications are rare, but include pneumothorax and bleeding, which should occur in much less than 10 per cent of cases.

Surgical mediastinal sampling

The usual indication is for the staging of lung cancer. It is also used when needle biopsy has failed to produce an accurate diagnosis of a mediastinal mass.

Mediastinoscopy

This was introduced by Karlens in 1959, who developed a rigid cervical mediastinoscope. Under general anaesthesia a small 3- to 4-cm transverse excision is made 1 to 2 cm above the suprasternal notch. Blunt dissection approaches the pretracheal fascia and the trachea is followed downwards, again by blunt dissection. The mediastinoscope is inserted and the anterior mediastinum can be dissected and sampled. Complications occur in less than 2 per cent of cases. Hilar nodes, and on the left side the aortic nodes, are best reached by anterior mediastinotomy, using a 6 cm incision in the 2nd intercostal space to allow direct inspection of the mediastinal and hilar structures below.

Special cases

Children

General anaesthesia is needed for both rigid and fibreoptic bronchoscopy. The 3.5-mm diameter paediatric fibreoptic bronchoscopes do not easily allow biopsy, although small forceps are now available. Other sample techniques are similar to those for adults.

The elderly

With appropriate attention to sedation and oxygenation, fibreoptic bronchoscopy and other biopsy techniques are safe and effective in the elderly.

The intensive care unit

Fibreoptic bronchoscopy is easily performed through an endotracheal tube with appropriate attention to oxygenation. Transbronchial biopsy is also possible, although pneumothorax is more likely. In difficult cases it is often better to request an urgent open lung biopsy through a mini-thoracotomy if non-invasive tests, including bronchoalveolar lavage, are non-diagnostic.

Diagnostic clinical applications

This section discusses the use of the techniques described above to assist in the diagnosis and management of different, common respiratory conditions.

Perihilar lesions

In modern adult practice the most common and important diagnosis is lung cancer. Usually, if simple investigations are inconclusive, fibreoptic bronchoscopy should be considered unless there are technical contraindications or good clinical reasons why further information is not needed. The advantage of bronchoscopy over information derived from further imaging is that a tissue diagnosis may be obtained and some aspects of operability can be assessed—such as the proximity of a tumour to the carina. However, recent evidence has suggested that if facilities exist, a better algorithm may be to request a spiral CT scan with contrast before bronchoscopy. This has been shown to reduce the number of negative bronchoscopies as the technique allows some benign diagnoses, can demonstrate that needle biopsy would be better for some patients, and it can direct bronchoscopy to a particular area of interest. This approach depends on having rapid access to scanning, and for most units bronchoscopy is much more easily available.

If plain radiology shows a perihilar lesion but the bronchoscopy is entirely normal, then most physicians would proceed to a conventional CT scan followed by appropriate sampling, usually by percutaneous needle aspiration biopsy or surgical approach. If an endobronchial lesion is seen, a biopsy is unhelpful, but then the options are a repeat bronchoscopy with more biopsies and transbronchial needle aspiration or rigid bronchoscopy.

Solitary pulmonary nodule

When these are detected on plain radiographs, the immediate concern is usually whether or not the nodule represents an early (therefore curable) primary lung cancer. Whether the policy should be one of immediate removal, biopsy, or observation depends upon a careful assessment of the probabilities of a particular diagnosis in any one case. For example, the probability of cancer would be very high in a heavily smoking elderly man with a recent haemoptysis, and it would be lower if the lesion appeared to be calcified or, for example, it had a very smooth edge and was growing slowly. Algorithms exist to assist physicians in what can be a complex decision. It is sensible in most cases to request a thoracic CT scan. This usually gives much helpful additional information such as the density of the lesion, whether it is truly solitary or multiple, whether there is associated lymphadenopathy, and it allows very precise localization. At the same time, if the probability of tumour is high and immediate resection is not planned, the scan can be combined with a fine-needle aspiration biopsy. The majority of nodules are probably better sampled by this technique than by directed bronchoscopy using screening, since the diagnostic sensitivity of bronchoscopic sampling of peripheral lesions that are not visible is only about 50 per cent. This might be an appropriate approach, however, if the patient was not thought to be able to tolerate a pneumothorax or percutaneous biopsy was not available.

An alternative in some cases might be a VATS procedure or a mini-thoracotomy and removal of the nodule, with immediate frozen-section examination to determine whether it is malignant. If so, a decision can be made by the surgeon as to whether to limit the resection to segmentectomy or to proceed to formal thoracotomy and lobectomy. Needle biopsy is not appropriate if the prebiopsy diagnosis is likely to be a vasculitis or other complex disease. A larger sample is required for an accurate diagnosis and a VATS or mini-thoracotomy biopsy should be obtained.

Diffuse parenchymal lung disease

Under this heading are both widespread bilateral interstitial alveolar shadows and also similar shadows confined to one lobe or segment of the lung, for instance a persistent 'pneumonia'. The role of tissue biopsy in the diagnosis and management of patients with these shadows is difficult to clarify, because published series do not necessarily give adequate answers to the questions of when and how the lung should be biopsied.

Practical points are as follows:

1. Biopsies should not be considered until an adequate history has been taken and there has been a careful physical examination, looking particularly for evidence of systemic disease, and the patient has had a full set of pulmonary function tests and a high-resolution CT scan. After these investigations there will be a high probability of a particular diagnosis in many cases, and in some the HRCT scan will show pathognomonic appearances, such as lymphangitis carcinomatosa or bronchiectasis, rendering a tissue diagnosis unnecessary.
2. Biopsy should not be considered if the tissue diagnosis is almost certain not to result in any change of management, increased precision of diagnosis, or a more accurate prognosis.
3. Any biopsy should be performed by an experienced operator, or under their immediate supervision, and the possible complications should be explained beforehand to the patient.
4. Biopsy should not be performed if the occurrence of such a complication, particularly a pneumothorax in the presence of poor lung function, would endanger the patient.

For a fuller discussion of the diagnostic approach to the patient with diffuse parenchymal lung disease, see Section 17.11.

Pleural disease

Most pleural effusions can be diagnosed confidently with a combination of basic clinical information and needle aspiration. This should always be the first approach. For the remainder the usual problem is to decide whether a persistent exudative effusion is or is not due to malignancy. If a first aspiration fails to provide a diagnosis then it should normally be repeated with closed punch biopsies and at least one of these sent for microbacterial culture and the others for histology. This approach is reasonable if there is no evidence from the plain radiographs that diffuse pleural thickening is present. If this is the case it is probably wiser to obtain a CT scan, and consider the next step in the light of the findings. The CT scan has a large advantage over plain radiology in that it can indicate the most appropriate point for pleural biopsy. Localized pleural thickening can be guided by this information and a percutaneous cutting-needle biopsy (for example, a Trucut or Biopty needle) is then superior to bedside biopsy with the Abram's punch.

An increasingly common problem in industrialized countries is the appearance of a pleural effusion due to mesothelioma in a previously well patient. This is notoriously difficult to diagnose. Early scanning is required, and if there is no obvious target for percutaneous needle biopsy, early thoracoscopy is recommended. This has the advantage that multiple samples can be taken, and if a frozen section demonstrates a malignancy, an immediate pleurodesis can be performed. However, some mesotheliomas have a florid fibrous stroma and all biopsies are negative, so that in a small proportion of cases confirmation of the diagnosis remains elusive and observation has to be advised.

There is a small risk that percutaneous procedures will be followed by tumour nodules as a result of seeding along the biopsy-needle tract. Trials have shown that this possibility is much reduced by a postprocedural, localized, short course of radiotherapy. It is the author's opinion that the advantages to the patient of a precise diagnosis and the possibility of better management of his/her effusion outweighs this risk. Bronchoscopy is usually unrewarding if the only radiographic abnormality is a small to moderate effusion.

Tuberculosis

Further sampling is often required in cases where tuberculosis is suspected on clinical grounds, but where conventional sputum specimens are negative or absent, and further information is thought necessary before treatment begins. Samples can be obtained either by induced sputum or at bronchoscopy. The former technique uses 3 per cent (hypertonic) saline, usually in volumes of 70 to 100 ml in an ultrasonic nebulizer, to induce coughing and sputum. At bronchoscopy a 40- to 60-ml wash of the affected segment is usually combined with brushing for microscopy, and occasionally with transbronchial biopsy. Comparative studies have shown that the diagnostic yield in patients with focal radiographic abnormalities is similar. Where miliary tuberculosis seems likely and sputum is absent, bronchoscopy is the preferred technique, with a diagnostic sensitivity of about 80 per cent. Florid endobronchial tuberculosis is a comparatively rare disease, but it can be mistaken for tumour. Biopsy shows profuse organisms.

Tuberculosis is often an important differential diagnosis of large pleural effusions, not only in younger patients where primary disease is likely, but also in the elderly where reactivation may have occurred. Pleural fluid sampling alone is much less satisfactory than combining this with closed pleural biopsies. Multiple samples should be sent both for histological examination and for culture. In parts of the world where tuberculosis is common, a high level of pleural fluid adenosine deaminase can be a strong indication that this is the underlying diagnosis, but false-positives occur in empyemas and sometimes in cancer.

Mediastinal disease

For details of the preoperative assessment of the patient with lung cancer, see Chapter 17.14.1.

A tissue diagnosis is required for most mediastinal masses. Sampling under CT guidance is best. Ultrasound is equally good if the mass is anterior or posterior and abuts the chest wall. If the prior working diagnosis is carcinoma, then fine-needle aspiration biopsy is recommended. If this test is negative (no malignant cells) or there is an indication on the smear that the diagnosis may be thymoma or lymphoma, or if the prior working diagnosis is either of these, then a cutting-needle biopsy should be preferred. It is unwise to diagnose thymoma or lymphoma on the results of a fine-needle aspiration. In all other cases, open surgical biopsy is required usually at mediastinotomy or mediastinoscopy.

Biopsy outside the thorax

It is always important to look at the whole patient, and not just the thorax or chest radiograph. Abnormal tissue outside the thorax may be considerably easier to biopsy than tissue within it. A good example would be enlarged supraclavicular nodes, easily accessible to fine-needle aspiration biopsy in cases of suspected cancer. On occasion, putative liver metastases may be easier to sample than a small thoracic primary.

Therapeutic clinical applications

Bronchoscopic suction and saline lavage through either a fibreoptic bronchoscope or a rigid bronchoscope can be used to relieve obstruction due to viscid secretions. Rigid bronchoscopy is necessary if these are inspissated or very tenacious, as in many cases of non-asthmatic mucus impaction in the elderly. Bronchoscopy should be considered for this reason in cases of 'resistant asthma' in this age group.

Carcinoma

Impressive palliation of distressing symptoms due to endobronchial tumour, such as stridor, breathlessness, or cough, can be obtained in a number of ways. Immediate relief can be produced by deploying endobronchial stents, or using diathermy, cryotherapy, or laser therapy to obliterate tumours. Insertion of stents usually requires rigid bronchoscopy, although techniques have been described allowing placement by physicians using fibreoptic bronchoscopes. In laser therapy, a plastic catheter containing an optical fibre is passed through the instrument channel of the bronchoscope and directed at a tumour. Pulses of high-energy light, usually from a neodynium–YAG laser, cause superficial vaporization and charring of tumour tissue whilst small blood vessels are sealed, providing a relatively dry field. Treatment of haemoptysis in this way is easy, but tumour ablation is a longer and more difficult procedure. Nevertheless, palliation is provided in about 60 to 80 per cent of cases.

Brachytherapy (endobronchial radiotherapy) can complement external beam radiation and has been shown to produce adequate palliation either as initial treatment or if further external beam treatment cannot be given. At fibreoptic bronchoscopy, a catheter is inserted into the narrowed bronchus and the tip passed peripherally. Under fluoroscopic guidance a marker wire is inserted to allow the prescription of treatment, the bronchoscope is withdrawn, and using a remote control device a radioactive source is advanced through the catheter, delivering a high dose of radiotherapy endobronchially, for example 10 Gy at a distance of 1 cm. A single treatment suffices. Relief is not immediate. Combining brachytherapy with other techniques appears to predispose patients to severe haemoptysis.

Photodynamic therapy utilizes the fact that previously injected haematoporphyrins are selectively taken up by tumour cells and, when activated by appropriate laser light, release active oxygen radicals which destroy these cells. There have been reports of treatment of early tumours by this technique, and in skilled hands it can be used to palliate, in a similar fashion to laser therapy. Disadvantages are that repeat bronchoscopy may be needed to remove tumour debris, and the requirement for the patient to remain out of bright light for a period after treatment.

New developments

Early cancer

It is difficult for even an experienced bronchoscopist to detect early tumours such as carcinoma *in situ*. Bronchial epithelium passes through a number of malignant stages before invasive carcinoma develops—these are metaplasia, dysplasia, and then carcinoma *in situ*. It is known that when the bronchial epithelium is illuminated with laser light 405 to 442 nm in wavelength, there is progressive reduction in fluorescence intensity as tissue becomes more abnormal. Thus, if at bronchoscopy the bronchial walls are illuminated with laser light, endoscopists are able to detect and biopsy areas that may be abnormal. Experience with this technique is limited at the moment, but it is likely that with greater refinement it will have an important role in the surveillance of those at very high risk, or in the investigation of 'difficult cases',

for example repeated minor haemoptyses with a normal routine white light examination.

Different degrees of epithelial abnormality are accompanied by an increase in number and a change in the nature of chromosomal abnormalities in exfoliated cells. Examples are loss of heterozygosity or the presence of DNA adducts, or the amplification of proto-oncogenes. With the ability of induced sputum techniques to obtain representative samples of bronchial epithelial cells, even in patients who do not routinely produce sputum, there is considerable interest in the possibility of using such techniques in screening programmes. At present, however, there is insufficient discrimination between minor abnormalities unlikely to develop in to cancer and those that are more likely to.

Tuberculosis

At present, if a sample is smear-negative, confirmation of a diagnosis of tuberculosis may wait upon a culture result taking up to 6 to 8 weeks to mature. Accelerated culture methods are now available, and in addition the introduction of the polymerase chain reaction (**PCR**), although beset by the problems of false-positives, does allow a more confident diagnosis to be made quickly in such cases.

17.4.1 Asthma: genetic effects

J. M. Hopkin

Introduction

Asthma is a heterogeneous syndrome characterized clinically by labile airflow obstruction. There are distinct pathological features of prominent eosinophilic inflammation, additional T-lymphocyte infiltration, mucous gland hypertrophy and hypersecretion, smooth muscle hypertrophy and hyper-reactivity, and, in a long-established case, epithelial basement membrane thickening. Asthma's closest correlate is atopy, the state of allergic response to common environmental antigens mediated by the antibody IgE, and both conditions are characterized by exuberant **TH2** (subset 2 of T-helper cells) immune mechanisms. Atopy is present in more than 90 per cent of people between 5 and 30 years of age with asthma, but only 30 per cent of those with atopy develop asthma. In older life asthma may arise in non-atopics exposed to isocyanates and other substances at work. Some develop the syndrome as a result of aspirin sensitivity. In others no 'trigger' is demonstrable—so-called intrinsic asthma, arising as a result of both environmental and genetic influences.

Environment and genetics

Besides the clear involvement of reaction to the extrinsic agents noted above, there has been a surge in the prevalence of atopic disorder, and with it asthma, in recent decades. This is centred on developed communities, pointing to important environmental determinants of atopy and asthma that relate to socioeconomic development.

Epidemiological and experimental findings suggest that the rise of atopy and asthma in developed countries may be due to changing patterns of microbial exposure in early childhood. Natural exposure to *Mycobacterium tuberculosis*, measles, *Helicobacter pylori*, *Toxocara carnis*, and hepatitis A all predict less subsequent atopy. Oral antibiotic receipt in early childhood predicts more subsequent atopy, perhaps because of the deletion of gut microflora. Hence it has been proposed that exposure to certain microbes in early childhood may strongly promote natural immune restraint mechanisms and that these, through the actions of TH3 and TR1 cells (and IL-10 and TGF-b), cause repression of TH2 mechanisms against allergens. Inoculations of mycobacteria do effectively prevent experimental allergy in mice.

Despite the evident importance of environmental factors, there are also clear indications of important genetic determinants. Both atopy and asthma aggregate in families, though there is no consistent pattern of inheritance. Twin studies, comparing concordance rates for asthma and IgE sensitization in monozygotic and dizygotic twins, indicate that genetic variables have accounted for approximately 50 per cent of atopy and asthma syndromes in recent decades.

Genome screening studies

The recognition of the genetic contribution to atopy and asthma has resulted in a clutch of genome screening studies over the past decade. The results have been predictably complex. The use of affected sibling-pairs and microsatellite DNA markers has identified linkages at a number of chromosomal locations, with a significant impression that the linkages may vary between racial groups. To date the following chromosomes have shown repeatable linkages—2q, 5q, 6p, 11q, 12q, 13q, 14q, and 16p—with either asthma *per se* or IgE levels.

However, the complex mix of heterogeneous genetic factors and environmental input places important limitations on exact gene mapping. Direct candidate gene approaches, based on the pathophysiology of asthma and allergy and allied to chromosomal approaches, are providing advance.

HLA

Genetic linkage studies and direct genetic association studies demonstrate a clear relationship between HLA variants on the long arm of chromosome 6 (that is, chromosome 6q) and clinical atopy or asthma. HLA variants relate to allergic responses to distinct antigens or epitopes, e.g. HLA-DR2 and one component of the ragweed antigen (Amb a V) and HLA-DR3 and acid-anhydride sensitization asthma. DR variants have also been associated with allergic aspergillosis.

Interleukin (IL)-4 and IL-13 signalling

Because of the prominent involvement of these cytokines in bronchial inflammation and IgE production they have been targets for direct genetic investigation, and a number of important relationships are emerging. Figure 1 illustrates the signalling pathways of IL-4 and IL-13 and emphasizes that the receptors for both include IL-4Ra, and that IL-13 in comparison with IL-4 has the greater actions in promoting bronchial mucosal pathology.

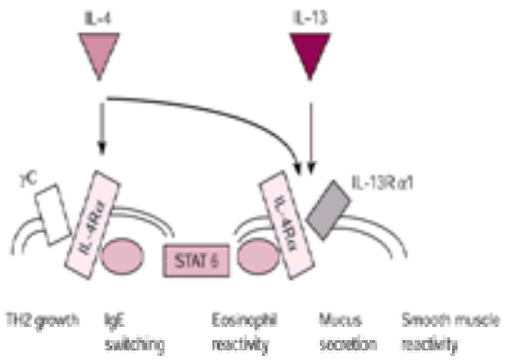

Fig. 1 Interaction between IL-4 and IL-13 signalling in overactive TH2 immunity in bronchial asthma. IL-4Ra is common to the receptors for both IL-4 and IL-13.

A number of coding variants of IL-4Ra (encoded on the short arm of chromosome 16; namely chromosome 16p) have been identified, and these relate to atopic disorder in genetic association studies. For instance, an extracellular variant—ILe50Val—is substantially more prevalent in its homozygous state in young Japanese asthmatics compared with controls. In transfection experiments it appears to upregulate receptor response to IL-4, with enhanced signalling transduction (through STAT 6 activation (**STAT**, signal transducers and activators of transcription)), increased TH2-cell growth and increased cellular IgE production. Intracellular variants of IL-4Ra, for example Gln551Arg, associate with total serum IgE levels, atopic eczema, asthma, and the rare hyper-IgE syndrome. Gln576Arg may also have an action on STAT-6 binding. Thus variants at the IL-4Ra locus enhance atopy *per se*, and have an important effect on predicting disease, including asthma, in the diverse populations.

A charge-changing variant (Gln110Arg) in the helical tail portion of IL-13 ligand (encoded on chromosome 5q) associates with asthma, both allergic and non-allergic, in Caucasian and Asian populations. Molecular modelling studies indicate that position 110 of IL-13 plays a crucial role in ligand receptor interaction (Fig. 2) and

suggest that the amino acid substitution results in increased affinity between ligand and receptor.

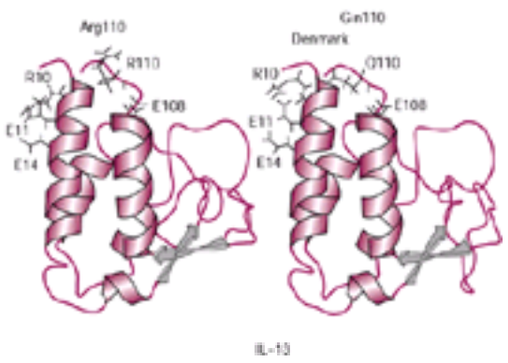

Fig. 2 The Gln110Arg variant of IL-13 is in the helical tail of the ligand, a position that critically mediates receptor binding.

One relatively common variant of IL-13Ra1 shows association with both high IgE levels and asthma. Of note, IL-13Ra1 is encoded on the X chromosome and the risk of atopic disorder and asthma for this variant is confined to young males.

In summary, relatively common variants of IL-4 and IL-13 signalling have been recognized which relate significantly to atopy and asthma in epidemiological and experimental studies. The existence of such TH2-promoting variants in human populations may relate to their potential to enhance protective TH2 mechanisms against certain phases of helminthic infestation—a regular threat to mankind in certain environments now, and almost ubiquitously in the past.

The IgE receptor

One of the first linkages noted for atopy was on chromosome 11q, a linkage that is variably present in different Caucasian and Asian populations. The principal candidate locus here is the b-subunit of the high-affinity IgE receptor. This is an important amplifier of signals through the receptor, and any genetic variants that would enhance its expression or its activity might have important effects on the allergen–IgE interaction and the triggering of mast cells in the bronchial mucosa to release proinflammatory mediators. A number of variants of FCeR1-b, both coding and non-coding, show association with high IgE levels and asthma. No functional effect has been demonstrated as yet, and studies continue.

Effector mechanisms

Although IL-4 and IL-13 signalling, and the secretion of IgE, are primary mediators of the asthma and atopy syndromes, their actions require the adjunctive activity of a whole set of effector molecules. Genetic variants also play some role here in predisposing to disease. A variant within the promoter of the 5-lipoxygenase gene (encoding for the synthesis of inflammatory leukotriene mediators) associates with the response to the antileukotriene, anti-asthma pharmacological agents. Variants of the leukotriene C4 synthase promoter associate with the increased risk of aspirin-sensitivity asthma. Variants of the b $_2$-adrenergic receptor, involved in smooth muscle activity and other inflammatory mechanisms, modulate receptor activity and associate with adverse clinical response to long-acting b-adrenergic bronchodilators seen in people with asthma.

Conclusion

Genetic and environmental factors play equally important parts in the development of asthma. Genetic factors are complex and heterogeneous. In keeping with the TH2-driven bronchial pathology typical of asthma, common variants pertinent to these mechanisms have an important impact on the risk of disease—including those in IL-4 and IL-13 signalling, and IgE binding to mast cells.

17.4.2Allergic rhinitis ('hay fever')

S. R. Durham

Introduction

Rhinitis refers to inflammation of the nasal mucosa. In clinical terms it may be defined as symptoms of nasal itching, sneezing, discharge, or blockage, which occur for more than 1 h on most days. Although frequently trivialized, allergic rhinitis remains a common cause of morbidity and social embarrassment. Estimates have suggested that 10 to 15 per cent of the population of the United Kingdom have perennial and/or seasonal rhinitis. Furthermore, the prevalence of hay fever appears to be increasing: in the United Kingdom: in 1955–56 there were 5.1 consultations with general practitioners for hay fever per 1000 population; in 1981–82 there were 19.8.

The lining of the nose and paranasal sinuses is in continuity with the lower respiratory tract and diseases of the upper and lower airways frequently coexist. The nose provides an accessible 'window' for studying allergic disorders and other diseases that can affect the lower airways. Nasal disease may also be the presenting feature of systemic disorders. The aetiology and pathogenesis of allergic rhinitis are described in this chapter, followed by practical guidelines for the diagnosis and management of allergic rhinitis.

Aetiology

Seasonal allergic rhinitis

Pollens of importance include tree pollens in the spring and grass pollens during the summer (Fig. 1). Weed pollens and mould spores predominate in the latter part of the summer and early autumn. Grass pollen counts above 50/m^3 are considered high and represent the threshold level at which most hay fever sufferers experience symptoms.

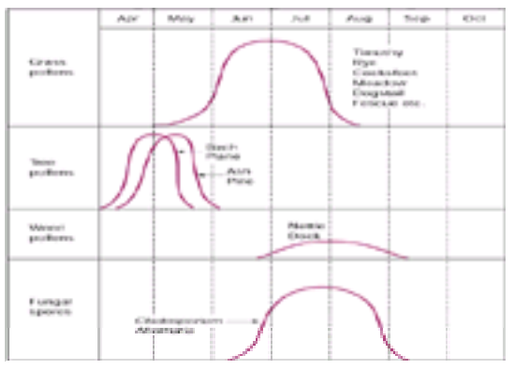

Fig. 1 Calendar of common seasonal aeroallergens (by courtesy of Professor A. B. Kay, Imperial College School of Medicine, London).

Perennial allergic rhinitis

By far the commonest cause of perennial allergic symptoms is the house dust mite (*Dermatophagoides pteronyssinus*, *Dermatophagoides farinae*, and *Euroglyphus maynei*). Mites are found in almost every home, where they live in the dust that accumulates in carpets, bedding, fabrics, and furniture. They live on shed human skin scales and thrive in temperatures of between 15 and 20 °C and a relative humidity of 45 to 65 per cent, which are typical of many modern centrally heated homes. The major allergen of the house dust mite (Der p1) is a digestive enzyme present in the gut and excreted in high concentrations in the mite faeces.

Domestic pets are the second important cause of perennial allergy, identifiable in up to 40 per cent of children with asthma and/or rhinitis. The major allergen (Fel d1) is a salivary protein, which is preened on to the fur and released on very small particles (less than 2.5 μm diameter) which remain airborne for many hours, explaining why a sensitized person can experience symptoms almost immediately upon entering a home containing a cat without being directly exposed to the animal. Dog allergens are less well characterized (Can F1). Recently, cockroaches have been described as a cause of perennial allergic symptoms, particularly in inner-city areas.

Food allergy is unusual as a cause of rhinitis in the absence of other organ involvement. However, rhinitis may be one component of IgE-mediated food-induced symptoms commonly due to egg, milk, and nuts in children; nuts, fish, shellfish, and fruit in adults. Preservatives such as tartrazine, benzoates, and sulphites may provoke symptoms of rhinitis. Important drugs that can trigger rhinitis include beta-blockers, aspirin, and (occasionally) angiotensin-converting enzyme (**ACE**) inhibitors.

Occupational rhinitis

Occupational rhinitis refers to rhinitis caused by an agent inhaled in the workplace. Like other causes of seasonal and perennial rhinitis, occupational rhinitis may also be associated with bronchial asthma. Occupations at risk include laboratory animal workers (rats, guinea-pigs, mice), bakers (flour, grain mites), agricultural workers (cows, pollens, fungal spores), electronic solderers (colophony), and health workers and users of rubber gloves (latex).

Pathophysiology

Immediate symptoms of allergic rhinitis occur as a consequence of allergen crosslinking adjacent IgE molecules on the surface of mast cells in the nasal mucosa (Coombs' classification type-1 immediate hypersensitivity). This results in the release of a range of granule-derived mediators, including histamine and tryptase, and the generation of bradykinin. IgE-dependent activation of mast cells also results in the release of newly formed membrane-associated mediators derived from arachidonic acid associated with the membrane lipid. These include leukotriene C4 (LTC4), LTD4 and LTE4 and prostaglandin D2.

In patients with allergic rhinitis, eosinophils are prominent in nasal washings and in biopsies of the nasal mucosa. The mechanism of this tissue eosinophilia is largely unknown. Chemotactic factors released following mast-cell activation may play a role. Recent evidence suggests that peptide messengers (cytokines) released predominantly from T lymphocytes—but also from mast cells, eosinophils and other cell types—may be important.

A hypothesis for the pathogenesis of allergic rhinitis is shown in Fig. 2. Helper (CD4+) T lymphocytes may be subdivided according to their profile of cytokine release: 'TH_1-type' cells producing predominantly interleukin-2 (**IL-2**) and interferon-g (**IFN-g**) and 'TH_2-type' cells producing mainly IL-4 and IL-5. The biological properties of TH_2-type cytokines suggest their involvement in allergic rhinitis, and increases in cells expressing these cytokines have been detected in the nasal mucosa during the 'late' nasal responses that occur in sensitized subjects between 6 and 24 h following experimental nasal provocation with allergen. IL-4 is the major cytokine responsible for switching B-cell immunoglobulin production from IgM and IgG to predominantly IgE. IL-3 is a growth factor for mast cells. IL-3, IL-5, and granulocyte-macrophage colony-stimulating (**GM-CSF**) factor are important in the proliferation of eosinophils from bone marrow precursors and their maturation, activation, and prolonged survival in tissues. IL-5 promotes the selective adhesion of eosinophils to vascular endothelium prior to diapedesis. **VCAM-1** (vascular cell-adhesion molecule-1) is selective for the ligand **VLA-4** (very late activation antigen-4; an integrin) expressed on eosinophils, and is upregulated by IL-4 and IL-13, an alternative pathway of eosinophil recruitment.

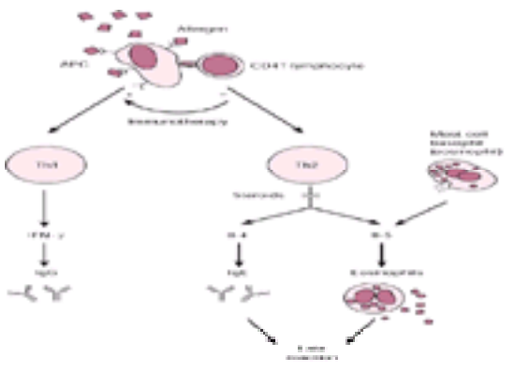

Fig. 2 Hypothesis: pathogenesis of allergic rhinitis and influence of treatment. TH2 cells are predominantly T lymphocytes, although mast cells, basophils, and eosinophils represent alternative sources of TH2-type cytokines. Topical corticosteroids downregulate the production of TH2-type cytokines from T lymphocytes and other cells. Allergen-immunotherapy alters the TH2/TH1 T lymphocyte balance, either by inducing immune deviation, TH2®TH1 responses and/or by inducing T-cell unresponsiveness (anergy) of TH0/TH2-type responses to specific allergens.

Mechanism of effect of treatments

Topical nasal corticosteroids and allergen injection immunotherapy (desensitization) are highly effective treatments for allergic rhinitis (see later). They appear to act by distinct mechanisms. Topical corticosteroids have multiple anti-inflammatory effects. They reduce the number of antigen-presenting cells (**APCs**; Langerhan's cells) within the nasal mucosa during natural pollen exposure. They also inhibit the recruitment of basophils and mast cells to the nasal epithelium and inhibit the production of TH2-type cytokines such as IL-4 and IL-5 from T lymphocytes and possibly other cell sources, including basophils. By contrast, immunotherapy acts by altering the TH2/TH1 balance in favour of the production of inhibitory cytokines such as IFN-g, which downregulate IL-4-induced B-cell switching in favour of IgE and IgG production. This shift may occur either as a consequence of immune deviation of TH2 responses (TH2®TH1) or induction of T-cell unresponsiveness (anergy) of TH0/TH2-type responses to aeroallergens (Fig. 2).

Clinical diagnosis

An approach to the diagnosis of patients presenting with nasal symptoms is summarized in Fig. 3. The diagnosis of allergic rhinitis is usually straightforward. However, the differential diagnosis should be considered in every case: frequently more than one cause coexists.

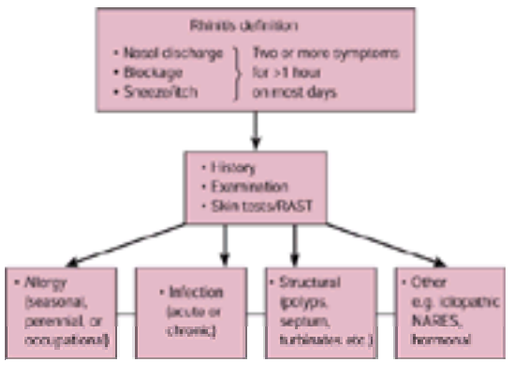

Fig. 3 Diagnostic approach to patients presenting with nasal symptoms. A careful history, clinical examination, and skin-prick tests and/or measurement of serum allergen-specific IgE (RAST or ELISA) should be performed in every case. More than one cause may be present. 'Other' causes include hormonal (pregnancy, premenstrual), drugs (aspirin, b-blockers, ACE inhibitors, cocaine abuse, and atrophic, postsurgical, and ageing). Idiopathic rhinitis refers to nasal hyper-reactivity of unknown cause, manifest as an exaggerated response to non-specific stimuli such as changes in temperature, tobacco smoke, domestic sprays, etc. The differential diagnosis includes vasculitis (Churg-Strauss syndrome), granulomatous conditions (Wegener's, sarcoidosis), atrophic (old age, surgical), and, rarely, tumours of the nose and paranasal sinuses.

History

A careful history is essential both to establish the diagnosis of rhinitis and to assess the severity of symptoms. An allergic aetiology is suggested by dominant itching, sneezing, and watery nasal discharge. Associated eye or chest symptoms (asthma) also point to an allergic cause, and a history of potential allergic triggers should always be sought. However, in addition to provoking immediate nasal symptoms, allergen may also cause late symptoms several hours after exposure, and these may not be recognized as being related. A history of potential allergic triggers includes enquiry into the seasonality of symptoms and whether symptoms are work-related (in other words, do they occur at work or in the evening following work, with improvement at weekends and during holiday periods). The home environment, including the presence of domestic pets, birds, fitted carpets, central heating, and the use of blankets on beds should be established. A personal or family history of atopy is extremely common in patients with allergic rhinitis.

There are many alternative causes of rhinitic symptoms. It is common for there to be more than one cause, and important to consider the differential diagnosis (Table 1). The presence of facial pain, fever, systemic upset, and mucopurulent discharge suggests infection. Nasal obstruction, which alternates with the nasal cycle, is common to both allergic and infective causes. Nasal crusting and/or bleeding may occur in granulomatous disorders, atrophic rhinitis, or, rarely, tumours (particularly if associated with persistent unilateral symptoms). Impaired taste and/or smell may occur with many forms of rhinitis. It is particularly common with nasal polyposis and may occasionally follow trauma (olfactory nerve damage).

The presence of infertility and recurrent respiratory infections (including bronchiectasis) should raise the possibility of mucus abnormalities (Young's syndrome or cystic fibrosis) or ciliary dysfunction (primary ciliary dyskinesia, Kartagener's syndrome). Recurrent respiratory infections or a history of chronic rhinosinusitis should

also raise the possibility of immune deficiency disorders including hypogammaglobulinaemia and acquired immune deficiency syndrome (AIDS).

Hormonal imbalance (premenstrual symptoms, pregnancy, hypothyroidism, or acromegaly) may be associated with rhinitis. A history of trauma or previous nasal surgery should be sought.

Enquiry regarding associated chest disease is important. Rhinitis and asthma frequently coexist and recognition and appropriate treatment of rhinitis may improve asthma control. The efficacy, frequency, and regularity of previous treatments should also be considered, as should the patient's perception of possible side-effects of treatment, a frequently missed cause of poor compliance.

Examination

Local examination may be performed with a head mirror and speculum or an auroscope. Allergic rhinitis is accompanied by a pale bluish 'boggy' appearance of the nasal mucosa only if the patient has current symptoms. A red inflamed appearance with pus suggests an infective cause. A granular appearance with fine pale nodules is diagnostic of sarcoidosis. Enlarged turbinates may be confused with polyps by the unwary. If doubt exists, further examination with a rigid and/or flexible endoscope should be performed. The identification of structural abnormalities such as polyps, deflected nasal septum, or enlarged turbinates is important: surgical treatment may be indicated (a major advance has been the development of minimally invasive endoscopic sinus surgery).

Examination of the nose should also include tests of smell and examination of the ears, eyes, mouth, and throat. Examination of the chest and a general examination should be performed when indicated, in view of the common association of nasal disease with lower respiratory and systemic conditions.

Investigations

Skin-prick tests

In the presence of a clear history, particularly of seasonal hay fever symptoms, skin-prick testing is not essential. However, skin-prick tests are useful for several reasons (Table 2). They should only be interpreted in conjunction with the clinical history, and not performed when the patient is taking antihistamines, if 'dermographism' (wealing in response to pressure) is present, or in the presence of severe eczema. In these circumstances measurement of serum IgE antibodies by radioallergosorbent test (**RAST**) or enzyme-linked immunosorbent assay (**ELISA**) is indicated. A useful basic skin-prick testing kit should include the following:

1. a positive control (histamine 10 mg/ml);
2. negative control (allergen diluent solution);
3. house dust mite (*D. pteronyssinus*);
4. grass pollen;
5. cat fur;
6. *Aspergillus fumigatus*.

Skin-prick tests should be performed with a sterile 23-gauge needle or lancet, which is lightly inserted through the epidermis without inducing bleeding. Responses are recorded as the mean weal diameter at 15 min. A positive prick test is defined as a weal diameter 3 mm or more greater than that of the negative control test.

Treatment

Treatment for allergic rhinitis involves the avoidance of provoking allergens where possible and the use of topical corticosteroids and H1 selective antihistamines. Allergen immunotherapy has a place in patients who do not respond to these measures. The approach is summarized in Table 3.

Allergen avoidance

It is impossible to avoid pollens, although sensible advice includes wearing sunglasses and keeping car windows tightly shut. All windows should be kept closed, particularly in high buildings. Walking in parks and wide open spaces should be avoided, particularly during the late afternoon or evening when pollen counts are highest. A holiday by the sea or abroad during the peak pollen season may be helpful.

House dust mite control and avoidance measures should be undertaken in the homes of sensitive individuals with disease. Precise advice concerning the bedroom can be provided, with avoidance of non-synthetic bedding, restriction of soft toys, which should be washable, the use of mattress covers, changes to vinyl or cork flooring, and thorough vacuum cleaning and damp-dusting at least once weekly. A leaflet entitled *House dust mites: avoidance measures for allergy sufferers* is available from the British Allergy Foundation, Deepdene House, 30 Bellgrove Road, Welling, Kent DA16 3BY. Treatment for adults should be concentrated on the bedroom and living room, while measures for mite-sensitive children should be extended to all parts of the home. Measures to eradicate mites and allergens should be undertaken only following proper diagnosis and with appropriate medical supervision. There is no firm evidence to recommend the additional use of air conditioners, air ionizers, or acaracides. A recent meta-analysis has questioned the value of avoidance measures in mite-allergic patients. Where animal exposure is relevant, there is frequent resistance to advice to remove a family pet. However, patients can be advised to avoid replacing animals, to confine them to the kitchen or outdoors where possible, and to avoid contact with them or contaminated clothing. Recent evidence suggests that washing both cats and dogs may be effective in reducing pet allergen exposure.

Pharmacotherapy

The availability of potent specific histamine H1 receptor antagonists with a low potential for anticholinergic side-effects and a low sedative profile has been a major advance. Antihistamines are particularly effective for sneezing, itching, and rhinorrhoea, but unlike topical corticosteroids they have less effect on nasal blockage. They are also effective for eye and throat symptoms.

A rare but important complication of terfenadine is prolongation of the QT interval on the electrocardiogram (**ECG**). This only occurs when doses in excess of those recommended are employed, or in the presence of hepatic impairment or concomitant use of ketoconazole or erythromycin, both of which modify the hepatic metabolism of terfenadine. Astemizole may have the same effect in overdose. Acrivastine, loratadine, des-loratidine, cetirizine, ebastine, fexofenadine, and mizolastine are effective second-generation H1 antihistamines with an extremely low (or absent) potential for cardiac side-effects. H1-selective antihistamines can also be given as a topical nasal spray (levocabastine, azelastine). Antihistamines should be avoided during pregnancy.

Topical corticosteroids are highly effective in the majority of hay fever sufferers. Preparations include beclometasone, budesonide, fluticasone, triamcinolone, and mometasone. Aqueous formulations are better tolerated and have a better local distribution in the nose. Treatment should begin before the hay fever season for maximal effect, and the importance of regular treatment, even when symptoms are absent, should be emphasized. Side-effects are minor. Systemic effects are virtually absent at conventional doses, but caution should be exercised in children, particularly those receiving additional corticosteroids by other routes (for example, for associated asthma and/or eczema).

The topical anticholinergic agent ipratropium bromide is a potent inhibitor of glandular secretion and may be effective where watery nasal discharge is the dominant symptom, uncontrolled by the measures described above.

Sodium cromoglycate is available as a topical nasal spray for use four times daily. It is less effective than topical corticosteroids. Topical cromoglycate eye drops are effective for allergic eye symptoms in the majority of patients. Topical nedocromil sodium eyedrops have the advantage of a longer duration of action, allowing twice daily administration.

In the small proportion of patients whose symptoms are not otherwise controlled, there is a place for a short course of prednisolone (20 mg daily for 5 days). This approach may unblock the nose, thereby improving access for topical corticosteroids, which may then be more effective.

Topical decongestants (oxymetazoline) are effective in treating nasal blockage, although they should only be used for short periods (no more than 2 weeks) in view of

the risk of tachyphylaxis and rebound persistent nasal blockage (so-called rhinitis medicamentosa).

Allergen immunotherapy

In patients with severe summer hay fever unresponsive to topical corticosteroids and antihistamines and in those reluctant to take long-term medication, immunotherapy (desensitization) is an alternative treatment option. Immunotherapy involves the subcutaneous injection of increasing concentrations of allergen (standardized pollen extract) at weekly intervals for 6 to 12 weeks, followed by monthly injections of a maintenance dose for 3 to 5 years. It should only be given by those who are properly trained, and with epinephrine (adrenaline) and facilities for cardiopulmonary resuscitation immediately available. Patients should be kept under medical observation for at least 60 min following injections.

Recent controlled studies have confirmed the efficacy of immunotherapy, particularly for patients with grass pollen-induced summer hay fever (WHO guidelines). It is less effective in those with perennial rhinitis and asthma, where the disease is frequently heterogeneous with multiple allergic sensitivities and/or other causes of ongoing symptoms. The risk/benefit is less favourable in patients with chronic bronchial asthma in whom the risks of systemic adverse reactions are greater. Recent data suggests that pollen immunotherapy may confer long-term benefit. In patients who had received 3 to 4 years' treatment, clinical improvement was maintained for at least 3 years following discontinuation. This suggests that allergen immunotherapy, unlike pharmacotherapy, confers long-term benefit and has the potential to modify the course of the disease.

Future prospects for immunotherapy include the use of alternative safer routes such as local nasal or sublingual immunotherapy. Low molecular weight allergen peptides represent an alternative strategy for vaccine development, with the potential to modify T-cell responses with clinical benefit without the potential for IgE crosslinking and attendant risk of serious IgE-mediated side-effects.

17.4.3Basic mechanisms and pathophysiology of asthma

Tak H. Lee

Introduction

Bronchial asthma is characterized by episodic wheezing, airways obstruction that is reversible, either spontaneously or with therapy, bronchial hyper-responsiveness to non-specific stimuli, and airways inflammation.

Risk factors for the development of asthma

Atopy is the strongest risk factor for the development of asthma. The most important mechanism by which IgE determines the expression of atopy is through its binding to high-affinity receptors (Fce-RI) expressed on the surface of tissue mast cells and basophils, and to lower-affinity receptors (Fce-RII or CD23) on macrophages, eosinophils, and platelets. Crosslinkage of IgE with a specific allergen results in the non-cytotoxic release of an array of preformed and newly generated mediators of inflammation.

The domestic house dust mite (**HDM**, *Dermatophagoides pteronyssinus*) is the major allergenic cause of perennial asthma. To date, seven groups of HDM allergens have been identified, the first four of which are known to exhibit proteolytic or other enzymatic activities. For example, Der p1, the major allergen of *D. pteronyssinus,* is a cysteine protease derived from the mite's gastrointestinal tract, whereas Der p2 is a lysozyme and Der p3 a chymotryptic enzyme. The potent biological activities of other allergens might explain why these particular proteins are able to penetrate epithelial surfaces so easily and lead to specific sensitization.

Maternal smoking, both before and after birth, is a risk factor for developing respiratory disease early in life. Exposure to environmental tobacco smoke has been shown to increase IgE in adults, and some studies have suggested that maternal smoking in pregnancy increases cord-blood IgE and the subsequent risk of atopic disease.

Other factors implicated in the early-life origins of asthma include respiratory-tract virus infections, particularly with the respiratory syncytial virus (**RSV**), possibly through damage to the bronchial epithelium, thereby augmenting the penetration of the airway mucosa by inhaled allergens. Exposure to environmental air pollutants, such as ozone, sulphur dioxide, and oxides of nitrogen, has recently been shown to enhance allergen sensitization of the lower respiratory tract.

Pathology

Histological examination of the airway tissue in an asthmatic lung shows the presence of an inflammatory reaction, with extensive remodelling of the airway wall. The inflammation is a multicellular process; even in the mildest of asthmatic individuals there is *in vivo* evidence of infiltration of the bronchial mucosa with mast cells, mononuclear cells, and granulocytes, of which the eosinophil is prominent. The tenacious plugs that fill the lumen are an exudate of plasma and inflammatory cells, particularly eosinophils, which have migrated into the lumen, as well as epithelial cells that have sloughed from the airway surface, often leaving the basement membrane denuded. The basement membrane appears thickened when viewed under the light microscope, which is due to an increase in the amount of collagen deposition at this site, but the lamina densa, which forms the true basement membrane, is normal when observed with the electron microscope.

The changes in the lumen and wall of the airways of asthmatic lungs are reflected in the cytological examination of sputum from patients with the disease. Early studies of the sputum showed the presence of Creola bodies (sloughed epithelial clumps), Charcot-Leyden crystals (remnants of eosinophils), and Curschmann spirals (casts of the airway formed by the exudate). More recent studies have established that the eosinophil is the prominent cell found in the sputum of asthmatic patients.

There is a clear increase in wall thickness throughout the bronchial tree in patients with asthma, and all the tissue layers participate in this generalized increase in airway wall thickness. The volume of the bronchial microvasculature is also increased in both the submucosa and the adventitia of the airways. It has been calculated that the thickening of the airway wall caused by asthma has only a minor effect on the lumen of a fully dilated airway, but when a modest increase in wall thickness is associated with smooth-muscle shortening, the two factors acting together produce markedly increased airway resistance.

Inflammatory cells

Bronchial inflammation is orchestrated by a network of cytokines and growth factors, including those encoded by the **GM-CSF/IL-4/IL-5** (granulocyte–macrophage colony-stimulating factor/interleukin-4/-5) gene cluster on chromosome 5, derived from both inflammatory and structural cells in the airways.

Mast cells

Mast cells are clearly important in initiating the acute bronchoconstrictor responses to allergen, and probably to other indirect stimuli such as exercise and hyperventilation (via osmolarity or thermal changes). When sensitized subjects inhale specific allergen it causes both early (5–15 min—early airway response, **EAR**) and late (2–6 h—late airway response, **LAR**) bronchoconstrictor responses, which last approximately 60 min and between 12 and 24 h, respectively. The LAR is accompanied by an acquired increase in bronchial responsiveness to such stimuli as inhaled histamine and methacholine (Fig. 1).

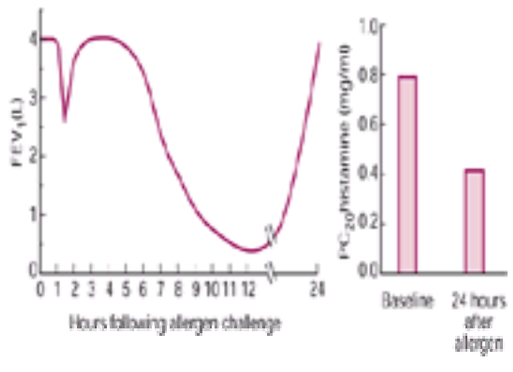

Fig. 1 Changes in **FEV_1** (forced expiratory volume in 1 second) and histamine airway responsiveness after allergen inhalation challenge in an asthmatic subject. PC_{20} histamine is the concentration of histamine producing a 20 per cent decrease in FEV_1. It is a measure of 'non-specific' airway responsiveness.

Measurement of mediators in the peripheral blood and bronchoalveolar lavage fluid together with their metabolites in urine has shown that the EAR is a mast cell-dependent response resulting from the IgE-dependent secretion of constrictor substances. The type of mast cell involved in this reaction contains predominantly tryptase as its neutral protease. Among its biological actions, tryptase is able to produce a prolonged increase in microvascular permeability, upregulate adhesion molecules, attract and activate eosinophils, and augment epithelial and fibroblast proliferation. Histamine exerts most of its airway effects via H1 receptors, which are present both on airway smooth muscle and on the microvasculature, whilst prostaglandin D2 (**PGD2**) contracts airway smooth muscle by interacting with thromboxane (TP1) receptors. Once released from mast cells, LTC_4 is rapidly metabolized to LTD_4 and subsequently to LTE_4, the three cysteinyl leukotrienes responsible for the smooth-muscle contractile and vasoactive properties of the biological activity previously described as **SRS-A** (slow-reacting substance of anaphylaxis) (Fig. 2).

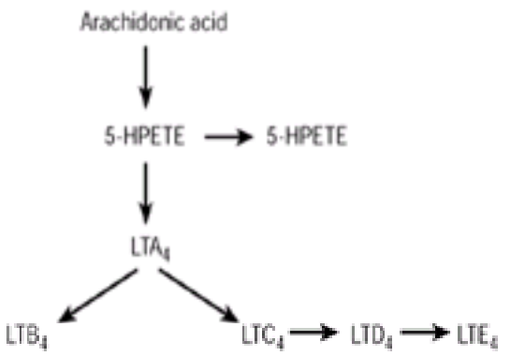

Fig. 2 The 5-lipoxygenase pathway. 5-HPETE = 5-hydroperoxy-eicosatetraenoic acid, 5-HETE = 5-hydroxy-eicosatetraenoic acid. LT = leukotriene.

Eosinophils

The late airway response has an inflammatory basis. During this response there is an increased bronchoalveolar lavage eosinophilia, suggesting the selective recruitment of these cells into airway tissue from the microvasculature. Eosinophil infiltration is a characteristic feature of asthmatic airways and differentiates asthma from other inflammatory airway conditions. There is a close relationship between eosinophil counts in peripheral blood or bronchoalveolar lavage (**BAL**) fluid and airway hyper-responsiveness.

Eosinophil migration may be due to the effects of lipid mediators, such as leukotrienes, or to the effects of cytokines such as GM-CSF, IL-5, RANTES, and eotaxin (**RANTES**, regulated upon activation, normal T-cell expressed and secreted chemokine). Several of these molecules might also be very important for the survival of eosinophils in the airways and may 'prime' eosinophils to exhibit enhanced responsiveness. There appears to be a co-operative interaction between IL-5 and chemokines, so that both cytokines are necessary for the eosinophilic response in airways. Once recruited to the airways, eosinophils require the presence of various growth factors, of which GM-CSF and IL-5 appear to be the most important. In the absence of these growth factors eosinophils undergo programmed cell death (apoptosis).

Within the airways, active eosinophils secrete a wide array of preformed and newly generated inflammatory products. These compromise the toxic granule components of the eosinophil (major basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxin) and a range of lipid products, including leukotrienes and platelet activating factor (**PAF**). The administration of LTD_4 antagonists prior to allergen provocation of sensitized airways produces marked inhibition of both the EAR and LAR and attenuation of the acquired increase in bronchial hyper-responsiveness. Although PAF was at one time regarded as a prime mediator of the late-phase inflammatory response and bronchial hyper-responsiveness, investigation of the orally active PAF receptor antagonist WEB 2086 has failed to reveal any inhibitory effect on either early- or late-phase, allergen-induced airway events. Eosinophils are also involved in the generation of oxygen-derived free radicals.

Other leucocytes

The mechanism(s) by which leucocytes move into the airway and become activated have attracted considerable interest. At 6 h following allergen challenge, there is marked upregulation of E-selectin, whose ligand on neutrophils and other leucocytes is sialyl-Lewis × and intercellular adhesion molecule-1 (**ICAM-1**), a member of the immunoglobulin superfamily. One ligand for ICAM-1 is lymphocyte function-associated antigen-1 (**LFA-1**) (an integrin heterodimer CD11a–CD18) expressed on a large number of leucocytes, but especially on lymphocytes, neutrophils, and eosinophils. Another member of the immunoglobulin superfamily, vascular cell-adhesion molecule-1 (**VCAM-1**), is expressed in the airway microvasculature at a low level, but this is not increased within the time frame of 6 h following allergen provocation. A positive correlation has been observed between the extent of ICAM-1 expression and leucocyte infiltration, and more specifically between E-selectin and the increase in neutrophil numbers, suggesting an important role for these molecules in the allergic inflammatory process.

The initial expression of P-, L-, and E-selectins, which contain lectin binding regions that interact with carbohydrate ligands and leucocytes (e.g. sialyl-Lewis ×) results in the rolling of leucocytes along the endothelial cell, whereas upregulation of ICAM-1 and VCAM-1 arrests the leucocytes, thereby facilitating transendothelial migration. In non-human primates naturally sensitized to *Ascaris* antigen, blocking antibodies directed to E-selectin and ICAM-1 abrogate the LAR and the resultant bronchial hyper-responsiveness following allergen challenge, in parallel with a reduction in neutrophils and eosinophils.

The role of neutrophils in human asthma is less clear. They are found in the airways of patients with chronic bronchitis and bronchiectasis who do not have the degree of airway hyper-responsiveness found in patients with asthma. Neutrophils are rarely seen in the airways of patients with chronic asthma, but large numbers are seen in those who die suddenly of asthma. This may reflect the rapid kinetics of neutrophil recruitment compared with eosinophil inflammation.

Macrophages, which are derived from blood monocytes, traffic into the airways and may orchestrate the inflammatory response. Macrophages may both increase and decrease inflammation, depending on the stimulus. Alveolar macrophages normally have a suppressive effect on lymphocyte function and may play an important role in preventing the development of allergic inflammation, but this may be impaired in asthma after allergen exposure. Macrophages can also act as antigen-presenting cells (**APCs**), processing allergen for presentation to T-lymphocytes, but alveolar macrophages are far less effective in this respect than macrophages from other sites. By contrast, dendritic cells, which are specialized macrophage-like cells in the airway epithelium, are very effective antigen-presenting cells and might play a very important role in the initiation of allergen-induced responses in asthma.

T lymphocytes play a very important role in co-ordinating the inflammatory response in asthma through the release of specific patterns of cytokines, resulting in the recruitment and survival of eosinophils and the maintenance of mast cells in the airways. T lymphocytes are coded to express a distinctive pattern of cytokines, which may be similar to that described in the murine TH_2 type of T lymphocyte that characteristically express IL-4, IL-5, and IL-13. There appears to be an imbalance of TH cells in asthma, with the balance in favour of TH2 cells. The balance between TH1 cells and TH2 cells may be determined by locally released cytokines such as IL-12, favouring the expression of TH1 cells, and IL-4, favouring TH2 cells. There is a suggestion that early infections might encourage TH1-mediated responses to predominate and that a lack of infection in childhood may favour TH2-cell expression and thus atopic diseases.

Structural cells

Structural cells of the airways, including epithelial cells, fibroblasts, and airway smooth muscle cells, are also important sources of inflammatory mediators, such as cytokines and lipid mediators, in asthma. In addition, epithelial cells may play a key role in translating inhaled environmental signals into an airway inflammatory

response and are probably a major target cell for inhaled glucocorticoids.

Inflammatory mediators

Many different mediators have been implicated in asthma. Those such as histamine, prostaglandins, and leukotrienes contract airway smooth muscle, increase microvascular leakage, increase airway mucus secretion, and attract other inflammatory cells. The availability of specific receptor antagonists has defined the critical role of certain mediators. For instance, the cysteinyl leukotrienes LTC_4, LTD_4, and LTE_4, are potent constrictors of human airways and have been reported to increase airway hyper-responsiveness, recruit eosinophils, and possibly play an important role in asthma. Potent LTD_4 antagonists protect against exercise-, aspirin-, and allergen-induced bronchoconstriction, suggesting that cysteinyl leukotrienes contribute to bronchoconstrictor responses. Chronic treatment with cysteinyl leukotriene antagonists improves lung function and symptoms in asthmatic patients.

Cytokines

Cytokines play a central role in orchestrating the type of inflammatory response. Many inflammatory cells (macrophages, mast cells, eosinophils, and lymphocytes) are capable of synthesizing and releasing these proteins, and structural cells such as epithelial cells and endothelial cells may also release a variety of cytokines and therefore participate in the chronic inflammatory response. While inflammatory mediators like histamine and leukotrienes may be important in the acute and subacute inflammatory responses and in exacerbations of asthma, it is likely that cytokines play a dominant role in chronic inflammation.

As atopy is a major risk factor for the development of asthma, it is essential to understand how IgE synthesis is regulated. IL-4 interacts with B cells via specific cell-surface receptors, and is a key cytokine involved in the isotype-switching of B cells from synthesizing IgM and IgG to IgE. An important accessory signal for IgE-switching is provided by CD40 on T cells signalling through the CD40 ligand on B cells. IL-13, which exhibits 30 per cent homology with IL-4, has also been shown to mediate IgE isotype-switching through its own specific receptors but, unlike IL-4, it is also a differentiation factor for dendritic cells. Switching of B cells to IgE synthesis is potently inhibited by interferon-gamma (IFN-g) from TH_1 cells and monocytes/macrophages.

In vivo evidence for cytokine involvement in asthma

Bronchoalveolar lavage (BAL)

Increased proportions of cells positive for IL-4 and IL-5 mRNA are found using the technique of *in situ* hybridization in atopic asthmatic subjects. Symptomatic asthmatic subjects have greater proportions of cells positive for IL-3, IL-4, IL-5, and GM-CSF mRNA in BAL fluid than asymptomatic asthmatics. No differences between the groups in the numbers of cells expressing IL-2 and IFN-g mRNA are detected. In addition, there are significant associations between the number of cells expressing mRNA for IL-4, IL-5, and GM-CSF and baseline airflow obstruction, airway hyper-responsiveness, and asthmatic symptoms. Increased levels of tumour-necrosis factor-a (**TNF-a**), GM-CSF, and IL-6 have been found in BAL fluid of symptomatic as compared to asymptomatic asthmatic subjects.

Studies on alveolar macrophages of asthmatic subjects showed that IL-1b expression is upregulated and that the level of IL-1b in BAL fluid of subjects with symptomatic asthma is higher than that of normal subjects or subjects with asymptomatic asthma. Additionally, bronchoalveolar lavage fluid from symptomatic non-allergic asthmatic subjects contains elevated levels of IL-1.

Evidence from challenge models further supports cytokine involvement in asthma. Increases have been shown in the number of cells expressing mRNA for the TH2 cytokines IL-4, IL-5, and GM-CSF but not IL-3, IL-2, or IFN-a after allergen challenge. Furthermore, IL-4 and IL-5 mRNAs transcripts were associated with activated CD4+ T cells.

Bronchial biopsies

Immunohistochemical analysis of bronchial biopsies from symptomatic and asymptomatic atopic and non-atopic asthmatics reveals increased immunoreactivity with IL-1/2/3/4/5, GM-CSF, **MCP-1** (monocyte chemotaxis protein-1), and TNF-a as opposed to asymptomatic control subjects.

Mucosal biopsies obtained from atopic asthmatics after allergen challenge demonstrate an increased influx of activated eosinophils and activated CD4+ T cells, and an increase in the number of cells expressing mRNA for IL-5 and GM-CSF. There is a significant inverse correlation between the numbers of cells expressing mRNA for IL-4 and IFN-a. This supports the hypothesis that allergen-induced late asthmatic responses are accompanied by T-cell activation, cytokine mRNA expression for IL-5 and GM-CSF, and local recruitment and activation of the eosinophils in the bronchial mucosa.

Effects of inflammation

The chronic inflammatory response may alter the structure and function of critical target cells in the airways.

Airway epithelium

Airway epithelial shedding may be important in contributing to airway hyper-responsiveness, and may explain how several different mechanisms (for example, ozone exposure, certain virus infections, chemical sensitizers, and allergen exposure) can lead to the development of this condition. All these stimuli may lead to epithelial disruption, which may contribute to airway hyper-responsiveness by the loss of barrier function to allow penetration of allergens, loss of enzymes (such as neutral endopeptidase) that normally degrade inflammatory mediators, and exposure of sensory nerves, which might lead to reflex neural effects on the airway.

Airway smooth muscle

An abnormality in smooth muscle function is thought to be the basis of the bronchial hyper-responsiveness in asthma, but studies of isolated human bronchi from asthmatic subjects have failed to demonstrate a clear consensus for the presence of a functional abnormality. Of eight reports of individuals who are hyper-responsive to histamine and methacholine *in vivo*, half have shown increased force generation by asthmatic airways *in vitro*, compared to control airway preparations; the remainder report no difference in force generation by asthmatic or normal isolated airway preparations. The reasons for this anomaly are unclear. In general, studies have been carried out using airways from mild asthmatics and differences in optimal length for maximum force generation and smooth muscle content have not been accounted for. Similarly, passive sensitization studies have produced conflicting data. In three of four studies, exposure of airways removed from non-atopic patients to serum from patients with high IgE levels confers increased responsiveness to specific allergen and hyper-responsiveness to non-specific stimuli such as histamine and neuropeptides.

Other functional changes may be important. Reduced responsiveness to b_2-adrenoceptor agonists has been reported in both postmortem and surgically removed bronchi from asthmatic patients, although the number of b-adrenoceptors is not reduced, suggesting that these receptors have in some way become functionally uncoupled. This aspect of altered airway smooth muscle function can be modelled *in vitro*, where treatment of airway smooth muscle cells with cytokines induces a similar refractoriness to b_2-adrenoceptor agonists.

Changes in compliance of the extracellular connective tissue components between individual muscle cells and in the stiffness of parallel elastic elements in the extracellular compartment may reduce the tethering loads of the muscle and allow greater shortening. Indeed, treatment of human airway smooth muscle preparations with the matrix degrading enzyme collagenase enhances force generation and shortening.

It seems likely that the involvement of the smooth muscle in excessive airway narrowing in asthma involves several mechanisms. These include an increased content of smooth muscle in the airway wall, or a combination of increased content and altered function. It is now recognized that, in addition to contractile function, airway smooth muscle can undergo hyperplasia and/or hypertrophy, leading to apparently irreversible changes in wall structure and contributing to the development of persistent airway obstruction and non-specific airway hyper-responsiveness. Numerous studies have characterized some of the proinflammatory mediators and growth factors that elicit proliferation of smooth muscle. Other trophic factors such as altered mechanical stress and reactive oxygen species have also been

identified. Components of the extracellular matrix that are increased in asthma may also impact on the proliferation of airway smooth muscle.

Proliferating airway smooth muscle cells undergo phenotypic modulation from a contractile to synthetic–proliferative state, where additional functions of airway smooth muscle such as cytokine/chemokine and extracellular matrix secretion become more apparent. This is likely to be of particular relevance in the diseased asthmatic lung where the content of airway smooth muscle as a fraction of the total cells in the airway wall is already increased. Human airway smooth muscle releases several chemokines important for the activation of eosinophils. These include chemotaxins such as RANTES and eotaxin, as well as GM-CSF. Airway smooth muscle cells also interact by direct contact with immunocytes such as T lymphocytes through the expression of cell-adhesion molecules and the induction of myocyte DNA synthesis. T lymphocytes derived from bronchoalveolar lavage fluid following antigen challenge of atopic subjects adhere to human airway smooth muscle cells in culture, inducing ICAM-1 and HLA-DR expression on the smooth muscle cells.

As additional functions of airway smooth muscle are described, a view (Fig. 3) is emerging that airway smooth muscle cells may adopt an immunoeffector role in chronic asthma by proliferating, secreting cytokines, expressing adhesion molecules, and by interacting with various immunocytes. This may involve changes in the phenotypic status of airway smooth muscle, and, as a result, these cells may play an active role in perpetuating and orchestrating airway inflammation in the remodelled airway. These novel insights question previously held paradigms of altered neural activity and inflammation in asthma, and emphasize the importance of the response of the end-organ, namely the smooth muscle cell.

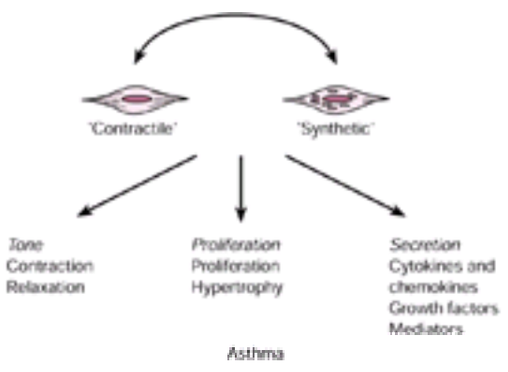

Fig. 3 The role of airway smooth muscle in chronic severe asthma (by courtesy of S. Hirst).

Vascular responses

Vasodilatation occurs in inflammation, yet little is known about the role of the airway circulation in asthma, partly because of the difficulties involved in measuring airway blood flow. The bronchial circulation may play an important role in regulating airway calibre, since an increase in the vascular volume may contribute to airway narrowing. Increased airway blood flow may be important in removing inflammatory mediators from the airway, and may play a role in the development of exercise-induced asthma.

Microvascular leakage is also an essential component of the inflammatory response. It may increase airway secretions, impair mucociliary clearance and enhance mucosal oedema, thereby contributing to airway narrowing and increased airway hyper-responsiveness.

Neural effects

Non-adrenergic, non-cholinergic (**NANC**) nerves and several neuropeptides have been identified in the respiratory tract, in addition to those involved in classical cholinergic and adrenergic mechanisms. It is unclear whether abnormalities of autonomic function in asthma are secondary to the disease or primary defects. It is recognized that inflammation may interact with autonomic control by several mechanisms. For instance, neuropeptides such as substance P, neurokinin A, and calcitonin gene-related peptide may be released from sensitized inflammatory nerves in the airways and may amplify the inflammatory response. There is evidence for an increase in substance P-immunoreactive nerves in the airways of patients with severe asthma, although this has not been confirmed in patients with mild disease. There may also be a reduction in the activity of enzymes such as neutral endopeptidase which degrade neuropeptides such as substance P. There may also be increased expression of the receptor that mediates the inflammatory effects of substance P.

Asthma

A. J. Newman Taylor

Introduction

Asthma is a chronic inflammatory disease of the bronchial airways, which is characterized by a desquamative eosinophilic bronchitis (Fig. 1). The defining clinical characteristics of asthma—reversible airway narrowing and increased airway responsiveness to non-specific provocative stimuli—are manifestations of the underlying chronic inflammatory process. Definitions of asthma that have focused on these clinical characteristics, to distinguish it from diseases associated with predominantly irreversible airway narrowing, have emphasized the intermittent nature of asthma rather than the persistence of the underlying inflammation, with potentially inappropriate implications for treatment.

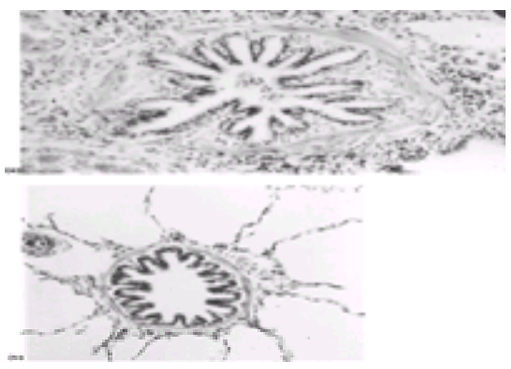

Fig. 1 The defining pathology of asthma: (a) desquamative eosinophilic bronchitis in patient with asthma, in comparison with (b) normal histological appearances.

The recognition that asthma is a chronic inflammatory disease implies that, in addition to identifying and avoiding inducing causes, such as domestic pets and occupational sensitizers, disease control is likely to require long-term anti-inflammatory treatment. Appreciation of the inflammatory nature of asthma has also led to recognition of the associated injury and damage to the airway wall—airway remodelling—which may lead to irreversible loss of function, and be preventable by the early institution of anti-inflammatory treatment.

Asthma and airway hyperresponsiveness: inducers and provokers

The distinguishing abnormalities of lung function in bronchial asthma are:

1. reversible airway narrowing and
2. airway hyperresponsiveness to non-specific provocative stimuli.

Airway responsiveness describes the ease with which acute airway narrowing can be provoked by a variety of stimuli. Non-specific provocative stimuli include exercise, inhalation of cold dry air, inhaled respiratory irritants such as sulphur dioxide, and pharmacological agents such as histamine and methacholine (Table 1). Provocation of asthma by specific allergens can induce hyperresponsiveness to non-specific stimuli, when smaller doses of such stimuli provoke acute airway narrowing. Inhaled non-specific provocative stimuli, such as histamine or methacholine, incite airway narrowing that usually resolves within minutes; exercise provokes asthma within minutes that resolves within 1 h.

The degree of airway responsiveness can be expressed as the dose or concentration of the stimulus which provokes a specified fall in the forced expiratory volume in 1 s (**FEV1**), commonly the dose or concentration of histamine or methacholine which provokes a 20 per cent fall in FEV_1—**PD20** or **PC20**, histamine or methacholine.

While provokers of asthma incite acute airway narrowing in individuals with hyperresponsive airways, inducers of asthma increase the magnitude of airway hyperresponsiveness and the clinical manifestations of asthma by increasing the severity of the underlying airway inflammation, which can persist for days or weeks. The principal inducers of asthma are inhaled allergens, low molecular weight chemicals encountered at work, and viral respiratory tract infections (Table 1).

Allergen inhalation tests are a good model of the airway response to an inducer and demonstrate the interrelationship between airway inflammation, airway narrowing, and airway hyperresponsiveness. Inhalation of an allergen by an individual allergic to it with asthma will provoke:

1. an immediate fall in FEV_1, which develops within minutes and usually resolves spontaneously within 1 to 1.5 h; and
2. a subsequent late fall in FEV_1, which develops in about 50 per cent of cases 1 h or more after the inhalation test and persists for several hours, on occasions for days.

The immediate fall in FEV_1 is IgE dependent and is due to airway smooth muscle contraction and airway wall oedema provoked by mediators, such as histamine,

released from mast cells resident in the airways. It is not associated with an increase in airway responsiveness. The late fall in FEV_1 is the outcome of recruitment to the airways of inflammatory cells, particularly T_{H2} lymphocytes and eosinophils, reducing airway calibre. It is associated with an increase in airway responsiveness (manifest as a reduction in PC_{20}) that can persist, with associated increased diurnal variation in airway calibre, for several days after resolution of airway narrowing (Fig. 2).

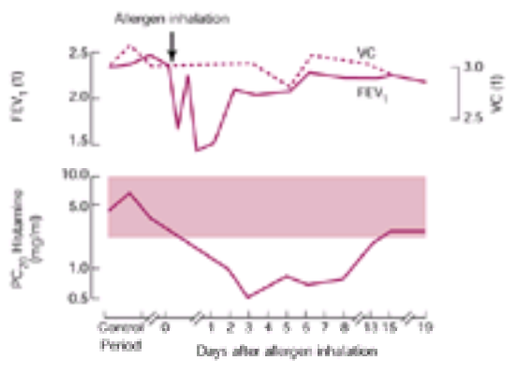

Fig. 2 Increased airway responsiveness associated with late asthmatic reaction provoked by inhalation of ragweed pollen.

Prevalence of asthma

Asthma is a common disease, frequently disabling and, uncommonly, the cause of death. In the Western world it now has an estimated prevalence of more than 10 per cent in children and more than 5 per cent in adults. In the United Kingdom in 1999 it was the cause of 86 000 hospital admissions and the certified cause of death of 1520 people.

The prevalence of asthma in children and young adults has increased markedly in the Western world during the past 20 to 30 years (Fig. 3). Although in part this increase may reflect a greater awareness of and tendency to diagnose asthma, repeat cross-sectional studies of children in the United Kingdom, using identical methods of ascertainment at different time points, have shown a definite increase in disease prevalence. A study of Aberdeen school children found the prevalence of wheeze and of diagnosed asthma had increased 2.5-fold between 1964 and 1989. A similar study in South Wales, made at two time points 15 years apart, found a history of reported asthma to have doubled from 6 to 12 per cent. This study also reported a similar increase of reported hay fever and eczema, and in the proportion of children in whom exercise provoked asthma.

Fig. 3 Increasing prevalence of asthma in Finnish military recruits.

Comparison of the prevalence of asthma in different parts of the world suggests that the high and increasing prevalence in the Western world is associated with urbanization and material prosperity. A study of school children in Zimbabwe found asthma to be uncommon in those living in a rural area, more common in poor urban dwellers, and most common in affluent urban dwellers, equally in the black and white population, in Harare. In Europe the reunification of Germany allowed comparison of the prevalence of asthma and associated conditions in cities in former East and West Germany. The prevalence of asthma, hay fever, eczema, and atopy (identified as immediate skin test responses to common inhalant allergens) was greater in school age children living in the West German city of Munich than in the East German cities of Leipzig and Halle. This greater prevalence of asthma, atopy, and atopic diseases in Western compared with Eastern Europe has been replicated in comparison studies between other countries (such as Finland compared with Estonia). Interestingly, the prevalence of atopy (particularly skin test responses to pollens) and hay fever, but not asthma, has subsequently increased in children now living in reunified Germany who had lived the first 5 years of their lives in Leipzig.

Many explanations have been advanced to explain these observations. These include increased indoor allergen exposure (particularly house dust mite and cat), increased exposure to vehicle exhaust pollution, increased tobacco smoking by women of childbearing age, changing diet, and reduced infection rates in childhood. Of these, outdoor air pollution has, until recently, attracted most public attention, although there is no substantive evidence in its support: the prevalence of asthma in urban parts of the United Kingdom is no greater (and possibly less) than in rural parts, including Skye, where measured levels of air pollutants are the lowest in the United Kingdom. Similarly, there is little evidence that the increased prevalence of asthma and other atopic disease has been caused by increased indoor allergen exposure or tobacco smoking, although the increase in asthma has been parallelled by an increase in cigarette smoking by women of childbearing age. Several dietary explanations have also been advanced, including increased salt and reduced antioxidant intake. The most plausible explanation advanced to date is that the increase in atopy and asthma is a consequence of a reduction in rates of infection during childhood. The evidence is both indirect and direct, although not yet conclusive. The most consistent observation, now from several studies, is of an inverse relationship between family size, and birth order, and the risk of atopy and hay fever. This has been interpreted as being consistent with the age at which a child encounters infectious agents having a decisive influence on the development of atopy and associated diseases: children in large families and those with older siblings are more likely to encounter infections earlier in life, reducing their risk of becoming atopic. Several, although not all, subsequent studies of the relationship of atopy and atopic disease to childhood infection have supported this hypothesis. In a group of children studied in Guinea-Bissau, West Africa the risk of being atopic (and in particular having specific IgE to *Dermatophagoides pternonyssinus*) was inversely related to having had measles in early childhood. Similarly, the risk of atopy, hay fever, and asthma was inversely related to having been infected with *Mycobacterium tuberculosis* in Japanese school children, and to having serum antibodies to hepatitis A, considered an indicator of hygiene in early life, in Italian military recruits.

Risk factors for asthma

The geographical variation and considerable increase in recent decades in the prevalence of asthma indicate important environmental influences on the development of the disease. There is also evidence for genetic susceptibility. The risk of asthma is associated with atopy, for which genetic influences are strong. As with many common complex diseases, such as diabetes mellitus, asthma is probably the outcome of multiple genes and their interaction with the environment.

Atopy

Atopy is defined as the production of specific IgE antibody to common inhalant allergens, such as grass pollen, house dust mite, and cat. Atopy may be identified by the presence of immediate skin prick test responses (or of specific IgE in serum) to extracts of common inhalant allergens and has a prevalence of some 40 per cent in the adult United Kingdom population. The risk of developing asthma as well as eczema and hay fever is increased in atopic individuals. In a random population sample in the south-west United States, a close relationship was found at all ages between skin test responses to local inhalant allergens and the prevalence of

asthma and allergic rhinitis. Similarly, in Canadian university students the prevalence of airway hyperresponsiveness to inhaled histamine correlated significantly with the degree of atopy. For further discussion see Chapter 17.4.1.1 and Chapter 17.4.1.2.

Genetic susceptibility

Asthma and atopy show clear indications of genetic susceptibility: the frequency of disease in family members is greater than in the population as a whole and is greater in identical than non-identical twins.

In one study the population prevalence of asthma was estimated at between 5 and 10 per cent; the risk for the child of a parent with asthma and atopy was 14 per cent when one parent was affected and 29 per cent when both parents were affected. The risk for the child of a parent with asthma but not atopy was little more than the population frequency of asthma; whereas atopy increased the risk of a child developing asthma some threefold. The reasons for genetic susceptibility are discussed in section 17.4.1.1, but it is important to recognize that genetic influences alone cannot explain the striking geographical variation and recent secular change in the prevalence of asthma.

Allergen exposure

In people with asthma, natural allergen exposure induces asthma and airway hyperresponsiveness. Both the severity of asthma and airway responsiveness increased in patients with asthma who were allergic to ragweed pollen during the ragweed pollen season. Similarly, avoidance of relevant allergen exposure is associated with an improvement or resolution of asthmatic symptoms, improved lung function, and decreased airway responsiveness. Patients with asthma who were allergic to house dust mite have shown considerable symptomatic and objective improvement when avoiding house dust mite for several months at altitude in Davos in the Swiss Alps; also for several weeks in a London hospital. In south-east United States, asthma deaths in patients allergic to the mould *Alternaria alternata* increase during the months of the year when *Alternaria* spore counts are highest.

Although there is clear evidence that natural exposure to allergens to which they are allergic can induce asthma in patients (and avoidance can improve it), the influence of allergen exposure on the development of asthma is less clear. Studies comparing populations born and living in different environments and climates, and therefore exposed to different allergens in childhood, demonstrate allergy and associated disease in relation to allergens present in the particular environment. Comparison of children born and living in Marseilles (humid and at sea level, encouraging the growth of house dust mite) and in Briancon, the highest town in the French Alps (not conducive to the growth of house dust mite, but encouraging to the growth of many flowering plants), showed that allergy to house dust mite was considerably more prevalent in Marseilles than in Briancon, whereas allergy to pollens was considerably more prevalent in Briancon than Marseilles. The prevalence of asthma was similar in both environments, although the associated allergies differed. The introduction of a new allergen into an environment can cause the development of allergy and asthma, particularly among adults. Unloading soya beans in Barcelona harbour caused 'epidemic days', when the number of hospital admissions with asthma increased several-fold: these continued for 7 years until the cause was identified and a filter placed on the silos to prevent the release and dissemination of soya bean during unloading.

Respiratory virus infections

While respiratory virus infections have long been suspected to be the major cause of exacerbations of asthma, it is only with the development and use of polymerase chain reaction in controlled studies that the true proportion of virus-induced exacerbations of asthma has become clear. In studies of asthma in the community, 85 per cent of asthma attacks in children and 44 per cent in adults were induced by upper respiratory tract infections, of which the great majority were caused by rhinoviruses. Seasonal patterns of respiratory infections are strongly correlated with hospital admissions for asthma. In school children the major determinant of paediatric admission is school attendance, with the peaks of respiratory infections and asthma admissions both occurring at the start of the school term.

Exacerbations of asthma provoked by respiratory infections are often severe and can be prolonged and associated with increased airway responsiveness. In school children, peak flow measurements can remain abnormal for several weeks after a respiratory tract infection.

Drugs

Relatively few drugs exacerbate asthma. Of those which do, b-blockers and non-steroidal anti-inflammatory drugs (**NSAIDs**) are the most important.

b-Blockers

Precipitation or worsening of asthma was first reported with propanolol, but subsequently found to occur with all non-selective b-adrenoceptor antagonists, implying adrenergic bronchodilator tone in asthmatic airways. The severity of the airway narrowing provoked by b-blockers is not predictable, nor is it closely related to the severity of airway hyperresponsiveness. The dose provoking asthma can be low: severe asthma can be precipitated by timolol eye drops, a non-selective b-blocker used to treat glaucoma. Selective b-antagonists, such as atenolol, acebutalol, and metoprolol, provoke less severe reactions than non-selective b-blockers. However, although the fall in lung function provoked by a b-blocker may be reversed by an inhaled b_2-agonist, the severity of airway narrowing is unpredictable; alternative drugs are available for their indications (such as hypertension and angina), and patients with asthma should avoid b-blockers including b_1-selective antagonists. Although ACE inhibitors can cause cough and occasionally rhinitis, they have not been associated with the provocation of asthma and are not contraindicated in asthma.

Aspirin and NSAIDs

Aspirin and other NSAIDs which inhibit cyclo-oxygenase 1, can provoke severe attacks of asthma in some 10 per cent adults with asthma, more frequently in women than men. Aspirin-induced asthma may be part of a well-recognized association of aspirin intolerance, asthma, and rhinitis with nasal polyps (Samter's triad), which is characterized by severe mucosal eosinophilic inflammation of the nose and airways. The onset is usually in the third or fourth decade, with chronic nasal congestion, discharge, and nasal polyps, followed by development of asthma and aspirin-induced asthma. Ingestion of aspirin or a NSAID then characteristically provokes acute severe asthma within 1 h, accompanied by profuse nasal discharge, peri-orbital oedema, conjunctival infection, in some cases with flushing of the head and neck and, on occasions, with vomiting and diarrhoea. Aspirin-induced asthma can provoke life-threatening asthma resistant to bronchodilators: in one survey, 25 per cent of 145 patients requiring mechanical ventilation for acute severe asthma had aspirin-induced asthma although aspirin ingestion had not necessarily provoked this attack.

Despite avoidance of aspirin and NSAIDs, severe asthma and rhinitis with nasal polyps usually persist, associated with a raised blood eosinophil count and intense eosinophil infiltration of the nasal and airway mucosa. The most plausible explanation of aspirin-induced asthma is that it occurs as a consequence of specific inhibition in respiratory cells of intracellular cyclo-oxygenase enzymes. NSAIDs which inhibit cyclo-oxygenase activity provoke asthma in patients with aspirin-induced asthma; NSAIDs which do not inhibit cyclo-oxygenase activity do not provoke asthma. The potency of NSAIDs to inhibit cyclo-oxygenases correlates with their ability to provoke asthma in individuals with aspirin-induced asthma; and cross-tolerance to NSAIDs that inhibit cyclo-oxygenase occurs after desensitization to aspirin. Cross-tolerance involving such chemically distinct moieties argues strongly against aspirin-induced asthma being an immunological reaction.

The intense tissue eosinophilia is accompanied by overproduction of cysteinyl leukotrienes. In aspirin-induced asthma, cyclo-oxygenase inhibition is associated with release of cysteinyl leukotrienes that are important mediators of nasal inflammation and asthma. Cysteinyl leukotrienes, continuously synthesized in patients with aspirin-induced asthma, even in the absence of aspirin ingestion, are released into nasal and bronchial secretions and can be collected in urine. Aspirin-provoked nasal and asthmatic reactions are attenuated by leukotriene antagonists, both cysteinyl leukotriene receptor antagonists (zafirlukast, montelukast, and pranlukast) and 5-lipoxygenase inhibitors (zileuton).

Patients with aspirin-induced asthma should avoid all aspirin-containing products and other analgesics that inhibit cyclo-oxygenase (Table 2). Patients with aspirin-induced asthma can usually, although not always, take paracetamol. Selective inhibitors of cyclo-oxygenase 2 (celecoxib and rofecoxib) should theoretically be safe, but have not yet been investigated for cross-reactions with aspirin.

Tolerance to aspirin and NSAIDs can be induced in patients with aspirin-induced asthma by the ingestion of increasing doses of aspirin over 2 to 3 days, until 400 to 650 mg of aspirin can be tolerated. Daily doses of between 80 and 325 mg of aspirin can maintain tolerance, allowing aspirin and other cyclo-oxygenase inhibitors to be taken safely. A dose of aspirin of 650 mg twice daily can provide improvement in asthma and particularly nasal inflammation. One report has suggested that

regular aspirin treatment after sinus surgery for polypectomy may delay recurrence of nasal polyps, on average by 6 years. However, aspirin desensitization requires daily maintenance of high-dose aspirin, which may not be well tolerated. Furthermore, omission of aspirin for 2 to 3 days can result in complete loss of tolerance, in which case the initial desensitization protocol needs to be repeated. It is also not clear whether aspirin desensitization has the potential to modify the long-term course of asthma. For these reasons, aspirin desensitization has not been widely adopted.

Clinical features of asthma

The development of asthma

Knowledge of the way that asthma develops has been hindered by the lack of a clear workable definition that includes all cases (sensitive) and excludes non-cases (specific), and by the relative paucity of longitudinal data on well-defined community cohorts, which include a representative group of cases of asthma and are not limited to those coming to medical attention. None the less, there is now sufficient information to allow a reasonable view of the situation.

The relationship between wheezing in preschool children and asthma in school-age children has been clarified by a number of overlapping studies. Wheezing and cough in children aged less than 2 to 3 years is common and typically associated with viral respiratory infections. The important risk factors are reduced lung function at birth, prematurity or low birth weight, and maternal smoking during pregnancy. The prognosis for such children is good, with remission in the majority by school age and normal lung function in adult life. 'Wheezy bronchitis' in preschool years does not occur more frequently in school-age children with asthma, whose risk factors are different, suggesting the two disorders are independent. The peak prevalence of asthma occurs between the ages of 5 and 10 years, is associated with eczema in infancy, and evidence of sensitization to common inhalant allergens (identified either by skin test responses or by increased total IgE).

The outcome for children who develop asthma has been the subject of several general-practice and hospital-based reports, which of necessity will describe the prognosis of more severe cases. The outcome for cases identified in random population samples has been reported from Australia and the United Kingdom. The Australian study found that the risk of asthma persisting at ages 21 and 28 years was associated with the frequency of wheezing at ages 7 and 14 years. Children who wheezed infrequently in childhood and adolescence were least likely to have continuing asthma as young adults: more than half of those with asthma before the age of 7 years that had remitted by the age of 14 years remained symptom free aged 21 years. However, less than 20 per cent of those with persistent symptoms in childhood were symptom free in adolescence, and frequent attacks in this group continued to the age of 28 years. Some two-thirds of those without symptoms in adolescence remained free of asthma at the age of 28 years. The United Kingdom study described the incidence of wheezing from birth to age 33 years. The incidence of wheezy illness at all ages was related to a history of eczema and hay fever. One-quarter of children with a history of asthma or wheezy bronchitis by the age of 7 years continued to have symptoms when aged 33 years. Asthma developing in adult life was strongly associated with cigarette smoking and a history of hay fever.

In both the United Kingdom and Australian studies, asthma recurred in adult life after a period of remission in adolescence. More than one-half of those in the United Kingdom study who had wheezed before the age of 7 years and reported wheezing aged 33 years had been free of symptoms for 7 years between the age of 16 and 23 years. Similarly, in the Australian study, wheezing had recurred in 30 per cent of those who were free of wheezing aged 21 years. In both studies asthma recurred in some individuals with mild symptoms in childhood, which were frequently not recalled, and who would otherwise have been labelled as having 'adult-onset' asthma.

Symptoms and signs

The symptoms of asthma are non-specific: shortness of breath, wheezing, chest tightness, and cough. These are manifestations of airway narrowing, which is usually variable in severity over short periods of time, but can be persistent, and of airway hyperresponsiveness. Asthma as the cause of these symptoms is suggested by the variability in their severity and distinguished by their periodicity (such as daily, weekly, monthly, or seasonal), their provocation by specific (such as allergen) and non-specific stimuli, and their reversibility with bronchodilators or corticosteroids.

Patients with asthma can be categorized, at any one time, by whether their symptoms are intermittent or persistent, and by the severity of their symptoms and underlying airway narrowing (measured by lung function tests. Even those with mild asthma–intermittent or persistent–can develop severe asthma.

1. Mild intermittent asthma—symptoms occur less than weekly with normal or near normal lung function between episodes.
2. Mild persistent asthma—symptoms occur more than weekly but less than daily with normal or near normal lung function between episodes.
3. Moderate persistent asthma—symptoms occur daily with mild to moderate variable airflow limitation.
4. Severe persistent asthma—symptoms occur daily and interfere with normal activities. There is frequent nocturnal waking and moderate to severe variable airflow limitation.
5. Severe asthma—severe distressing symptoms prevent sleep. Severe airflow limitation responds poorly to inhaled bronchodilators and can be life-threatening.

Symptoms of asthma are typically worse at night, waking the affected individual in the early hours of the morning (on occasion several times), and on first waking in the morning, when chest tightness may be the dominant symptom. Asthmatic symptoms may also be provoked by non-specific stimuli such as exercise and cold air, and by specific allergens such as domestic animals, particularly cats.

Respiratory viral infections that occur predominantly in the winter months are the most important precipitating causes of exacerbations of asthma. In patients allergic to pollens or moulds, asthmatic symptoms occur or worsen during the relevant season (in the United Kingdom—late spring: tree pollen; May and June: grass pollen; late summer months: mould spores). In those with asthma induced by occupational sensitizers, symptoms characteristically increase in severity during the working week and improve when away from work on holidays of 1 week or more, if not at weekends (see Chapter 17.4.1.5). In some women asthma has a monthly periodicity, becoming increasingly severe during the days before menstruation, improving with its onset.

Although breathlessness and wheeze are often considered the most characteristic symptoms of asthma, cough can be the dominant and on occasions, particularly in children, the only symptom of asthma. Nocturnal cough suggests asthma, although in community studies isolated nocturnal cough has been found to be a poor predictor of the condition. 'Cough-variant asthma' is occasionally seen in adults who do not have airway narrowing and in whom cough and eosinophil-rich sputum are the only manifestations of the disease.

The characteristic symptoms of asthma are manifestations of variable airway narrowing and airway hyperresponsiveness. Patients with chronic severe asthma have more persistent airway narrowing and are limited in their day to day activities by breathlessness. They may have less symptomatic evidence of spontaneous variability of airway narrowing, although they can be awoken by asthma at night as well as having symptoms provoked by inhalation of cold air or by laughter.

Patients with acute severe asthma are usually distressed by severe shortness of breath with wheezing, unable to sleep and to complete sentences in one breath because of the severity of the airway narrowing.

The physical signs of mild or moderate asthma may be limited to expiratory wheezes audible over the lungs. Because of the variable nature of the airway narrowing, some patients have normal lung sounds, although expiratory wheezes would be anticipated in patients with persistent symptomatic asthma. Patients with chronic persistent asthma can develop hyperinflated lungs.

In acute severe asthma, patients are usually severely short of breath, sitting up or leaning forward using their accessory muscles of respiration. With increasingly severe airway narrowing, expiration becomes increasingly prolonged and alternates with short inspiratory gasps, impairing speech. Tachycardia and pulsus paradoxus often accompany acute severe asthma, but pulsus paradoxus is not a reliable indicator of severity. Airway narrowing may become sufficiently severe for no wheeze to be audible (the 'silent chest') and gas exchange sufficiently impaired to cause detectable cyanosis. Patients with asthma of this severity are usually distressed, hyperventilating, anxious, apprehensive, and can be confused because of hypoxia. Exhaustion ultimately leads to inadequate ventilation and a rising PCO_2, the two cardinal features that indicate the need for transfer to an intensive care unit in the event that assisted ventilation is required.

Diagnosis of asthma

Although asthma is now defined by characteristic pathological changes in the airways, it is usually identified by its pathophysiological manifestations, variable or reversible airway narrowing and airway hyperresponsiveness. In some patients the presence of eosinophils in sputum or a raised eosinophil count in the blood can be

a valuable diagnostic pointer.

Asthma is usually diagnosed by the demonstration of airflow limitation that varies spontaneously over short periods of time, or which reverses after inhalation of short-acting b-agonists or, over a more prolonged period, in response to inhaled or oral corticosteroid. In a small minority of patients, provocation tests using exercise, or pharmacological agents such as histamine or methacholine can be valuable. In suspected cases of occupational asthma, inhalation tests with the specific agent may be indicated (see Chapter 17.4.1.4); inhalation tests with common inhalant allergens are rarely indicated in clinical practice.

Airflow limitation

The most clinically useful measurements of airflow limitation are: (i) forced expiratory volume in 1 s (FEV_1), which may be expressed as a proportion of the forced vital capacity (**FVC**) as FEV_1/FVC per cent, and (ii) peak expiratory flow rate (**PEFR**). Both tests require the patient to provide a reproducible maximal forced expiratory manoeuvre using tested and validated equipment. FEV_1 has the advantage of a visible tracing of the expelled volume of air over time, which allows the observer to determine whether reproducible maximal forced expiratory manoeuvres have been made. PEFR testing does not provide this opportunity. However, peak flow meters employed to measure PEFR, unlike spirometers required to measure FEV_1, can be used regularly by patients to monitor their lung function, indicating the need for altered treatment at an early stage. Whether abnormality of FEV_1 and PEFR should be expressed in absolute or proportional terms remains undecided. Expression as an absolute difference from the average value anticipated for an individual of given age, gender, and height has more physiological validity, but the majority of lung function laboratories in the United Kingdom continue to define as abnormal, values of FEV_1 or PEFR of 20 per cent or more below the mean predicted value.

The difference of the measured from the predicted mean value for an individual can be conveniently expressed as a Z value, which is the number of standard deviations the measured value is from the predicted mean:

$$Z = \frac{\text{predicted mean value} - \text{measured value}}{\text{standard deviation (c.0.5)}}$$

The distribution of FEV_1 around the mean predicted value is similar at all ages (from 25 to 70 years) with a standard deviation of some 0.5 litres. The disadvantage of using a proportional rather than an absolute difference can best be appreciated by comparing a patient whose predicted FEV_1 is 5 litres with one whose predicted FEV_1 is 2.5 litres. In the first patient a 20 per cent reduction equates to a loss of 1 litre (2 standard deviations); in the second a 20 per cent reduction equates to a loss of 0.5 litres (1 standard deviation).

Variability and reversibility of airflow limitation

Serial measurements of PEFR in most patients with asthma show spontaneous variability. The most characteristic pattern is of a circadian variation, with airflow limitation most severe on waking in the morning (and during the night if awoken) with improvement occurring during the morning after waking (Fig. 4). A small circadian variation in PEFR or FEV_1 is seen in normal individuals; in asthma a difference of 20 per cent or more between the highest and lowest values may be found. Other patterns of variation in severity of airflow limitation may be imposed on this circadian rhythm, such as falls in PEFR provoked by exercise or exposure to an allergen or occupational sensitizer, which resolve after avoidance of the stimulus. While variations of 20 per cent or more in FEV_1 or PEFR are commonly regarded as indicating asthma, in patients with severe airflow limitation, with an FEV_1 of 1 litre, 20 per cent variability equates to 200 ml, a level of spontaneous variation observed in people without asthma.

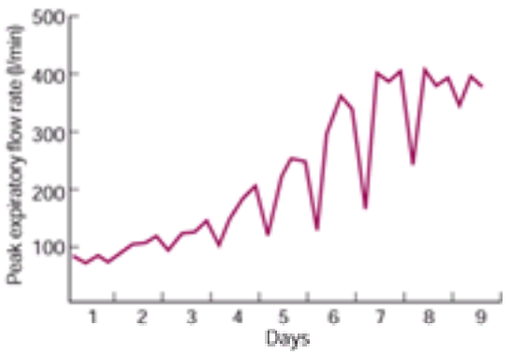

Fig. 4 Circadian rhythm in peak expiratory flow rate in a patient with asthma recovering from an acute attack.

The most commonly used means to identify asthma in clinical practice is an improvement after 15 to 20 min in airflow limitation, identified by FEV_1 or PEFR, after inhalation of a bronchodilator, usually a short-acting b-agonist such as salbutamol in a dose of 200 µg—evidence of asthma is usually regarded as an improvement in FEV_1 or PEFR of 20 per cent or greater. However, it is important to appreciate that the absence of a significant improvement in lung function after inhalation of a bronchodilator does not exclude a diagnosis of asthma (that is, it is a more specific test than it is sensitive). Rapid reversibility of airflow limitation is more readily seen in young adults with mild or moderate asthma than in older patients with more severe airflow limitation. Reversibility cannot be tested in a patient whose lung function is normal at the time of testing.

An increase of 20 per cent or more from baseline FEV_1 or PEFR is generally accepted as diagnostic of asthma. Expressing change as a proportion of baseline will exaggerate the degree of improvement in those with a low initial FEV_1 or PEFR. A 20 per cent increase in FEV_1 in a patient with a baseline FEV_1 of 4 litres is 800 ml, but only 200 ml in a patient whose baseline FEV_1 is 1 litre. Studies of short-term (20 min) variability in FEV_1 in patients with airflow limitation have found that the increase in FEV_1 needed to exclude natural variability with 95 per cent confidence was 160 ml. This value did not differ significantly from the value in normal individuals, in whom an absolute increase in FEV_1 of 190 ml was needed to exclude a chance increase with 95 per cent confidence. In both normal individuals and those with an airflow limitation, expression of variability as an absolute difference was similar at all levels of FEV_1, whereas when expressed as a percentage change, the degree of variability decreased with increasing FEV_1. Selecting a specific percentage change in FEV_1 (or PEFR) to define asthma will necessarily include a greater proportion of patients with lower prebronchodilator FEV_1. Equally, patients with a higher baseline FEV_1 need to achieve a greater absolute increase to fulfil the defined criterion. Expression of variability as an absolute change has more biological and statistical validity, and an increase of more than 200 ml in FEV_1 has a probability of less than 5 per cent of occurring by chance. As with expression of lung function, it is unlikely that the use of results based on absolute values, although biologically more valid, will be adopted. It should be appreciated, however, that in patients with a low FEV_1 a 20 per cent increase in FEV_1 may have occurred by chance, and in those with a high FEV_1 an increase of more than 200 ml is unlikely to have occurred by chance.

In some patients with asthma, particularly those with severe airflow limitation, inhalation of a short-acting bronchodilator does not provide significant improvement in FEV_1 or PEFR. In these circumstances the diagnosis of asthma and differentiation from less reversible causes of airflow limitation, such as chronic bronchitis and emphysema, can be made with a 'trial' of treatment with corticosteroids. Significant improvement in airflow limitation both implies a diagnosis of asthma and demonstrates that corticosteroids (inhaled or oral) are effective treatment. However, corticosteroids can also improve exercise tolerance by enhancing mood and outlook, hence the benefit of a trial of steroids has to be judged by its effect on lung function. Although there is no formally agreed protocol for a steroid trial, a generally acceptable trial would be oral prednisolone taken in a dose of 0.6 mg/kg, (40 mg/day in a 70 kg male) for 3 weeks, with measurement of spirometry made on at least two separate occasions, once before and once at the end of the trial supplemented by three times daily home peak flow measurements. Symptomatic improvement with an increase in FEV_1 or PEFR of 20 per cent or more during the trial is generally considered as evidence of asthma and an indication for treatment with corticosteroids, inhaled or oral.

Tests of airway hyperresponsiveness

Airway hyperresponsiveness—an exaggerated response to non-specific provocative stimuli—is a cardinal feature of asthma. Tests of airway responsiveness to exercise and to inhaled histamine or methacholine, which can provoke acute airway narrowing in a dose-dependent fashion, can be of value in the diagnosis of asthma, particularly in patients with symptoms suggestive of the condition but in whom measured lung function is normal or, if abnormal, shows no reversibility with inhaled bronchodilators. These tests are required in only a few patients and each has its limitations: exercise testing can be insensitive (false negatives) and tests of airway reactivity to inhaled histamine or methacholine non-specific (false positives), although the provocation of a 20 per cent fall in FEV_1 by histamine at 4 mg/ml or less (or equivalent) occurs uncommonly in those without asthma.

Exercise testing

Acute airway narrowing provoked by exercise is a common feature of asthma, particularly in children. Testing for exercise-provoked asthma requires continuous exertion for 5 min. This is most conveniently undertaken in a lung function laboratory by running on a treadmill or exercising on a cycle ergometer, although free running is more likely to provoke an asthmatic reaction. Measurements are made of FEV_1 or PEFR 5 min before, during, and at 5 min intervals for 30 min after the test. A normal individual will have a less than 5 per cent increase in FEV_1 or PEFR during and a less than 10 per cent fall after exercise. Depending on the level of baseline, patients with asthma can have a greater than 5 per cent increase during exercise and greater than 10 per cent fall from pretest value afterwards. Exercise is a valid and reproducible test for asthma, although it can have false negatives, particularly when undertaken by methods other than free running.

Airway reactivity to inhaled histamine or methacholine

Acute airway narrowing can be provoked in a dose-dependent manner by the inhalation of increasing doses of a bronchoconstrictor, of which histamine or methacholine are the most commonly used. The test as described by Cockcroft and colleagues consists of tidal breathing of doubling doses of histamine, with measurement of FEV_1 6 min after each inhaled dose. The percentage change in FEV_1 from a post-saline baseline after each concentration of inhaled (histamine) can be plotted, the test being terminated when either a 20 per cent or greater fall in FEV_1 is provoked or the maximum concentration (usually 16 or 32 mg/ml) is reached. The level of airway reactivity is usually expressed as the concentration of histamine that provokes a 20 per cent fall in FEV_1 (PC_{20} histamine), which can be identified by linear interpolation. The lower the PC_{20}, the more reactive the airways. The test is usually repeatable within one doubling dose, but may not be consistent in any individual, PC_{20} falling, for instance, after exposure to allergen or occupational sensitizer.

In population studies the major determinants of airway reactivity have been atopy (in children and young adults) and smoking in older adults (probably reflecting reduced FEV_1). Airway responsiveness can be increased in atopic children with rhinitis and in healthy adults after a viral respiratory tract infection. Hence, evidence of measurable airway reactivity is not necessarily evidence of asthma, but it is uncommon for individuals without asthma to have a PC_{20} histamine of methacholine of less than 8 mg/ml. Measurement of airway reactivity to histamine or methacholine is more sensitive than exercise testing, although a less specific test for asthma. Like exercise testing its value in clinical practice is primarily in symptomatic patients with normal or near normal FEV_1 and without evidence of spontaneous variability or reversibility. A negative test in a symptomatic patient suggests that current asthma is unlikely to be the cause of their symptoms.

Imaging in asthma

Imaging of the chest is not commonly of diagnostic value in asthma, but can be important in identifying its complications. In patients in whom asthma develops over the age of 30 years, the chest radiograph is usually normal. However, about one-quarter of children and one-fifth of adults show changes of hyperinflation on the chest radiograph. These changes include a low diaphragm (below the sixth intercostal space anteriorly) and an increased retrosternal space. In some children with chronic persistent asthma, the length of the lung becomes greater than the width of the thorax, with the posterior ends of the ribs becoming more horizontal.

The most commonly observed radiographic sign in asthma is of thickened bronchial walls due to eosinophilic infiltration of the airways: these are visible on the chest radiograph as parallel lines ('tram lines') or as a thick-walled ring shadow when seen end on.

Complications of asthma that can be seen on the chest radiograph include pneumothorax, pneumomediastinum, pulmonary collapse, and eosinophilic pneumonia. The physical signs of pneumothorax can be difficult to detect in an asthmatic attack, but its detection can be lifesaving. Pneumomediastinum is of less clinical importance. Plugging of the airways by a mucus plug characteristically occurs in allergic bronchopulmonary aspergillosis, but also in asthmatic patients without this condition: in both it can cause atelectasis, which is usually lobar or segmental. Eosinophilic pneumonia is characterized by consolidation on the chest radiograph accompanied by a raised blood eosinophil count. This can be a manifestation of several conditions that include allergic bronchopulmonary aspergillosis, helminth infections, and drug reactions, as well as being of unknown cause—acute and chronic eosinophilic pneumonia. Of these, allergic bronchopulmonary aspergillosis and chronic eosinophilic pneumonia (which can be a manifestation of Churg–Strauss syndrome—allergic granulomatosis) are the most common causes of eosinophilic pneumonia in patients with asthma. (See Chapter 17.11.5, Chapter 17.11.9 and Chapter 17.11.11 for further discussion of these conditions.)

Differential diagnosis of asthma

Asthma needs to be differentiated from:

1. localized airways obstruction;
2. other causes of generalized airways obstruction; and
3. other causes of intermittent breathlessness.

Localized airways obstruction

Upper airways obstruction, of the larynx or trachea, causes a monophonic inspiratory wheeze (stridor) audible over the trachea with a characteristic abnormality of the flow volume loop—decreased inspiratory flow rates. In a child, wheezing can be caused by an inhaled foreign body (classically a peanut), which should be particularly suspected when the problem develops suddenly in a previously healthy individual. The chest radiograph may show the foreign body if it is opaque, or distal atelectasis, consolidation, or air trapping on an expiratory film (which may not be possible to obtain in small children). However, it can be normal and, if foreign body inhalation is suspected, bronchoscopy should be undertaken to identify and remove it or to exclude the possibility. In adults, localized airway narrowing is more likely to be due to a tumour—benign or malignant—which may occasionally cause a unilateral monophonic wheeze. The tumour may be visible on the chest radiograph, but definitive diagnosis will require bronchoscopy and biopsy.

Generalized airways obstruction

The major causes of generalized airways obstruction from which asthma needs to be distinguished are chronic bronchitis and emphysema, although in some cases these may coexist with asthma. Other causes such as obliterative bronchiolitis are less common. In general, chronic bronchitis and emphysema cause breathlessness on exertion that increases slowly in severity over years and only uncommonly causes breathlessness before the age of 40 years. Nocturnal waking by respiratory symptoms is uncommon in chronic bronchitis and emphysema, although not universal in asthma. Chronic severe asthma responsive to corticosteroids, but without significant reversibility to inhaled bronchodilators, may have similar radiographic and spirometric abnormalities. In both, the lungs may be hyperinflated on the chest radiograph, but in asthma, unlike emphysema, there is no associated loss of vascular markings. Lung function tests in both asthma and emphysema can show airflow limitation with reduced FEV_1, reduced FEV_1/FVC ratio, and hyperinflated lungs with increased total lung capacity. However, while factor transfer ($TLCO$) and gas transfer coefficient (KCO) are reduced in emphysema, in asthma KCO is normal or increased. Differentiation from chronic bronchitis can be difficult because, like asthma, there is no loss of vascular markings on the chest radiograph or reduction of KCO. If present, sputum (and blood) eosinophilia suggests asthma, but differentiation in these circumstances often depends on the outcome of a trial of steroids.

In young children asthma needs to be differentiated from wheezing episodes associated with viral respiratory tract infections, and in children and adolescents from cystic fibrosis. Cystic fibrosis is suggested by disproportionate production of (usually discoloured) sputum, weight loss, and an abnormal chest radiograph. The

presence of staphylococci in sputum and development of nasal polyps in childhood is very suggestive of cystic fibrosis.

Other causes of intermittent breathlessness

The most important causes of intermittent breathlessness from which asthma should be differentiated are left ventricular failure, pulmonary emboli, extrinsic allergic alveolitis, hyperventilation, and vocal cord dysfunction.

Left heart failure sufficient to cause breathlessness will usually be apparent on clinical examination, chest radiograph, ECG, and echocardiogram. The heart is clinically and radiographically enlarged, with the exception of pulmonary venous hypertension caused by mitral stenosis. Inspiratory crackles are usually audible at the lung bases and the jugular venous pressure may be elevated. In addition to an enlarged heart the chest radiograph may show upper lobe venous distension, Kerley 'B' lines, and pleural effusion. Echocardiography will usually show evidence of left ventricular disease, or in the case of mitral stenosis, left atrial enlargement. Identification of the cause of breathlessness can be difficult when left heart failure is provoked by an intermittent arrhythmia.

Pulmonary embolism causes breathlessness that can occasionally be associated with wheezing; the diagnosis is suggested by associated pleuritic pain and haemoptysis. The chest radiograph and CT scan may show pleural-based 'humpback' opacities and pleural effusion. The diagnosis is most securely made angiographically, but more usually from a ventilation perfusion scan or spiral CT scan. A normal ventilation perfusion scan makes all but the smallest emboli unlikely, although interpretation can be difficult in patients with widespread ventilatory disease. A normal spiral CT scan excludes pulmonary emboli to subsegmental level.

Extrinsic allergic alveolitis

Extrinsic allergic alveolitis can provoke recurrent episodes of breathlessness which characteristically develop 4 to 8 h after exposure to the cause (usually mouldy hay or birds—pigeons or budgerigars). Breathlessness in extrinsic allergic alveolitis is usually not accompanied by wheeze but with fever, flu-like symptoms, and a neutrophil leucocytosis. The chest radiograph often shows widespread nodular or groundglass shadowing and the CT scan discrete areas of groundglass opacification. Lung function tests show a proportionate reduction in FEV_1 and FVC, which may be accompanied by a reduced *TL*CO and *K*CO. (See Chapter 17.11.11 for further discussion.)

Hyperventilation

Episodes of hyperventilation may be difficult to distinguish symptomatically from asthma, and can in some cases complicate asthma. The diagnosis should be suspected in a patient who complains of breathlessness that occurs without identifiable cause (for example while sitting reading), may be associated with pins and needles in the fingers and dizziness (attributable to hypocapnia), and does not disturb sleep. The symptoms complained of can often be reproduced by a short period of voluntary overbreathing; 20 deep breaths is usually sufficient. The reason why some patients present with hyperventilation is unknown: Howell has suggested that it develops in obsessional (perfectionist) personalities and is usually precipitated by one of three events: bereavement, resentment, or concern about illness. However, it is important to recognize that asthma is characteristically a variable condition and a diagnosis of hyperventilation should not be made on the basis of absent physical signs or normal lung function at the time of consultation, but based on the characteristics described above.

Vocal cord dysfunction

Vocal cord dysfunction is easily misdiagnosed as asthma and may coexist with asthma. Wheezing, in vocal cord dysfunction, is caused by paradoxical adduction of the anterior two-thirds of the vocal cords on inspiration, and does not occur during sleep. The diagnosis is best made by direct examination of the cords during an attack. Management can be difficult, but recognition of the condition can allow high-dose oral corticosteroid treatment for 'uncontrolled asthma' to be avoided.

Hyperventilation and vocal cord dysfunction can each occur in patients with underlying asthma, frequently in association with underlying psychosocial problems. A critical point can be to determine the relevant life events associated in time with the onset of deterioration in the patient, who has often had previously well-controlled asthma. Vocal cord dysfunction is more common in women and in those engaged in health care provision.

Management of asthma

Objectives

The objectives of treating patients with intermittent or persistent asthma are:

1. to prevent troublesome symptoms (such as cough, shortness of breath) at night or with exercise;
2. to enable patients to achieve normal levels of activity;
3. to maintain normal or near normal lung function; and
4. to prevent recurrent episodes of acute severe asthma and minimize the need for emergency hospital treatment.

These objectives are most likely to be achieved by treatment that reduces airway inflammation, either by avoidance of its inducing cause or by drugs with anti-inflammatory activity. The risk of side-effects of asthma treatment should be appreciated and minimized, patients' concerns about the potential side-effects of long-term treatment should be recognized, and relevant information provided to them.

Treatment selection

Randomized controlled trials of asthma treatments published in the past decade have shown the magnitude of benefit of different treatment interventions in patients with asthma of varying severity. This information has provided a secure basis for deciding which treatment is likely to be most effective in individual patients. Of particular importance has been the broadening of the indications for the use of inhaled corticosteroids. Inferences from these studies on the optimal treatment for asthma of differing degrees of severity has informed the published guidelines for asthma management in the United Kingdom, United States, and elsewhere.

The targets for effective asthma treatment in individual patients are:

1. normal daytime activities, such as going to work and to school, as well as the ability to enjoy physically demanding activities (such as sport);
2. sleeping through the night without awakening by respiratory symptoms;
3. use of 'rescue' medication with inhaled b_2-agonists needed less than once per day;
4. normal or near normal PEFR and FEV_1, with less than 20 per cent variability between best and worst values; and
5. avoidance of drug side-effects.

Targets 1, 2, and 5 are of the most interest to the patients, who will primarily be seeking improvement in their quality of life from treatment. Zealous pursuit of restoration of normal lung function in a patient whose quality of life has already been restored by treatment is of questionable value.

Asthma, except where caused by a dominant and avoidable agent (such as a domestic pet or occupational sensitizers), is not usually curable, but current treatment offers the great majority of patients the opportunity to enjoy a normal life. Most asthma is mild: in one community survey only 15 per cent of patients had persistent asthma of moderate severity (step 3 of British Thoracic Society (**BTS**) guidelines or worse—see below). However, some 5 per cent of patients have severe asthma that responds poorly to conventional treatment. These patients suffer most, both from their disease and from the side-effects of its treatment, and are at highest risk of admission to hospital and death from asthma.

Treatments for asthma

Allergen avoidance

The identification and, where feasible, the avoidance of relevant allergens at home or at work should be considered an essential part of the management of asthma. It enables patients to recognize important causes of their asthma and to take responsibility for their avoidance. Allergen avoidance should be regarded as complimentary to drug treatment of asthma, with the advantage in some cases (where a single allergen is the dominant cause) of providing a cure with avoidance of the possible side-effects of drugs. Complete avoidance of exposure to house dust mite, domestic pets, and occupational causes of asthma has been associated with marked improvement in respiratory symptoms, lung function, and airway hyperresponsiveness. Avoidance of exposure is most clearly indicated and usually most feasible when the cause of asthma is an agent inhaled at work (see Chapter 17.11.1.5). Removal of a pet, particularly a cat from the home, is most effective when accompanied by thorough cleaning and washing of the house to remove residual allergen, which can otherwise persist in concentrations sufficient to provoke asthma for many months. Avoidance of exposure to the house dust mite, *D. pternonyssinus*, by spending several months in the Alps or in a hospital, has been shown to provide symptomatic and functional improvement. However, house dust mites are ubiquitous in many environments, including much of the United States, United Kingdom, and Europe, and it can be difficult to eliminate mites sufficiently from the home so that exposure to the relevant allergens (such as Der p1) is reduced to concentrations which do not continue to induce airway inflammation. The issue with house dust mite avoidance is the feasibility of securing an effective intervention.

Drug treatment

The drugs primarily used to treat asthma are the progeny of two hormones secreted by the adrenal glands: cortisol and adrenaline. Pharmaceutical research in the past 50 years has led to the development of selective b $_2$-agonists, both short and long acting, and lipid-soluble topically active inhaled corticosteroids. b $_2$-Agonists and corticosteroids account for nearly 90 per cent of prescriptions for asthma in the United Kingdom. Other drugs used include sodium cromoglycate and nedocromil sodium amongst the prophylactic agents, and ipratropium bromide and theophyllines amongst the bronchodilators. The core treatment for mild and moderately severe persistent asthma is inhaled corticosteroids and inhaled b $_2$-agonists. Other agents are used as additional treatments when these alone are not sufficient to provide control. Leukotriene receptor antagonists and 5-lipoxygenase inhibitors have been introduced recently; their place in the treatment of asthma is currently being assessed.

Corticosteroids

Corticosteroids are the most effective treatment for asthma. Systemic corticosteroids were introduced for this purpose in the 1950s, but their use was limited by serious unwanted side-effects, which stimulated research into the development of equally effective but safer alternatives. The introduction of topically active corticosteroids that can be administered by inhalation and are free of the systemic side-effects of oral corticosteroids at therapeutically effective doses has revolutionized the treatment of asthma.

Corticosteroids suppress airway inflammation, with improvement in airway hyperresponsiveness, lung function, and associated respiratory symptoms. Although the mechanism of action of steroids in asthma continues to be debated, they inhibit the formation of cytokines relevant to asthmatic inflammation, such as interleukin 4 (**IL-4**), IL-5, IL-13, and granulocyte–macrophage colony-stimulating factor, by lymphocytes and macrophages, by inhibition of transcription of cytokine genes.

Corticosteroids suppress the chronic inflammation in the asthmatic airways, but do not cure the disease. To be effective they must therefore be taken continuously—oral steroids usually daily and inhaled steroids usually twice daily.

Oral corticosteroids

Oral corticosteroids—prednisolone and prednisone—are rapidly absorbed from the gut, achieving peak plasma levels at 1 to 2 h. Prednisone is biologically inactive but rapidly and completely converted in the liver to the active form, prednisolone. Some 20 per cent of prednisolone is inactivated in the liver by first-pass metabolism leaving 80 per cent of the oral dose bioavailable. The plasma half-life of prednisolone is usually 2 to 3 h. Corticosteroids are inactivated in the liver by conjugation. Hepatic enzyme inducers such as rifampicin, barbiturates, and phenytoin can reduce the half-life of prednisolone by 50 per cent. To counter the consequent reduction in anti-inflammatory activity, the dose of oral prednisolone should be doubled in patients concurrently receiving these treatments.

Oral corticosteroids effect detectable improvement in airflow limitation in patients with asthma within 6 to 12 h of administration. In cases of severe asthma, maximum improvement can take several days, probably reflecting the time to reverse the inflammatory changes in the airways.

The early use of oral corticosteroids in the treatment of asthma was severely limited by the high risk of unwanted effects, which include osteoporosis, hypertension, diabetes mellitus, cataract formation, and (in children) growth suppression. The introduction in the 1970s of inhaled corticosteroids revolutionized the treatment of asthma by providing local anti-inflammatory activity in doses that did not cause these limiting systemic side-effects.

Inhaled corticosteroids

Inhaled corticosteroids are highly lipophilic and rapidly enter cells within the airways. They combine high topical potency with low systemic bioavailablilty of the swallowed dose and rapid metabolic clearance of any corticosteroid reaching the systemic circulation, conferring a high benefit:risk ratio. Although 80 to 90 per cent of a dose from a metered dose inhaler is deposited in the oropharynx, swallowed, and absorbed, more than 80 per cent of beclomethasone, 90 per cent of budesonide, and 99 per cent of fluticasone is inactivated by first-pass metabolism in the liver. The 10 to 20 per cent of the inhaled dose deposited in the airways is available for absorption into the systemic circulation. For fluticasone and budesonide, devices that increase lung deposition (such as large volume spacer and Turbohaler) therefore increase the dose available for systemic absorption.

At present, three inhaled corticosteroids are generally available: beclamethasone diproprionate, budesonide, and fluticasone proprionate. Beclomethasone and budesonide are equipotent; fluticasone is twice as potent, requiring half the dose to achieve the same benefit. In general, most of the benefit of inhaled corticosteroids in the treatment of asthma is effected at low doses, where there is little evidence of adverse effects. By contrast, adverse effects develop at higher inhaled doses, where there is little evidence of greater benefit.

The clinical effects and side-effects of inhaled corticosteroids have been the subject of considerable clinical investigation. A systematic review of five randomized controlled trials comprising 141 adults with mild, persistent asthma that compared inhaled steroids with b $_2$-agonists found significant improvement in lung function in those receiving inhaled steroids. A randomized controlled trial that compared inhaled budesonide at 1200 µg/day with regular inhaled terbutaline in adults found improvement in the budesonide group during the 2 years of the study in respiratory symptoms, morning peak flow rates, airway hyperresponsiveness to inhaled histamine, and requirement for symptomatic b$_2$-agonists. In a subsequent study of the same population, no deterioration in symptoms or lung function, including airway responsiveness to inhaled histamine, occurred in three-quarters of those randomly assigned to reduce their dose of budesonide from 1200 to 400 µg/day, whereas deterioration in symptoms and lung function occurred in two-thirds of those assigned to discontinue budesonide and take placebo. Symptoms and lung function improved in those patients who had received terbutaline during the initial study and were subsequently assigned to budesonide at 1200 µg/day. However, the extent of improvement was less than in those originally assigned budesonide 2 years earlier, suggesting possible benefit from the earlier institution of inhaled corticosteroid treatment.

Several recent studies have compared the benefit of increasing the dose of inhaled steroid with the addition of a long-acting b $_2$-agonist (salmeterol or formoterol) in patients whose asthma was not controlled by conventional doses of inhaled steroids. Two randomized controlled trials found that the addition of twice daily inhaled salmeterol provided more benefit in terms of symptom-free days and nights, improvement in FEV_1 and PEFR, and need for rescue b$_2$-agonists than doubling the dose of inhaled steroids (Fig. 5). A third randomized controlled trial of 852 patients with moderately severe asthma investigated (i) the addition of formoterol 12 µg twice daily to budesonide 100 µg, (ii) increasing the dose of budesonide to 400 µg twice daily, and (iii) the addition of formoterol 12 µg twice daily to budesonide 400 µg twice daily. Symptoms of asthma and lung function were improved with both higher dose budesonide and with formoterol, but greater improvements were obtained with the additions of formoterol.

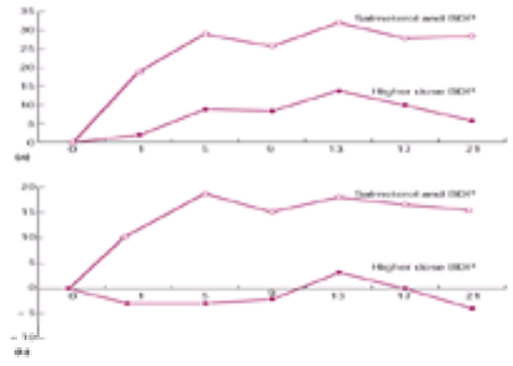

Fig. 5 Comparison of addition of salmeterol compared with doubling dose of inhaled steroid (BDP).

Inhaled corticosteroids are as effective in the treatment of asthma in children as in adults. Comparison in a randomized controlled trial of inhaled budesonide (600 µg/day) with an inhaled placebo for an average of 22 months in 116 children aged between 7 and 16 years also taking inhaled salbutamol at 200 µg/day showed marked benefit in the group taking inhaled budesonide: 26 children (45 per cent) in the placebo group withdrew from the study compared with only 3 (5 per cent) in the budesonide group. Symptoms and lung function (FEV_1, PEFR, and airway response to inhaled histamine) improved significantly in the budesonide group. Cessation of inhaled budesonide treatment in a randomized controlled trial in children aged 11 to 18 years previously treated for 28 to 36 months was associated with: recurrence of symptoms, in some of sufficient severity to need treatment with prednisolone; increased use of inhaled b_2-agonists; and deterioration in lung function, both FEV_1 and airway response to inhaled histamine. Such deterioration did not occur in the group continuing to take budesonide at 600 µg/day.

Side-effects of inhaled corticosteroids

Local side-effects

The severe adverse effects of systemic steroids and the widening indications for the use of inhaled corticosteroids has led to close scrutiny of the side-effects of inhaled corticosteroids. Local side-effects are well recognized and are dose dependent. These are oropharyngeal candidiasis (thrush) and dysphonia. Oropharyngeal candidiasis occurs in about 5 per cent of patients and can be a problem, particularly in the elderly. The risk of its development can be reduced by the use of a large volume spacer and rinsing the mouth out after each inhaled dose. Dysphonia occurs in at least one-third of patients and can cause particular problems for public speakers and professional singers. It is believed to be due to a myopathy of the laryngeal muscles and reverses when treatment is stopped. Inhaled corticosteroids do not cause atrophy of the airway epithelium after 10 years of treatment and are not associated with an increased risk of pulmonary infection, including tuberculosis.

Systemic side-effects

Concern about systemic side-effects of inhaled steroids stems from the need for their regular use for prolonged periods (years or decades) both in adults and children. Because many patients who take inhaled corticosteroids have also required oral corticosteroids, distinguishing the adverse systemic effects of inhaled corticosteroids can be difficult. In general, current evidence indicates that inhaled corticosteroids do not cause important side-effects in doses of up to 400 µg/day in children and 800 µg/day in adults. There is some evidence of side-effects at higher doses, more with beclomethasone than with budesonide or fluticasone. However, systemic absorption and the risk of systemic side-effects can be reduced by the use of a spacer with metered dose inhalers and by rinsing the mouth after inhalation of a dry powder inhaler, which should be recommended when doses of 400 µg/day or more in children and 800 µg/day or more in adults are prescribed.

Two important risks of inhaled corticosteroids that have been the subject of recent concern are osteoporosis in adults and growth suppression in children. A cross-sectional study of 81 patients with asthma aged between 20 and 40 years compared bone mineral density in 47 (19 men) who had taken inhaled steroids in doses of between 100 and 3000 µg/day (mean dose 620 µg/day) for at least 5 years with 34 (19 men) who had never taken inhaled or oral corticosteroids. Bone mineral density was not different in the two groups, but cumulative inhaled steroid dose was associated with a reduction of bone mineral density in the lumbar spine of 0.1 standard deviations per 1000 µg inhaled corticosteroid per year. In a subsequent study of adults aged between 20 and 40 years, who had taken inhaled steroids on average for 6 years, bone mineral density of the lumbar spine and femoral neck was inversely correlated with cumulative inhaled corticosteroid dose: doubling of inhaled corticosteroid dose was associated with an estimated decrease in bone mineral density of 0.16 standard deviations. Although unlikely to be associated with fracture in this age group, these results imply that bone mineral density would become significantly decreased in adults taking inhaled corticosteroids by their fifth and sixth decades, potentially increasing the risk of osteoporotic fracture substantially in later life.

Inhaled corticosteroids also increase the risk of posterior subcapsular cataract, glaucoma, and easy skin bruising.

Both asthma and oral corticosteroids can impair growth in children, but longitudinal studies have found no evidence of growth impairment in children taking inhaled corticosteroids in doses of up to 800 µg/day. A meta-analysis of 21 studies, including more than 800 children, found no effect of inhaled beclamethasone on height. None the less, the potential of inhaled corticosteroids taken in high doses for prolonged periods to impair growth remains, and regular monitoring of the growth of children taking inhaled steroids should be undertaken.

Beclomethasone and budesonide in doses of more than 160 µg/day taken by a metered dose inhaler cause a dose-dependent reduction in morning plasma cortisol and 24-h urinary cortisol excretion. However, 2000 µg/day of these inhaled corticosteroids when taken via a spacer has no effect on 24-h urinary cortisol. In children, beclomethasone in daily doses of 800 µg had no effect on 24-h urinary cortisol excretion.

The evidence of side-effects caused by inhaled corticosteroids, particularly osteoporosis, is now sufficient to mean that the lowest dose of inhaled corticosteroid which is clinically effective should be prescribed in both children and adults, and particularly in patients taking topical corticosteroids by other routes (such as nose or skin), and the dose tapered to the minimum necessary when symptomatic and functional improvement is achieved.

b_2-Adrenoreceptor agonists

b-Agonists are sympathomimetic amines that include catecholamines—both naturally occurring adrenaline, noradrenaline, and dopamine and synthetic isoprenaline—and non-catecholamines, both short-acting, such as salbutamol and terbutaline, and long-acting, such as salmeterol and formoterol. Catecholamines have been replaced in the treatment of asthma by b_2-selective non-catecholamines, which have a longer half-life than catecholamines because they are not subject to catecholamine uptake mechanisms and not broken down by catechol-*O*-methyl transferase. The duration of bronchodilatation after inhalation of non-catecholamines is longer; the effects of salbutamol and terbutaline persisting for 3 to 6 h and of salmeterol and formoterol for up to 12 h.

The actions of b-agonists in asthma are the result of stimulation of b-adrenoreceptors that are located in the airways, on airway epithelium, submucosal glands, airway and vascular smooth muscle. b-Receptors in the airways are entirely $b_{2,}$ with the exception of some b_1 -receptors on submucosal glands.

b_2-Agonists can influence airways function through several mechanisms:

1. relaxation of bronchial smooth muscle by direct effect on b_2-receptors;
2. inhibition of mast cell mediator release; and
3. enhanced mucociliary clearance.

Inhalation of a b_2-agonist by a patient with asthma increases airway calibre and reduces airway hyperresponsiveness. b_2-Agonists also cause tachycardia and increased cardiac output, systemic vasodilatation, and increased muscle blood flow. The tachycardia and increased cardiac output are the results of both stimulation of cardiac b-adrenoreceptors and a reflex response to peripheral vasodilatation. In addition b_2-agonists cause tremor and have metabolic actions, of which

hypokalaemia is probably the only potentially important clinical effect.

Inhaled, selective, short-acting b $_2$-agonists reverse mild acute airway narrowing and are sufficient treatment, alone, for mild intermittent asthma causing occasional symptoms. (Step 1 of BTS guidelines: Table 3.)

Studies comparing regular with as-needed inhaled b $_2$ -agonists in patients with asthma not taking inhaled corticosteroids have shown that regular treatment confers no benefit over as-needed inhalation and can have adverse consequences. A randomized controlled trial in 255 patients with mild intermittent asthma, comparing salbutamol taken as-needed with regular treatment, found no difference at 16 weeks in respiratory symptoms, airway function, or frequency of exacerbations. However, those taking regular salbutamol took more salbutamol, showed more variability in peak flow rates, and had increased airway responsiveness to inhaled methacholine. Short-acting b $_2$-agonists should, in general, be reserved to provide reversal of acute airway narrowing, taken as-needed or prior to exercise in patients with exercise-provoked asthma, except in cases of severe asthma not controlled with maximal doses of inhaled corticosteroids and additional long-acting b $_2$-agonist (step 4 BTS guidelines), when regular inhaled short-acting b $_2$-agonists can be added.

By contrast, long-acting b $_2$-agonists—salmeterol and formoterol—are taken regularly and their addition to inhaled corticosteroids has been shown to be more effective than doubling the dose of the inhaled corticosteroids in improving symptoms and lung function in patients not controlled by low-dose inhaled corticosteroids. Regular treatment with long-acting b $_2$-agonists, when taken with inhaled corticosteroids, has not been associated with deterioration in asthma control.

Two epidemics of asthma deaths, the first in the 1960s in six countries which followed the introduction of Isoprenaline Forte, the second in the mid-1970s in New Zealand after the introduction of fenoterol, have led to concerns about the safety of inhaled b-agonists. Case–control studies have also identified an association between asthma deaths and overuse of inhaled b $_2$-agonists. However, the evidence for cause and effect is confounded because overuse of b $_2$-agonists to treat frequent symptoms is more likely to occur in patients with severe uncontrolled asthma who are at high risk of a fatal attack. The evidence for cause and effect in the asthma epidemics is stronger: the increased death rates that followed the introduction of the particular inhaled b-agonists fell rapidly after recognition of the association and no other plausible explanation has been advanced. Isoprenaline is a non-selective b-agonist and fenoterol is less selective than salbutamol and terbutaline. Both drugs were marketed in high dose and are cardiotoxic in the presence of hypoxia, hence both epidemics may have been due to the acute cardiac effects of b-agonists inhaled in high dose by hypoxic patients with acute severe asthma. The evidence that selective b $_2$-agonists formulated in lower doses have a similar cardiotoxic effect and cause asthma deaths outside these epidemics is limited to associations in case–control studies, from which it is not possible to infer cause and effect. However, a small effect can be difficult to detect and, as pointed out by Tattersfield, if a fatal arrhythmia occurred in 1 in 8000 patients treated with b-agonists each year this would account for 50 per cent of asthma deaths in patients under 65 years, but its detection would require observation of many thousands of patients.

Methylxanthines

Theophylline is the pharmacologically active methylxanine most usually employed in clinical medicine, because of its greater bronchodilator activity, less erratic absorption, and longer half-life. More predictable theophylline absorption can be obtained by slow-release formulations and the addition of ethylene diamine to theophylline (aminophylline) provides the increased solubility required for intravenous administration. None the less, theophylline has a relatively narrow 'therapeutic window' for a safe and effective dose, with wide differences among individuals in its metabolism, which can also be adversely affected by several extrinsic factors to cause clinically important side-effects. The most common side-effects are 'caffeine-like': anorexia, nausea, and vomiting, followed by headache and insomnia. At higher concentrations, potentially fatal fits and arrhythmias can occur.

Theophylline relaxes bronchial smooth muscle and, like b-agonists, is a functional antagonist that causes bronchial muscle relaxation irrespective of the constrictor stimulus. Its action was thought to be mediated via phosphodiesterase inhibition increasing intracellular cyclic AMP. However, the intracellular concentration necessary for theophylline to achieve this is some 20 times greater than its therapeutic plasma levels. More recently, anti-inflammatory activity in 'subtherapeutic' concentrations has been suggested as a possible mechanism of action in asthma.

In addition to bronchodilatation, theophylline increases the force and rate of heart contraction and causes vasodilatation. In toxic doses it can cause arrhythmias, which may be fatal. It is also a central nervous system stimulant, causing increased alertness and, in toxic doses, confusion, irritability, and fits.

Theophylline is metabolized to inactive products by cytochrome P-450 enzyme-dependent pathways in the liver. The variation in its metabolism among individuals is large, and the half-life of theophylline can vary between 4 and 24 h. This may in part reflect the wide range of exogenous factors that influence hepatic metabolism of the drug: its half-life is increased by several drugs—cimetidine (but not ranitidine), erythromycin, ciprofloxacin, and oral contraceptives—and decreased by rifampicin, barbiturates, and carbamazepine (Table 4).

Bronchodilatation increases linearly with increase in serum theophylline concentration. Toxic effects also show a similar linear relationship, but at higher concentrations, although there are considerable differences between individuals in the serum concentration at which side-effects occur, in some occurring at low serum concentrations. Serum concentrations of between 10 and 20 $\mu g/ml^{-1}$ combine substantial bronchodilatation with a low risk of side-effects.

Safe and effective theophylline treatment requires monitoring of plasma concentration at the start of treatment to ensure a concentration within the therapeutic window, and subsequently to ensure its maintenance. This can be measured by immunoassay, when in patients on regular, twice daily, maintenance treatment the difference between peak and trough levels is usually between 5 and 10 $\mu g/ml^{-1}$, although greater in smokers, who may require treatment three times daily.

Theophyllines are now most commonly used as an additional treatment in asthma that is inadequately controlled by inhaled corticosteroids. Comparison in a randomized controlled trial of budesonide at 400 µg twice daily plus theophylline (250 or 375 mg twice daily) with budesonide at 800 µg twice daily for 3 months in 62 patients, whose asthma was not controlled by the lower dose of inhaled steroid, found the combination of low-dose inhaled corticosteroid and theophylline provided the greater improvement in lung function, peak flow variability, and b $_2$-agonist use. In those receiving it, median theophylline concentration was 8.7 µg/ml, hence this additive effect was achieved at doses lower than those conventionally considered therapeutic (10 to 20 µg/ml) and similar to that provided by inhaled salmeterol. This suggests that oral theophylline may therefore be an appropriate alternative to inhaled salmeterol at stage 3 of BTS guidelines.

Sodium cromoglycate

Sodium cromoglycate is a bischromone that has prophylactic but not bronchodilator activity in asthma. Originally available as a dry powder (mixed with lactose), it is now also formulated as a metered dose inhaler and as a nebulizer solution for children.

In inhalation tests, sodium cromoglycate inhibits asthmatic reactions provoked by inhaled allergen, exercise, and other provocative stimuli including sulphur dioxide and adenosine, although it is less effective in a dose of 20 mg than salbutamol at 200 µg in preventing asthma provoked by exercise. The major benefit of sodium cromoglycate is its safety. However, it is less effective than inhaled corticosteroids, needs to be taken four times daily, and its use is now generally reserved for children with mild asthma and taken immediately prior to exercise to prevent exercise-induced asthma. Sodium cromoglycate is no longer recommended in the new BTS Guidelines.

Nedocromil sodium

Nedocromil sodium has a similar activity profile to sodium cromoglycate. It is available as a metered dose inhaler and needs to be taken four times a day.

Its activity is equivalent to low-dose inhaled corticosteroid and it can be used either in place of inhaled corticosteroid or to reduce the dose of inhaled corticosteroid. Nedocromil sodium is an alternative to inhaled corticosteroids if inhaled steroids cannot be used in step 2 of BTS guidelines.

The 'stepped' approach to treatment of asthma

The purpose of treatment of asthma varies from the reversal of occasional mild symptoms to the restoration of normal life in a patient with severe disabling ill health. Treatment needs will vary greatly among different patients and underlie the 'stepped' approach to treatment, which is the basis of current guidelines for asthma

management, including the British Thoracic Society (BTS) guidelines published in 1997. In the stepped approach, asthma severity is defined by the treatment step (1 to 5) needed to achieve and maintain good control. Inhaled corticosteroids form the mainstay of maintenance treatment for the majority of patients. In deciding the starting treatment step, a 'start high–go low' policy has been recommended, recognizing that initial control of airway inflammation is likely to need a higher dose of inhaled corticosteroid than will subsequent maintenance of disease control. Sodium cromoglycate or nedocromil sodium may be used as alternative inhaled anti-inflammatory drugs, but are less efficacious than inhaled corticosteroids and are now primarily used for the treatment of mild asthma in children.

Inhaled b_2-agonists are used primarily for symptomatic relief. There is good evidence that regular treatment with short-acting b_2-agonists alone is less effective than regular inhaled corticosteroids, and provides less good control of asthma—both symptomatically and of lung function—when taken regularly than as-needed.

Steps 1 to 5 of the BTS guidelines identify the treatment requirements for asthma of increasing severity (Table 3). Failure to achieve treatment targets at any step implies the need to increase treatment to a step that provides good control. Figure 6 shows the proportion of patients on each of the BTS guideline steps.

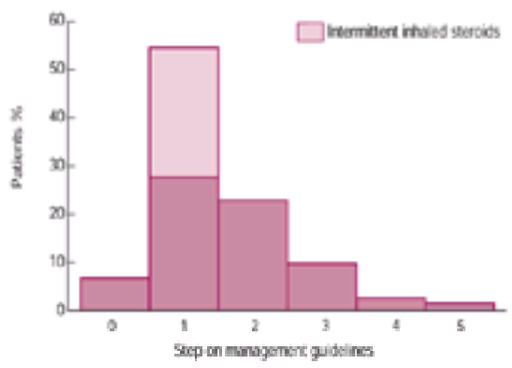

Fig. 6 Proportion (per cent) of 3372 patients with asthma on each of the BTS guideline steps.

Step 1

This comprises patients with mild intermittent asthma whose asthma is controlled by the use of an inhaled shorter-acting b_2-agonist (such as salbutamol or terbutaline) less than once a day. Requirement for more regular treatment implies the need for regular anti-inflammatory treatment (that is, a higher step).

Step 2

This comprises patients with mild persistent or intermittent asthma that is of sufficient frequency to require regular anti-inflammatory treatment. Inhaled corticosteroids are the most effective and commonly used anti-inflammatory drugs, with sodium cromoglycate and nedocromil sodium as alternatives. Treatment with an inhaled corticosteroid should be started at a dose of 400 µg of beclomethasone twice daily or equivalent. This dose should be continued for at least 3 months, the period when most benefit of the inhaled steroid is obtained, before reducing the dose to the minimum required for maintenance of good control. This can be achieved by reducing the dose by 25 to 50 per cent every 1 to 3 months. Short-acting b_2-agonists are used as required for symptomatic relief.

Step 3

- This comprises patients with moderate persistent asthma that is not controlled despite adherence to inhaled steroid (or equivalent prevention) treatment and correct inhaler technique. The recommended treatment is a regular long-acting b_2-agonist (salmeterol or formoterol) added to low-dose beclomethasone (less than 800 µg/day) or equivalent.

Two randomized controlled trials have shown that the addition of salmeterol to a low-dose inhaled corticosteroid was more effective than doubling the dose of inhaled corticosteroid in improving symptoms and lung function. In a third randomized controlled trial the addition of formoterol increased the benefit provided by both low-dose and high-dose budesonide. These studies suggest that the addition of a long-acting b_2-agonist to low-dose inhaled corticosteroid is the preferred option for improvement of day to day control of asthma that is not controlled by low-dose inhaled corticosteroid, whereas reducing the frequency of exacerbations of asthma was best achieved by increasing the dose of inhaled steroid and additional long-acting b_2-agonist.

If there is no benefit, stop long-acting b_2-agonist and consider:

a. trial of: slow-release theophylline added to low-dose inhaled corticosteroid. (One randomized controlled trial of 133 patients found the addition of oral slow-release theophylline to beclomethasone at 400 µg/day for 6 weeks was as effective in improving symptoms and lung function as doubling the dose of beclomethasone to 800 µg/day.)
   or
b. b_2-agonist tablet
   or
c. leucotriene receptor antagonist.

Step 4

This involves a combination of the alternatives in step 3—high-dose inhaled corticosteroid (up to 2000 µg/day of beclomethasone or equivalent) together with a long-acting b_2-agonist or alternative bronchodilators, such as an oral b_2-agonist or slow-release theophylline or leucotriene receptor antagonist, if these were not tried at Step 3.

Step 5

Patients who fail to respond to these combinations of step 4 treatments will require the addition of an oral corticosteroid. This is an important decision, which should be made in consultation with a respiratory physician and requires continuous monitoring to identify, and where possible avoid, the associated side-effects. The risk of osteoporosis can be reduced by taking regular exercise, and by not smoking. Bone density should be monitored regularly and where appropriate calcium, vitamin D, and bisphosphonates given. Postmenopausal women can benefit from hormone replacement therapy.

Most patients with asthma in the community have disease of severity indicated for steps 1 and 2 of the BTS guidelines; 'difficult' asthma, requiring treatment equivalent to step 5, constitutes less than 5 per cent of patients. A recent community study of five large general practices in south Nottinghamshire (a population of 38 865) found a prevalence of asthma of 9 per cent, with a peak of 17 per cent in 10 to 14 year olds, falling to less than 6 per cent in adults aged over 70 years. Most of those diagnosed with asthma were either not receiving treatment (8 per cent) or receiving treatment equivalent to steps 1 and 2 (76 per cent); 11 per cent were on step 3, and some 5 per cent on steps 4 and 5. The authors endeavoured to assess the effectiveness of asthma treatment in this population by measuring the proportion of patients who during a 1-year period required oral corticosteroid courses or were prescribed 10 or more short-acting b_2-agonist inhalers: 12.5 per cent of patients not taking them regularly had been prescribed one or more courses of oral corticosteroids, 1.6 per cent on three or more occasions; 13.6 per cent of patients had been prescribed 10 or more short-acting b_2-agonist inhalers. Both were increasingly more frequent in patients on steps 3 or higher of the BTS guidelines. However, because only a minority of patients (15 per cent) were in these categories, more than half of the patients who required either oral corticosteroids or 10 or more b_2-agonist inhalers were on steps 1 or 2, indicating continuing significant morbidity among some patients with asthma receiving either low-dose or no anti-inflammatory treatment.

Difficult asthma

Difficult asthma is asthma not controlled by maximum doses of inhaled treatment, including inhaled corticosteroids in doses of beclomethasone of up to 2000 µg/day or equivalent, with additional treatment such as long-acting b $_2$-agonists. It occurs uncommonly, probably in less than 5 per cent of patients with asthma, but is important. The severity of disease and associated disability is considerable, the risk of near fatal and fatal asthma is high, and the adverse consequences of treatment are severe, and only worthwhile if treatment is demonstrably effective.

Failure to respond to maximal inhaled treatment can result from several causes (Table 5). It is clearly important to confirm the diagnosis of asthma and exclude other diseases that may be mistaken for it. Demonstration of spontaneous variability or reversibility of airflow limitation is important to avoid treatment of irreversible airflow limitation, due either to localized obstruction or chronic obstructive pulmonary disease, with ever increasing doses of oral corticosteroids. Assessment of reversibility may require a formal trial of oral prednisolone in a dose of 30 to 40 mg taken each morning for 1 month to determine whether this provides a significant improvement in airway function.

The conditions most easily mistaken for asthma were considered earlier (see differential diagnosis). Once the diagnosis of asthma has been confirmed, it is important to ensure good inhaler technique and adherence to prescribed treatment: failure to take treatment properly is a common reason for failure to respond. This may reflect lack of understanding that preventive treatment needs to be taken regularly and not 'as needed', or poor inhaler technique. Patients may take preventive treatment irregularly because, unlike short-acting b $_2$-agonists, it does not provide immediate symptomatic relief. Others may be inappropriately concerned about potential side-effects or resent the need to take regular treatment. In patients taking oral corticosteroids, blood eosinophil count is markedly reduced and often reported as zero, hence a blood eosinophil count above 0.3 in a patient prescribed oral steroids suggests that these are not to being taken regularly, or alternatively another disease, particularly Churg–Strauss syndrome, may accompany the asthma.

One study, using a computerized timing device in a dry powder inhaler, found that only 18 per cent of patients took inhaled steroids as prescribed. Adherence to inhaled treatment is difficult to monitor, and poor adherence to treatment may be suspected as a cause of difficult asthma in patients whose asthma improves when treatment, although unchanged, is supervised. Patient understanding of the effectiveness of regular treatment may also be reinforced by this means.

Unidentified provoking factors include allergens, commonly domestic pets, in particular cats, whose allergens can be present in sufficient concentrations to cause asthma for several months after cats have left the home. Sensitizing agents encountered at work can also cause asthma that is poorly controlled by inhaled treatment. Early identification and avoidance of the cause is important to minimize the risk of development of chronic asthma. Aspirin, NSAIDs, and b-blockers can also be important provoking factors.

Rhinitis commonly accompanies asthma and its treatment can be assocaited with improvement in asthma and airway hyperresponsiveness. The explanation for this association is unclear, but may be a consequence of inflammatory mediators in post-nasal drip increasing airway responsiveness and provoking cough. Similarly gastro-oesophageal reflux can provoke cough and worsen asthma; where this is suspected a trial with a proton pump inhibitor such as omeprazole should be instituted, but objective improvement in asthma with such treatment is uncommon.

Uncommonly asthma may be a manifestation of systemic disease, particularly a systemic vasculitis, Churg–Strauss syndrome, when asthma, which can be difficult to control, is accompanied by a high blood eosinophil count (usually more than 1.5). Other manifestations including eosinophilic pneumonia, pleural and pericardial effusions, and mononeuritis multiplex. Effective treatment requires high-dose oral corticosteroids and in some cases immunosuppressant treatment, initially with cyclophosphamide and subsequently azathioprine (see Chapter 17.11.5).

Nocturnal asthma can persist in some patients despite treatment with inhaled corticosteroids, which provides good daytime control. This may be improved by the addition of a long-acting b $_2$-agonist or slow-release theophylline.

Premenstrual deterioration of asthma is not uncommon, and can in some patients be severe and unresponsive to corticosteroid treatment. Symptoms characteristically increase, and PEFR falls, 2 to 5 days before the menstrual period, improving with the onset of menstruation. This coincides with the fall in progesterone secretion and increase in oestrogen:progesterone ratio. Asthma in some patients is improved by treatment with intramuscular, but not oral, progestogen during the week before menstruation. Patients with severe premenstrual exacerbations can require hospital admission, in some cases ventilation, and may (very rarely) experience improvement only by surgical removal of the ovaries.

Brittle asthma is characterized by widely varying peak flow rates uncontrolled by maximum inhaled treatment. Two patterns of brittle asthma have been distinguished:

1. type I—persistent daily chaotic variability in peak flow (usually greater than 40 per cent diurnal variation in PEFR more than 50 per cent of the time); and
2. type II—sporadic sudden falls in PEFR against a background of usually well-controlled asthma with normal or near normal lung function.

Treatment of brittle asthma of both types is difficult. Type I brittle asthma, not responding to inhaled long-acting b $_2$-agonists, can be improved by subcutaneous terbutaline administered via an insulin infusion pump, usually in a dose of between 3 and 12 mg in 24 h: this treatment is limited by side-effects, of which the most important is muscle cramp associated with increased levels of serum creatinine kinase.

Type II brittle asthma requires immediately available treatment for what can be catastrophic falls in peak flow. The speed of onset of attacks requires immediately injected bronchodilator and such patients should have preloaded adrenaline syringes (such as Epi-pen) available at all times and wear a Medic-alert bracelet. Potential provoking factors, such as foods, should be sought and avoided.

Asthma in a very few patients is only controlled with continuous oral corticosteroids, often in high doses; reduction in dose is followed by worsening of asthma. The term corticosteroid-dependent asthma has been used for the condition in these patients. They differ from those with corticosteroid-resistant asthma in their response to oral corticosteroids. Patients with corticosteroid-resistant asthma show no response to oral corticosteroids, even in high dose, but do show spontaneous variability of peak flow and reversibility with inhaled bronchodilators. Corticosteroid-resistant asthma is very uncommon, estimated at between 1 in 1000 and 1 in 10 000 patients. It probably forms the end of a spectrum of resistance to the anti-inflammatory activity of corticosteroids, to which corticosteroid-dependent asthma also belongs. Treatment of corticosteroid-resistant asthma is difficult, but should include stopping oral corticosteroids, which still cause side-effects, and relying on other forms of treatment, including long-acting b $_2$-agonists.

Treatment of acute exacerbations of asthma

Asthma exacerbations are episodes of progressively worsening airway narrowing, associated with increasing shortness of breath, cough, wheezing, chest tightness, or some combination of these. Exacerbations can vary in severity from episodes which patients are able to manage themselves by following an agreed treatment plan, to severe and potentially life-threatening episodes that require medical attention and hospital admission. Severe attacks also vary in their speed of onset, ranging from deterioration over days to episodes that progress rapidly and can become life-threatening within minutes or hours. In about one-half of cases of fatal asthma the attack lasted more than 24 h, in one-quarter less than 1 h. Fatal or near fatal attacks of asthma are associated with the following.

1. Attacks may occur in patients who have previously required hospital admission for severe asthma and who require regular oral steroid treatment.
2. The doctor may fail to recognize the severity of the asthma. This can be minimized by making appropriate objective measurements of respiratory, heart, and peak flow rates to assess severity.
3. Patients may fail to recognize the severity of their asthma. Those with long-standing asthma can become accustomed to their symptoms and not appreciate an important increase in their severity, which may persist for days or weeks. This may also be associated with psychosocial problems and poor adherence to treatment.
4. The asthma attack may have been undertreated or given inappropriate treatment. Failure to use oral corticosteroids in adequate doses early in an exacerbation is probably the single most remediable factor. The use of sedatives or anxiolytics to reduce the anxiety or agitation that can often accompany acute severe asthma is absolutely contraindicated.

Many of these problems can be overcome by improved patient understanding, allowing them to have control over their illness supported by a jointly agreed

management plan. A systematic review of 22 studies comparing self management education for asthma with usual care found that self management reduced hospital admissions and days off work by nearly one-half and emergency room visits by one-quarter. Results were best when self management included a written action plan.

Moderate exacerbations

Exacerbations of asthma with increased symptoms, both during the daytime and at night, frequently follow an upper respiratory tract infection, allergen exposure in allergic individuals, or a reduction in anti-inflammatory treatment. Increase in symptoms associated with deterioration in peak flow can often be treated adequately by the patient increasing their frequency of inhaled short-acting bronchodilators, doubling the dose of inhaled steroids, or taking a short course of oral steroids. Several studies have shown that a short course of oral steroids taken at the start of an acute exacerbation reduces the need for hospital admission, the frequency of relapse, and the need for b_2-agonists. One recent overview of seven randomized controlled trials in 320 persons found that systemic corticosteroids, taken at the onset of an acute exacerbation, reduced hospital admissions in both children and adults by 65 per cent in the first week compared with placebo, an effect maintained for 21 days. No difference was observed between the use of oral and intramuscular corticosteroids.

Acute severe asthma

Acute severe asthma is a potentially life-threatening increase in the severity of asthma that can develop over minutes, hours, or usually days and which has often failed to respond to conventional, inhaled bronchodilator treatment. It is usually the outcome of airways increasingly narrowed by the consequences of chronic inflammation, resulting in increasing resistance to airflow identified as a reduction in PEFR and FEV_1, hyperinflated lungs, ventilation–perfusion inequality, and hypoxia, which is the most serious consequence of severe asthma. Initially this stimulates alveolar hyperventilation, but with increasing airway narrowing and exhaustion, arterial PO_2 continues to fall while arterial PCO_2 rises to normal, and subsequently increases steeply, due to alveolar hypoventilation: PCO_2 rises into the normal range when FEV_1 is some 25 per cent and PEFR 30 per cent of predicted normal values.

The clinical features of importance in identifying acute severe asthma and assessing its severity are shown in Table 6. Patients are usually extremely breathless and unable to complete sentences in one breath. A rapid respiratory rate and heart rate are good markers of severity of asthma and hypoxia. Although anxiety and increased use of b_2-agonists can increase heart rate, tachycardia should not be ignored by attributing it to these factors. An objective measure of airflow limitation should be made because severity is difficult to assess clinically with accuracy. Although PEFR is an effort-dependent measurement, it can usually be obtained from patients with severe asthma: a value of less than 50 per cent of predicted or of the recent best value in an adult aged less than 50 years indicates severe asthma, a value of less than 33 per cent, a potentially life-threatening attack.

Blood gas measurements should be made in adults seen in hospital as an important guide to the severity of asthma; children can often safely be managed by measurement of SaO_2 alone. Most patients admitted to hospital with acute severe asthma are hypoxic, of whom about one-third will have a PO_2 of less than 8 kPa (60 mmHg). PCO_2 is reduced in patients with moderately severe asthma, but with increasingly severe airways obstruction and fatigue, PCO_2 falls and subsequently rises in parallel with a falling PO_2. A normal PCO_2 in a hypoxic patient with acute severe asthma indicates impending hypoventilation, with a rapidly increasing PCO_2, falling PO_2, acidosis, narcosis, and death.

Treatment of acute severe asthma

The aims of the treatment of acute severe asthma are to reverse the hypoxia, airflow limitation, and airway inflammation with oxygen, bronchodilators, and corticosteroids (Table 7).

Oxygen

Oxygen relieves the hypoxia present in most patients with acute severe asthma. High concentrations of inspired oxygen are safe in patients with asthma, and certainly in those aged less than 50 years; a high $PaCO_2$ in acute severe asthma reflects fatigue and the severity of airways obstruction and is not a contraindication for a high concentration of inspired oxygen. Oxygen can be administered by nasal cannulas or by facemask in the highest available concentration (usually FiO_2 between 40 and 60 per cent). The aim is to increase SaO_2 to above 92 per cent or PaO_2 to above 9 kPa (80 mmHg).

Bronchodilators

The purpose of bronchodilator treatment in acute severe asthma is to reverse airway narrowing due to smooth muscle contraction, before the onset of the anti-inflammatory action of corticosteroids, which usually takes 6 to 12 h from administration.

Inhaled high-dose b_2-agonists, salbutamol and terbutaline, are now used as initial treatment, usually from a nebulizer. The benefit of the nebulizer is that it allows inhalation of bronchodilator to be driven by a high flow of oxygen. This can be important in severe asthma as b_2-agonists may increase ventilation–perfusion inequality and consequently arterial hypoxia, hence in hypoxic patients b_2-agonists should not be administered without oxygen. Nebulized salbutamol in a dose of 5 mg, or terbutaline in a dose of 10 mg, driven by 6 litre/min oxygen can be given safely by trained ambulance crews during transfer to hospital. However, nebulizers are inefficient and widely variable in their performance, which has led to the suggestion of large volume spacers as alternative delivery systems. In adults and children with severe but not life-threatening asthma treated outside hospital, inhalation of b_2- agonist by nebulizer has not been found to provide additional bronchodilatation compared with use of a metered dose inhaler via a spacer, but it is important to note that the studies on which this is based are of patients without life-threatening asthma who did not require hospital admission. Spacers do not easily allow concurrent administration of oxygen and require patient co-operation, which can be difficult in severely breathless patients.

The available intravenous bronchodilators are b_2-agonists and theophylline. The theoretical advantage of intravenous b_2-agonists is access to peripheral airways so narrowed that they cannot be reached by inhalation. However, inhaled salbutamol is rapidly absorbed from the lungs, reaching a peak concentration within 10 min of inhalation. The major disadvantage of intravenous b_2-agonists, by comparison with inhalation, is the greater frequency of systemic side-effects. What is relevant is whether intravenous b_2-agonists provide additional improvement in bronchodilator response to inhaled b_2-agonists and corticosteroids. In adults with acute asthma, intravenous salbutamol at 12 µg/min given 4 hourly after an initial dose of 5 mg of nebulized salbutamol and intravenous hydrocortisone provided greater bronchodilation compared with three further doses of nebulized salbutamol given during 2 h, although the patients receiving intravenous salbutamol had a greater increase in heart rate. Similarly, in a study of children with acute severe asthma, the addition of salbutamol (15 µg/kg) in a 10-min infusion to nebulized salbutamol and intravenous hydrocortisone was associated with a reduced period of need for inhaled salbutamol, a decreased requirement for oxygen, and earlier discharge from the emergency department.

The use of intravenous aminophylline in the treatment of asthma has decreased with the recognition that it does not provide additional benefit to repeated nebulized b_2-agonist bronchodilators in the initial hour of emergency treatment. This, together with its narrow therapeutic window, need for drug monitoring, and interactions with other drugs has led to its replacement as first-line bronchodilator treatment of asthma by inhaled b_2-agonists. However, it is recommended as additional therapy for patients not responding to initial treatment with inhaled b_2-agonists and corticosteroids, and as initial treatment in the very severely ill patient with a normal or high PCO_2. In those who have not been taking theophylline prior to admission, a loading dose of 5 mg/kg body weight over 20 min should be followed by a maintenance dose of 0.5 to 0.9 mg/kg body weight per hour until a serum level of 10 to 20 µg/ml is obtained. The loading dose should be omitted in patients currently taking theophyllines, in whom the serum concentration should be measured. The infusion rate should be decreased in patients with liver or heart failure or those taking cimetidine, macrolide antibiotics, or ciprofloxacin (Table 4). Toxic side-effects are increasingly common in patients with serum levels exceeding 25 µg/ml, ranging from gastrointestinal symptoms to fits and cardiac arrhythmias.

The BTS guidelines for the treatment of acute severe asthma recommend the administration of intravenous b_2-agonist or aminophylline to patients not responding to oxygen, inhaled b_2-agonists, and corticosteroids after the addition of inhaled ipratropium, or as initial treatment for those with life-threatening features.

Antimuscarinics

The purpose of antimuscarinic treatment is to reverse airway narrowing caused by increased vagal tone and not responsive to high-dose inhaled b $_2$-agonists. Several studies have suggested the addition of an inhaled antimuscarinic provides additional benefit in the treatment of acute severe asthma. One multicentre study found the addition of inhaled ipratropium to inhaled salbutamol increased bronchodilation by 10 to 20 per cent compared with inhaled salbutamol alone. However, other studies have failed to demonstrate additional benefit from the addition of ipratropium to inhaled high-dose b $_2$- agonist. The evidence is consistent with considerable individual variation in response to inhaled antimuscarinics, maximal response occurring in those with exaggerated cholinergic tone. Inhaled antimuscarinics have few side-effects, can provide benefit in some patients, and are recommended in the guidelines as additional treatment in a dose of 0.25 to 0.5 mg for patients not responding to initial high-dose inhaled b $_2$-agonists.

Corticosteroids

Systemic corticosteroids are given in acute severe asthma to reverse the underlying airway inflammation. The anti-inflammatory action requires 6 to 12 h from administration for demonstrable bronchodilatation to occur. Steroids may also reverse b $_2$-receptor desensitization induced by regular b $_2$- inhalation within 1 h of their administration. The value of corticosteroid treatment in acute severe asthma was first demonstrated in a randomized controlled trial in 1956 and their value in the treatment of acute severe asthma has since been generally accepted. They are usually given by intravenous administration, but other than in life-threatening asthma and in patients vomiting or unable to swallow, there is no demonstrable advantage of intravenous over oral administration. When indicated, intravenous doses initially of 200 mg every 4 to 6 h can be followed by oral prednisolone in a dose of 40 to 60 mg/day. The duration of treatment with oral prednisolone will depend on the severity and rate of recovery of the acute episode. In general, oral prednisolone should be continued until resolution of the acute episode with return to usual daytime activities, resolution of nocturnal symptoms, and PEFR within 80 per cent of the patient's predicted or best values. Short courses of oral corticosteroids (taken for less than 3 weeks) do not need to be tapered, provided patients are taking an appropriate dose of inhaled corticosteroid. Although some studies in patients with relatively mild exacerbations of asthma (PEFR greater than 60 per cent of predicted or best) have suggested that high-dose inhaled steroids are an effective alternative to oral corticosteroids, these results should not be extrapolated to acute severe asthma where the recommended guideline is that all patients should be treated with systemic corticosteroids.

Intensive care and intermittent positive-pressure ventilation

Most attacks of acute severe asthma respond to treatment with high-concentration inspired oxygen, systemic corticosteroids, and inhaled b $_2$-agonists. However, this treatment is insufficient in a few patients who require intensive care and, on occasion, intermittent positive-pressure ventilation (**IPPV**). This occurs in two particular situations: patients who have a catastrophic hyperacute attack, and patients whose asthma progressively increases in severity despite maximal bronchodilator and corticosteroid treatment. The indications for intensive care and IPPV are given in Table 8. Patients with increasing drowsiness or who lose consciousness with hypoxia and worsening hypercapnia require IPPV, as do those who suffer a respiratory arrest. However, because of the high inflation pressures needed to overcome the high airway resistance and poorly compliant hyperinflated lungs and chest wall, IPPV in acute severe asthma can be difficult and hazardous. High inflation pressures can cause barotrauma with pneumomediastinum and, on occasion, pneumothorax. In addition up to one-third of patients can develop clinically significant hypotension, requiring inotropic support.

17.4.5Occupational asthma

A. J. Newman Taylor

Occupational asthma is asthma induced by an agent inhaled at work. Agents inhaled at work can aggravate pre-existing asthma, but the term occupational asthma is usually restricted to asthma initiated or induced by such agents.

Asthma may be initiated or 'switched on' either by respiratory irritants inhaled in toxic concentrations—irritant-induced asthma—or as the outcome of an acquired specific hypersensitivity response. Hypersensitivity-induced occupational asthma is considerably more common than irritant-induced asthma and is important to recognize because in the majority of cases it improves or resolves with the avoidance of further exposure. Furthermore, the earlier further exposure is avoided, the more probable is complete resolution of the asthma. Identification and avoidance of the specific occupational cause therefore provides one of the few opportunities to cure asthma in adult life.

Causes of occupational asthma

The known causes of irritant-induced asthma are relatively few and include well-recognized respiratory irritants such as chlorine and ammonia, as well as others such as toluene di-isocyanate inhaled in toxic concentrations. However, any respiratory irritant inhaled in concentrations toxic to the epithelial cells in the airways is a potential cause of reactive airways dysfunction syndrome.

By contrast, the number of reported causes of hypersensitivity-induced occupational asthma is considerable, and with the rapid development of biotechnology and the continuous introduction of newly synthesized organic chemicals is likely to increase. The causes described include proteins of animal, vegetable, and microbiological origin, naturally occurring organic chemicals, synthetic chemicals, and inorganic chemicals, particularly metal salts. Some of the more important are listed in Table 1.

Agents and occupations associated with occupational asthma

The proportion of cases of asthma in the general population that are attributable to an occupational cause is not known, although estimates have varied between 2 and 15 per cent. A recent community-based study in Spain of adults aged between 20 and 44 years estimated that the risk of asthma attributable to occupation was between 1 in 20 (5 per cent) and 1 in 15 (6.7 per cent). The highest risks occurred in spray painters, bakers, and laboratory technicians. During the past 10 years a voluntary reporting scheme for registering new cases of occupational lung disease seen by respiratory and occupational physicians in the United Kingdom (SWORD) has estimated the incidence of occupational asthma in different occupations and provided information about the relative importance of its causes. Both have remained remarkably stable during 10 years of reporting to the scheme. Organic agents, such as flour/grain, colophony, wood dust, and laboratory animals, and chemicals, isocyanates, and glutaraldehyde, account for some two-thirds of the reported cases (Table 2). The relative frequency of the different causes has also remained similar during this period, with the exception of some reduction in the proportion of cases attributed to isocyanates and an increase in the number of cases attributed to latex (Fig. 1).

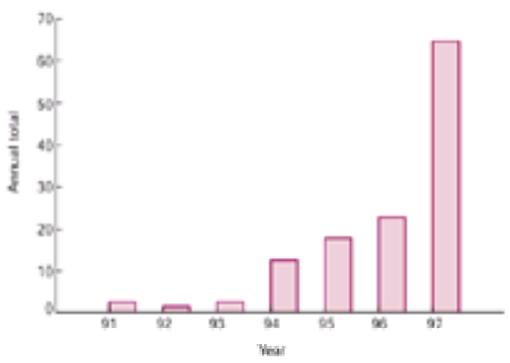

Fig. 1 Annual reports to SWORD of occupational asthma attributable to latex (1991–7).

The estimated annual incidence by occupation varied from 1380 per million per year in coach and other spray painters to 12 per million per year in transport and storage workers (i.e. a range of two orders of magnitude). The estimated annual incidence in high-risk occupations between 1992 and 1997 is shown in Table 3.

Determinants of occupational asthma

Four major determinants of occupational asthma have been identified, which vary in their importance in relation to different causes: exposure intensity, atopy, smoking, and HLA genotype. Intensity of exposure is the single most important determinant of irritant-induced occupational asthma. Evidence for exposure–response relationships has also been found for many of the causes of hypersensitivity-induced occupational asthma, both for proteins, including laboratory animal proteins and enzymes, and for low-molecular-weight chemicals, including acid anhydrides and complex platinum salts. The risk of asthma is increased in atopics exposed to many of the protein causes of occupational asthma such as enzymes, latex, and laboratory animals, and in cigarette smokers exposed to low-molecular-weight chemicals that induce IgE production, such as complex platinum salts and acid anhydrides. HLA DR3 has been associated with an increased risk of developing specific IgE and asthma in those exposed to acid anhydrides and complex platinum salts. It should be appreciated, however, that the prevention of occupational asthma is more effectively achieved by reducing the intensity of exposure to its causes in the workplace than by exclusion of 'susceptible' individuals who are atopic, cigarette smokers, or HLA DR3 positive.

Pathology and pathogenesis

The pathological changes in the airways of patients with asthma of occupational cause are no different in any important way from those in patients with asthma of other or unknown cause: a desquamative eosinophilic bronchitis with infiltration of the airway wall by eosinophils and lymphocytes, accompanied by desquamation of bronchial epithelial cells.

In common with asthma caused by allergy to proteins encountered in the general environment, hypersensitivity-induced occupational asthma is probably the outcome of T_{H2} lymphocyte stimulation, and the pathological features observed are primarily the consequence of T_{H2} lymphocyte–eosinophil interaction. The evidence for T_{H2} lymphocyte stimulation is in part direct, but primarily comes from evidence of specific IgE antibody to many, although not all, of the causes of occupational asthma. In a few cases specific IgG antibodies can also be detected. These seem to reflect exposure, whereas IgE is more closely associated with disease. In general, specific IgE has been identified with the protein causes of occupational asthma, but only with a minority of the non-protein causes. Whilst it is likely that the majority of the low-molecular-weight chemicals that cause occupational asthma do so by binding to body proteins and acting as haptens, the difficulties of preparing the relevant hapten–protein conjugate *in vitro* have limited demonstration of this process, other than with chemicals such as acid anhydrides and reactive dyes that form stable conjugates with human serum albumin.

Clinical features

Irritant-induced asthma

Asthma caused by the inhalation of an irritant chemical in toxic concentrations is usually one manifestation of general tissue injury to exposed mucosal surfaces—eyes, nose, throat, and bronchial airways. The onset of symptoms follows a single identifiable exposure to a toxic chemical. Running, swelling, and discomfort of the eyes, running and obstruction of the nose, and painful throat usually occur within minutes of the exposure, and symptoms of asthma (shortness of breath, wheezing, chest tightness, and cough) develop within a few hours—certainly within 24 h—of inhalation of the chemical in toxic concentrations. Respiratory symptoms often have the characteristic circadian pattern characteristic of asthma: they are more severe during the night and on waking than during the daytime. In most cases asthma resolves spontaneously within a few weeks, but can occasionally persist for several years, if not indefinitely.

Hypersensitivity-induced asthma

In the commoner cases of hypersensitivity-induced occupational asthma respiratory symptoms develop insidiously and do not follow a single identifiable exposure to its cause. Asthma develops after an initial symptom-free period of exposure, commonly within 1 year of starting a new job or changing duties at work, although in some cases asthma may not develop until there have been several years of exposure. The onset of asthma may have been preceded or be accompanied by 'hay fever'-like symptoms of the nose and eyes. Characteristically, symptoms become increasingly severe during the working week and improve during absences from work during holidays and at weekends. However, the patient may not appreciate the relationship of respiratory symptoms to work, particularly when symptoms develop during the second half of the day and are most severe, as is characteristic of asthma, in the evenings, during the night, and on waking in the morning. Asthmatic symptoms can also persist for several days after avoidance of exposure, in which case appreciable symptomatic improvement at weekends does not occur, but improvement is usually sufficient to be appreciated by the end of a 2-week holiday or deterioration to be recognized on return to work. With continuing exposure asthma can become chronic and the relationship between symptoms and periods at work less clear, although even in these circumstances it is usual for some symptomatic improvement to occur on avoidance of exposure, although this may take several weeks.

The findings on clinical examination depend upon the severity of the asthma at the time of the examination. There may be no abnormal findings if seen when away from exposure. During a period of symptomatic exposure the patient will have typical signs of airflow limitation with breathlessness and wheeze, and depending on severity, other signs described in Section 17.4.

Diagnosis

The diagnosis of occupational asthma should be considered in any adult who develops asthma or whose asthma has deteriorated in working life. In the case of irritant-induced asthma the association of the onset of asthma with inhalation of a toxic chemical is usually clear. The association of asthma caused by a specific hypersensitivity reaction is often less apparent, and the diagnosis is based on the following:

1. Exposure to a sensitizing agent at work.
2. Characteristic history of:
   a. onset of asthma after an initial symptom-free period of exposure;
   b. deterioration in symptoms during periods at work and improvements during absence from work.
3. Results of objective investigations:
   a. lung function tests
   b. immunological tests
   c. inhalation tests.

Objective investigations

Lung function tests

The most commonly used criterion for diagnosing asthma—improvement in airflow limitation (usually measured as forced expiratory volume in 1 s (**FEV1**) or peak expiratory flow (**PEF**)) after inhalation of broncho-dilator—is often absent in cases of occupational asthma because lung function may be normal when the patient is seen away from work and, if present, does not identify a work relationship.

The measure of lung function most commonly used to identify work-related asthma is serial self-recorded PEF. A patient with suspected occupational asthma is asked to record his or her PEF at intervals of 2 to 3 h for a month from waking to sleeping, and at night if awoken, both during periods at and absences from work. The results can be summarized in a graphical display that records the best, worst, and average values for each day, allowing comparison of PEF during days at work with days away from work (Fig. 2). The diagnostic value of the test depends on the reproducibility of the patient's forced expiratory manoeuvres and their honesty and compliance. Concurrent treatment can influence the results, particularly when treatment is systematically increased during periods at work and reduced during absences from work. When possible treatment should be kept constant during the period of testing, or at least recorded. Comparisons with the results of inhalation testing as the 'gold standard' have shown that serial self-recorded PEF measurements are a sensitive and specific index of work-related asthma. Patients with evidence of work-related asthma on PEF records reacted on inhalation testing to a specific agent inhaled at work and had occupational asthma; patients who did not show evidence of asthma on PEF records (i.e. less than 20 per cent within-day variability) did not react in inhalation tests. The major diagnostic difficulties were patients with evidence of asthma on PEF records without a work relationship, of whom a proportion were eventually shown to have occupational asthma; the commonest reason for this false-negative response was insufficient time away from work for significant improvement to have occurred.

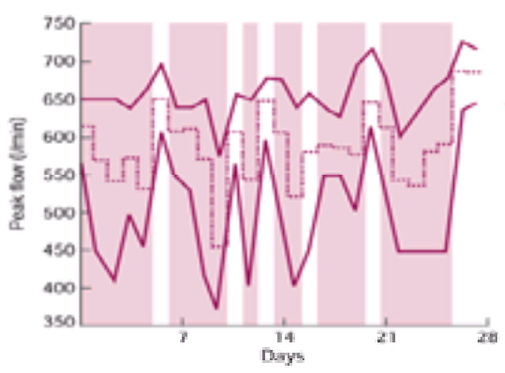

Fig. 2 Serial peak expiratory flow results in a baker sensitive to flour. The best, worst, and average values are plotted for each day. Shaded areas are periods at work; unshaded areas are periods away from work. Peak flows are consistently worse in each work period and improve during each period away from work.

Immunological tests

The presence of specific IgE antibody, identified either by immediate skin test response to a soluble protein extract or a hapten–protein conjugate or by immunoassay in serum (usually radio-allergosorbent testing) is evidence of sensitization to a specific agent. The diagnostic value of a positive test depends upon its predictive value in cases of asthma among those exposed to the specific agent. Specific IgE can be identified in most, if not all, protein causes of occupational asthma, and in a small number of low-molecular-weight chemical causes of asthma, notably complex platinum salts, acid anhydrides, and reactive dyes. No reliable immunological test has been developed for sensitivity to the other important causes of asthma such as isocyanates and colophony. The diagnostic value of a positive test has been formally examined for few of the causes of occupational asthma, and in these cases has been found to be significantly associated with asthma caused by both proteins and low-molecular-weight chemicals inhaled at work.

Inhalation testing

The objective of an inhalation test is to expose the individual under single-blind conditions to the putative cause of their asthma in circumstances that resemble as closely as possible the conditions of exposure at work. The different test methods used depend upon the physical state of the test material, which can be water soluble (most proteins) and inhaled in solution, a volatile organic liquid inhaled as a vapour, or a dust. Any change in lung function in both airways calibre (usually measured as FEV_1 or PEF) and airways responsiveness to inhaled histamine or methacholine, measured as PC_{20}, (concentration of inhaled histamine or methacholine which provokes a 20 per cent fall in FEV_1) is compared with results on appropriate control days. The patterns of airways response provoked by specific inhalation tests have been distinguished by their time of onset and duration. Immediate asthmatic responses occur within minutes of the test exposure and usually resolve spontaneously within 1 to 2 h (Fig. 3). Late asthmatic responses develop 1 h or more after the test exposure and can persist for 24 to 36 h (Fig. 4). Late asthmatic (but usually not immediate) responses are accompanied by an increase in non-specific airways responsiveness 3 h and, less reliably, 24 h after the test inhalation. An immediate response followed by a late response has been called a dual response.

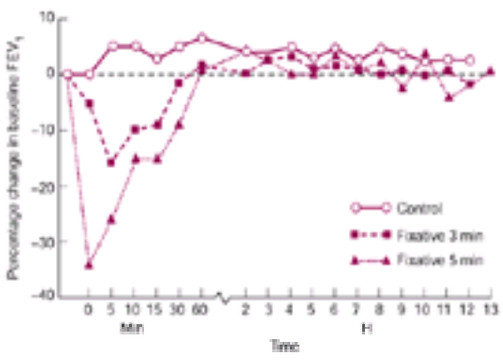

Fig. 3 Immediate asthmatic reactions in a radiographer provoked in inhalation tests of 3 and 5 min with X-ray fixative material, but not by the control test.

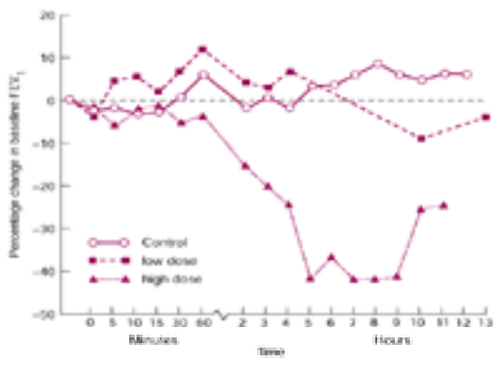

Fig. 4 Late asthmatic reaction in a platinum refiner provoked by exposure to the complex platinum salt ammonium hexachloroplatinate in a concentration of 10 mg (high dose) but not 1 mg (low dose) in 250 g of lactose (the control material).

Inhalation testing allows the identification of specific causes of asthma in individuals exposed to them. Provided that the agent being tested is not a non-specific mucosal irritant and does not provoke an immediate asthmatic response in patients with hyper-responsive airways, for example sulphur dioxide, histamine, or exercise, the provocation of an asthmatic response by an occupational agent implies that it is a cause of asthma. This causal relationship is strengthened if the agent reproducibly provokes a late asthmatic response and increases non-specific airways responsiveness.

There are four major indications for inhalation testing in the diagnosis of occupational asthma:

1. Where the agent considered responsible for causing asthma has not previously been reliably shown to do so.
2. Where an individual with occupational asthma is exposed at work to more than one potential cause that cannot be distinguished by other means.
3. Where asthma is of such severity that further uncontrolled exposure at work is unjustifiable.
4. Where the diagnosis or cause of occupational asthma remains in doubt after other investigations, including serial PEF and immunological tests where applicable, have been completed.

Inhalation tests should be undertaken only for clinical purposes, to provide information important for future management advice. Inhalation tests undertaken solely for medicolegal purposes are not justified.

Differential diagnoses

The diagnosis of occupational asthma requires differentiation:

1. from other causes of similar respiratory symptoms, in particular chronic airflow limitation and hyperventilation;
2. of occupational from non-occupational cause;
3. of asthma initiated by an agent inhaled at work from pre-existing or incidental asthma aggravated by non-specific provocative stimuli encountered at work, such as sulphur dioxide, exercise, and cold air.

Prognosis

Asthma initiated by an agent inhaled at work and caused by toxic damage to the airway epithelium (irritant-induced asthma) or as the outcome of a hypersensitivity response may become chronic and persist for several years, if not indefinitely. Chronic asthma induced by a hypersensitivity response has been reported most frequently in cases caused by low-molecular-weight chemicals such as isocyanates, colophony, plicatic acid from western red cedar, and acid anhydrides. Continuing asthmatic symptoms and airways hyper-responsiveness have been reported in 50 per cent or more of patients several years after avoidance of exposure to the initiating cause. Chronic asthma has also been reported in snow crab process workers in Canada in whom airways responsiveness improved during the first 2 years of

avoidance of exposure but subsequently reached a plateau.

The only important determinant for developing chronic asthma identified to date has been the duration of symptomatic exposure to the initiating cause after the onset of asthma: those who remain exposed to the cause are more likely to develop chronic asthma.

Management

Patients who develop occupational asthma in whom a specific cause is identified should be advised to avoid further exposure to that cause. This seems particularly important where low-molecular-weight chemicals such as isocyanates, plicatic acid, or anhydrides are the cause, as continuing symptomatic exposure to these is particularly associated with the development of chronic asthma and airways hyper-responsiveness.

Avoidance of further exposure may require a change or loss of job that, for social or financial reasons, may not be possible. A change of occupation can be particularly difficult for those who are highly trained, such as experimental scientists whose livelihood depends on their knowledge and experience of working with laboratory animals. Such individuals and others sensitized to biological dusts who are unable to change their job, at least in the short term, should be advised to minimize exposure to the cause of their asthma and to wear adequate respiratory protection, most conveniently laminar-flow equipment, when in contact with the organic dust. In addition, background prophylaxis such as sodium cromoglycate can minimize the risk of the provocation of asthma by indirect allergen contact, such as dust on colleagues' clothing. None the less, it should be emphasized that such measures are temporary, and in the long term means should be sought to avoid exposure to the cause of asthma.

When individuals remain in employment exposed to the cause of their asthma, either directly or indirectly, the effectiveness of relocation or of respiratory protection needs to be monitored. This can be conveniently done by serial self-recordings of PEF to determine whether or not asthma is continuing and, if so, whether it is work related.

Compensation

Statutory compensation in the United Kingdom

Occupational asthma is a prescribed disease for 'employed earners'. The terms of prescription have recently been broadened considerably. They now include asthma caused by exposure to 22 specified groups of agents (listed below) as well as a 'z' category, which specifies 'any other sensitizing agent inhaled at work':

a. isocyanates
b. platinum salts
c. acid anhydride and amine hardening agents
d. fumes arising from the use of rosin as a soldering flux
e. proteolytic enzymes
f. animals including insects and other arthropods or their larval forms used for the purposes of research, education, in laboratories, pest control, or fruit cultivation
g. dusts arising from barley, oats, rye, wheat or maize, or meal or flour made from such grain
h. antibiotics
i. cimetidine
j. wood dusts
k. ispaghula
l. castor bean dust
m. ipecacuanha
n. azodicarbonamide
o. glutaraldehyde
p. persulphate salts or henna arising from their use in the hairdressing trade
q. crustaceans or fish or products arising from these in the food processing industry
r. reactive dyes
s. soya bean
t. tea dust
u. green coffee bean dust
v. fumes from stainless steel welding
w. and
x. any other sensitizing agent inhaled at work.

Byssinosis

In the United Kingdom byssinosis occurs most commonly in cotton mill workers, usually after some 20 to 25 years of exposure to cotton dust. It is probably a response to agents inhaled in the cotton bract and is characterized by chest tightness on the first day of the working week, which usually develops some 3 to 4 h after the start of a work shift. Typically, the chest tightness improves on subsequent working days, despite continuing exposure to cotton dust. The symptoms are often, although not always, accompanied by changes in lung function and the majority of cases of byssinosis have hyper-responsive airways. Cotton dust also provokes acute airway narrowing in about one-third of persons exposed to an extract of cotton bract for the first time; this reaction is probably an important contributory factory in the high turnover in the early months of employment in cotton mills. Whether byssinosis causes long-term respiratory impairment and disability remains controversial. Several studies have failed to find an increase in mortality from respiratory causes, which has been interpreted as suggesting that exposure to cotton dust does not cause chronic lung disease. However, in one survey of a community which included ex-cotton workers, a reduction in FEV_1 of between 2 and 8 per cent was observed in the ex-cotton textile workers and a loss of lung function in those with 15 years' heavy exposure to cotton dust that was equivalent to that observed in light and ex-smokers.

Byssinosis should probably be considered as a form of occupational asthma: the characteristic symptoms are associated with acute reductions in FEV_1 and patients with byssinosis commonly have hyper-responsive airways.

17.5.1 Upper respiratory tract infections

P. Little

Introduction

Acute upper respiratory tract infections (URTIs) include acute pharyngitis/tonsillitis and acute rhinitis. Acute sinusitis, acute otitis media, and influenza also come under the umbrella of infections of the upper respiratory tract. Otitis media and influenza will be discussed elsewhere: this chapter will concentrate on acute pharyngitis/tonsillitis, acute rhinitis, and acute sinusitis.

Acute URTIs are the commonest reason for patients to seek medical advice in the United Kingdom, and nearly all cases are managed in primary care. Respiratory tract infections are also the commonest reason for antibiotics to be prescribed. A serious concern is that the inappropriate use of antibiotics for predominantly self-limiting conditions will foster the development of antibiotic resistance, with the danger that serious infections will become untreatable. Thus it is currently a national priority in the United Kingdom, and should be in other countries, to discourage the use of antibiotics unless there is good evidence of their efficacy. The evidence for the effectiveness of treatments for URTI in this chapter comes from a search of the Cochrane Library databases of systematic reviews and randomized controlled trials.

Pharyngitis/tonsillitis

Clinical presentation

Pharyngitis is caused by both bacterial and viral organisms, and has been somewhat arbitrarily divided into nasopharyngitis (with nasal symptoms, that is to say rhinitis), and pharyngitis or tonsillopharyngitis (without nasal symptoms). Causal organisms include group A beta-haemolytic streptococcus (**GABHS**); adenoviruses; influenza A and B; parainfluenza 1,2,3; Epstein–Barr virus (**EBV**); enteroviruses; *Mycoplasma pneumoniae*; and *Chlamydia pneumoniae*. In addition to a sore throat, pharyngitis is often accompanied by fever, headache, nausea, vomiting, anorexia, and sometimes abdominal pain, with or without enlarged and tender cervical lymph nodes, tonsillar erythema and exudate. Scarlet fever has a characteristic 'scarlatiform' rash caused by GABHS exotoxins. Infectious mononucleosis due to the Epstein–Barr virus may present with or without exudative tonsillitis, cervical or general lymphadenopathy, palatal petechiae, splenomegaly, rhinitis, and cough.

Throat swabs, rapid tests, and clinical algorithms

Antibiotics can be targeted to those patients who have positive throat swabs for group A streptococcus, a positive rapid streptococcal test, or clinical characteristics associated with a positive throat swab (for example, the 'Centor' criteria of fever, tonsillar exudate, anterior cervical adenopathy, and absence of cough). However, the throat swab is not a very good test: in both unselected and clinically selected populations in primary care practice it is neither particularly sensitive nor specific when compared to a rise in Anti Streptolysin O Titres (**ASOT**) or Anti DNAse B titres. A rise in ASOT or Anti DNAase B are better indicators of true infection and predict complications, but are not suitable for clinical diagnosis. The results of throat swabs take days to return to the clinic, and they greatly increase the costs of managing what is mostly a self-limiting condition. Furthermore, evidence suggests that in practice clinicians do not use the results, even of rapid tests, and that the overall accuracy of decision-making is little changed when they are used.

Attempts to derive algorithms or clinical-decision rules based on the throat swab have the same limitations of validity as the throat swab itself. Although clinical scoring methods may provide a crude method of identifying patients at a higher risk of complications (see below), better evidence is needed about how well each clinical sign correlates with proof of infection.

Treatment

Antibiotics for symptoms

The Cochrane review of the efficacy of antibiotics for the treatment of sore throat indicates that antibiotics have modest benefit in reducing the duration of symptoms—by a few hours to half a day—but may have a role in preventing complications (acute otitis media, sinusitis, rheumatic fever, and quinsy). This marginal benefit of antibiotics in resolving symptoms suggests that, for patients who are not unwell systemically, the physician should either not prescribe, or use a delayed prescribing approach, advising the patient to wait for several days before collecting or using their prescription. Both these approaches have been shown in a large randomized controlled trial to be acceptable, change attitudes and behaviour, and not to delay symptom resolution appreciably.

In the context of a likely streptococcal infection, trial evidence suggests that delaying the prescription results in 20 per cent fewer recurrences than the immediate prescriptions of antibiotics, presumably because antibiotics modify local or systemic immune mechanisms. Thus, any marginal symptomatic benefit from an immediate prescription of antibiotics for the current illness must be weighed against the disadvantage that the patient is more likely to suffer symptoms from a recurrence.

Antibiotics to prevent complications

The Cochrane review of antibiotics for treating a sore throat supports the use of antibiotics to prevent complications, but the evidence is limited by both clinical importance and generalizability. For the commoner complications, for example otitis media, 30 children and 140 adults would have to be treated to prevent one case of a self-limiting illness, in other words it is not important clinically. For the rarer complications the evidence is not generalizable; for instance, evidence of efficacy in rheumatic fever is based largely on trials where intramuscular penicillin was used in barracked military personnel after the Second World War. This evidence cannot be sensibly applied to healthier modern settings where the attack rate is much lower, and oral antibiotics are used.

The commonest complication of practical importance to the health service is quinsy; this is relatively uncommon, about 1 in 400 following presentation in primary care with sore throat. The Cochrane systematic review, which demonstrates that antibiotics prevent quinsy, relies on data from patients with tonsillitis who were systemically unwell enough to be admitted to hospital shortly after the Second World War, when the prevalence of quinsy in untreated patients was very high (1:18). Clearly, this data cannot be extrapolated to patients presenting from healthier modern populations who are not systemically unwell, treated with oral antibiotics, and where the prevalence of quinsy is much lower. Quinsy following sore throat is possibly slightly more common (1:60) in those who are unwell, with three out of four Centor criteria, most of whom have fever. Rigorously conducted placebo-controlled trials in patients with these criteria suggest quinsy may be prevented by oral penicillin. However, in routine clinical practice, where compliance is not assessed, the preventive benefit of penicillin is not likely to be 100 per cent, as reported in the trials where compliance was assured. Limited routine data suggests that many patients who develop quinsy after being seen in primary care do this despite being given penicillin. Whether using the clinical Centor criteria is better than the primary care physician's assessment of how unwell patients are is unclear: 20 per cent of those considered 'not to be very unwell systemically' by the physician will still have three out of four of the Centor criteria, and the criteria do not necessarily predict the very few individuals who will develop quinsy. Thus, where the primary care physician judges the patient to be both systemically unwell and/or have three out of

four of the Centor criteria, it would be reasonable to treat with penicillin or at least discuss with patients the likely risks of non-treatment.

Which antibiotic and for how long?

If an antibiotic is to be prescribed, then it is probably preferable to use one of the narrow-spectrum agents (for example, penicillin V) to minimize both side-effects and the risk of resistance. There are arguments for using a large dose, given the variable absorption of penicillin V (e.g. 2 g per day for adults and 1 g per day for children). The length of course is debatable: 10 days may better eradicate streptococcus microbiologically, but the clinical significance of this in affluent western populations is unclear. Longer courses also have the theoretical disadvantage of poorer compliance, and concerns about antibiotic resistance. There is preliminary evidence that a twice-daily dosing of penicillin V, compared to the same amount spread over four doses, results in better compliance, and also better clinical and microbiological outcomes. Amoxicillin and ampicillin are effective against streptococcus but cause a rash in patients with glandular fever: this can be very severe, such that amoxicillin or ampicillin should not be used to treat sore throat, and erythromycin used where penicillin allergy has been documented.

Treatment of patients with rheumatic fever

Patients who have had one attack of rheumatic fever are at a higher risk from new infections since they are likely to develop recurrent attacks of rheumatic fever and complications. Although most of the evidence for the prevention of rheumatic fever comes from old trials in unusual settings, it seems reasonable to treat patients with a past history who are at a high risk of recurrence and secondary complications **,** since what evidence there is suggests penicillin prevents rheumatic fever. (See Chapter 15.10.1 for further discussion of the issues involved.)

Other medical treatments

Treatment with aspirin in children is contraindicated due to the small but avoidable risk of Reye's syndrome. There are several trials of the use of non-steroidal anti-inflammatory drugs (**NSAIDs**) in providing effective relief of pain and fever in tonsillitis and pharyngitis. However, only one trial has made a key clinical comparison of NSAIDs with standard treatment (paracetamol), demonstrating no superiority of NSAIDs. Limited trial data suggests that other useful analgesic adjuncts include caffeine, and benzydamine hydrochloride gargle.

Recurrent attacks

A Cochrane review identified only one published randomized trial of tonsillectomy in children (with serious methodological problems) and none in adults. Further evidence is needed before surgery can be advocated firmly for recurrent tonsillitis. There is preliminary trial evidence for the use of a-streptococci spray, immune stimulants, and pneumococcal vaccination, but further confirmation is required.

Nasal congestion and rhinorrhoea

Nasal symptoms are a common reason for attending the doctor. They may be due to a variety of causes, commonly acute viral infection (common cold), allergic rhinitis and sinusitis, vasomotor rhinitis and rhinitis medicamentosa, and less commonly atrophic rhinitis, hormonal rhinitis, and mechanical/obstructive rhinitis. Colds are responsible for significant morbidity: on average there are 0.4 episodes and 1.2 days of restricted activity per person per year for the common cold.

Acute rhinitis

Symptoms are acute nasal congestion and rhinorrhoea, mild malaise, sneezing, sore throat, variable loss of taste and smell, and usually last from 1 to 2 weeks unless sinusitis is present. Examination reveals a hyperaemic and oedematous mucosa, with or without purulent secretions.

Treatment

Symptomatic treatment

Trial evidence supports the use of both oral and topical decongestants for the symptoms of rhinitis. Intranasal ipratropium bromide is also effective symptomatic treatment, but is only available (in the United Kingdom) on prescription. However, topical decongestants should probably not be used for more than a maximum of 7 days: rhinitis medicamentosa starts to develop at 10 days. Due to their moderate systemic effects, care should be taken with oral decongestants in patients with heart disease and hypertension. Saline drops are commonly advocated, but saline or medicated nose drops have been shown to be ineffective in trials in both children and adults. A Cochrane review suggests that steam may provide some relief of symptoms.

Antibiotics

The use of antibiotics for the common cold has been assessed in a Cochrane systematic review and shown not to be helpful.

Other treatments

Reviews of trials indicate little benefit from antihistamines, nor from zinc lozenges. A Cochrane review of the herb echinacea demonstrated positive results in most studies, but there was not enough evidence to recommend the use of a specific product. Trials in adult volunteers with URTI indicate that intranasal sodium cromoglycate may help to relieve symptoms, and limited evidence suggests that NSAIDs may improve both symptoms and mucociliary clearance. There is also preliminary evidence of promise for the use of immune stimulants in preventing recurrent URTIs.

Acute sinusitis

Diagnosis

Acute sinusitis, usually defined as an infection that lasts for less than 3 weeks, is an uncommon complication of coryzal illness and pharyngitis. There is no absolute standard against which symptoms and signs can be compared for accuracy of diagnosis: aspiration by sinus puncture is probably the definitive investigation, since it indicates the presence of infecting organisms, but for obvious reasons this is rarely performed, and contamination by commensal organisms can occur.

The four-view radiographs show acceptable agreement with aspiration and culture, although only moderate interobserver agreement. The US Agency for Health Care and Policy Research (**AHCPR**) has reviewed the diagnosis and treatment of sinusitis: combining all studies comparing sinus radiographs with sinus puncture demonstrated a sensitivity of 73 per cent and specificity of 80 per cent. A history of purulent nasal discharge, maxillary toothache, purulent secretions on examination, poor response to decongestants, and abnormal illumination of the sinuses, are all predictive of sinusitis defined using four-view radiographs as the standard: four or more symptoms or signs giving a likelihood ratio of a positive test of six. A problem with sinus illumination as a diagnostic tool in primary care is that it performs differently in different settings, probably due to operator sensitivity. There is preliminary evidence comparing symptoms with computed tomography (**CT**) as the 'standard', which is justified since the presence of fluid and total opacification of the sinuses on CT predicts antibiotic response. Purulent rhinorrhoea, purulent secretion in the cavum nasae, a history of 'double sickening' (getting better, then getting worse again), and an erythrocyte sedimentation rate (**ESR**) of greater than 10 are predictive of a CT diagnosis of sinusitis—three of these features giving a likelihood ratio of a positive test of 1.8.

However, using a four-item clinical risk score—of purulent rhinorrhoea with unilateral predominance, local pain with unilateral predominance, bilateral purulent rhinorrhoea, and presence of pus in the nasal cavity—is as sensitive and specific as any other method in predicting the results of sinus puncture. Thus, for acute sinusitis, diagnostic tests are not currently indicated, and until valid near-patient tests are available clinical targeting probably performs as well as any other method.

Treatment

Antibiotics

A Cochrane review of all controlled trials suggests that the absolute benefit for symptom resolution is moderate, and must be balanced against the disadvantages of prescribing antibiotics. Furthermore, this review does not include all the trials from primary care, which show moderate or no effect, and thus both the effectiveness and cost-effectiveness of antibiotic treatment of acute sinusitis in primary care is questionable for most patients.

Other treatments

Preliminary trial evidence shows that decongestants are unlikely to be helpful. There is limited evidence that antihistamines may be helpful for patients with a history of allergic rhinitis who develop sinusitis, and some evidence that proteolytics (e.g. bromelain) and mucolytics may help.

There is mixed trial evidence for the benefit of topical steroids. Although trials of NSAIDs suggest they are helpful, they may not be significantly more effective than paracetamol.

17.5.2.1 Pneumonia—normal host

John G. Bartlett

Introduction

Pneumonia is an acute or chronic infection involving the pulmonary parenchyma. Most cases are caused by microbial pathogens, including bacteria, viruses, fungi, and parasites. Pneumonia may also refer to inflammation involving the pulmonary parenchyma due to non-microbial causes such as chemical pneumonia. Other modifying terms are used as follows: pneumonia may be acute, subacute, or chronic, depending on the duration of symptoms; it may be described as bronchopneumonia, consolidated (lobar) pneumonia, or interstitial pneumonia based on chest radiography changes; or it may be named after the putative agent, for example pneumococcal pneumonia, mycoplasma pneumonia, *Pneumocystis carinii* pneumonia, etc. Pneumonia is also identified by the place of acquisition—as community-acquired, nursing home-acquired, or hospital-acquired. This chapter will be restricted to community-acquired pneumonia in the adult immunocompetent host.

Aetiology

Although the list of microbes that can cause pneumonia is legion, only a relatively small number are frequent pathogens, for example: *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Legionella* spp., anaerobic bacteria, and viruses. Less common pathogens are *Moraxella catarrhalis*, *Streptococcus pyogenes*, *Acinetobacter* spp., *Chlamydia psittaci*, *Coxiella burnetii*, *Neisseria meningitidis*, *Staphylococcus aureus*, and enteric Gram-negative rods. In most reported series, each of these generally accounts for less than 1 to 2 per cent of cases. The relative frequencies of different pathogens causing community-acquired pneumonia in two large studies are summarized in Table 1. However, important limitations of these studies should be acknowledged: all the cases in the review conducted by the British Thoracic Society were inpatients, as were the great majority of those reviewed in the meta-analysis. Most studies of pneumonia show that only 20 to 30 per cent of patients are sufficiently sick to require hospitalization. Furthermore, nearly all studies, including those that use extensive diagnostic resources, only identify a likely aetiological agent in 40 to 60 per cent of cases. This suggests that fastidious microbes are under-represented and that many cases of pneumonia may be caused by, as yet, unidentified organisms.

Epidemiology

Pneumonia is the most important infectious disease in terms of morbidity and mortality. It is estimated that in the United States there are four million cases of pneumonia per year (45 000 deaths), and worldwide there are 4400 million cases per year (4 million deaths). In the United States, data suggest that between 20 and 30 per cent of all patients with a diagnosis of pneumonia are hospitalized, and that the mortality rate for this subpopulation is about 14 per cent. The crude death rate from influenza and pneumonia in the United States for 1994 was 31.8 deaths per 100 000 of the population; this represents a 59 per cent increase over the 20.0 deaths per 100 000 recorded in 1979, suggesting that the frequency of lethal pneumonia in the United States is increasing. Those aged 65 or older accounted for 89 per cent of the deaths in 1994, suggesting that increases in longevity account for most of this increase in mortality rate.

Those pathogens associated with specific epidemiological and underlying conditions are summarized in Table 2.

When an aetiological agent is identified, just three microbial agents account for the majority of lethal cases of community-acquired pneumonia. Influenza accounts for an average of 20 000 deaths per year in the United States: the majority involve influenza A, occur in patients over 65 years of age, and most deaths are due to complications of influenza rather than influenza *per se.* The second common cause of lethal pneumonia is pneumococcal pneumonia; risk factors for a fatal outcome include: bacteraemia, advanced age, and concurrent alcoholism. Legionella is the third agent, with associated mortality rates generally reported between 15 and 25 per cent for patients with community-acquired infections.

Nearly all studies show that the risk of death with pneumonia is strongly associated with age extremes. Concurrent conditions that contribute to increased mortality rates include neoplastic disease, hepatic failure, congestive heart failure, cerebrovascular disease, and renal disease.

Pathogenesis

As with nearly all infectious diseases, the probability of disease depends on the virulence of the organism, the inoculum size, and the status of host defences. The normal tracheobronchial tree and lung parenchyma is sterile below the level of the larynx, so that agents of pneumonia must reach this site from external or adjacent sources, usually either by aspiration or inhalation. Organisms may also reach the lung by haematogenous seeding, direct extension from infection in a contiguous structure, or by activation of dormant organisms in the lung. These mechanisms are pathogen-specific, as summarized in Table 3.

Most pneumonias are probably caused by aspiration, which is defined as the abnormal entry of endogenous secretions or exogenous substances into the lower airways. There is a problem here with semantics because most cases of pneumonia are probably due to aspiration as classically described, but 'aspiration pneumonia' probably accounts for only 5 to 10 per cent of cases. The explanation is presumably quantitative, 'aspiration' generally referring to the abnormal entry of relatively large volumes in patients who are so predisposed due to dysphagia or a compromised level of consciousness. The alternative form is presumed to be 'microaspiration', involving the aspiration of very small numbers of microbes, a process that commonly takes place in healthy patients during sleep and with no apparent sequelae.

Clinical features

The classic presentation of pneumonia is of a cough and fever with the variable presence of sputum production, dyspnoea, and pleurisy. Most patients have

constitutional symptoms such as malaise, fatigue, and asthenia, and many also have gastrointestinal symptoms. Although patients with pneumonia usually possess these characteristic clinical features, there can be major differences in presentation based on the host and the aetiological agent, as summarized below.

Pneumococcal pneumonia

Streptococcus pneumoniae is nearly always the most commonly identified pathogen in patients hospitalized with a community-acquired pneumonia. A meta-analysis of 122 reports of community-acquired pneumonia by Fine *et al*. for the period 1966 to 1995 showed that *S. pneumoniae* accounted for 65 per cent of all cases where a microbial pathogen was defined and 66 per cent of all bacteraemic cases (referenced in the Further reading list). Studies using transtracheal aspiration or transthoracic aspiration, methods that avoid the problem of expectorated sputum contamination, show the presence of *S. pneumoniae* in 50 to 80 per cent of cases.

The classic presentation is of a previously healthy adult with an upper respiratory tract infection who then develops a rigor followed by fever, dyspnoea, pleurisy, and a cough that usually becomes productive with a purulent, blood-streaked or 'rusty' sputum. However, many patients show variations in this pattern, including one of a more subtle onset. Moreover, atypical presentations are particularly common in elderly patients. Chest radiography invariably shows an infiltrate, and lobar consolidation specifically suggests this diagnosis (Fig. 1). A pleural effusion is present in about 25 per cent of patients, but only 1 to 2 per cent have an empyema.

Fig. 1 Chest radiograph showing a left lower lobe pneumonia. Blood cultures grew *S. pneumoniae.*

Important observations over the past decade include the declining frequency of cases where this organism is identified and the increasing resistance of *S. pneumoniae* to penicillin and a variety of other antibiotics. The declining frequency is commonly ascribed to a general decline in the quality of microbiological testing currently performed in cases of pneumonia in general, and decreased antibiotic susceptibility is thought to reflect antibiotic abuse. The question still remains as to why, when these drugs were introduced in the 1940s but penicillin resistance was not really encountered until the 1990s, has there been such a long delay in the development of resistance?

Poor prognostic findings in patients with pneumococcal pneumonia include advanced age, bacteraemia, alcoholism, and multiple lobe involvement.

The preferred antibiotics are amoxicillin for oral treatment and ceftriaxone or cefotaxime for parenteral treatment; penicillin-resistant strains may be treated with fluoroquinolones, vancomycin, or linazolide.

Haemophilus influenzae

This organism was originally described in 1892 by Pfeiffer who erroneously thought it was the agent of influenza; it was sometimes referred to as 'Pfeiffer's bacillus'. *H. influenzae* is always the second most common agent (behind *S. pneumoniae*) when an identified bacterial pathogen is found in community-acquired pneumonia. However, the diagnosis is difficult owing to problems with its recognition by direct Gram stain, the fastidious growth requirements of the organism, and with interpretation—even when it is recovered—because it commonly colonizes the upper airways, leading to contamination of expectorated specimens. Type-B *H. influenzae* is a well-established pathogen primarily in infants and young children, but is a relatively rare cause of disease in adults or anyone who has received *H. influenzae* vaccine. *H. influenzae* strains causing pneumonia in adults are usually non-typable.

The clinical features are rather non-specific and include fever, cough, purulent sputum, leucocytosis, and radiographic evidence of pneumonia—usually in a bronchopneumonic pattern, but it may occasionally be lobar. Patients with chronic obstructive lung disease often harbour *H. influenzae* in their lower airways and, allegedly, are prone to pneumonia caused by this organism, although supporting data for the association are not strong. Bacteraemia with *H. influenzae* in adults is infrequent. Most patients simply have a non-specific pneumonia, with *H. influenzae* as the only potential pathogen identified in expectorated sputum.

About 30 to 45 per cent of strains produce b-lactamase so that penicillin and amoxicillin are often ineffective. When *H. influenzae* is suspected or established the preferred agents are second- and third-generation cephalosporins, any combination of a b-lactam–b-lactamase inhibitor, azithromycin, or a fluoroquinolone.

Anaerobic bacteria

These organisms are the dominant components of the microbial flora in the upper airways and average 10^{12}/ml in the gingival crevice. Anaerobes are the major pathogens identified in aspiration pneumonia and its sequelae, lung abscess and empyema. The major pathogens in this group are *Peptostreptcocci* spp., *Bacteroides* spp. (other than *B. fragilis*), *Prevotella* spp., and *Fusobacterium nucleatum*.

The typical patient has gingival crevice disease combined with a predisposition for aspiration that is usually due to a suppressed level of consciousness or dysphasia. The clinical presentation is usually more subtle than that for pneumococcal pneumonia in that the infection evolves over a period of many days, weeks, or even months. Chest radiographs usually show infection in a dependent segment (usually the superior segments of the lower lobes or posterior segments of the upper lobes since these are dependent in the recumbent position), fever, sputum that is often putrid, and evidence of chronic disease with weight loss or anaemia. Putrid discharge is very characteristic and diagnostic of anaerobic bacterial infection (Fig. 2).

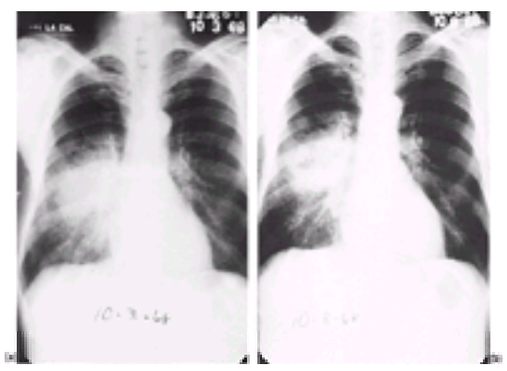

Fig. 2 (a) Consolidated pneumonia in the superior segment of the right lower lobe in a 56-year-old alcoholic. A transtracheal aspirate showed numerous anaerobic bacteria including *Prevotella melaninogenicus* and *Peptostreptococcus* spp. (b) A follow-up radiograph five days later showing cavitation.

Aspiration pneumonia may also be due to chemical insults from gastric acid or other toxins, or may reflect the aspiration of foreign bodies or fluids (victims of drowning). However, the most common sequel to aspiration is bacterial infection involving the anaerobes that normally colonize the upper airways, and such bacteria account for 60 to 80 per cent of cases of aspiration pneumonia, lung abscess, and, in many case series, empyemas. Although the bacterial aetiology can be identified from anaerobic cultures of uncontaminated specimens, these are generally not obtained except in the case of pleural fluid in the presence of empyema; even then the cultures are often falsely negative due to inadequate techniques used to recover oxygen-sensitive bacteria. Thus, the aetiological diagnosis is usually based on the clinical features—where key clues are the chronicity of the infection, associated conditions suggesting aspiration, tissue necrosis with abscess formation, or a bronchopleural fistula leading to empyema and/or putrid discharge.

The preferred drugs are clindamycin or a b-lactam–b-lactamase inhibitor.

Mycoplasma pneumoniae

This organism is one of the most common causes of lower airways' infection in young adults, and it is now more frequently recognized in older adults. The original appellation was 'primary atypical pneumonia', a term applied in the 1930s to a relatively benign form of pneumonia to distinguish it from pneumococcal pneumonia. Early work showed that it was associated with a serum factor that agglutinated erythrocytes in the cold; furthermore, Eaton reported that the infection was transmissible from person to person by intracheal inoculations. Thus, atypical pneumonia, cold-agglutinin pneumonia, and Eaton-agent pneumonia were found to be synonymous.

The typical patient is usually a young adult who experiences a respiratory tract infection accompanied by headache, myalgia, cough, and fever and with a chest radiograph that shows bronchopneumonia. The cough is often non-productive, but when sputum is obtained it is mucoid, shows predominantly mononuclear cells, and no dominant organism. A characteristic feature is the relatively high frequency of extrapulmonary complications such as rash, neurological syndromes (aseptic meningitis, encephalitis, neuropathies), myocarditis, pericarditis, and haemolytic anaemia. The diagnosis should be suspected in those patients with a relatively mild form of pneumonia, particularly in previously healthy young adults.

Most laboratories do not cultivate mycoplasma due to the effort needed to recover the organism, the long time required, and the ease of empirical treatment. Serological tests may be used, but their merits are disputed. Polymerase chain reaction (**PCR**) and other rapid diagnostic tests are under development.

With regard to treatment, the pathogen lacks a cell wall and hence is not susceptible to penicillin, cephalosporins, or other cell-wall active antibiotics. The usual therapeutic agents are macrolides (such as erythromycin, clarithromycin, or azithromycin) or doxycycline; fluoroquinolones are also active.

Chlamydia pneumoniae

This relatively recently identified pathogen is now thought to account for about 5 to 10 per cent of all community-acquired cases of pneumonia, often in young adults who present in a fashion quite similar to that of patients with a mycoplasma pneumonia. *C. pneumoniae* continues to be regarded as a relatively benign agent of pneumonia: most patients have an upper airways' infection with this organism, laryngitis is relatively common, bronchitis is less common, and pneumonitis is an infrequent complication. *C. pneumoniae* plays a role in exacerbations of asthma, and the organism may also be involved in some chronic conditions such as cardiovascular disease.

The diagnosis of chlamydia pneumonia is difficult. The organism is cultivated like a virus using tissue cultures, but few laboratories offer this test. Serology is difficult to interpret; the usual titres for IgM or serial changes with acute and convalescent sera are arbitrary. Like mycoplasma, this is an organism that is often suspected, infrequently proven, and easily treated empirically.

The usual treatment is doxycycline, a macrolide (erythromycin, clarithromycin, or azithromycin), or a fluoroquinolone.

Legionella spp.

Legionnaires' disease was originally described during the American Legion Convention in Philadelphia in 1976, with the putative agent reported the following year. Legionella cause two major syndromes: the pneumonic form or legionnaires' disease, referring to the American Legion Convention epidemic, and a benign influenza-like illness called 'Pontiac fever' in reference to an outbreak in 1967 in Pontiac, Michigan. Although legionnaires' disease is often grouped with mycoplasma and chlamydia infection as being an 'atypical pneumonia', it is a quite different pulmonary infection because it occurs primarily in older adults, is a serious and often lethal form of pneumonia, and most hospital laboratories have diagnostic resources to establish the aetiology. Legionnaires' disease is defined as pneumonia caused by any species of the genera *Legionella*, but the great majority of cases are caused either by *L. pneumophila* (80 to 90 per cent of cases) or *L. mcdadei* (5 to 10 per cent). This disease may be epidemic or sporadic. Epidemics usually occur in buildings, especially hotels and hospitals, and they reflect legionella contamination of the potable water or cooling systems of air conditioners. Predisposing factors include exposure to environmental sources of legionella (there is no patient-to-patient transmission), age over 40 years, smoking, or reduced cell-mediated immune responses as with organ transplantation, cancer chemotherapy, or chronic corticosteroid usage; patients with AIDS do not seem to be uniquely susceptible.

There are no remarkable features of the clinical presentation, except that patients are almost invariably quite sick and may be critically ill. In addition to the typical symptoms of pneumonia with cough and dyspnoea, most present with a profound systemic illness with high fever and myalgias, often with gastrointestinal and neurological symptoms.

The diagnosis can be established with a urinary antigen assay for the detection of *L. pneumophila* serogroup I, culture of respiratory secretions on selective media, serology, or direct fluorescent stain (**DFA**) of sputum. All these tests are quite specific, but none are sufficiently sensitive to exclude the diagnosis when they are negative.

The drugs of choice are fluoroquinolone or a macrolide, or one of these given with rifampicin. However, the mortality rate is generally reported to be 5 to 15 per cent even with proper therapy.

Staphylococcus aureus

Staphylococcus pneumonia was classically described as a complication of influenza during the 1918 epidemic of 'Spanish Flu'. This organism continues to be a potentially important superinfecting pathogen in influenza, and is the most common form of embolic pulmonary infection with injection-drug use and tricuspid valve endocarditis. Staphylococcal pneumonia may be acute or chronic and, despite common impressions to the contrary, pulmonary abscess is a relatively unusual complication. Most patients simply have bronchopneumonia; lobar pneumonia is rare. Those patients with embolic pneumonia show multiple embolic infiltrates that are diffusely scattered and which often cavitate.

The organism can usually be recovered in blood cultures and in respiratory secretions. However, care must be exercised when interpreting respiratory secretion cultures that yield *S. aureus* since this may be a contaminant, and it is particularly common as a contaminant in those patients who have received previous antibiotic treatment.

The treatment should be based on *in vitro* susceptibility tests, usually an antistaphylococcal penicillin (flucloxacillin, oxacillin, or nafcillin), a first-generation cephalosporin (cefazolin), or vancomycin (for methicillin-resistant strains and for patients with severe penicillin allergy).

Gram-negative bacilli

Klebsiella pneumoniae was originally described in 1882 by Friedlander, who believed it was the cause of pneumococcal pneumonia. This organism has continued to be a rare but important cause of community-acquired pneumonia, accounting for about 0.5 to 1.5 per cent of all cases. The classic presentation of 'Friedlander's pneumonia' was a serious pneumonia in an alcoholic patient with a chest radiograph that showed upper lobe involvement and the 'bulging fissure sign' (indicating abscess formation) and sputum that resembled currant jelly. This form of klebsiella pulmonary infection is rarely encountered now, although klebsiella infection is

occasionally implicated in community-acquired pneumonia.

Other Gram-negative bacilli may also cause pneumonia, but the frequency in immunocompetent hosts is very low. A possible exception is *Acinetobacter* spp., which may cause pneumonia in otherwise healthy adults. *Pseudomonas aeruginosa* is a rare pulmonary pathogen, but should be suspected when recovered in respiratory secretions from patients with specific predisposing conditions including structural lung disease, neutropenia, cystic fibrosis, or advanced AIDS. Gram-negative bacteria are commonly encountered in cultures of respiratory secretions, but care must be exercised in interpretation because they are often contaminants reflecting upper airway colonization, especially in patients who have previously received antibiotics.

Treatment should be based on *in vitro* sensitivity tests.

Viruses

Viral infections of the lower airways account for pneumonia in 10 to 15 per cent of inpatients, and probably a substantially larger number of those managed as outpatients. The most frequent pathogens are influenza, parainfluenza, and respiratory syncytial virus (**RSV**). Influenza infections with bronchitis occur in epidemics, but influenza pneumonia is rare. More common in influenza patients with chest radiographs showing infiltrates is bacterial superinfection, most frequently with *S. pneumoniae* or *S. aureus*; less common superinfecting pathogens in this setting are *N. meningitis* and group A streptococcus. The diagnosis of influenza can be made by the combination of an established epidemic and typical influenza symptoms, especially fever. The alternative is to establish the presence of the organism by one of several rapid tests for influenza-A or influenza-B antigen. These rapid tests provide results that are available in about 20 minutes and have a sensitivity of about 70 to 80 per cent.

Clinical features of influenza are generally well known and include cough, fever, purulent sputum, and myalgias. Patients with bacterial superinfections will usually have typical flu-like symptoms, improve, and then deteriorate after 1 to 2 weeks.

Infections involving influenza A may be treated with amantidine or rimantadine; influenza A or B may be treated with these agents, or the neuraminidase inhibitors Relenza (zanamivir) or oseltamivir. If given within 48 h of the onset of symptoms, these anti-influenza drugs reduce the duration of typical symptoms by 1 to 1.5 days and are more effective in seriously ill patients. However, their role in primary influenza pneumonia or in patients with complications of influenza is unknown.

RSV has usually been considered a pathogen in paediatric patients, but is now recognized with increasing frequency in adults, especially the elderly. The diagnosis is easily established with a DFA stain of respiratory secretions for RSV. Ribivirin is active against RSV and is sometimes used by inhalation therapy in children, but there is no treatment with established merit for adult cases.

Laboratory diagnosis

Laboratory tests are used to establish the diagnosis, evaluate the severity, and identify the aetiological agent (Table 4).

Tests to establish the diagnosis and evaluate severity

Chest radiography

The chest radiograph is a pivotal test for the confirmation of pneumonia. It is impossible to make this diagnosis in the absence of a new infiltrate, with four possible exceptions:

1. Although severe dehydration allegedly accounts for a false-negative chest radiograph, animal studies do not support this contention and clinical evidence is weak.
2. Severe neutropenia may give rise to a false-negative radiograph due to the patient's inability to generate an acute inflammatory response. While this is theoretically possible, data suggest that the frequency is low.
3. Some patients have a normal radiograph early in the course of disease, and physicians in the pre-penicillin era claimed they could detect rales before the radiograph showed an infiltrate. This appears to be true, but it applies only to the first 24 h and even then is uncommon.
4. *Pneumocystis carinii* pneumonia may present with a completely normal chest radiograph in 20 to 30 per cent of cases, and probably represents the only form of pneumonia commonly seen nowadays where false-negative routine chest radiographs are common.

Most patients with symptoms of pneumonia and a negative chest radiograph have acute bronchitis, which is generally caused by viral pathogens that do not respond to antibiotic treatment. Thus, the importance of the chest radiograph is in confirming pneumonia, which is a critical feature in avoiding antibiotic abuse. Additional advantages of the chest radiograph is that it provides assistance in identifying the aetiological agent, establishes a baseline for subsequent evaluation, provides prognostic information, and permits the detection of underlying or associated conditions such as a neoplasm.

Other laboratory tests

The most useful additional laboratory tests to determine the severity of illness and need for hospitalization are evaluation of blood oxygenation with pulse oximetry or arterial blood gas determination, blood chemistries (glucose, blood urea nitrogen, and serum sodium levels), and a full blood count. Patients who are hospitalized should generally undergo HIV serology, provided their informed consent is given.

Studies to determine microbial aetiology

Laboratory studies for identifying pulmonary pathogens are among the most controversial issues in pneumonia management. The American Thoracic Society guidelines endorse a nihilistic approach, with the conclusion that microbial studies in pneumonia cases are usually negative, are not cost-effective, and are largely unnecessary since empirical treatment is generally successful. The guidelines from the Infectious Diseases Society of America emphasize the conduct of studies to identify the microbial pathogen(s) in order to promote pathogen-specific treatment and reduce antibiotic abuse, and to identify epidemiologically important organisms such as penicillin-resistant *S. pneumoniae*, *Legionella* spp., influenza, or Hantavirus. It is acknowledged that many recent reports show a low yield of such organisms and fail to document a benefit in terms of cost or outcome; nevertheless, this is attributed to the serious decline in the quality of microbiological standards in recent years.

While empirical therapy is generally advocated for outpatients, routine microbiological testing to identify the aetiological agent of pneumonia is generally only recommended for inpatients. Such tests include blood cultures (from blood samples taken prior to the initiation of antibiotic treatment), which yield a pathogen in about 12 per cent of cases. In general, the only additional test commonly performed to identify an aetiological agent is an expectorated sputum Gram stain and culture. Practice standards for this process include the following:

- The specimen should be obtained by deep cough and should be grossly purulent. It should be collected before antibiotic therapy, preferably in the presence of a physician or nurse.
- The specimen should be promptly transported to the laboratory for processing and incubation within 2 to 5 h.
- A qualified technician should select a purulent portion for Gram stain and culture.
- Cytological screening should be done under low-power magnification (× 100) to determine cellular composition as a contingency for culture.
- The sample should be cultured using standard techniques, with results reported by semiquantitative assessment; most pathogens are recovered in 3 to 4 plus growth, indicating more than five colonies in the second streak.
- Interpretation should be based on the correlation of the Gram stain, semiquantitative culture results, and clinical observations.

The aetiological agent of pneumonia is considered to be clearly established if a likely pulmonary pathogen is recovered from an uncontaminated specimen such as blood culture, pleural fluid, transtracheal aspiration, or transthoracic aspirate. Alternatively, the very presence of a likely pathogen recovered from respiratory secretions is tantamount to a diagnosis; organisms in this category include *Legionella* species, *Mycobacterium tuberculosis*, most viruses other than the herpesvirus group (influenza virus, respiratory syncytial virus, Hantavirus, parainfluenza virus, and adenovirus), and certain fungi (*Histoplasma capsulatum*, *Coccidioides immitis*,

Blastomyces dermatitidis, and *P. carinii*). Organisms such as *S. pneumoniae*, *M. catarrhalis*, *H. influenzae*, and *S. aureus* may be pulmonary pathogens, but interpretation is problematic due to possible contamination with specimens from the upper airway flora. Organisms that virtually never represent pulmonary pathogens include *S. epidermidis*, *Enterococcus* spp., *Neisseria* spp. other than *N. meningitidis*, *Candida* spp., and Gram-positive bacilli other than *Nocardia* spp. or actinomyces.

Transtracheal aspiration was once a popular method of obtaining specimens from the lower airways that avoided upper airway contamination, but the technique requires a skilled clinician and is generally thought to be too invasive for routine use. Transthoracic aspiration has the same limitations, and furthermore seems to give a relatively large number of false-negative results. Bronchoscopy is an attractive method for obtaining respiratory secretions directly from the lower airways; however, the procedure is complicated by contamination with instrument passage through the upper airways so that routine cultures of bronchoscopic aspirates are no better than expectorated sputum. These results may be substantially improved with quantitative cultures of bronchoalveolar lavage specimens or quantitative brush specimens, but many laboratories do not offer this type of analysis, and many pulmonary services cannot provide the samples in a timely fashion.

Most hospital laboratories offer diagnostic tests for detecting the atypical causative agents of pneumonia, for instance of *Legionella* spp. The preferred tests for legionella detection are the urinary antigen assay and culture. Urinary antigen testing is advocated because it is rapid, simply performed, and highly specific; disadvantages include the fact that it only detects *L. pneumophila* serogroup 1, although this accounts for 70 per cent of cases. The alternative test for detecting *Legionella* spp. is culture, which has the advantage of detecting all species of *Legionella*; but the disadvantage is that it requires three days, requires specialized media, and is technically demanding. Most laboratories do not offer diagnostic tests to detect *M. pneumoniae* or *C. pneumoniae*, despite their presumed frequency. This reflects the lack of an acceptable test that is easily performed, provides adequate sensitivity and specificity, and can provide results in a timely fashion.

Treatment

Critical components of initial treatment may include intravenous hydration, oxygenation, and/or intubation and mechanical ventilatory support. Pleural effusions should be sampled to exclude empyema and, when the effusions are large, drained to improve oxygenation. Most authorities feel that expectorants, cough suppressants, and chest physiotherapy are of little value.

Antibiotic therapy

Antibiotics are the mainstay of therapy. Suggestions for specific agents according to microbial pathogen are summarized in Table 5. Most of these are relatively non-controversial and demonstrate the advantage of establishing an aetiological agent. However, as noted above, no pathogen can be detected in 40 to 60 per cent of cases despite arduous attempts to do so; even when an agent is found, this information is usually not available when initial therapeutic decisions are needed. For this reason, most patients are treated empirically, at least initially, whilst microbiological results are pending. Recommendations for empirical treatment are summarized in Table 6. These options are selected on the basis of predicted activity against the most likely pathogens and extensive clinical trials. Nevertheless, this is one of the most controversial areas in medicine based on concerns for antibiotic abuse, increasing resistance of *S. pneumoniae* to many antimicrobials, and sharp geographical differences in the rates of *S. pneumoniae* resistance.

Of major concern in recent years is *S. pneumoniae*, the most common identified agent of pneumonia, because it shows escalating rates of resistance to penicillin, other b-lactams, macrolides, trimethoprim–sulfamethoxazole (**TMP–SMX**), clindamycin, and tetracycline. The only drug that is virtually always active is vancomycin, but the use of this agent in pulmonary infections is discouraged due to a somewhat limited published experience of using vancomycin to treat pneumonia, and concern for the possible promotion of vancomycin-resistant enterococci. Fluoroquinolones with enhanced activity against *S. pneumoniae* include levofloxacin, moxifloxacin, clinafloxacin, trovafloxacin, and gatifloxacin. Most strains of *S. pneumoniae* are susceptible, although some laboratories are reporting increasing resistance to the fluoroquinolones as well as the other antibiotics noted. Multiple large therapeutic trials are underway of patients randomized to receive macrolides, fluoroquinolones, or b-lactams, nearly all of which show therapeutic equivalence. However, there are also reports of anecdotal cases of failure correlating with *in vitro* resistance to b-lactams, macrolides, and fluoroquinolones.

Timing of antibiotic therapy

A large retrospective trial showed that mortality increased with a progressive delay in the time taken to initiate antibiotic therapy after patients had been evaluated. The increase in mortality became statistically significant when the delay exceeded 8 hours. This observation is not surprising since pneumonia is a potentially lethal infection that usually responds to antibiotics, so any delay in treatment would be expected to have deleterious effects. As a result of these observations, many hospitals in the United States are now audited to determine their compliance with antibiotic administration, where necessary, within 8 hours of a patient's admission to the emergency room or admission to the hospital.

Monitoring response to therapy

Subjective responses are usually noted within 3 to 5 days of initiating treatment. Objective parameters to monitor include fever, oxygen saturation, peripheral leucocyte count, and changes on serial chest radiographs. The most carefully documented responses are mortality rates, time to defervesence, and duration of hospital stay. With regard to fever, the temperature in young adults with pneumococcal pneumonia usually drops within 2 to 3 days, patients with bacteraemic pneumococcal pneumonia usually require 6 to 7 days, and elderly patients often respond more slowly. Blood cultures in bacteraemic patients are usually negative within 24 to 48 h. Cultures of sputum will usually show eradication of bacterial pathogens within 24 to 48 h, a major exception being *P. aeruginosa*. Radiographic appearances are slow to improve and much less useful than clinical observations for evaluating response. Follow-up radiographs are generally not recommended, except for patients who are over 40 years of age or are smokers, and the suggested time to do this is 7 to 12 weeks after initiating treatment. Patients who are initially treated with intravenous antibiotics can usually be changed to receive oral agents when they are able to take oral medications and show clinical improvement, such as a temperature below 38 °C for 24 h, a respiratory rate of less than 24/min, and when the PO_2 has returned to normal.

Failure to respond

The major considerations in patients who fail to respond according to the guidelines noted above are:

- The disease is too far advanced at the time of treatment, or treatment is delayed for too long: this is most commonly seen with pneumonia caused by *Streptococcus pneumoniae* or *Legionella* spp.
- The wrong antibiotic was selected: but this is uncommon.
- An inadequate antibiotic dosage is given: this is most common with the aminoglycosides
- The wrong diagnosis is made: for example, a non-infectious disease such as pulmonary embolism with infarction, congestive failure, Wegener's granulomatosis, sarcoidosis, atelectasis, chemical pneumonitis.
- The wrong microbial diagnosis is made.
- The patient may be debilitated, have a severe associated disease, or be immunosuppressed: or there may be other host inadequacies.
- There may be a complicated pneumonia with undrained empyema, metastatic site of infection (meningitis), or bronchial obstruction (foreign body, carcinoma).
- There may be a pulmonary superinfection: most patients in this category respond and then deteriorate with a new fever.

Prognosis

The overall mortality for patients who are hospitalized with community-acquired pneumonia, according to a meta-analysis of 122 reports, is 14 per cent. Risk factors for lethal outcome were well described in the pre-penicillin era, when extremes of age were probably the most important factor. Other risks included bacteraemia, the concentration of bacteria according to quantitative blood cultures in those who were bacteraemic, the extent of changes on chest radiography, alcohol consumption, and the extent of leucocytosis. More recent studies have continued to show that these factors, especially age, are major risk factors for morbidity and mortality. Investigators from the Pneumonia Patient Outcomes Research Team (**PORT**) have developed a prediction rule using a cumulative point score obtained from five categories comprising 19 variables (Table 7). This prediction rule was applied retrospectively to 38 039 inpatients and showed a direct correlation between numerical score and mortality, the authors concluding that these factors predict outcome and can also be used to determine the need for hospitalization.

With regard to specific pathogens, the major agents of community-acquired pneumonia associated with high mortality rates are bacteraemic pneumococcal pneumonia and Legionnaires' disease. Influenza is directly or indirectly implicated in about 20 000 deaths per year in the United States, but primary influenza

pneumonia is relatively rare and most of the influenza-associated deaths are of elderly patients who succumb to complications of influenza. It should also be noted that pneumonia is an extremely common terminal event in patients who die of other conditions, presumably because of aspiration in the terminal stages. Thus, pneumonia is a common autopsy finding when other medical conditions are actually the major cause of death.

Prevention and control

The major preventive measures are influenza and *S. pneumoniae* vaccines. The components selected for the influenza vaccine each year are based on the anticipated strains for the forthcoming season, a prediction that has been quite accurate in 10 of the 11 influenza seasons from 1988 to 99 through 1999 to 2000. Protective efficacy is generally 60 to 70 per cent in the general population when there is a good match between the vaccine strains and the epidemic strain; it is less in elderly vaccinees, but those who develop influenza after vaccination usually have attenuated courses with significant reductions in mortality. The current recommendation is for vaccination between October and November of patients living in the Northern hemisphere. Targeted populations are summarized in Table 8. Amantadine, rimantadine, zanamivir, and oseltamivir may be used to prevent influenza in unvaccinated patients who are so exposed.

The 23-valent vaccine for *S. pneumoniae* contains capsular polysaccharide from 23 serogroups that are responsible for 80 to 85 per cent of bacteraemic pneumococcal infections. Studies of this vaccine suggest a 60 per cent efficacy in preventing bacteraemic pneumococcal infection in immunocompetent adults in the United States, but efficacy is reduced or negligible in immunosuppressed hosts. There is a newly developed 7-valent protein-conjugated pneumococcal vaccine that has the advantage of stimulating a good antibody response in children under 2 years of age, but this vaccine has not been extensively tested in adults.

Controversies

There are probably few diseases in medicine that have been better studied than pneumonia, but with such extraordinary controversy in management guidelines. The major controversies are the utility of microbiology studies, the empirical selection of antibiotics, and the use of pneumococcal vaccine.

Studies of microbial aetiology

Culture and Gram stain of expectorated sputum is the time-honoured method for determining the microbiology of community-acquired pneumonia. Nevertheless, there is substantial controversy regarding the worth of this exercise and a wealth of medical reports with highly divergent findings that simply fuel the debate. In general, the optimal results were achieved in the pre-penicillin era when sputum bacteriology was an art and many patients underwent transthoracic needle aspiration. The reason being that the only available therapy was type-specific antisera for *S. pneumoniae*, thus requiring retrieval of the specific strain. High-quality laboratory technology persisted through the mid-1980s, when the yield of *S. pneumoniae* in expectorated sputum samples for inpatients with community-acquired pneumonia was generally reported at 40 to 70 per cent. The more recent experience is much different, in that the yield of *S. pneumoniae* in expectorated sputum by either Gram stain or culture is only 10 to 20 per cent in most series. Occasional investigators report a higher yield, but they generally employ an antigen-detection method using blood, urine, or respiratory secretions for pneumococcal polysaccharide, which is controversial based on disagreements about specificity. An additional concern is that antigen detection fails to identify other microbial agents of pneumonia, so that culture is generally required to determine *in vitro* sensitivity test results in an era of escalating resistance. Arguments favouring sputum microbiology are the benefits of pathogen-directed therapy that restrains antibiotic abuse, limits side-effects, and reduces cost. In addition, this permits the identification of epidemiologically important organisms, knowledge of which provides the database for empirical therapy recommendations. Arguments against microbiological studies include the facts that: this procedure, as currently performed in most laboratories, shows a low yield; the information is infrequently available when therapeutic decisions are made; empirical treatment usually works (Fig. 3); and, even if a pathogen is recovered, there is no good way to exclude the presence of a copathogen.

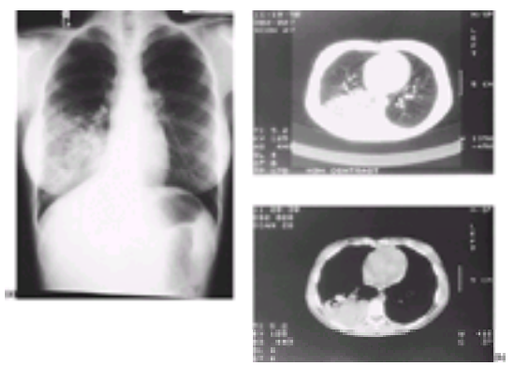

Fig. 3 Chest radiograph (a) and CT scan (b) showing pneumonitis in the right lower lobe of an 18-year-old college student. The patient responded to empirical antibiotic treatment.

Antibiotic selection

Recommendations for the empirical selection of antibiotics include drugs that are active against the major pathogens, including *S. pneumoniae*, *H. influenzae*, and the atypical agents. The favoured classes are tetracyclines, macrolides, and fluoroquinolones. When *S. pneumoniae* is identified or strongly suspected, many authorities conclude that b-lactams are the preferred drugs, despite the fact that b-lactam resistance is 10 to 20 per cent, is substantially higher in some regions, and is increasing in virtually all areas. *S. pneumoniae* is also increasingly resistant to tetracyclines and macrolides, and to a lesser extent, fluoroquinolones. As noted above, large therapeutic trials comparing these four categories of drugs have shown no differences, but there are multiple reports of anecdotal cases with failures involving resistant strains. The controversy regarding empirical therapy is largely explained by geographical differences in resistance patterns, and the concern for fluoroquinolone abuse. With regard to geography, the rates of resistance to the various categories of drugs are highly variable in different parts of the world and within different parts of individual countries. Thus, doxycycline or a macrolide may be rational options in one area, but not another. With regard to the fluoroquinolones, these drugs are active *in vitro* against more than 98 per cent of *S. pneumoniae* strains as well as virtually all atypical organisms, but there is concern that extensive use will result in increasing resistance, a concern that is already being witnessed in some parts of the world. The attractive feature of the fluoroquinolones is the nearly uniform activity against *S. pneumoniae*, the ease of once-daily administration, the availability of both parenteral and oral forms, extensive therapeutic trials to confirm efficacy, and good *in vitro* activity against virtually all treatable pulmonary pathogens.

Pneumococcal vaccine

The polysaccharide vaccine has established merit in young adult African men, but some retrospective analyses and most prospective, randomized, controlled trials have failed to show a significant benefit in terms of reducing the rates of pneumonia, rates of pneumococcal pneumonia, or rates of bacteraemic pneumococcal pneumonia. Most reports of a beneficial effect of vaccination have been based on statistical analyses of the serotype of patients with pneumococcal infection, which demonstrated higher rates of vaccine strains in unvaccinated patients. Even these studies failed to show a benefit in the highest risk group, namely the elderly and the immunosuppressed. The need for a pneumococcal vaccine is widely appreciated due to the extent of morbidity and mortality caused by *S. pneumoniae* and the increasing difficulty caused by resistance in treating these infections. Many authorities feel that the best solution to the dilemma is a better pneumococcal vaccine.

17.5.2.2Nosocomial pneumonia

John G. Bartlett

Introduction

Nosocomial pneumonia is generally defined as a new pulmonary infiltrate on chest radiography, combined with evidence of infection expressed as fever, purulent respiratory secretions, and/or leucocytosis, with onset at least 72 h after admission. These infections account for only about 15 per cent of all nosocomial infections, but they are the most frequent, lethal, nosocomial infection. The bacteriology and management are different than that of community-acquired infections of the lung (see Chapter 17.5.2.1).

Aetiology

The microbiology of nosocomial pneumonia shows that Gram-negative bacteria account for 50 to 70 per cent of cases; other common pathogens include *Staph. aureus*, anaerobic bacteria, *H. influenzae*, and *Streptococcus pneumoniae* (Table 1). Legionella accounts for about 4 per cent of all nosocomial pneumonia, but the frequency may be much higher when it is epidemic or endemic within a hospital. Viruses are implicated in 10 to 20 per cent, primarily influenza and respiratory syncytial virus and, in the immunocompromised host, cytomegalovirus. Tuberculosis is rare, but important to remember. Fungi are also rare, with the exception of *Aspergillus* in selected immunocompromised patients.

Epidemiology

Most reports indicate that 0.5 to 1 per cent of all hospitalized patients develop nosocomial pneumonia. The rates in intensive care units are generally reported at 15 to 20 per cent, and among patients who are mechanically ventilated, the rate is 20 to 50 per cent. However, it should be noted that some of these incidence statistics are disputed due to the lack of precision in the diagnosis of nosocomial pneumonia: other processes that may cause pulmonary infiltrates with variable presence of fever, purulent respiratory secretions, and/or leucocytosis include congestive heart failure, pulmonary embolism, atelectasis, adverse drug reactions, pulmonary haemorrhage, and the acute respiratory distress syndrome.

The epidemiology of the pathogens in nosocomial pneumonia is highly variable. Some organisms become endemic, especially in intensive care units; the major pathogens in this setting being *Acinetobacter*, *Serratia*, *Xanthomonas*, *Pseudomonas*, *Enterobacter*, and methicillin-resistant *S. aureus*. Another important nosocomial pathogen is *Legionella*, which may cause outbreaks of Legionnaire's disease in hospitals that can sometimes be traced to water supplies with distribution via air conditioning cooling systems or showerheads. In these cases, the same species and serogroup found in the nosocomial cases should be found in the epidemiologically-linked water supply. Aspergillosis may occur as epidemics among vulnerable patients with compromised cell-mediated immunity, neutropenia, or both. Influenza is highly contagious, and patients with influenza are commonly hospitalized, hence it is now recommended that all patients with suspected influenza have confirmation of this diagnosis by rapid influenza testing, and the preference is for a single room when this is feasible.

Pathogenesis

The relatively high rates of pulmonary infections among patients who are hospitalized reflects (Table 2):

1. clustering of highly vulnerable patients;
2. patients rendered particularly vulnerable by violations of the integrity of the upper airways by intubation or tracheostomy;
3. many patients who are prone to aspiration due to compromised consciousness caused by associated medical conditions and anaesthesia;
4. patients rendered susceptible due to organ transplantation, cancer chemotherapy, and AIDS.w

The dominant pathogen in nosocomial pneumonia are Gram-negative bacteria, which reach the lung by aspiration of gastric contents or by microaspiration of upper airway secretions. The best explanation for this association between bacteriology and pathogenesis is the observation that patients with serious illness commonly have abnormal colonization of the upper airways by Gram-negative bacteria. Thus, throat cultures show that Gram-negative bacteria are found in only 2 to 3 per cent of healthy persons, psychiatric patients, physicians, and medical students, whereas the rate of colonization in patients who are moderately ill is 30 to 40 per cent, and in intensive care units the rate is 60 to 70 per cent. These colonization rates are independent of antibiotic administration. It can also be shown that buccal epithelial cells from patients who are seriously ill have enhanced attachment by Gram-negative bacteria *in vitro*. The frequency of positive throat cultures for Gram-negative bacteria and the number that attach to respiratory cells is directly correlated with the severity of the associated disease. The usual mechanism of Gram-negative bacillary pneumonia in most hospitalized patients is aspiration of these organisms in the upper airways, or aspiration of these organisms from gastric contents after they are swallowed.

Pathogenesis of other organisms is quite different. *Legionella*, tuberculosis, influenza, and *Aspergillus* are inhaled, the usual source being environmental (*Legionella* or *Aspergillus*) or another patient (influenza or tuberculosis).

Clinical features

The classic presentation for pneumonia is cough and fever, usually with purulent respiratory secretions. The diagnosis of pneumonia requires the demonstration of a pulmonary infiltrate on chest radiography. These same symptoms may be present in patients with acute bronchitis, which is virtually always a viral infection that does not merit antibacterial treatment. A notable exception is patients who have violation of the airways with endotracheal tubes or tracheostomies who may have 'febrile tracheobronchitis' due to bacterial infection, most frequently at the tip of the tube, the site of the cuff, or the site of insertion. As noted previously, many patients who satisfy the definition for nosocomial pneumonia based on a pulmonary infiltrate accompanied by fever and purulent respiratory secretions have alternative diagnoses when studied by reliable microbiological techniques using bronchoscopy with quantitative cultures of a bronchial-protected brush or bronchoalveolar lavage (BAL).

Laboratory diagnosis

Tests to establish diagnosis and evaluate severity

The chest radiograph is critical for the confirmation of pneumonia. Major causes of false-negative radiographs in the presence of nosocomial pneumonia are severe neutropenia and pneumonia caused by *P. carinii*. CT scans may reveal infiltrates that are not present on plain films, but it is not clear that this distinguishes a group that requires antibiotic treatment. Thus, the chest radiograph is generally viewed as adequately sensitive for detection of nosocomial pneumonia.

It is important to monitor blood gases to determine severity of illness and to monitor respiratory support.

Studies to determine microbial aetiology

Blood cultures are positive in 2 to 6 per cent of patients with nosocomial pneumonia and clearly identify the causative agent. Some patients will have empyemas, and thoracentesis is necessary for both diagnosis and treatment. Again, this represents an uncontaminated source for culture, providing definitive evidence of the responsible pathogen. Empyema is an infrequent complication of nosocomial pneumonia, excepting in patients who have undergone thoracotomy who often have an empyema as a complication of chest tube placement.

Legionella, *M. tuberculosis,* and respiratory viruses (influenza, parainfluenza, and respiratory syncytial virus) represent definitive pathogens when recovered in respiratory specimens since these organisms do not colonize the normal respiratory tract.

The majority of patients with nosocomial pneumonia do not have bacteraemia, empyema, or the pathogens that do not colonize the normal airway. In these cases, the physician usually must rely on routine bacterial cultures of respiratory secretions or resort to invasive diagnostic tests using bronchoscopy with quantitative cultures of BAL specimens or of the protected brush. Multiple studies have tested the validity of these techniques for distinguishing contaminants and pathogens. The results are somewhat variable, but often dependent on the precision of methodology. The use of these techniques has also resulted in substantial controversy in the management of nosocomial pneumonia, especially in intensive care units where the stakes are high due to high mortality rates. Arguments in favour of invasive diagnostic studies with bronchoscopy are the facts that the technology is well studied, about one-half of patients with suspected pneumonia have negative results and antibiotics can be avoided in this population, and the clear definition of pathogens permits pathogen-specific antibiotic treatment. Others argue that the invasive methods are unrealistic or unnecessary because many hospital laboratories do not provide an adequate microbiology service, patients with the characteristic clinical features will be treated with antibiotics regardless of the bronchoscopy results, or because of the perception that semiquantitative cultures of tracheal aspirates are cheap, easy, and provide information that is equally valid.

Regardless of the method to obtain respiratory secretions for microbiology studies, it is usually beneficial to examine the specimen cytologically. Cultures should be reported with either quantitative or semiquantitative results. For quantitative results, the usual threshold for significance with the protected brush is 10^3/ml, and for BAL specimens it is usually 10^3 or 10^4/ml. With semiquantitative techniques, moderate or heavy growth usually indicates 'significant concentrations.' The major pathogens are summarized in Table 1: *S. epidermidis*, diphtheroids, *H. parainfluenza*, *Entero-coccus*, and a-haemolytic *Streptococcus* are generally regarded as contaminants, regardless of concentrations. Anaerobic bacteria are frequently neglected pulmonary pathogens, but it is difficult to obtain specimens valid for anaerobic cultures, and many laboratories struggle with anaerobic microbiology even when the right specimens are obtained. The diagnosis of anaerobic pneumonia should be suspected when Gram stains show mixed bacteria, especially when there are morphotypes suggesting anaerobes, and specimens obtained by tracheal aspirate or bronchoscopy should be examined for these organisms. Putrid drainage always indicates anaerobic infection.

Treatment

The major management issues are antibiotic selection and respiratory support. The optimal method to select antibiotics is to base this decision on results of Gram stains and cultures (Table 3). When empiric decisions are necessary in seriously ill patients, agents are directed against Gram-negative bacteria, and the favoured drugs in this context are ceftazidime, cefepime, imipenem/meropenem, piperacillin/piperacillin–tazobactam, ticarcillin/ticarcillin–sulbactam, or ciprofloxacin. For *S. aureus*, vancomycin is often added on the basis of Gram stain results or the perceived need to cover this pathogen. Treatment for *P. aeruginosa*, the predominant Gram-negative bacillus in nosocomial pneumonia in intensive care units, should be based on *in vitro* sensitivity tests. Anaerobic bacteria are well treated with imipenem/meropenem or any b-lactam–b-lactamase inhibitor; clindamycin can be used if these organisms are suspected and the alternatives are not used for other pathogens. The role of aminoglycosides in pulmonary infections involving Gram-negative bacilli is controversial because these agents appear to have a marginal activity at the concentrations achieved in the lung and at the pH of pulmonary secretions. Nevertheless, they appear to work well in animal experiments. The recommendation is that if they are used, they are always combined with a second agent that should have activity against Gram-negative bacilli as summarized above, and that there is assurance of adequate levels with either once-daily dosing or with monitoring of levels with thrice-daily dosing.

It should be emphasized that cultures of respiratory secretions obtained after the inception of antibiotic treatment have substantially reduced validity. This observation emphasizes the importance of pretreatment cultures and caution with therapeutic decisions based on post-treatment cultures other than those of blood and plural fluid.

Outcome

Nosocomial pneumonia is associated with a mortality rate reported at 8 to 20 per cent for all cases. The mortality rate for infections acquired in the intensive care unit is 20 to 40 per cent, with a mean of 25 per cent. In the latter group the attributable mortality is 30 to 33 per cent, meaning that associated conditions are the major factors in causing death.

Prevention

The frequency of nosocomial pneumonia and high mortality rate, especially in intensive care units, has prompted extensive studies of prevention. The methods that have withstood the test of time and have proven meritorious are the use of the semiupright position to reduce the risk of aspiration, and hand washing between patients to prevent transmission of nosocomial pathogens.

The concern for patient positioning is based on marker studies showing that stomach contents are displaced to the lower respiratory tract with high frequency in patients in the recumbent position, and this can be easily corrected by use of an upright or semiupright position. The assumption is that nosocomial pneumonia is frequently due to bacteria that reside in the stomach as a result of oral colonization. With regard to hand washing, this is a time-honoured method to reduce nosocomial infection that is commonly neglected by hospital personnel. It appears to be particularly important in the transmission of *S. aureus*, and is often important in organisms that are endemic or epidemic within hospital units such as *Acinetobacter*, *Serratia*, *Xanthomonas*, *Pseudomonas*, and *Enterobacter*.

A common practice in intensive care units is prophylaxis to prevent peptic ulceration of the stomach, but neutralization of gastric acid eliminates the gastric barrier, the defence mechanism that prevents colonization of the stomach by bacteria, including Gram-negative bacteria from the upper airways. As a result, sucralfate is commonly advocated in place of H2 agonists or antacids. Another approach to dealing with colonization of the upper airways and stomach is 'selective decontamination' to interrupt the cycle of colonization of the colon by Gram-negative bacteria followed by colonization of the upper airways by the same organisms. The goal of selective decontamination is elimination or reduction in Gram-negative bacteria in the gastrointestinal tract with antibiotics that also preserve the anaerobic bacteria in the flora, since these are largely responsible for population control in the colon. Drugs that are commonly used are oral preparations of polymyxin, aminoglycosides, poorly absorbed fluoroquinolones, aztreonam, trimethoprim–sulfamethoxazole, or cephalosporins. These drugs are given orally with the expectation that they will have a major impact on the colonic flora, and they are sometimes also incorporated into paste formulations for application to the upper airways as well. Extensive trials with selective decontamination show that they achieve a substantial reduction in nosocomial pneumonia, but do not seem to influence mortality due to nosocomial pneumonia. Major concerns are:

1. the failure to reduce mortality rates;
2. excessive costs of the regimens; and
3. the perception of antibiotic abuse with encouragement of resistance.

Topical antibiotics have also been tested for utility in prophylaxis. The method is installation of drugs (usually polymyxin or aminoglycosides) through tracheostomies, endotracheal tubes, or by aerosolization. Extensive therapeutic trials with this tactic have shown that they are sometimes successful in interrupting epidemics due to susceptible bacteria, especially *P. aeruginosa*, but mortality rates have generally remained unchanged, and there is concern about the evolution of resistant bacteria. Topical antibiotics are generally not recommended, excepting for some patients with cystic fibrosis.

Interruption of epidemics involving *Legionella* and *Aspergillus* requires different tactics because these organisms are inhaled. For *Legionella* and *Aspergillus*, the goal is to eliminate the environmental source. Influenza is transmitted from person-to-person, so the goal is to eliminate this type of contact, which must include removal of health-care workers with influenza from jobs that require patient contact. All hospital personnel should have influenza vaccine as a method to protect patients, and

hospital personnel with jobs that require patient contact must be furloughed if they have suspected or established influenza.

17.5.2.3 Pulmonary complications of HIV infection

Mark J. Rosen

Since 1995, the relentless increase in death rates from AIDS in developed nations has reversed due to the use of highly active antiretroviral therapy (HAART), and there is now hope that AIDS may not be uniformly fatal. Nevertheless, thousands of people are infected with HIV each year, and thousands more still develop opportunistic infections and HIV-associated neoplasms because they do not know they are infected, have limited access to these treatments, choose not to use them, or the treatments are unsuccessful. Antiretroviral therapy is too expensive to be available to millions of people with AIDS worldwide, and the AIDS epidemic will be devastating in Africa, Asia, and South America.

Spectrum of pulmonary disorders

Lung diseases have been important causes of illness and death in AIDS since the beginning of the epidemic. The first cases of AIDS were described in homosexual men in Los Angeles who had *Pneumocystis carinii* pneumonia, without a known reason for immunodeficiency. The incidence of *Pneumocystis carinii* pneumonia is declining because of the widespread use of prophylaxis and HAART, but it is still the most common AIDS-defining opportunistic infection in the United States and Western Europe. Despite the importance of *Pneumocystis carinii* pneumonia as an AIDS-defining disorder, clinicians should not assume that most HIV-infected persons with pulmonary disease have *Pneumocystis carinii* pneumonia, because there is a wide range of pulmonary infections, neoplasms, and inflammatory disorders associated with HIV infection (Table 1). These range from mild abnormalities in pulmonary function unaccompanied by respiratory symptoms to fatal opportunistic infections.

Early investigations of the types of pulmonary disorders that occur in patients with HIV infection were limited by analysis of data from single sites, and by restricting the scope of analysis to patients who had an opportunistic infection or neoplasm. This approach systematically underestimated the incidence and importance of pulmonary disorders that occur in early HIV infection. In the Pulmonary Complications of HIV Infection Study, 1353 subjects were followed prospectively in six American cities to determine the prevalence, incidence, and types of lung diseases that occur in persons in selected HIV transmission categories. After 18 months of follow-up, the most frequent respiratory diagnoses in the HIV-seropositive subjects were upper respiratory infection (33.4 per cent), acute bronchitis (16 per cent), and acute sinusitis (5.3 per cent). Although these disorders were also common in a control group of HIV-seronegative gay men and injecting drug users, bronchitis and sinusitis were reported more frequently in the HIV-infected subjects. The types and frequencies of lower respiratory tract disorders diagnosed in the first 18 months of follow-up are listed in Table 2. After 64 months of follow-up, the incidence of bacterial pneumonia remained higher than that of *Pneumocystis carinii* pneumonia.

Pulmonary tuberculosis and fungal infections are also common in patients with AIDS, and are addressed in other sections of this textbook. Non-infectious disorders may also involve the lung in HIV-infected individuals: these include neoplasms (especially Kaposi's sarcoma), non-specific and lymphocytic interstitial pneumonitis, primary pulmonary hypertension, and bronchiolitis obliterans organizing pneumonia. These disorders may vary in severity from asymptomatic to life threatening.

Diagnostic approach

When a homosexual man or an injecting drug user presents with a respiratory illness, most clinicians will suspect an HIV-related disorder. However, the incidence and prevalence of HIV infection is increasing rapidly among patients who acquired HIV infection by heterosexual contact, and should be considered in all patients with pneumonia, especially in communities where the prevalence of HIV infection is high. Conversely, many patients with known HIV infection have disorders that are common in the community.

The initial approach to patients with suspected HIV-related pulmonary disorders is the same as for any other patient: the clinician will take a careful history, perform a physical examination, and determine whether or not to perform diagnostic tests. In HIV-infected patients, careful consideration of risk factors for specific pulmonary diseases and the chest radiograph are especially important in formulating a differential diagnosis.

Patients with HIV-associated pulmonary disorders typically present with non-specific symptoms such as cough, dyspnoea, sputum production, and wheezing. Pulmonary symptoms are more common in HIV-infected people than in the general population; in the Pulmonary Complications of HIV Infection Study, 15 per cent of 1171 HIV-infected persons who did not have a diagnosed pulmonary disorder or an AIDS diagnosis complained of cough and dyspnoea at the time of enrolment. Both dyspnoea and cough were more prevalent in injecting drug users than others, and were strongly associated with cigarette smoking. Respiratory symptoms may be unrelated to the HIV infection, and disorders that are common in the general population, such as asthma or bronchitis, must be considered.

Risk factors for specific pulmonary disorders

The risk of developing particular HIV-associated disorders is strongly influenced by the patient's immune status, demographic characteristics, current or prior place of residence, use of antiretroviral agents, and prophylaxis against common HIV-associated infections. Genetic factors are undoubtedly important, but are less precisely defined.

Immune status

The severity of immunosuppression probably has the strongest influence on the risk of specific AIDS-associated disorders, and the CD4+ lymphocyte count is the best surrogate marker for immune function and predictor of the probability of developing specific diseases. In early HIV infection, when the immune system is not severely compromised, respiratory disorders are similar to those that affect the general population, while opportunistic infections occur only with severe immunodeficiency. The CD4+ lymphocyte count, together with quantitative assay of plasma HIV RNA (a surrogate marker of HIV replication), provides the best predictor for disease progression and death.

The association between the CD4+ lymphocyte count and the risk of developing specific diseases was explored in a survey of more than 18 000 HIV-infected subjects who received care in 10 American cities as part of the Adult/Adolescent Spectrum of HIV Disease surveillance system (Table 3). Common problems like sinusitis, bronchitis, and pharyngitis occurred at all strata of CD4+ cell counts. With lower counts, different pulmonary infections occurred with increasing frequency. Bacterial pneumonia and pulmonary tuberculosis occur with relatively intact CD4+ lymphocyte counts, while opportunistic infections like *Pneumocystis carinii* pneumonia and disseminated *Mycobacterium avium* complex and fungi are likely to occur only with severe immunosuppression. Conversely, if the CD4+ lymphocyte count has a sustained increase to more than 200 cells/μl following HAART, the risks of developing *Pneumocystis carinii* pneumonia and other opportunistic infections decline to the point that prophylaxis can be discontinued. Hence knowing the CD4+ count is very helpful in formulating a differential diagnosis in a patient with known or suspected HIV infection. Respiratory problems like sinusitis and bronchitis may occur at any level of CD4+, and bacterial pneumonia and tuberculosis often occur before AIDS-defining opportunistic infections and neoplasms. Declining immune function increases the risk for all HIV-associated respiratory disease, except perhaps for mild upper respiratory tract infections.

Demographic factors

The demographic characteristics of those infected with HIV influence the incidence of specific pulmonary disorders, and the changing demographics of HIV infection in the United States and Europe are accompanied by a changing spectrum of disease. Injecting drug users are at increased risk of developing bacterial pneumonia and pulmonary tuberculosis, and HIV-infected drug users are at especially high risk.

Race and ethnicity may also influence the risk of developing bacterial pneumonia and tuberculosis, but these associations are confounded by differences in access to health care, the higher prevalence of tuberculosis in minority communities, and disproportionately high numbers of injecting drug users who are Black or Hispanic. Nevertheless, the risk of tuberculosis is higher in Blacks and Hispanics than Whites, while Whites have a higher risk of HIV-associated malignancies and cytomegalovirus disease.

Residence

Geographical considerations influence the types of diseases that HIV-infected individuals are at risk of developing. In the United States, the incidence of HIV-associated tuberculosis is highest in the northeast. The high incidence of *Pneumocystis carinii* pneumonia in the United States and Europe contrasts sharply with most regions in Africa, where it is much less common. It is still unknown whether inherited differences in susceptibility to *Pneumocystis carinii* or environmental factors account for the lower incidence of *Pneumocystis carinii* pneumonia in Africa.

The geographical distribution of endemic fungi is also a strong determinant of risk of those infections; disseminated histoplasmosis and coccidioidomycosis are common in patients with AIDS who live in endemic areas. These infections may also occur as reactivation disease after HIV-infected persons move to other areas and develop immunocompromise. For example, cases of disseminated histoplasmosis were reported in New York in patients with AIDS who had relocated from Puerto Rico years before.

Antiretroviral therapy

The availability of potent drugs that inhibit HIV replication led to the development of combination regimens that can accomplish prolonged and near complete suppression of viral replication, with improvement in immune function and clinical outcomes. The standard care of those infected with HIV now includes use of combination antiretroviral therapy with a goal of suppressing HIV replication below the limits of detection, guided by monitoring plasma HIV RNA levels and CD4+ lymphocyte counts. Since the introduction of HAART into clinical practice, death rates from AIDS and AIDS-related opportunistic disorders have fallen dramatically. In a study of 1255 patients with severe immune deficiency, defined by at least one CD4+ count of less than 100 cells/µl, morbidity, mortality, and the incidence of opportunistic infections declined as the use of combination antiretroviral therapy including protease inhibitors increased. These trends were not explained by patient characteristics (sex, age, race/ethnicity, HIV risk) or increasing use of prophylaxis against opportunistic infections. Rather, improving outcomes were attributable to the intensity of antiretroviral therapy, especially with protease inhibitors.

The new antiretroviral agents, and especially the protease inhibitors, interact with many other drugs, and clinicians must investigate possible drug interactions when prescribing new medications for patients taking antiretrovirals. These drug interactions have particular importance in the treatment of tuberculosis in patients with HIV infection, discussed in Chapter 7.10.21 and Chapter 7.11.22.

Pneumocystis carinii prophylaxis

Even before the introduction of HAART, anti-*Pneumocystis* prophylaxis had a profound impact on the spectrum of HIV-associated pulmonary diseases by reducing the incidence and mortality rate due to that infection, and the prognosis for survival after developing immunosuppression or an AIDS-defining diagnosis also improved, largely attributable to that treatment. However, mortality from non-tuberculous mycobacterioses, cytomegalovirus disease, bacterial infections, non-Hodgkin's lymphoma, tuberculosis, and other opportunistic infections increased.

Chest radiography

The chest radiograph is extremely useful in evaluating symptomatic HIV-infected patients, because different radiographic patterns are associated with specific disorders. These are shown in Table 4. A normal radiograph may be seen with common disorders like bronchitis or asthma, but also with *Pneumocystis carinii* pneumonia or tuberculosis. Patients with normal films who are suspected of having one of these infections should proceed to CT scan or pulmonary function tests with carbon monoxide diffusing capacity: if either of these studies is normal, the diagnosis of *Pneumocystis carinii* pneumonia is extremely unlikely. An abnormal film will prompt a diagnostic evaluation based on the pattern of the abnormality, and influenced by the clinician's perception of the relative risk of different disorders. For example, focal infiltrates are usually caused by bacterial pneumonia or tuberculosis, but fungal infection is possible in endemic areas. Diffuse opacities are usually associated with *Pneumocystis carinii* pneumonia, but may also be seen with other disorders. Diagnostic algorithms based on the radiographic findings in patients with suspected HIV-associated pulmonary disorders are summarized in Table 5.

Specific pulmonary diseases

Bacterial pneumonia

HIV infection impairs humoral as well as cellular immunity, increasing the risk of developing bacterial infections, including sinusitis and pneumonia. lthough a first episode of bacterial pneumonia usually occurs before the diagnosis of AIDS, the risk of developing pneumonia increases as the CD4+ lymphocyte count declines. Drug users are at higher risk than other groups, and neutropenia is an independent risk factor. Patients who use trimethoprim-sulfamethoxazole to prevent *Pneumocystis carinii* pneumonia have a reduced risk of developing bacterial pneumonia.

Streptococcus pneumoniae, *Haemophilus influenzae*, and *Staphylococcus aureus* are the most common bacterial pathogens, but disturbing patterns of antimicrobial resistance are emerging, and new aetiologies of pneumonia are recognized more commonly, especially in patients with advanced HIV disease. For example, pneumonia caused by *Pseudomonas aeruginosa,* which was rarely diagnosed in the 1980s, is a relatively common pathogen in severely immunocompromised patients, typically with CD4+ counts of less than 50 cells/µl, and especially following another opportunistic infection. Although pneumonia due to 'atypical' pathogens like *Mycoplasma*, *Chlamydia*, and *Legionella* is reported, these pathogens are relatively uncommon. *Rhodococcus equii*, an aerobic Gram-positive acid-fast bacillus, may cause focal consolidation, endobronchial disease, and cavitation, usually in patients with advanced HIV disease. *Nocardia asteroides* may cause nodules, consolidation, cavitation, pleural effusions, empyema, and intrathoracic lymphadenopathy in patients with HIV infection.

Bacterial pneumonia usually presents with the same symptoms as those who are HIV seronegative, with fever, chills, productive cough, and localized areas of consolidation on chest radiography. While this clinical picture strongly suggests bacterial pneumonia, it may also occur with tuberculosis and fungal infection, and patients with bacterial pneumonia sometimes have diffuse pulmonary opacities that resemble *Pneumocystis carinii* pneumonia.

The approach to diagnosis and treatment is the same as that for HIV-seronegative patients (see section 17.5.2.1). Polyvalent pneumococcal vaccine is recommended for all HIV-infected people, although they may not mount an adequate antibody response. The vaccine against *Haemophilus influenzae* type b is not used in patients with HIV infection because most *Haemophilus* infections are with strains not covered by this vaccine. Although annual influenza vaccine is recommended, there are no data indicating that patients with HIV infection are at increased risk of contracting influenza, or that the illness is more severe than in the general population.

Pneumocystis carinii pneumonia

Clinical features

Pneumocystis carinii pneumonia typically presents with gradually increasing dyspnoea and cough over weeks, but sometimes as an acute illness with rapid deterioration over a few days. The chest radiograph usually has diffuse ground glass opacities, which strongly suggests the diagnosis, but sometimes shows nodular opacities, lobar consolidation, or a normal film. All of these radiographic patterns may also occur with other infections and neoplasms. Cystic abnormalities and

spontaneous pneumothoraces in patients with known or suspected HIV infection are usually caused by *Pneumocystis carinii* pneumonia.

The diagnosis of *Pneumocystis carinii* pneumonia may be supported by adjunctive tests. *Pneumocystis carinii* pneumonia is unlikely in a patient who had a CD4+ cell count above 200 cells/µl in the preceding 2 months in the absence of other HIV-associated symptoms. Approximately 90 per cent of patients with *Pneumocystis carinii* pneumonia have an elevated serum lactic dehydrogenase, but this may occur with other pulmonary diseases. Oxygen desaturation with exercise is a relatively sensitive and specific test in patients suspected to have *Pneumocystis carinii* pneumonia, but is not diagnostic. Gallium-67 and indium-111 lung scans are highly sensitive indicators of *Pneumocystis carinii* pneumonia, but isotope uptake also occurs in other pulmonary infections, so they are seldom useful in a diagnostic evaluation.

Microbiological diagnosis

Pneumocystis carinii cannot yet be cultured *in vitro*, so the diagnosis of *Pneumocystis carinii* pneumonia can be confirmed only by demonstrating organisms in a lung-derived specimen. The least invasive diagnostic test is the analysis of sputum induced with 3 per cent saline delivered by ultrasonic nebulization. Using modified Giemsa, methenamine silver, or immunofluorescent staining, and depending on the experience of the laboratory, *Pneumocystis carinii* can be identified in up to 80 per cent of cases. Other pathogens, particularly *Mycobacterium tuberculosis* and fungi, may also be found using appropriate staining and culture techniques.

It is controversial whether to routinely proceed with fibreoptic bronchoscopy to confirm the diagnosis of *Pneumocystis carinii* pneumonia in patients suspected of having the disease, but who have non-diagnostic sputum specimens. Some prefer to treat empirically for *Pneumocystis carinii* pneumonia, and establish a diagnosis only if there is no clinical response within 5 days. Proponents of this approach hold that a presumptive diagnosis of *Pneumocystis carinii* pneumonia is usually accurate, and that the procedure carries unnecessary inconvenience, risk, discomfort to patients, and expense. Proponents of early bronchoscopy maintain that using an empirical approach will subject many patients to treatment and its attendant toxicity for a disease that they do not have, and non-responders may be too ill to undergo bronchoscopy after several days of inappropriate therapy. Furthermore, coinfection with other pathogens is common, may not be diagnosed in patients treated empirically, and adjunctive corticosteroid therapy may transiently improve symptoms in patients with other pulmonary disorders, contributing to the emergence of other opportunistic infections such as aspergillosis and cytomegalovirus.

Patients with suspected *Pneumocystis carinii* pneumonia who have non-diagnostic sputum studies should have fibreoptic bronchoscopy with bronchoalveolar lavage as the next procedure in the diagnostic evaluation. The complication rate is very low, and the yield is over 90 per cent in most centres. This yield is optimized by performing lavage in more than one lobe, and is higher in the upper lobes than the lower. All lavage specimens should be examined for the presence of acid-fast bacilli, fungi, and viral cellular inclusions, since patients with suspected *Pneumocystis carinii* pneumonia may have another infection, or may be coinfected with other pathogens. The role of bronchoalveolar lavage in the diagnosis of bacterial pneumonia in HIV-infected persons is not established. Some clinicians also perform bronchoscopic lung biopsies routinely during bronchoscopy, as this procedure increases the diagnostic yield for *Pneumocystis carinii* and other disorders. Others reserve biopsy for patients who have no diagnosis after bronchoalveolar lavage. Bronchoscopic biopsy is contraindicated in the presence of bleeding disorders, and the high risk of pneumothorax usually precludes biopsy in patients undergoing mechanical ventilation. Diagnosing *Pneumocystis carinii* pneumonia by video-assisted thoracoscopy or an open procedure is rarely necessary.

Respiratory failure caused by *Pneumocystis carinii* pneumonia

Despite HAART, antipneumocystis prophylaxis, and declining mortality rates from *Pneumocystis carinii* pneumonia, it is still the most common cause of respiratory failure and admission to intensive care units in patients with AIDS. When treatment of *Pneumocystis carinii* pneumonia is postponed or ineffective, a clinical syndrome develops that resembles the acute respiratory distress syndrome, with severe hypoxaemia, intrapulmonary shunt, reduced pulmonary compliance, and the appearance of diffuse radiographic opacities. Just as severe *Pneumocystis carinii* pneumonia clinically resembles acute respiratory distress syndrome, the supportive treatment, including intubation, mechanical ventilation, and application of positive end-expiratory pressure, is similar. Continuous positive airway pressure delivered by mask may improve gas exchange without endotracheal intubation, but its usefulness is limited in patients with severe disease. However, it may afford the patient and physician more time to consider whether mechanical ventilation is desirable.

As changes in therapy have modified the prognosis, three distinct 'eras' of critical care for patients with *Pneumocystis carinii* pneumonia and respiratory failure can be identified. Initially, the outlook for survival was dismal, at around 15 per cent, and in some centres admissions to intensive care units declined because physicians did not recommend aggressive interventions, and patients were more likely to decline them. After 1986, mortality rates seemed to improve to around 50 per cent, attributed to selection of patients with a better prognosis and to the benefits of adjunctive corticosteroid therapy. We are now in a third 'era' of outcomes, when patients who require mechanical ventilation for *Pneumocystis carinii* pneumonia again have a high mortality rate since they are more likely to have failed prophylaxis, anti-*Pneumocystis* treatment, or adjunctive corticosteroid therapy, and therefore are expected to have a poor prognosis. Recent studies show that when respiratory failure follows several days of appropriate therapy for *Pneumocystis carinii* pneumonia, the probability of survival is only around 20 per cent.

The prospects for long-term survival following *Pneumocystis carinii* pneumonia and respiratory failure are more hopeful than earlier in the epidemic. Prolonged survival is probably related to the selection of patients with a better prognosis for mechanical ventilation, and to the use of HAART and prophylaxis against subsequent infections.

Airway diseases

For unknown reasons, patients with advanced HIV infection may have chronic bronchitis and bronchiectasis, even if they do not smoke. These patients usually have severe immunodeficiency, with CD4+ counts of less than 100 cells/µl. Standard antimicrobial agents are usually effective, but symptoms are likely to recur, especially when *Pseudomonas aeruginosa* is isolated from the sputum. The role and efficacy of bronchodilators and antiinflammatory agents in HIV-associated airway diseases have not been studied systematically. HIV infection also predisposes to early emphysema, possibly related to enhanced pulmonary cytotoxic T-lymphocyte activity.

Kaposi's sarcoma

Kaposi's sarcoma, probably caused by human herpevirus 8, is the commonest malignancy in people with HIV infection, and the skin is the major site of involvement. This virus infects many healthy adults, and may be isolated commonly in saliva, prostatic tissue, and semen. It is probably transmitted by sexual contact, and causes disease when activated by HIV-associated immunosuppression. This hypothesis helps to explain why Kaposi's sarcoma is much more common among HIV-infected gay men than in other transmission groups.

Kaposi's sarcoma may involve many organs, including the lung. Patients with pulmonary Kaposi's sarcoma usually have obvious mucocutaneous lesions, but the lung may be the only site of disease in up to 15 per cent of cases. Involvement of the airways, parenchyma, pleura, and intrathoracic lymph nodes causes a diverse range of symptoms and radiographic findings. The majority of patients with pulmonary Kaposi's sarcoma diagnosed antemortem have cough, dyspnoea, and fever.

Kaposi's sarcoma lesions in the airways do not usually cause symptoms, but sometimes lead to obstruction or haemoptysis. The finding of typical lesions on inspection of the airways is usually considered diagnostic. Histological diagnosis may be difficult because the yield of forceps biopsy is low, and some authors believe that forceps biopsy of Kaposi's sarcoma lesions places the patient at significant risk of bleeding, but this is controversial.

Parenchymal involvement with Kaposi's sarcoma is suggested by bronchial wall thickening, nodules, Kerley B lines, and coexisting pleural effusions, especially in patients with cutaneous disease. Patients may be bronchoscoped to determine whether diffuse radiographic opacities are caused by Kaposi's sarcoma or an opportunistic infection. The yield of bronchoscopic lung biopsies in the diagnosis of Kaposi's sarcoma is low, and even open lung biopsy is non-diagnostic in approximately 10 per cent of cases because of the focal distribution of lesions. The diagnosis of pulmonary parenchymal Kaposi's sarcoma is therefore usually inferred in patients with cutaneous disease, chest radiographs that suggest this disorder, visual confirmation of airway lesions, and no evidence of opportunistic infection on bronchoalveolar lavage or bronchoscopic lung biopsy. Patients with parenchymal opacities who have typical lesions in the airways and no identified pulmonary infection are assumed to have parenchymal Kaposi's sarcoma.

When Kaposi's sarcoma involves the pleura, effusions are usually exudative and sanguinous, but cytological examination is non-diagnostic. Closed pleural biopsy is rarely positive due to the focal nature of pleural lesions and predominant involvement of the visceral rather than parietal pleura. Since establishing a diagnosis usually necessitates a thoracoscopic or open pleural biopsy, the presence of pleural involvement with Kaposi's sarcoma is usually inferred in a patient with cutaneous

disease and a serosanguinous effusion without a reasonable alternative explanation.

Lymphoma

Non-Hodgkin's B-cell lymphoma is associated with HIV infection. Although pulmonary involvement is usually clinically innocuous, the lung is a common site of extranodal disease. Even in patients with an established diagnosis of lymphoma, lung involvement is usually a late feature of disease. If symptoms occur, they are usually late in the course of HIV disease, and simulate common opportunistic infections, presenting with lobar consolidation, nodules, reticular opacities, and masses. Intrathoracic lymphoma usually presents with lymphadenopathy, pleural effusions, or pleural thickening. Airway involvement may cause atelectasis, and pulmonary involvement may be seen in the form of nodules or consolidation. The diagnosis is established by lung or lymph node biopsy, or by cytological analysis of pleural fluid.

Carcinoma of the lung

A few series report an increased incidence of lung cancer in those infected with HIV, and that these cancers are more aggressive, diagnosed at a more advanced stage, and are associated with shorter survival than lung cancer in HIV-negative individuals. The link between HIV infection and lung cancer is supported by genomic differences between lung cancers in patients with and without HIV infection. However, lung cancer is still very rare compared with opportunistic infections and Kaposi's sarcoma.

17.6 Chronic obstructive pulmonary disease

William MacNee

Introduction

Chronic obstructive pulmonary disease (**COPD**) produces considerable morbidity and mortality: it is the sixth commonest case of death worldwide, and set to become the third commonest cause by the year 2020. It is a slowly progressive condition characterized by airflow limitation that is largely irreversible.

Definitions

The group of conditions characterized by airways obstruction that is incompletely reversible have no universally accepted definition. The term COPD has become accepted in recent years, but is not truly a disease, rather a group of diseases. A major problem in defining COPD is the difficulty in differentiating this condition from asthma, particularly the persistent airways obstruction of older chronic asthma sufferers that is often difficult or even impossible to distinguish clinically from that in COPD, although a history of heavy cigarette smoking, evidence of emphysema by imaging techniques, decreased diffusing capacity for carbon monoxide, and chronic hypoxaemia favour a diagnosis of COPD.

Chronic bronchitis is defined clinically as the presence of a chronic productive cough on most days for 3 months, in each of two consecutive years, in a patient in whom other causes of chronic cough have been excluded. Chronic bronchitis can be classified into three forms: simple bronchitis, defined as mucus hypersecretion; chronic or recurrent mucopurulent bronchitis in the presence of persistent or intermittent mucopurulent sputum; and chronic obstructive bronchitis when chronic sputum production is associated with airflow obstruction.

Emphysema is defined as abnormal, permanent enlargement of the distal airspaces, distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis. As with chronic bronchitis the definition of emphysema does not require the presence of airflow obstruction. Thus emphysema is defined pathologically.

Bronchiolitis or small airways disease results from inflammation, squamous cell metaplasia, and/or fibrosis in airways less than 2 mm in diameter. These changes are amongst the earliest to appear in cigarette smokers but are difficult to detect by physiological measurements. Although relatively little is known of the natural history of this condition, it is considered to contribute increasingly, as it progresses, to the airways obstruction of COPD.

The relative contribution made by airway abnormalities or distal airspace enlargement to the airways obstruction in an individual patient with COPD is difficult to determine. Thus in the United States the term COPD was introduced in the early 1960s to describe patients with largely irreversible airways obstruction, due to a combination of airways disease and emphysema, without defining the contribution of these conditions to the airways obstruction.

In their statement on the Standards for Diagnosis and Care of Patients with COPD, the American Thoracic Society defined COPD as 'a disease state characterized by the presence of airflow obstruction due to chronic bronchitis or emphysema; the airflow obstruction is generally progressive, may be accompanied by airway reactivity, and may be partially reversible'. The European Respiratory Society has adopted a similar definition—'a disorder characterized by reduced maximum expiratory flow and slow forced emptying of the lungs, features which do not change markedly over several months'. The definition produced by the British Thoracic Society is similar— 'a slowly progressive disorder characterized by airways obstruction (reduced FEV_1 and FEV_1/VC ratio), which does not change markedly over several months. Most of the lung function impairment is fixed, although some reversibility can be produced by bronchodilator (or other) therapy'. Recently, the global initiative on obstructive lung disease introduced the concept of COPD as an inflammatory disease by suggesting in their definition that COPD was characterized by 'an abnormal inflammatory response in the lungs to inhaled particles or gases'.

In clinical practice a diagnosis of COPD is usually associated with:

1. a history of chronic progressive symptoms (cough, wheeze, and/or breathlessness), with little variation;
2. usually a cigarette smoking history of more than 20 pack years (1 pack year is 20 cigarettes per day for 1 year); and
3. objective evidence of airways obstruction, ideally by spirometry, that does not return to normal with treatment.

The term COPD excludes a number of specific causes of chronic airways obstruction, such as cystic fibrosis, bronchiectasis, and bronchiolitis obliterans (for example associated with lung transplantation or chemical inhalation). The differentiation of COPD from asthma remains a problem, particularly as a large proportion of patients with COPD show some reversibility of their airflow obstruction with bronchodilators.

Aetiology

Chronic mucus hypersecretion

Population studies of respiratory symptoms show a much higher prevalence of cough and sputum among smokers than among non-smokers. A survey in urban and rural populations in the United Kingdom found that a history of chronic bronchitis was present in 17.6 per cent of males aged 55 to 64 years who were heavy smokers, in 0.9 per cent of light smokers, 4.4 per cent of ex-smokers, and was absent in non-smokers. Stopping smoking produces cessation of the sputum production in 90 per cent of cases. Pipe and cigar smokers have a much lower prevalence of chronic bronchitis and less impairment of respiratory function, possibly reflecting lower rates of smoke inhalation.

The 'British hypothesis' suggested that chronic airflow obstruction resulted from the development of chronic mucus hypersecretion as a result of recurrent bronchial infection. This hypothesis was tested in the landmark studies of Fletcher and Peto in working men in London followed up between 1961 and 1969, which showed that smoking accelerated the decline in forced expiratory volume in 1 s (**FEV1**), but failed to show a correlation between the degree of mucus hypersecretion and an accelerated decline in FEV_1 or mortality. By contrast, mortality was strongly related to the development of low FEV_1.

More recent data, from a study of 15 000 adults from the general population in Copenhagen followed up between 1976 and 1994, suggested that mucus hypersecretion was not such an innocent phenomenon, since it was associated with increased risk of hospital admission and accelerated decline in FEV_1. Moreover, as the FEV_1 decreases, the association between mucus hypersecretion and mortality becomes stronger. Differences in the degree of airflow obstruction between the populations in these two studies may explain the different findings.

Cigarette smoking

Cigarette smoking is the single most important identifiable aetiological factor in COPD. However, only 10 to 20 per cent of smokers develop clinically significant COPD, whilst approximately half will never develop a clinically significant physiological deficit. In general, the greater the total tobacco exposure, the greater the risk of developing COPD. However, for any exposure there are clearly individual variations in susceptibility to the effects of tobacco smoke (Fig. 1). Although smoking is the dominant risk factor, COPD does occur in non-smokers, such as in patients with a_1-antitrypsin deficiency.

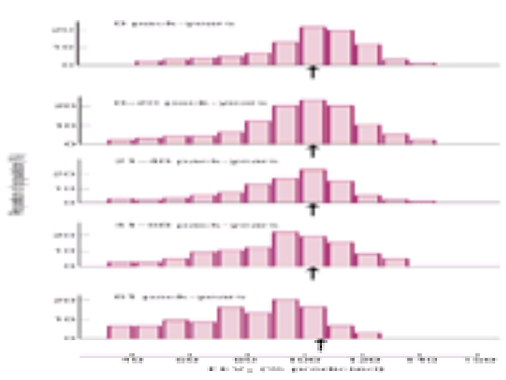

Fig. 1 Effect of increasing cigarette smoke consumption on FEV_1. Although the mean FEV_1 falls as smoking consumption increases, there is a wide variation in this effect, suggesting variable susceptibility to the effects of tobacco smoke. (Adapted from Burrows B *et al*., 1977, *American Journal of Respiratory and Critical Care Medicine* **115**, 195–205.)

The most important evidence linking smoking and mortality from bronchitis comes from a study of 40 000 medical practitioners in the United Kingdom who recorded their smoking habits. In male doctors, mortality from chronic bronchitis fell between 1953 and 1967 by 24 per cent, compared with a fall of only 4 per cent in other men in the United Kingdom of the same age. This difference was attributed to the decrease in smoking in doctors compared with an overall increase in smoking in the general population.

Passive smoking

There is a trend to an increased relative risk of the development of chronic airflow obstruction from passive smoking, but not powerful enough to demonstrate statistical significance. Cumulative lifetime exposure to environmental tobacco smoke during childhood is associated with significantly lower peak levels of FEV_1 in adulthood. Maternal smoking is associated with low birth weight, and smoking by either parent is associated with an increased incidence of respiratory illnesses in the first 3 years of life.

Air pollution

The introduction of the clean air acts (1956, 1965) led to a reduction in smoke and sulphur dioxide levels during the 1960s, which produced less discernible peaks of pollution related to morbidity and mortality, compared with the 1950s. More recent studies show an association between respiratory symptoms in patients with airways disease, general practitioner consultations, and hospital admissions in patients with airways diseases at levels of particulate air pollution below 100 $\mu g/m^3$, levels that are currently experienced in many urban areas in Europe and the United Kingdom. Furthermore, levels of particulate air pollution are associated with deaths from all

causes, particularly cardiorespiratory deaths.

Although there have been associations between exacerbations of airways diseases and photochemical air pollutants, such as nitrogen dioxide and ozone, this association has been largely confined to patients with asthma. There are a few longitudinal studies on the effects of air pollution on decline in lung function, but the data are conflicting. Indoor air pollution, for example as a result of the use of biomass fuel for cooking is associated with the development of COPD in low income countries, particularly in women.

Protease inhibitor deficiency

a_1-Antitrypsin or a_1-protease inhibitor is a polymorphic glycoprotein that is responsible for most of the antiprotease activity in the serum. Laurell and Eriksson in 1963 were the first to describe the association between a_1-antitrypsin deficiency and the development of early onset emphysema, and that the abnormality was transmitted as an autosomal recessive gene. Since the discovery of the deficiency, over 75 biochemical variants have been described relating to their electrophoretic properties, giving rise to the phase inhibitor (**Pi**) nomenclature. The commonest allele in all populations is PiM and the most common genotype is PiMM, which occurs in around 86 per cent of the United Kingdom population. PiMZ and PiMS are the next two commonest genotypes and are associated with a_1-protease inhibitor levels of between 50 and 75 per cent of mean levels of PiMM subjects, as is the much less common PiSS type. The homozygous PiZZ type, in which serum levels are 10 to 20 per cent of the average normal value, is the strongest genetic risk factor for the development of emphysema. The most important other type is PiSZ, where basal levels are 35 to 50 per cent of normal values. A few rare variants that result in complete functional absence of a_1-protease inhibitor account for the remainder of the severely deficient patients.

In the United States, screening of adult blood donors identified a 1 in 2700 prevalence of PiZZ subjects, of which most had normal spirometry. Around 1 in 5000 children in the United Kingdom are born with the homozygous deficiency (PiZZ). However, the number of subjects identified with disease is much less than predicted from the known prevalence of the deficiency. Therefore it is by no means inevitable that all individuals with a homozygous deficiency develop respiratory disease. Indeed a few PiZZ individuals live beyond their sixth decade and escape the development of progressive airways obstruction. Prospective follow-up of PiZZ subjects has shown a greatly accelerated decline in FEV_1, but with large variations among individuals. There is a clear interaction with cigarette smoking, but this cannot entirely account for the variation in the decline in FEV_1 observed. Life expectancy of subjects deficient in a_1-protease inhibitor is significantly reduced, especially if they smoke.

Occupation

It is generally accepted that there is a causal link between occupational dust exposure and the development of mucus hypersecretion. Cigarette smoke has been a confounding feature since the prevalence of smoking remains disproportionately high in many workers who are exposed to dust. Longitudinal studies on workforces exposed to dusts show an association with dust exposure and a more rapid decline in FEV_1 and increased mortality.

The accumulating evidence for an association between coal dust exposure and the development of COPD led recently to the establishment of COPD as a disease that is considered for compensation in miners in the United Kingdom. A small, but significant effect of exposure to welding fumes on the development of COPD was shown in a study of shipyard workers. Workers exposed to cadmium have an increased risk of emphysema.

Chronic bronchopulmonary infection

Studies in the 1960s and 1970s in men with chronic bronchitis demonstrated that prophylactic antibiotics to prevent recurrent infective exacerbations did not slow the decline in lung function. However, acute bronchopulmonary infection was associated with an acute decline in lung function that may persist for several weeks, but which usually recovers completely.

Cough and sputum production between the ages of 20 and 36 years is more commonly reported in those with a history of chest illness in childhood. The association between childhood respiratory illness and ventilatory impairment in adulthood is probably multifactorial. Several factors such as low economic status, greater exposure to passive smoking, poor diet and housing, and residence in areas of high pollution may all contribute to this finding.

Growth and nutrition

Several recent studies have suggested that mortality from chronic respiratory diseases and adult ventilatory function correlate inversely with birth weight and weight at 1 year of age. Thus, impaired growth *in utero* may be a risk factor for the development of chronic respiratory diseases.

One study of British adults has shown that there is a correlation between consumption of fresh fruit in the diet and ventilatory function, a relationship that held both in smokers and in those who had never smoked. Dietary factors, particularly a low intake of vitamin C and low plasma levels of ascorbic acid, were related to a diagnosis of bronchitis in the United States National Health and Nutrition Examination Survey.

Atopy and airway hyperresponsiveness

In the 1960s Dutch workers proposed that smokers with chronic, largely irreversible airways obstruction and subjects with asthma shared a common constitutional predisposition to allergy, airway hyperresponsiveness, and eosinophilia—the 'Dutch hypothesis'. Numerous studies have shown that smokers tend to have higher levels of IgE and higher eosinophil counts than non-smokers, but the levels are not as high as those in individuals with asthma. Studies in middle-aged smokers with a degree of impairment of lung function show a positive correlation between accelerated decline in FEV_1 and increased airway responsiveness to either methacholine or histamine. However, atopic status, as defined by positive skin tests, does not differ between smokers and those who have never smoked.

Whether airway hyperresponsiveness is a cause or consequence of COPD is still a matter of debate.

Epidemiology

Prevalence

The symptom of mucus hypersecretion has been extensively studied in general population surveys over the last 40 years. In these studies, usually in middle-aged men, the prevalence of chronic cough and sputum production ranges between 15 and 53 per cent, with a lower prevalence of between 8 and 22 per cent in women, being more prevalent in urban than in rural areas. A study in the late 1980s showed a decline in the prevalence of chronic cough and phlegm in middle-aged men to 15 to 20 per cent, with little change in women.

Prevalence studies of COPD are normally based on values of percentage of predicted FEV_1, which defines individuals with and without airways obstruction. In a survey in 1987 of a representative sample of 2484 men and 3063 women in the United Kingdom, in the age range 18 to 64 years, 10 per cent of men and 11 per cent of women had an FEV_1 that was greater than 2 standard deviations below their predicted values, the numbers increasing with age, particularly in smokers. In current smokers in the age range 40 to 65 years, 18 per cent of men had an FEV_1 greater than 2 standard deviations below normal and 14 per cent of women, compared with 7 and 6 per cent of male and female non-smokers, respectively.

Studies from the United States, which used a lower limit of normal for FEV_1 of less than 65 per cent of the predicted value, show the prevalence of COPD in men falling from 8 per cent in the 1960s to 6 per cent in the late 1970s, whereas in women the prevalence of 3 per cent did not change over a similar period. National surveys of consultations in British general practices have shown a modest decline in the number of middle-aged men consulting their doctor with symptoms suggestive of COPD and a slight increase among middle-aged women. These trends are confounded by changes over the years in the application of the diagnostic labels for this condition, particularly the overlap between COPD and asthma.

Mortality

There are large international variations in the death rate for COPD, which cannot be entirely explained by differences in diagnostic patterns, labels, or by differences in smoking habits (Fig. 2). COPD is often a contributory factor to the cause of death, and thus figures from death certification underestimate the mortality from COPD. Most of the mortality from this condition occurs in the over 65 years age group. Within the United Kingdom, age-adjusted death rates from chronic respiratory diseases vary by a factor of 5 to 10 in different geographical locations. Mortality rates tend to be higher in urban areas than in rural areas.

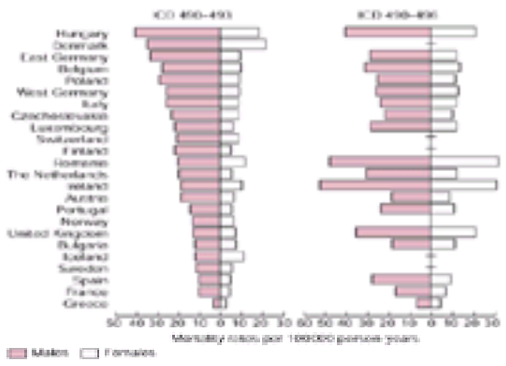

Fig. 2 Age standardized mortality rates in Europe, 1988 to 1991, for chronic obstructive pulmonary disease (COPD). ICD 490–496 = COPD and similar conditions. Closed bars to the left indicate mortality rates in males; open bars to the right in females. (Adapted from Siafakas NM *et al*., 1995, *European Respiratory Journal* **8**, 1398–420.)

Mortality from chronic respiratory disease (ICD 9 490–493 and 496) in males aged 55 to 84 years has been falling, except in the group over 75 years of age. Similar trends have been recorded in American men, whereas in women (whose mortality is one-third that of men) the decline in mortality which was recorded until 1975 has since shown a slight increase in those over the age of 65 years. These trends presumably relate to the later time of the peak prevalence of cigarette smoking in women compared with men.

In the United Kingdom there are around 30 000 deaths per year from COPD. These accounted for 6.4 per cent of all male deaths and 3.9 per cent of all deaths in females in 1994.

Morbidity/use of health resources

COPD places an enormous burden on health-care resources. An estimate of the annual workload in primary and secondary care attributable to COPD and its associated conditions in an average United Kingdom health district is shown in Table 1. It has been calculated that airways diseases (chronic bronchitis and emphysema, COPD, and asthma) account for 24.4 million lost working days per year in the United Kingdom, which represents 9 per cent of all certified sickness absence among men, and 3.5 per cent of the total among women. Respiratory diseases in the United Kingdom rank as the third commonest cause of days of certified incapacity; COPD accounting for 56 per cent of these days lost in males and 24 per cent in females.

History and prognosis

Severe airways obstruction occurs in susceptible smokers as a result of years of an accelerated decline in FEV_1. In non-smokers the FEV_1 declines at a rate of 20 to 30 ml/year (Fig. 3); this occurs at a faster rate in smokers, reported changes in FEV_1 in patients with COPD being more than 50 ml/year. Fletcher and colleagues found a relationship between the initial level of FEV_1 and the annual rate of decline in FEV_1 over a follow-up period of 8 years in working men in London. From these data they suggested that susceptible cigarette smokers could be identified in early middle age by a reduction in the FEV_1 (Fig. 3). They also suggested that there was a tracking effect, whereby individuals in the highest or lowest FEV_1 percentiles remained in the same percentiles over subsequent years. Support for the tracking effect comes from a study of 2718 working men, whose pulmonary function was assessed in the 1950s and subsequently followed up over 20 years. In those whose initial FEV_1 was more than 2 standard deviations below predicted values, the risk of death from chronic airways obstruction was 50 times greater than those whose initial FEV_1 was above average. There is a tendency for annual rates of decline in FEV_1 to be slower in advanced than in mild disease.

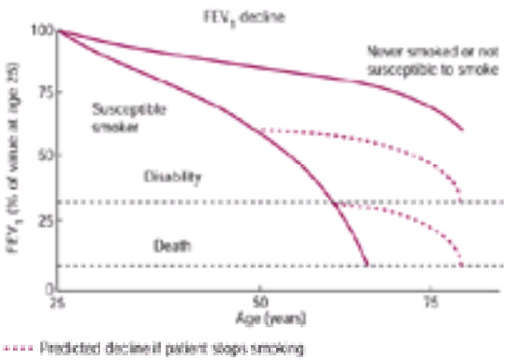

Fig. 3 The effect of age upon airflow obstruction in normal subjects and susceptible cigarette smokers. Cessation of smoking (dotted curved lines) returns the rate of decline to normal.

The strongest predictors of survival in patients with COPD are age and baseline FEV_1. Less than 50 per cent of patients whose FEV_1 has fallen to 30 per cent of predicted are alive 5 years later. There is an even stronger relationship between survival and the post-, rather than prebronchodilator FEV_1. Other unfavourable prognostic factors include severe hypoxaemia, raised pulmonary arterial pressure, and low carbon monoxide transfer, which become apparent in patients with severe disease. Factors favouring improved survival are stopping smoking and a large bronchodilator response. A reduced FEV_1 is also an important additional risk factor for lung cancer, independent of age or cigarette smoking.

Pathology

The pathological changes in patients with COPD are complex and occur in both the large and small airways, and in the alveolar compartment. The relative contributions that the pathological changes in the airways and those of emphysema make to airways obstruction have been the subject of considerable study. In general, pathological changes correlate rather poorly with both clinical and functional patterns of the disease. As a result there is still no clear consensus on whether the fixed airway obstruction in COPD is largely due to inflammation and scarring in the small airways, resulting in narrowing of the airway lumen, or to loss of support for the airways due to loss of alveolar walls, as in emphysema. Although the pathology of COPD is complex, it can be simplified by considering separately the three sites described above in which pathological changes could, in smokers, produce a clinical pattern of largely fixed airways obstruction. The clinicopathological picture is complicated by the fact that these three entities, or any combination of the three, may exist in an individual patient.

Chronic bronchitis

The pathological basis of hypersecretion of mucus is an increase in the volume of the submucosal glands, and an increase in the number and a change in the distribution of goblet cells in the surface epithelium. Submucosal glands are confined to the bronchi, decrease in number and in size in the smaller, more peripheral bronchi, and are not present in the bronchioles.

In healthy subjects who have never smoked, goblet cells are predominantly seen in the proximal airways, and decrease in number in more distal airways, being normally absent in terminal or respiratory bronchioles. By contrast, in smokers, goblet cells not only increase in number, but extend more peripherally.

The use of bronchoscopy to obtain airway cells by bronchoalveolar lavage and bronchial tissue samples by biopsy has added new insights into the role of inflammation in COPD. Bronchial biopsy studies confirm those of resected lung material, which show bronchial wall inflammation in this condition. As in asthma, bronchial biopsies in patients with chronic bronchitis reveal that activated T lymphocytes are prominent in the proximal airway walls. However, in contrast to asthma, macrophages are also a prominent feature and the CD8 suppresser T-lymphocyte subset, rather than the CD4 subset, predominates.

Bronchial biopsies from limited studies in patients during exacerbations of chronic bronchitis show increased numbers of eosinophils in the bronchial walls, although their numbers are small compared with exacerbations of asthma and, by contrast to those in asthma, these cells do not appear to have degranulated.

Bronchoalveolar lavage, or more recently studies of spontaneously produced or induced sputum, have shown increased intraluminal airspace inflammation in patients with chronic bronchitis, with or without airways obstruction, and predominantly neutrophils and macrophages in bronchoalveolar lavage studies. There is also evidence that airspace inflammation in patients with chronic bronchitis persists following smoking cessation if the production of sputum persists.

These studies of sputum and bronchial biopsies in chronic bronchitis have mainly sampled the proximal airways. Recent studies suggest that inflammatory changes present in the large airways may reflect those present in the small airways, and perhaps even in the alveolar walls.

Emphysema

Airspace enlargement can be identified macroscopically on the cut surface of an inflated lung when the airspace size reaches 1 mm. Two major types of emphysema are recognized, according to the distribution of enlarged airspaces within the acinar unit (Fig. 4):

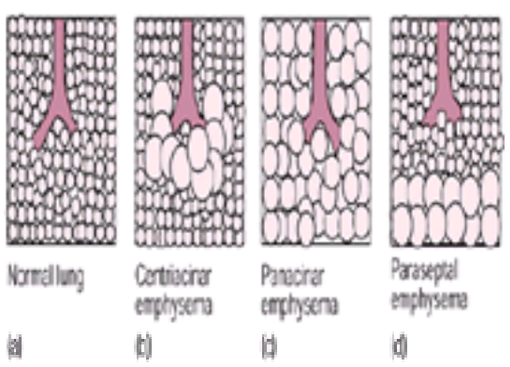

Fig. 4 Diagramatic representation of the distribution of abnormal airspaces within the acinar unit in different types of emphysema. (a) This represents the acinar unit in a normal lung, (b) shows the focal enlargement airspaces around the respiratory bronchioles in centriacinar emphysema, (c) shows the confluent even involvement of the acinar unit in panacinar emphysema, and (d) shows the peripherally distributed enlarged airspaces abutting the pleura in paraseptal emphysema. (Adapted from Lamb (1995). In: Calverley P, Pride N, eds. *Chronic obstructive pulmonary disease*, pp.9–34. Chapman and Hall, London.)

1. centriacinar (or centrilobular) emphysema, in which enlarged airspaces are initially clustered around the terminal bronchiole; and
2. panacinar (or panlobular) emphysema, where the enlarged airspaces are distributed throughout the acinar unit.

Centriacinar emphysema is more common in the upper zones of the upper and lower lobes: panacinar emphysema may be found anywhere in the lungs, but is more prominent at the bases, and is associated with a_1-protease inhibitor deficiency. Both types of emphysema can occur alone or in combination in a patient with emphysema. There is still debate over whether centriacinar and panacinar emphysema represent different disease processes, and hence have different aetiologies, or whether panacinar emphysema is a progression from centriacinar emphysema. There is a clearer association between centriacinar emphysema and cigarette smoking than with panacinar emphysema. Smokers with centriacinar emphysema have more small airways disease than those patients with predominantly panacinar emphysema.

Periacinar (or paraseptal or distal acinar) emphysema describes enlarged airspaces along the edge of the acinar unit, but only where it abuts against a fixed structure such as the pleura or a vessel. This is less common and usually of little clinical significance except when extensive in a subpleural position and may be associated with pneumothorax.

Scar or irregular emphysema is used to describe enlarged airspaces around the margins of a scar, unrelated to the structure of the acinus. This lesion is excluded from the current definition of emphysema.

A bulla represents a localized area of emphysema that has locally overdistended; conventionally greater than 1 cm in size.

Absence of fibrosis is a prerequisite in the most recent definition of emphysema. However, fibrosis occurs in the terminal or respiratory bronchioles as part of a respiratory bronchiolitis in asymptomatic cigarette smokers. Furthermore, there is an increase in collagen in the lung parenchyma in smokers compared with non-smokers.

The bronchioles and small bronchi are supported by attachment to the outer aspect of their walls of adjacent alveolar walls. This arrangement maintains the tubular integrity of the airways. It has been suggested that loss of these attachments may lead to distortion and irregularity of airways, which results in airflow limitation (Fig. 5).

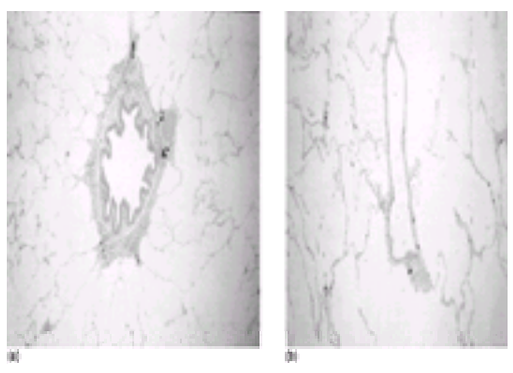

Fig. 5 (a) Cross-section of a normal small peripheral bronchiole, showing a circular outline supported by adjacent alveolar walls. (b) A small bronchiole at the same

magnification in a patient with emphysema. The loss of alveolar supporting walls results in an eliptical airway.

Bronchiolitis/small airways disease

Hogg, Macklem, and Thurlbeck introduced the concept of 'small airways disease' in studies using a retrograde catheter in which they showed that the increased flow resistance in the lungs in patients with COPD largely occurred in the small airways at the periphery of the lungs. Several pathological changes are found in small airways (Fig. 6):

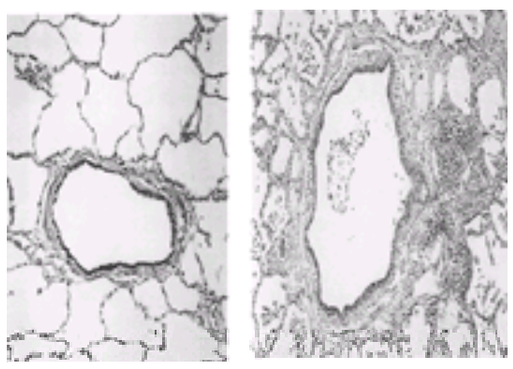

Fig. 6 Normal bronchiole (left) and a bronchiole of a patient with small airways disease/bronchiolitis (right), showing marked increase in inflammatory cells in the walls and in the airway lumen.

- inflammatory infiltrate in the airway wall
- mucus and cells in lumen
- goblet cell hyperplasia
- fibrosis in the airway wall
- squamous cell metaplasia
- mucosal ulceration
- increased amount of muscle
- pigmentation.

The pathological changes in the pulmonary vasculature and the right ventricle are described in Section 15.15.2.

Pathogenesis of COPD

Important to the pathogenesis of COPD were the observations of an association between a $_1$-antitrypsin deficiency and the development of early onset emphysema, and the development of emphysema following instillation of the proteolytic enzyme papain into rat lungs. These two important observations form the basis of the protease/antiprotease theory of the pathogenesis of emphysema. This hypothesis states that under normal circumstances the release of proteolytic enzymes from inflammatory cells that migrate to the lungs to fight infection does not cause lung damage because of inactivation of these proteolytic enzymes by an excess of inhibitors. However, in conditions of excessive enzyme load, or where there is an absolute or a functional deficiency of antiproteases, an imbalance develops between proteases and antiproteases in favour of proteases, leading to uncontrolled enzyme activity and degradation of lung connective tissue in alveolar walls, resulting in emphysema (Fig. 7).

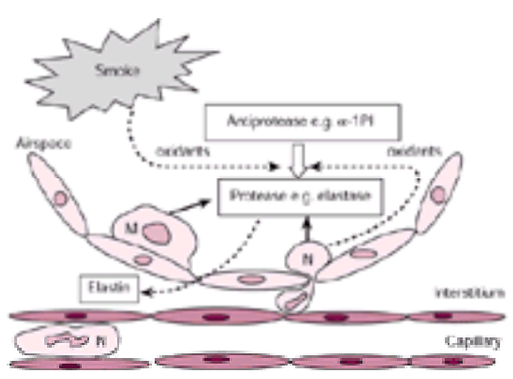

Fig. 7 Simplified protease/antiprotease theory of the pathogenesis of emphysema. Neutrophils (N) sequester in the pulmonary capillaries, initially as a result of the oxidant effect of cigarette smoke that decreases neutrophil deformability. Activated neutrophils adhere to the endothelial cells and subsequently migrate into the airspaces. Oxidants either directly from cigarette smoke or released from activated airspace neutrophils inactivate antiproteases such as a $_1$-protease inhibitor (a_1-PI) reducing its ability to bind to and hence inactivate proteases, particularly elastase. This allows active elastase to enter the lung interstitium and bind to and destroy elastin, causing destruction and enlargement of the distal airspace walls. This simplified protease/antiprotease theory is complicated by the presence of other antiproteases such as antileucoprotease, and other proteases such as metalloproteases released from macrophages (M). There is also the potential for neutrophils to be activated and release elastase while sequestered in the pulmonary capillaries without the need to migrate.

a_1-Antitrypsin/a_1-protease inhibitor

a_1-Antitrypsin is a potent inhibitor of serine proteases, and has greatest affinity for the enzyme neutrophil elastase. It is synthesized in the liver and increases from its usual plasma concentration of approximately 2 g/l as part of the acute-phase response. The activity of the protein is critically dependent on the methionine–serine sequence at its active site.

The average a_1-antitrypsin plasma levels for the more common phenotypes are shown in Table 2. The Z deficiency state (PiZ) is associated with periodic acid–Schiff (PAS)-positive inclusion bodies in the liver, which represent accumulations of the a $_1$-antitrypsin protein. Although liver and mononuclear cells from PiZ patients can manufacture normal amounts of mRNA, and the protein can be translated, there is little secretion of the protein. It is now recognized that the Z a $_1$-antitrypsin gene is normal except for a single point mutation, resulting from substitution of a glycine nucleotide for adenine in the DNA sequence that codes for the amino acid at position 342 on the molecule. This results in spontaneous polymerization of the protein. Large polymers of a $_1$-antitrypsin accumulate in the liver and are unable to pass through the rough endoplasmic reticulum. Their accumulation impairs a $_1$-antitrypsin secretion.

Pathogenesis of emphysema in patients without a_1-antitrypsin

The pathogenic mechanisms of emphysema and also of the small airways disease in COPD are clearly more complex than in patients with a $_1$-antitrypsin. In this case

the clearest association is with cigarette smoking, but since only 15 to 20 per cent of cigarette smokers develop COPD, the question of susceptibility has to be considered. The development of pulmonary emphysema in smokers is thought to occur as a result of several mechanisms:

- increased protease burden
- oxidant/antioxidant imbalance
- decreased antiprotease function
- decreased synthesis of elastin.

Proteases other than neutrophil elastase and antiproteases other than a $_1$-protease inhibitor may be involved in the protease–antiprotease imbalance in emphysema (Fig. 7).

Pathophysiology

Lung mechanics

The characteristic physiological abnormality in COPD is a decrease in maximum expiratory flow. Two major factors can reduce forced expiratory flow:

1. loss of lung elasticity; and
2. an increase in airways resistance in small and/or large airways.

In healthy young subjects significant airway closure only occurs below functional residual capacity (**FRC**). However, enhanced airway closure occurs in the early stages of COPD, which can be measured by plotting the nitrogen concentrations against expired volume following a single vital capacity breath of 100 per cent oxygen. The 'closing volume' measures the lung volume at which expired nitrogen concentrations increase abruptly during slow deflation from total lung capacity (**TLC**) and is determined by the lung volume at which some lung units close their airways and hence stop emptying. In healthy young non-smokers, closing volume is about 5 to 10 per cent of vital capacity (**VC**), rising to 25 to 35 per cent of VC in old age. Compared with non-smokers, young asymptomatic adult smokers have an increase in closing volume. As airways disease progresses the ability to define a closing volume decreases and therefore the test is not useful in established disease. Asymptomatic smokers who develop a reduced FEV_1, initially had an abnormal single-breath nitrogen washout test. Conversely, many subjects who have an abnormal single-breath nitrogen washout test do not develop an abnormal FEV_1.

In comparison with non-smokers, asymptomatic smokers also show frequency dependence of lung compliance, implying increased inequality of time constants in the lungs, resulting from changes in the compliance and resistance of parallel lung compartments. The pathological changes that occur in the peripheral airways in COPD are thought to be reflected in changes in maximum flow at lung volumes below 50 per cent of VC.

Tests of overall lung mechanics such as the FEV_1 and airways resistance are usually abnormal in patients with COPD when breathlessness develops. Residual volume, FRC, and (in some cases) TLC increase. Maximum expiratory flow–volume curves (MEFV) show a characteristic convexity towards the volume axis, initially with preservation of peak expiratory flow (Fig. 8).

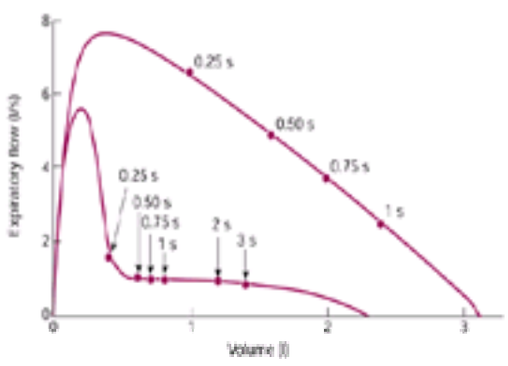

Fig. 8 Maximum flow–volume curves in a healthy subject (FEV_1 2.4 litres) and a subject with COPD and airways obstruction (FEV_1 0.8 litres). The development of convexity of the expiratory curve in mild obstruction is characteristic, as is the relative preservation of peak expiratory flow in the patient with COPD compared to the FEV_1. The figures on the flow–volume curve represent time in seconds for both curves.

The uneven distribution of ventilation in advanced COPD causes a reduction in 'ventilated' lung volume and thus the carbon monoxide transfer factor (*TL*CO) is almost always reduced, although the *TL*CO normalized to ventilated alveolar volume (*K*CO) may remain relatively well preserved in those without emphysema.

The characteristic changes in the static pressure/volume (*P*/*V*) curve of the lungs in COPD are an increase in static compliance and a reduction in static transpulmonary pressure at a standard lung volume (Fig. 9). These changes are generally thought to indicate emphysema.

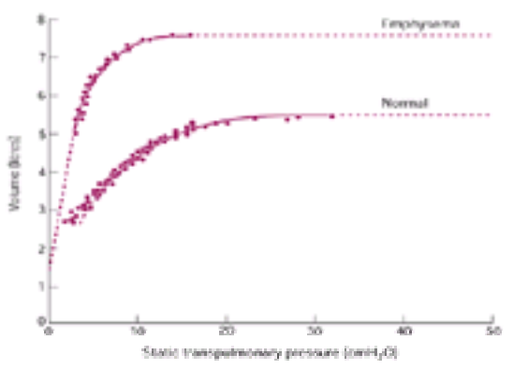

Fig. 9 Static expiratory pressure–volume curves of lungs in a subject with severe emphysema compared with a normal subject. The broken lines represent extrapolation of the curve to infinite pressure and to the volume axis at zero pressure.

The major site of the fixed airway narrowing in COPD is in the peripheral airways less than 2 to 3 mm in diameter. In addition, loss of lung elastic recoil pressure is also important in terms of airways obstruction, particularly in those with severe emphysema, as a result of a reduction in the distending force on all of the intrathoracic airways. Dynamic expiratory compression of the airways is enhanced by loss of lung recoil and by atrophic changes in the airways and loss of support from the surrounding alveolar walls, allowing flow limitation at lower driving pressures and flows.

Pulmonary gas exchange

Ventilation–perfusion (*V*/*Q*) mismatching is the most important cause of impaired pulmonary gas exchange in COPD. Other causes such as alveolar hypoventilation, impaired alveolar–capillary diffusion to oxygen, and increased shunt are of much less importance. The distribution of ventilation is very uneven in patients with COPD.

A reduction of blood flow is produced by several mechanisms including local destruction of vessels in alveolar walls as a result of emphysema, hypoxic vasoconstriction in areas of severe alveolar hypoxaemia, and passive vascular obstruction as a result of increased alveolar pressure and distension.

Respiratory muscles

In patients with severe COPD a combination of pulmonary overinflation and malnutrition, resulting in muscle weakness, reduces the capacity of the respiratory muscles to generate pressure over the range of tidal breathing. In addition, the load against which the respiratory muscles need to act is increased, due to the increase in airways resistance. Overinflation of the lungs leads to shortening and flattening of the diaphragm, thus impairing its ability to generate pressure in order to lower pleural pressure. During quiet tidal breathing in normal subjects, expiration is largely passive and depends on the elastic recoil of the lungs and the chest wall. Patients with COPD increasingly need to use their rib cage muscles and inspiratory accessory muscles, such as the sternomastoids, even during quiet breathing. During exercise, this pattern may be even more distorted and result in paradoxical motion of the rib cage.

Patients with COPD have impaired values of global function of the respiratory muscles such as maximum inspiratory mouth pressures ($P\mathrm{e}_{\mathrm{max}}$), although these measurements are very effort dependent. Diaphragmatic function can be assessed during inspiration by measurement of transdiaphragmatic pressure (Pdi), using balloon-tipped catheters with small transducers placed in the oesophagus and stomach. Measurements of Pdi are reduced in patients with COPD.

Cor pulmonale

Pulmonary arterial hypertension occurs late in the course of COPD with the development of hypoxaemia ($P\mathrm{aO}_2$ less than 8 kPa) and usually also hypercapnia. It is the major cardiovascular complication of COPD and is associated with the development of right ventricular hypertrophy ('cor pulmonale') and poor prognosis. Further details can be found in Section 15.15.2.

Clinical features

Symptoms

Patients with COPD characteristically complain of the symptoms of breathlessness on exertion, sometimes accompanied by wheeze and cough, which is often, but not invariably, productive. Breathlessness is the symptom that commonly causes the patient to seek medical attention and is usually the most disabling problem. Patients often date the onset of their illness to an acute exacerbation of cough with sputum production, which leaves them with a degree of chronic breathlessness. However, close questioning will usually reveal the presence of a 'smoker's cough', with the production of small amounts of mucoid sputum, often predominating in the morning, for many years.

A smoking history of at least 20 pack years is usual before symptoms develop, commonly in the fifth decade, following which there is progression through the clinical stages of mild, moderate, and severe disease. Breathlessness, usually first noticed on climbing hills or stairs, or hurrying on level ground, heralds the development of moderate impairment of airway function and patients may adapt their breathing pattern and their behaviour to minimize the sensation of breathlessness. The perception of breathlessness varies greatly for individuals with the same impairment of ventilatory capacity. However, when the FEV_1 has fallen to 30 per cent or less of the predicted values, breathlessness is usually present on minimal exertion. Severe breathlessness is often affected by changes in temperature and occupational exposure to dust and fumes. Some patients have severe orthopnoea, relieved by leaning forward, whereas others find greatest ease when lying flat. Breathlessness can be assessed on the Medical Research Council, Borg, and Visual Analogue scales.

A productive cough occurs in up to 50 per cent of cigarette smokers, may precede the onset of breathlessness, and many patients may dismiss this as simply a 'smoker's cough'. The frequency of nocturnal cough does not appear to be increased in stable COPD. Paroxysms of coughing in the presence of severe airway obstruction generate high intrathoracic pressures, which can produce syncope and 'cough fractures' of the ribs. Wheeze is common, but not specific to COPD, since it is due to turbulent airflow in large airways from any cause.

Chest pain is common in patients with COPD, but is often unrelated to the disease itself, and may be due to underlying ischaemic heart disease or gastro-oesophageal reflux. Chest tightness is a common complaint during exacerbations of breathlessness, particularly during exercise, and this is sometimes difficult to distinguish from ischaemic cardiac pain. Pleuritic chest pain may suggest an intercurrent pneumothorax, pneumonia, or pulmonary infarction.

Haemoptysis can be associated with purulent sputum and may be due to inflammation or infection. However, this symptom should be treated seriously and the need for investigations for bronchial carcinoma should be considered.

Weight loss and anorexia are features of severe COPD and thought to result from both decreased calorie intake and hypermetabolism. Psychiatric morbidity, particularly depression, is common in patients with severe COPD, reflecting social isolation and the chronicity of the disease. Sleep quality is impaired in advanced COPD, which may contribute to the impaired neuropsychiatric performance.

Occupation/smoking history

A detailed smoking history is important in patients with COPD since the disease is rare in lifelong non-smokers. Although there is, in general, a dose–response relating the number of cigarettes smoked and the level of the FEV_1, there are huge individual variations, reflecting variations in the susceptibility to cigarette smoke (Fig. 1). Occupational exposure to dusts has an additive effect on the decline in lung function, as has been shown in coal miners, where both smoking and years of dust exposure contribute to the decline in FEV_1, although the contribution of smoking was three times as great as that of the dust exposure.

Clinical signs

General examination

The physical signs in patients with COPD are not specific, and depend on the degree of airflow limitation and pulmonary overinflation. The sensitivity of physical signs to detect or exclude moderately severe COPD is poor. Tachypnoea may be present in patients with severe COPD and prolonged forced expiratory time (more than 5 s) can be a useful indicator of airway obstruction. The breathing pattern in COPD is often characteristic, with a prolonged expiratory phase, some patients adopting pursed lipped breathing on expiration, which reduces expiratory airway collapse. Use of the accessory muscles of respiration, particularly the steromastoids, is often seen in advanced disease and these patients often adopt the position of leaning forward, supporting themselves with their arms to fix the shoulder girdle, allowing the use of the pectorals and the latissimus dorsi to increase chest wall movement.

Tar-stained fingers emphasize the smoking habit. In advanced disease cyanosis may be present, indicating hypoxaemia, but may be diminished by anaemia or accentuated by polycythaemia, and is a fairly subjective sign. The flapping tremor, associated with hypercapnia, is neither sensitive nor specific, and papilloedema associated with severe hypercapnia is rarely seen. Weight loss may also be apparent in advanced disease, as well as a reduction in muscle mass. Finger clubbing is not a feature of COPD and should suggest the possibility of complicating bronchial neoplasm or bronchiectasis.

Examination of the chest

In the later stages of COPD the chest is often barrel-shaped with a kyphosis and an apparent increased anterior/posterior diameter, horizontal ribs, prominence of the sternal angle, and a wide subcostal angle. Due to the elevation of the sternum, the distance between the suprasternal notch and the cricoid cartilage (normally three finger-breadths) may be reduced. These are all signs of overinflation. An inspiratory tracheal tug may be detected, which has been attributed to the contraction of the low flat diaphragm. The horizontal position of the diaphragm also acts to pull in the lower ribs during inspiration—Hoover's sign. Widening of the xiphisternal angle and abdominal protuberance occur, the latter due to forward displacement of the abdominal contents, giving the appearance of apparent weight gain. Increased intrathoracic pressure swings may result in indrawing of the suprasternal and supraclavicular fossas and of the intercostal muscles.

On percussion of the chest there is decreased hepatic and cardiac dullness, indicating overinflation. A useful sign of gross overinflation is the absence of a dull

percussion note, normally due to the underlying heart, over the lower end of the sternum. Breath sounds may have a prolonged expiratory phase, or may be uniformly diminished, particularly in the advanced stages of the disease. Wheeze may be present both on inspiration and expiration, but is not an invariable clinical sign. Crackles may be heard particularly at the lung bases, but are usually scanty and vary with coughing.

Cardiovascular examination

The presence of emphysema or overinflation of the chest produces difficulty in localizing the apex beat and reduces the cardiac dullness. The characteristic signs that indicate the presence or consequences of pulmonary arterial hypertension may be detected in advanced cases. The heave of right ventricular hypertrophy may be palpable at the lower left sternal edge. Heart sounds are generally soft, although the pulmonary component of the second heart sound may be exaggerated in the second left intercostal space. A gallop rhythm may be detectable, with a third sound audible in the fourth intercostal space to the left of the sternum. The jugular venous pressure can be difficult to see in patients with COPD as it swings widely with respiration and is difficult to discern if there is prominent accessory muscle activity. When the fluid retention of cor pulmonale occurs there may be evidence of functional tricuspid incompetence, producing a pansystolic murmur at the left sternal edge. The liver may be tender, pulsatile, and a prominent 'v' wave may be visible in the jugular venous pulse. The liver may also be palpable below the right costal margin as a result of overinflation of the lungs.

Peripheral vasodilatation accompanies hypercapnia, producing warm peripheries with a high-volume pulse. Pitting peripheral oedema may also be present as a result of fluid retention.

Investigation

Physiological assessment

The most important disturbance of respiratory function in COPD is obstruction to forced expiratory airflow. The degree of airflow obstruction cannot be predicted from the symptoms and signs and therefore an assessment of the degree and the progression of airways obstruction should be made. At an early stage of the disease conventional spirometry may reveal no abnormality, since the earliest changes in COPD affect the alveolar walls and small airways, producing a modest increase in peripheral airway resistance that is not reflected in spirometry measurements. Tests of small airway function, such as the frequency dependency of compliance and closing volume may be abnormal. These tests are difficult to perform, have high coefficients of variation, and are only valid when lung elastic recoil is normal and there is no increase in large airway resistance. They are therefore not recommended in normal clinical practice.

Spirometry

Spirometry is the most robust test of airflow limitation in patients with COPD. A low FEV_1 with an FEV_1/VC ratio below the normal range is a diagnostic criterion for COPD. The rate of decline of the FEV_1 can be used to assess susceptibility in cigarette smokers, progression of the disease, and to test reversibility of the airways obstruction. It is important that a volume plateau is reached when performing the FEV_1, which can take 15 s or more in patients with severe airways obstruction. If this manoeuvre is not carried out the FVC can be underestimated. The FEV_1 as a percentage of the predicted value can be used to assess the severity of the disease (Table 3).

Flow volume loops

Expiratory flows at 75 or 50 per cent of vital capacity have been used as a measure of airflow limitation. These measurements are less reproducible than spirometry, so that abnormal values must fall to below 50 per cent of the predicted values. Flows at lung volumes less than 50 per cent of vital capacity were previously considered to be an indicator of small airways function, but probably provide no more clinically useful information than measurements of FEV_1.

Peak expiratory flow

Peak expiratory flow can either be read directly from the flow volume loop or measured with a hand-held peak flow meter; the latter are relatively easy to use and are particularly useful in subjects with asthma for revealing variations in serial measurements. However, in COPD many variations are often within the error of the measurement. The peak expiratory flow may underestimate the degree of airflow obstruction in COPD (Fig. 8).

Lung volumes

Static lung volumes such as total lung capacity (TLC), residual volume (RV), and functional residual capacity (FRC) are measured in patients with COPD to assess the degree of overinflation and gas trapping. Dynamic overinflation occurs particularly during exercise and may be an important determinant of the symptom of breathlessness.

The standard method of measuring static lung volumes, using the helium dilution technique during rebreathing, may underestimate lung volumes in COPD, particularly in those patients with bullous disease, where the inspired helium does not have time to equilibrate properly in the airspaces. Body plethysmography uses Boyle's law to calculate lung volumes from changes in mouth and plethysmographic pressures. This technique measures trapped air within the thorax, including poorly ventilated areas, and therefore gives higher readings than the helium dilution technique.

Reversibility to bronchodilators

Assessment of reversibility to bronchodilators is recognized as an essential part of the investigation and management of patients with COPD. Reversibility tests are important:

1. to help distinguish those patients with marked reversibility who have underlying asthma;
2. to aid with future management; and
3. since the post-bronchodilator FEV_1 is the best predictor of survival.

There is, however, no agreement on a standardized method of assessing reversibility, which is usually recorded as change in FEV_1 or peak expiratory flow. However, there may be changes in other lung volumes after bronchodilators, such as inspiratory capacity: this may explain why symptoms improve in some patients following a bronchodilator without change in spirometry. An improvement in FEV_1 in response to a bronchodilator does not necessarily predict a symptomatic response.

The European Respiratory Society and the British Thoracic Society guidelines both recommend that changes should only be considered significant if they exceed 200 ml and represent a 15 per cent improvement over the baseline value. A change over baseline of greater than 12 per cent of the predicted normal value is regarded as a significant bronchodilator response by the American Thoracic Society. A third approach, which has received less support, is to express the change in FEV_1 as a percentage of the potential possible change, which is the predicted value minus the baseline value. Daily variations in airway smooth muscle tone may affect the response to bronchodilators in patients with COPD. Thus, when airway smooth muscle tone is higher, and thus FEV_1 is lower, a response to bronchodilators may be more likely to be achieved than when muscle tone is lower and FEV_1 is higher.

It is usually recommended that the response to a bronchodilator be assessed with a large dose, either using repeated doses from a metered dose inhaler, or by the nebulized route, since this produces a larger number of patients with a significant response. In some cases the addition of a second drug, such as an anticholinergic drug to a b-agonist, will produce a further increase in FEV_1.

Reversibility to corticosteroids

Whether all patients with symptomatic COPD should have a formal assessment of steroid reversibility remains controversial. The commonest regimen is the administration of 30 mg of prednisolone for a period of 2 weeks. Those patients who have previously shown a response to nebulized bronchodilators are more likely to

show a response to steroids. However, it is not possible to predict the response to corticosteroids in an individual patient.

An alternative approach is to assess the response to inhaled steroids, usually over a 6-week period, measuring the FEV_1 before and after the average of the first 5 days and the last 5 days measurements of peak expiratory flow.

Gas transfer for carbon monoxide (*TL*CO)

A low *TL*CO is present in many patients with COPD. Although there is a relationship between the *TL*CO and the extent of microscopic emphysema, the severity of the emphysema in an individual patient cannot be predicted from the *TL*CO, nor is a low *TL*CO specific for emphysema. The commonly used method is the single-breath technique, which uses alveolar volume calculated from helium dilution during the single-breath test. This will underestimate alveolar volume in patients with severe COPD, producing a lower value for the *TL*CO.

Arterial blood gases

Arterial blood gases are needed to confirm the degree of hypoxaemia and hypercapnia in patients with COPD. It is essential to record the inspired oxygen concentration when reporting blood gases. It is also important to note that it may take at least 30 min for a change in inspired oxygen concentration to have its full effect on the PaO_2, because of long time constants for alveolar gas equilibration in COPD, particularly during exacerbations. Pulse oximetry is increasingly used to measure the level of oxygenation, but should not replace an assessment of blood gas tensions, since measurements of $PaCO_2$ are often required. Acid–base status can also be assessed from the arterial pH (hydrogen ion concentration) and the bicarbonate. Increases in $PaCO_2$, which can occur rapidly, can be compensated by renal conservation of bicarbonate ions, which is a relatively slow process. Acid–base status, particularly mixed respiratory and metabolic disturbances, can be characterized by plotting values on an acid–base diagram (Fig. 10).

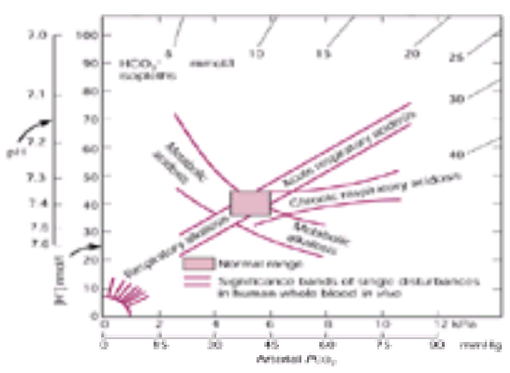

Fig. 10 A non-logarithmic acid–base diagram derived from the measured acid–base status of patients within the five abnormal bands illustrated and of normal subjects (hatched box). This plot of carbon dioxide tension against hydrogen ion concentration (pH) allows the likely acid–base disturbance and calculated bicarbonate value (obtained from the relevant isopleth) to be determined, whilst changes during treatment can be plotted serially for each patient. (Adapted from Flenley DC, 1971, *Lancet* **i**, 961–5.)

Exercise tests

Exercise increases oxygen consumption and carbon dioxide production from skeletal muscle. Patients with COPD have the same oxygen consumption for a given workload as normal subjects, but because their dead-space ventilation is higher, a larger minute ventilation is needed to maintain a constant carbon dioxide level. Since in many patients expiratory airflow is limited within the tidal volume range, the only way to increase minute ventilation is to increase inspiratory flow and/or shift the end expiratory position. Both of these manoeuvres are problematic in patients with COPD and require more work from already compromised inspiratory muscles, or result in progressive overinflation, which increases both the work of breathing and symptoms. Metabolic acidosis develops at lower work rates in patients with severe COPD. In patients with COPD, progressive cycle exercise is limited by dyspnoea in 40 per cent and by leg fatigue in 25 per cent, probably reflecting general debility.

Three forms of exercise test can be performed, which provide useful information.

Progressive symptom-limited exercise

In this test the patient is encouraged to maintain exercise, on a treadmill or a cycle, until symptoms prevent them from continuing. A maximum test is usually defined as a heart rate of greater than 85 per cent of predicted or ventilation greater than 90 per cent predicted. The results are useful to assess whether coexisting cardiac or psychological factors contribute to exercise limitation.

Self-paced exercise

These tests are easy to perform. The 6-min walk is the most commonly used test and has a coefficient of variation of around 8 per cent. Shortening the walk to 2 min decreases the reproducibility. The test is only useful in patients with moderately severe COPD (FEV_1 less than 1.5 litres) who would be expected to have an exercise tolerance of less than 600 m in 6 min. There is a weak relationship between walking distance and FEV_1.

Steady-state exercise

This involves exercise at a sustainable percentage of maximum capacity for 3 to 6 min, during which blood gases are measured, enabling calculation of dead space:tidal volume ratio (*V*D/*V*T) and shunt. This assessment is seldom required in patients with COPD.

Sleep studies

Hypoxaemia occurs during sleep, particularly rapid eye movement sleep, in patients with COPD. However, measurement of nocturnal hypoxaemia does not provide any further prognostic or clinically useful information in the assessment of patients with COPD, unless coexisting sleep apnoea syndrome is suspected.

Non-physiological assessments

Identifying polycythaemia is important in patients with severe COPD since it predisposes to vascular events. Polycythaemia should be suspected when the haematcrit is greater than 47 per cent in women and 52 per cent in men, and/or the haemoglobin is greater than 16 g/dl in women and 18 g/dl in men, provided other causes of spurious polycythaemia, due to decreased plasma volume, such as caused by dehydration or diuretics, can be excluded.

There is no indication for measuring blood biochemistry routinely in patients with clinically stable COPD. a $_1$-Antitrypsin levels and phenotype should be measured in all patients under the age of 40 years, and in those with a family history of emphysema at an early age.

Routine electrocardiography is not required in the assessment of patients with COPD and is an insensitive technique in the diagnosis of cor pulmonale.

Radiology

Plain chest radiography

The features on a plain posterior–anterior chest radiograph are not specific for COPD and are usually those of severe emphysema. There may be no abnormalities, even in patients with very appreciable disability. Bronchial wall thickening, shown as parallel line opacities on plain chest radiography, has been described, but this finding may relate to coincidental bronchiectasis. The most reliable radiographic signs of emphysema can be divided into those due to overinflation, vascular changes, and bullae.

Overinflation of the lungs results in the following.

1. There is a low flattened diaphragm (Fig. 11). Low means that the border of the diaphragm in the mid-clavicular line is at or below the anterior end of the sixth or seventh rib. In a flattened diaphragm the maximum perpendicular height from a line drawn between the costal and cardiophrenic angles to the border of the diaphragm is less than 1.5 cm.

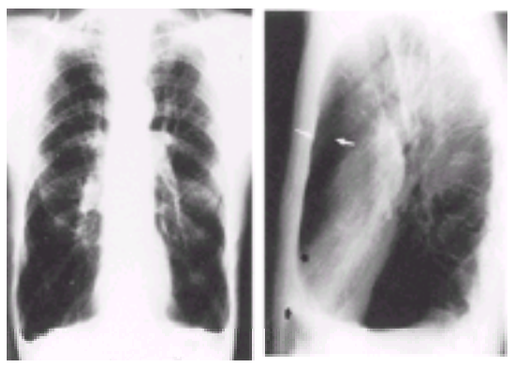

Fig. 11 Generalized (panacinar) emphysema on plain chest radiograph. The diaphragm is low (below the anterior ends of the seventh ribs) and flat. The lower zones are transradient because of oligaemia and there are obtuse costophrenic angles. On the lateral chest radiograph the diaphragm is mildly inverted, the retrosternal transradiency is wide (white arrows) and inferiorly it closely approaches the diaphragm (black arrow).

2. An increased retrosternal airspace occurs when the horizontal distance from the anterior surface of the aorta to the sternum exceeds 4.5 cm on the lateral film at a point 3 cm below the manubrium.
3. There is an obtuse costophrenic angle on the posterior–anterior or lateral chest radiograph.
4. The inferior margin of the retrosternal airspace is 3 cm or less from the anterior aspect of the diaphragm.

The vascular changes associated with emphysema result from loss of alveolar walls and appear as:

1. a reduction in size and number of pulmonary vessels, particularly at the periphery of the lung;
2. vessel distortion, producing increased branching angles, excess straightening, or bowing of vessels; and
3. areas of transradiency.

A general increased transradiency may be due to an overexposed chest radiograph. Focal areas of transradiency surrounded by hairline walls represent bullae. These may be multiple, as part of a generalized emphysematous process, or localized. An 'increase in lung markings' rather than areas of increased transradiency has often been described in patients with COPD: the cause of these changes is unknown, but may at least be contributed to by non-vascular linear opacities due to scarring.

The accuracy of diagnosing emphysema on the plain chest radiograph increases with the severity of the disease and has been reported as being 50 to 80 per cent accurate in patients with moderate to severe disease. However, the sensitivity has been reported as being as low as 24 per cent in patients with mild to moderate disease.

Computed tomography (CT)

CT scanning has been used since the early 1980s to detect and quantify emphysema. Studies using CT scanning can be divided into those that use visual assessment of low-density areas of the CT scan, which can be either semiquantitative or quantitative, and those that use CT lung density to quantify areas of low x-ray attenuation. These studies roughly divide into those that measure macroscopic or microscopic emphysema, respectively.

A visual assessment of emphysema on CT scan (Fig. 12(a) and Fig. 12(b)) reveals:

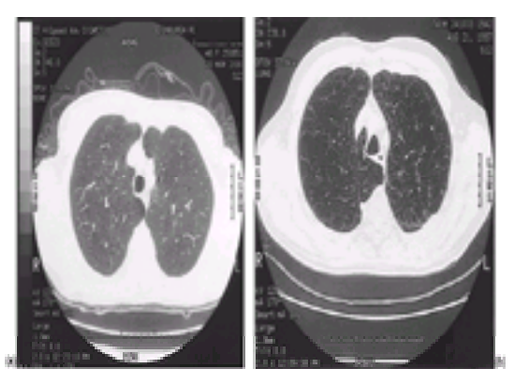

Fig. 12 High resolution CT scan of (a) normal lung, (b) panacinar emphysema.

1. areas of low attenuation without obvious margins or walls;
2. attenuation and pruning of the vascular tree; and
3. abnormal vascular configurations.

The sign that correlates best with areas of macroscopic emphysema is an area of low attenuation. However, visual assessment of the extent of macroscopic emphysema by CT scanning is insensitive, subjective, and has a high intra- and interobserver variability. Thus, in most of this type of study CT scanning tends to underestimate the severity of the disease, with centrilobular lesions smaller than 5 mm particularly likely to be missed.

It is possible using high-resolution CT to distinguish the various types of emphysema, particularly when the changes are not severe, depending on the distribution of the lesions.

A more quantitative approach of assessing macroscopic emphysema is by highlighting pixels within the lung fields in a predetermined low-density range, between –910 and –1000 Houndsfield units, the so-called 'density mask' technique. The choice of the density range is fairly arbitrary. A good correlation has been shown

between pathological emphysema scores and CT 'density mask' score, but this technique may still miss areas of mild emphysema.

Microscopic emphysema can be quantified by measuring CT lung density. CT density is expressed on a linear scale in Houndsfield units (water = 0; air = –1000). In this range, CT lung density is a direct measure of physical density and is determined by the relative mix of air, blood, and interstitial fluid in tissue. Thus, as emphysema develops, a decrease in alveolar surface area would occur as alveolar walls are lost, associated with an increase in distal airspace size, which would decrease lung CT density in association with a decrease in lung function.

More studies are required before CT lung density can be used as a standardized technique to quantify microscopic emphysema. It is particularly important to define the range of normality, and to standardize the calibration of CT scanners and the lung volume at which scans should be performed. However, at present, CT scanning is the most sensitive and specific imaging technique for assessing emphysema in life and can detect mild emphysema in symptomatic patients with a normal chest radiograph.

Pulmonary hypertension/cor pulmonale

Right ventricular hypertrophy or enlargement produces non-specific cardiac enlargement on the plain chest radiograph, the most widely used measurement to assess the presence of pulmonary hypertension being the width of the right descending pulmonary artery, measured just below the right hilum, where the borders of the artery are delineated against air in the lungs laterally and the right main-stem bronchus medially. The upper limit of the normal range of the width of the artery in this area is taken as 16 mm in males and 15 mm in females. Other studies have suggested an upper limit of normal ranging between 16 and 20 mm, which gives a sensitivity of detecting a pulmonary arterial pressure greater than 20 mmHg of 68 to 95 per cent, with a specificity of 65 to 88 per cent. Although these measurements can be used to detect the presence or absence of pulmonary arterial hypertension, they cannot accurately predict the level of the pulmonary artery pressure, and can therefore only be used as a screening test.

Emphysematous bullae

A bulla has been defined arbitrarily as an emphysematous space greater than 1 cm in diameter. On the plain chest radiograph a bulla appears as a localized avascular area of transradiency, usually separated from the rest of the lung by a curvilinear hairline wall. Marked compression of the surrounding lung may be seen, and bullae may also depress the diaphragm. CT scanning is much more sensitive than plain chest radiography at detecting bullae and can be used to determine their number, size, and position. Ventilation of the bullae can also be assessed using inspiratory/expiratory images. It is also possible to estimate the volume of bullae by measuring the area of the bullae in each CT lung slice.

Prevention

Since tobacco smoking is the major aetiological factor in COPD, the disease is theoretically preventable, with cessation of cigarette smoking the single most important way of affecting the outcome. Other important aetiological factors such as atmospheric pollution are also preventable. In the United Kingdom around 31 per cent of men and 29 per cent of women are current cigarette smokers, and around 80 to 90 per cent of patients with COPD have been regular smokers at sometime in their life. At least 90 per cent of smokers are aware of the adverse health effects of cigarette smoking, 70 per cent wish to give up smoking, and the majority of these have made a serious attempt to quit. However, only 40 per cent of regular smokers have succeeded in quitting cigarette smoking by age 60. Nicotine in tobacco smoke is addictive and regular smokers who reduce or cease their nicotine intake experience the characteristic withdrawal syndrome resulting from nicotine craving, manifest as anxiety, lack of concentration, irritability, restlessness, and increased appetite. Nicotine addiction develops rapidly and withdrawal symptoms can be shown to occur even in adolescent smokers. Thus a critical preventive measure is to reduce the number of children starting smoking.

Smoking cessation

Smoking cessation reduces the subsequent decline in lung function (Fig. 3), therefore smoking cessation is the single most important step that can be taken to prevent the progression of the disease. This is particularly true during the early stages of COPD, where both symptoms and lung function may improve. In advanced disease, quitting smoking may not improve pulmonary function, but symptoms such as cough may still improve.

Every patient who smokes should have a discussion of the implications for their future health. Asking about smoking habit in every patient may have a positive reinforcing effect against starting smoking in non-smokers. The reported success rates of smoking cessation interventions come mainly from studies conducted in a primary care setting, and vary between 10 and 30 per cent. A recent review of the literature suggests that in those who request extra help to stop smoking, and when this is given in the form of nicotine replacement or even contact with a support group, the success rate can be up to 25 per cent.

Although it would seem logical, as in other addictions, to suggest a reduction in nicotine levels by a gradual reduction in the number of cigarettes smoked, so as to reduce the severity of withdrawal symptoms, it has been shown that patients who gradually cut down the number of cigarettes smoked tend to inhale more to maintain their usual blood nicotine levels. It has also been shown that those who are unable to quit abruptly are not successful in reducing their consumption of cigarettes over the long term.

The intensity of the strategy employed in a cessation programme should depend on the motivation of the patient to give up smoking. There is no difference in the success rates between regimes involving brief intervention and those with more prolonged intervention in unselected smokers, whereas it is clear that those who are motivated to attend smoking cessation clinics have a better chance of long-term cessation than those who have a brief intervention by the general practitioner. It is therefore better to put time and effort only into those patients who are motivated to give up, and offer only a brief intervention in those with less motivation.

It is important that patients are given a clear strategy for smoking cessation and that the success rates are measured by corroboration with carbon monoxide measurements in breath, or urinary cotinine levels. Meta-analysis of randomized controlled trials of nicotine gum found a clear benefit in terms of abstinence rates at 1 year (23 compared with 13 per cent) in a smoking cessation clinic, but no effect in a general practice setting (11 compared with 12 per cent). Similar abstinence rates at 1 year have been quoted in a general hospital study in the United Kingdom.

Nicotine skin patches allow a slow infusion of nicotine, which creates plasma nicotine levels up to half of those produced by smoking. Trials carried out with nicotine patches indicate that similar success rates to nicotine chewing gum can be achieved. Recent studies using the antidepressant drug bupropion have also shown quit rates similar to those of nicotine replacement therapy in smokers. Based on a recent review of the literature, a strategy for smoking cessation has been suggested (Table 4).

Management of stable COPD

Bronchodilators

Bronchodilator therapy is the cornerstone of treatment in patients with COPD to reduce symptoms and increase exercise tolerance. By contrast with bronchial asthma, the effects are small in patients with COPD, due to structural changes within the airways. The principal bronchodilators—b_2-agonists, anticholinergic drugs, and theophylline derivatives—relax airway smooth muscle as their primary action and hence decrease airway resistance. However, these drugs may also reduce overinflation of the lungs, allowing the lungs to empty more completely. It should be emphasized that relatively small changes in airway dimensions can have major effects on respiratory mechanics, which may be translated into improvement in symptoms and exercise capacity.

b-Agonists

Inhaled b_2-agonists are preferred to oral preparations, since they are as efficacious in much smaller doses and have fewer side-effects. They have a relatively rapid onset of action and are therefore used for symptomatic relief, and can also increase exercise tolerance in patients with COPD. There is no evidence that the response to a b-agonist diminishes with time and patients with COPD should be told to take them as required, although those with severe disease may prefer to take regular doses three to four times daily to obtain symptomatic relief.

There is limited information on the effects of long-acting b_2-agonists in patients with COPD. In randomized placebo-controlled studies there was an improvement in

symptoms and a small improvement in spirometry, without any significant change in exercise capacity but with an improvement in symptoms and quality of life. There is little evidence to support the use of sustained-release oral b $_2$-agonists in patients with COPD.

Anticholinergics

Like b$_2$-agonists, anticholinergics affect both central and peripheral airways and also reduce functional residual capacity (FRC). They have a 30- to 60-min time to peak effect in most patients with COPD, which is slower than b $_2$-agonists, but act for longer than b$_2$-agonists (6 to 10 h).

Optimal bronchodilatation occurs with 80 µg of ipratropium and 200 µg of oxitropium bromide, and studies comparing these treatments suggest no difference in the peak or duration of bronchodilatation. Thus 80 µg of ipratropium should be used in patients with COPD, rather than the customary 40 µg, to produce maximum effect. Tiotropium bromide is a newly developed anticholinergic agent that appears to have a longer time course of action than ipratropium.

Some studies found an increase in maximum exercise and a reduction in oxygen consumption at any given workload with both ipratropium bromide and oxitropium bromide. In a large group of patients with COPD the Lung Health Study showed that treatment with ipratropium bromide produced a small but significant beneficial effect on FEV$_1$ during treatment, but had no other effect on the decline in FEV $_1$ over a 5-year period.

Clinical studies of anticholinergic drugs show that they are at least as efficacious as b $_2$-agonists in patients with COPD and some report a more prolonged bronchodilator response.

Theophyllines

Theophyllines, or methylxanthine derivatives, produce a modest bronchodilator effect in patients with COPD. Their effect on symptoms and on exercise tolerance is variable and often occurs at the top of the therapeutic range. Long-term treatment with theophyllines is limited to the oral route, resulting in a slower onset of action compared with inhaled bronchodilators. Improvement in the phamacokinetics of oral theophyllines has occurred with the production of long-acting formulations.

The bronchodilator action of theophyllines is relatively limited in patients with COPD. Exercise tolerance in patients with COPD changes little with theophylline treatment, showing no or little improvement. Any improvement in exercise tolerance has been thought to result from an effect on respiratory muscles or a fall in trapped gas volume, but these mechanisms are still the subject of debate. Other non-bronchodilator effects of theophylline, such as improving right ventricular performance or anti-inflammatory actions, are of questionable clinical significance.

Theophyllines have a narrow therapeutic index and patients often experience side-effects within the therapeutic range. Other factors that are common in COPD, such as smoking, hypoxaemia, and infection, all alter theophylline clearance and make the control of theophylline dosage difficult, requiring measurement of plasma theophylline levels (Table 5). The possible beneficial effects of theophyllines have to be balanced against their potential side-effects and the fact that a similar benefit may be achievable with inhaled bronchodilators, hence theophyllines are reserved for patients in whom other treatments have failed to control symptoms adequately.

Combination therapy

Studies of combination therapy are difficult to assess owing to problems of suboptimal dosing. Some studies suggest that drug combinations such as salbutamol and ipratropium or salbutamol and aminophylline produce improvement in exercise tolerance in the face of trivial changes in spirometry. It is unclear whether higher doses of salbutamol could have achieved a similar effect. Thus, combinations of bronchodilator drugs should only be used if single drugs have been tried and have failed to give adequate symptomatic relief. Combination therapy should only be continued if there is good subjective or objective benefit.

Drug delivery devices

Compliance with inhaled treatment is poor. In the Lung Health Study the overall compliance with therapy was 65 per cent. Since many patients with COPD are elderly, the difficulties encountered with standard metered dose inhalers (MDI) are exaggerated. These problems can often be overcome by dry powdered formulations or by a spacer device. However, patients with severe COPD are only able to achieve low inspiratory flow rates, and rates as low as 40 litre/min may cause failure of the one-way valve in a spacer device to open.

Home nebulizer therapy

There is controversy over the use of home nebulizer therapy in patients with COPD. Using end-points such as spirometry and corridor walking exercise, it has been shown that nebulized salbutamol is no more effective in patients with COPD than lower doses of the same drug given through a spacer device. However, patients appear to prefer nebulized bronchodilator therapy. This may be because the total dose of the drug delivered by nebulizer therapy is higher, and the facial cooling that occurs with the nebulized solution itself may have an effect on dyspnoea, independent of any effect on airway calibre.

Acute improvement in spirometry with nebulized bronchodilator therapy does not necessarily predict a long-term response and only a minority of patients are likely to obtain benefit from high-dose bronchodilator therapy. Patients should only be supplied with a nebulizer if they have been fully assessed by a respiratory physician who is able to assess the risk/cost benefit. This assessment should include ensuring that optimal use is made of a simple metered dose inhaler or dry powdered device and that some assessment is made of the patient's response to nebulizer therapy, including a home trial with peak expiratory flow measurements. Dosage regimes must be tailored to individual patient's needs and their side-effects monitored.

Corticosteroids

The chronic inflammation that occurs in the large and small airways provides a rationale for the use of corticosteroids in COPD. However, the use of corticosteroids in patients with COPD remains contentious, particularly the prediction of which patients will respond to this treatment.

Oral corticosteroids

A subgroup of patients respond to corticosteroids. A meta-analysis of trials of oral corticosteroids indicates that a significant improvement in FEV $_1$ (over 15 per cent and greater than 200 ml improvement) occurs in 10 to 20 per cent of patients with clinically stable COPD. There are no reliable predictors of which patients will respond. Furthermore, the response to high doses of oral prednisolone in short-term studies does not necessarily predict continued FEV $_1$ response to long-term inhaled steroids. Data from uncontrolled retrospective studies of oral corticosteroids suggest that long-term treatment may slow the decline in FEV $_1$, although 10 mg of prednisolone per day was required to prevent the decline in FEV $_1$ and patients with asthma may have been included. This treatment cannot be recommended in view of adverse side-effects.

Inhaled corticosteroids

Two large controlled trials of the effects of inhaled corticosteriods in patients with mild COPD have now been published. Both the Copenhagen City Lung study and the EUROSCOP study showed no effect of budesonide at a dose of 800 µg twice daily on the rate of decline in FEV $_1$over a follow-up period of 3 years. In patients with a mean FEV$_1$ of 77 per cent of predicted (i.e. mild airways obstruction) who continued to smoke, the EUROSCOP study showed an initial improvement in FEV $_1$ over the first 6 months (at a rate of 17 ml/year—Fig. 13), which was maintained over the 3-year follow-up period. This was not the case in the Copenhagen study. A third trial in moderate COPD (FEV$_1$ 50 per cent of predicted) in a mixed group of smokers and ex-smokers also showed a similar small improvement in FEV$_1$ over 3 months in a group treated with fluticasone at a dose of 1000 µg/day, but no significant effect on the rate of decline in FEV $_1$. However, there was a significant benefit in health status, and a reduction in exacerbation rates by 25 per cent. Since exacerbations of COPD have an adverse effect on health status, these two effects may be linked.

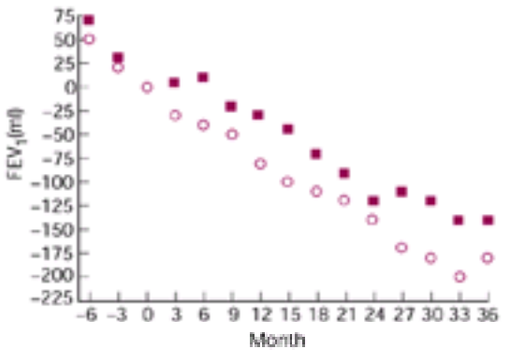

Fig. 13 Effects of budesonide at 800 µg twice daily (closed squares) or placebo (open circles) on the rate of decline in FEV $_1$ in patients with COPD and mild airways obstruction. There is a small decrease in the rate of decline in FEV $_1$ over the first 3 months of treatment in the budesonide but not in the placebo group, but no subsequent difference in the rate of decline in either group.

Based on the results of these large-scale trials there appears to be no effect of inhaled corticosteroids on the prognosis of mild to moderate COPD as assessed by the decline in FEV_1. However, there may be an effect on health status and exacerbation rates in moderate COPD. Inhaled corticosteroids may therefore be of benefit to patients with moderate to severe COPD who have frequent exacerbations, as well as those who show reversibility of their airway obstruction. Further studies are required to distinguish the subpopulation of patients with COPD who show a response to inhaled corticosteriods.

Other therapeutic agents

There is no evidence for the use of anti-inflammatory drugs such as sodium cromoglycate, nedocromil sodium, or antihistamines in patients with COPD. Although used widely in continental Europe, mucolytic drugs are rarely used in the United Kingdom. There is no evidence to support the use of continuous or intermittent prophylactic antibiotics in patients with COPD.

British Thoracic Society guidelines suggest an approach to management of patients with COPD based on the severity of disease (Fig. 14).

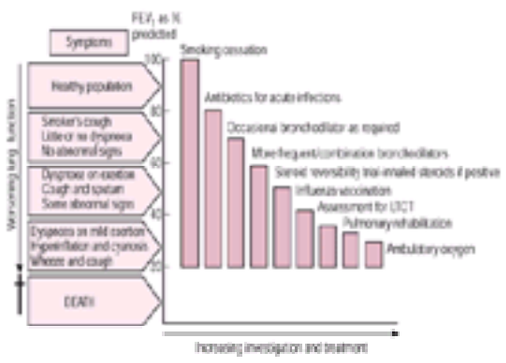

Fig. 14 The chronic obstructive pulmonary disease escalator: as lung function declines the treatments need to be increased. LTOT, long-term oxygen therapy. (Adapted from BTS Guidelines, 1997, *Thorax* **52**, S1–S18.)

Domiciliary oxygen therapy

The only treatment that improves the long-term prognosis in patients with COPD is long-term domiciliary oxygen therapy, given for at least 15 h per day, as shown by two multicentre trials, one conducted by the Medical Research Council (**MRC**) in the United Kingdom, and the other by the nocturnal oxygen therapy trial (**NOTT**). These are discussed in Chapter 17.7.

The reasons for the improvement in survival with oxygen therapy in patients with COPD are still uncertain, but are not clearly related to improvements in pulmonary haemodynamics. As usual, survival is related to the level of pulmonary arterial hypertension in patients who receive long-term oxygen therapy. In the MRC trial, there was no significant improvement in pulmonary arterial pressure following oxygen therapy, but the increase of 3 mmHg per year in pulmonary arterial pressure in the control group did not occur in those who were treated. Overnight oxygen therapy, which abolishes nocturnal desaturation, also decreases pulmonary arterial pressure. However, since the changes in pulmonary haemodynamics produced by long-term oxygen therapy are small, it seems unlikely that these have a major influence on survival.

In addition to the improvement in survival, a number of studies have examined other effects of supplementary oxygen therapy. The effects of oxygen therapy on breathlessness remain unclear, but several studies have shown that oxygen therapy can lead to an improvement in exercise endurance in patients with COPD, associated with a reduction in ventilation at a given submaximal work rate, and an improvement in walking distance and in ability to perform daily activities. Assessment of patients taking part in the NOTT study showed that they have marked disturbances in mood and quality of life: after 6 months of oxygen therapy, 42 per cent showed evidence of an improvement in cognitive function, but little change in mood or quality of life. As in all studies of patients with COPD, the FEV $_1$ is the strongest predictor of survival in patients receiving long-term oxygen therapy, but this does not influence the decline in FEV $_1$.

Long-term oxygen therapy has been shown to affect the polycythaemia that occurs in patients with chronic hypoxaemia, by reducing both the haematocrit and the red cell mass. The clinical relevance of these haematological changes produced by oxygen therapy remains unclear. Continued cigarette smoking should be a relative contraindication to long-term oxygen therapy.

Criteria for the prescription of domiciliary oxygen therapy

There are three forms of domiciliary supplemental oxygen therapy:

1. long-term controlled oxygen therapy for at least 15 h per day in patients with chronic respiratory failure;
2. portable oxygen therapy for exercise-related hypoxaemia; and
3. short-burst oxygen therapy, as a palliative treatment for the temporary relief of symptoms.

The criteria for the prescription of long-term oxygen therapy are based on the clinical parameters of those patients with COPD who showed an improved survival in the two controlled trials of long-term oxygen therapy. Central to the prescription criteria is the demonstration of significant hypoxaemia in a patient with COPD breathing room air, measured when clinically stable (Table 6).

In the United States, long-term oxygen therapy can be prescribed based on pulse oximetry and in patients whose PaO_2 lies between 7.3 and 7.9 kPa, provided there is evidence of cor pulmonale or polycythaemia.

Long-term oxygen therapy is usually prescribed in the United Kingdom in the form of oxygen concentrators, although the majority of home oxygen therapy is given to patients with COPD as cylinder oxygen therapy for the relief of breathlessness. Adherence to the criteria for the prescription of long-term oxygen therapy is less than

optimal, applying to around 40 per cent of patients. Data from the NOTT study showed that 43 per cent of patients who were initially shown to fit the criteria for long-term oxygen therapy were no longer eligible when reassessed 4 weeks later. It is therefore essential that clinical stability is demonstrated, with no exacerbation of COPD for at least 4 weeks, before a decision is made to prescribe long-term oxygen therapy, and that other treatments such as bronchodilators and inhaled steroids are optimized before the prescription of long-term oxygen therapy. Furthermore, reassessment is recommended to ensure that the patient remains significantly hypoxaemic and still fits the criteria for long-term oxygen therapy and to ensure that adequate oxygenation is achieved while breathing oxygen. A PaO_2 of 8 kPa is desirable, and this can usually be achieved by nasal prongs at flow rates between 1 and 3 litre/min. Precipitation of increasing hypercapnia with long-term oxygen therapy is seldom a problem in clinically stable patients. Long-term oxygen therapy should be prescribed continuously during sleeping hours, which prevents episodes of oxygen desaturation at night, and improves sleep quality.

Portable oxygen therapy

There are no established criteria for the prescription of portable oxygen in the form of small light-weight cylinders or liquid oxygen therapy (available in the United States and continental Europe, but not currently in the United Kingdom). Patients who desaturate during exercise by 5 per cent or more may be suitable for this treatment, although exercise capability may improve irrespective of arterial oxygen desatuation. The use of portable oxygen therapy to enhance mobility should be encouraged in patients to help to prevent the downward spiral of immobility and physical deconditioning.

Controlled oxygen is typically delivered by means of nasal prongs, or by mask in patients who are intolerant of nasal cannulas owing to local irritation and dermatitis. Patient compliance with masks is generally less than with nasal prongs. In patients in whom there is refractory hypoxaemia, oxygen can be delivered by the trans-tracheal route. This can reduce the resting flow rate requirements by 25 to 50 per cent compared with nasal cannulas, resulting in considerable savings, particularly if liquid oxygen is the supply mode. However, there are complications, including the formation of mucus balls in 25 per cent of cases, cough, infection, and catheter dislodgement. Reservoir devices have also been developed to reduce total oxygen requirement and cost: these work on the basis that the reservoir fills during the patient's exhalation and supplies oxygen only during inspiration.

Travel

Commercial aircraft cabins are pressurized to the equivalent of an altitude of no greater than 2600 m, producing a cabin oxygen tension of around 100 mmHg. Worsening hypoxaemia may exacerbate the symptoms of breathlessness, particularly in patients who are already hypoxaemic with a PaO_2 less than 8 kPa, in which case the airline should be contacted by letter by the patient's respiratory physician, recommending the use of oxygen: most will provide oxygen throughout the flight.

Pulmonary rehabilitation

The aim of pulmonary rehabilitation is to prevent or reverse the deconditioning that occurs with lack of exercise and immobility due to dyspnoea, thereby allowing the patient to cope with his/her disease. Before considering rehabilitation, it is vital that investigations and therapy are directed towards any reversible component of the airflow limitation and that this treatment is optimized. Patients with moderate to severe COPD should be considered for pulmonary rehabilitation programmes and each rehabilitation programme should be tailored to fit individual patient's needs, depending on the factors that are deemed to limit exercise.

Pulmonary rehabilitation programmes

Establishing a pulmonary rehabilitation programme requires a multidisciplinary approach and appropriate health-care resources. Exercise training programmes have taken two approaches. The first is to attempt to improve cardiorespiratory fitness by aerobic exercises of 20 to 30 min duration at least three times per week. However, patients with COPD may be unable to achieve the necessary increase in oxygen uptake to produce the required 'training effect' because of breathlessness, hence this approach is usually restricted to those with mild to moderate exercise limitation. The second approach, used in patients unable to sustain sufficient exercise to improve anaerobic fitness, aims to improve mobility. This can be achieved by providing regular exercise sessions so that the patient works to his/her maximum tolerable ventilatory limit. In patients with very severe COPD there are no established guidelines for pulmonary rehabilitation programmes, but carefully supervised exercise conditioning in the hospital setting, with oxygen supplementation, should be considered in those who develop hypoxaemia during exercise.

Respiratory muscle training

A meta-analysis of 17 randomized trials of respiratory muscle training in patients with COPD showed that although training, using either resistance breathing or isocapnic hyperventilation, improved respiratory muscle strength and endurance, there was no overall improvement in exercise tolerance.

Numerous *in vitro* studies have shown that methylxanthines, such as theophyllines (in doses not possible in humans), potentiate the response of fresh and fatigued muscle strips to an electrical stimulus. Studies *in vivo* in humans have been less convincing, reporting either little or no improvement in the transdiaphragmatic pressure (*P*di) generated during maximal voluntary effort.

Some uncontrolled studies have suggested that resting the respiratory muscles, by long-term nocturnal use of either negative pressure, applied to the chest wall, or intermittent positive pressure ventilation (IPPV) using a nasal mask, results in some improvement in respiratory muscle function. However, a large controlled study failed to show any benefit on respiratory muscle function in patients with COPD.

The results of controlled trials on the effects of nutritional supplementation on respiratory muscle function in malnourished patients with COPD have shown no consistent benefit. Those studies that have achieved positive results have done so in association with an increase in weight.

Controlled breathing techniques have been used as part of a pulmonary rehabilitation programme to diminish breathlessness by training patients to breathe efficiently. This treatment aims to:

1. restore the diaphragm to a more normal position and function;
2. decrease the respiratory rate by using a breathing pattern that diminishes air trapping;
3. diminish the work of breathing; and
4. reduce dyspnoea and patient anxiety.

Techniques such as pursed lip breathing have been employed and some studies have shown an improvement in blood gases.

The outcome of a pulmonary rehabilitation programme is usually assessed by measuring improvement in lung function or exercise tolerance, but benefit may not always be apparent in these variables. In general, studies show a favourable effect on exercise tolerance and a reduction in symptoms such as breathlessness during exercise. Since social factors contribute to the disability in COPD, assessment of quality of life should be included in a rehabilitation programme (measured by a health profile questionnaire), as should that of compliance, longevity, and cost–benefit.

Other aspects

Nutrition

Weight loss is common in patients with COPD, particularly those with severe airways obstruction, and is associated with high mortality. However, studies that have addressed this issue have produced variable results, although those who do show weight gain may have improved survival. Obesity should be discouraged by appropriate dietary advice in patients with COPD to avoid additional strain on the cardiorespiratory system.

Depression

Mood disturbances, particularly depression, are very common in patients with advanced disease and often contribute to an enhanced perception of symptoms, particularly breathlessness, and to social isolation. Antidepressant drugs can often produce encouraging results in these patients.

Vaccination

Influenza vaccination is recommended for patients with COPD, although specific evidence is lacking. The rationale relates to other studies in elderly patients, not specifically with COPD, where a 70 per cent reduction in mortality from influenza can be demonstrated.

Management of acute exacerbations of COPD

Exacerbations of COPD occur on a background of established disease and are amongst the commonest acute respiratory problems presenting to either primary or secondary care. Many patients can be managed in the community.

Antibiotics

Infection is a common precipitating feature in exacerbations of COPD, although only 50 per cent of patients with severe exacerbations with associated respiratory failure will have a positive sputum culture for a bacterium. The commonest organisms are *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarralis*. However, patients with COPD are often chronically colonized with common bacterial pathogens, hence culture of one of these organisms during an acute exacerbation does not imply that this organism is responsible for the exacerbation. Viral infections have been shown to be responsible for up to 30 per cent of all exacerbations of COPD.

There is limited information from controlled trials on the effects of antibiotics in exacerbations of COPD. In a trial of 173 patients with 362 exacerbations of COPD, patients received either a 10-day course of sulphamethoxazole, amoxycillin, doxycycline, or placebo: relief of symptoms within 21 days was achieved in 68 per cent of the antibiotic-treated group and in 55 per cent of the placebo-treated exacerbations. Peak expiratory flow recovered faster with antibiotics, although the differences were small, and treatment failures were twice as common with placebo. The difference in successful outcome between antibiotic and placebo were significant if two of the following symptoms were present—increase in dyspnoea, increase in sputum volume, and increase in sputum purulence: antibiotics are recommended if two of these symptoms are present.

In view of the limited range of bacteria present in the sputum of these patients, broad-spectrum antibiotics such as amoxycillin at a dose of 250 mg three times daily or clarithromycin at 250 to 500 mg twice daily—as an alternative in patients with penicillin allergy—are recommended. Prescription of antibiotics should take into account local bacteriological sensitivity patterns, particularly the prevalence of b-lactamase-positive *H. influenzae*, which is around 20 per cent in most areas, and *Moraxella catarralis*, of which 90 per cent are b-lactamase positive. If the patient is known to have had b-lactamase -positive organisms previously in sputum, or fails to respond to amoxycillin, then co-amoxiclav should be considered. Antibiotics should be given orally unless there is a specific indication for intravenous treatment.

Bronchodilators

The use of nebulized bronchodilators in acute exacerbations of COPD is recommended. These should be given as soon as possible on admission and at 4- to 6-hourly intervals thereafter, or more frequently if required. In patients with COPD, particularly in those with an elevated $PaCO_2$, the nebulizer should be driven by compressed air and not by oxygen, to avoid a further rise in $PaCO_2$. Oxygen can be given by nasal prongs at 1 to 2 litre/min during nebulization. b-Agonists (salbutamol at 2.5 to 5 mg, or terbutaline at 5 to 10 mg) or an anticholinergic drug (ipratropium bromide at 0.5 mg) are the drugs commonly used. In acute exacerbations of COPD, no difference has been shown between these drugs given alone or in combination in nebulized form.

A response to a nebulized bronchodilator in an acute exacerbation does not imply long-term benefit and assessment for a home nebulizer should be made when the patient is in a stable condition. Several studies have shown no difference in the degree of bronchodilatation achieved when the same dose of bronchodilator is given by a metered dose inhaler, with or without a spacer device, or via a nebulizer, even in patients with an acute exacerbation of airways obstruction. However, patients with respiratory failure have been excluded from these studies and hence nebulized bronchodilators are still recommended, but in most cases these should only be necessary for 24 to 48 h and a change to a metered dose inhaler, or a dry powder device should be made 24 to 48 h before discharge.

If a patient is not responding to nebulized bronchodilators during an exacerbation, then intravenous methylxanthines should be considered. However, a small randomized placebo-controlled trial of intravenous aminophylline showed no differences in spirometry, arterial blood gases, or the sensation of dyspnoea between the aminophylline and placebo groups over a period of 72 h following admission with exacerbation of COPD. Thus, the prescription of theophyllines has no clear role in management of acute exacerbations of COPD and the possible benefits should be weighed against the side-effects, particularly in patients with COPD who have hypoxaemia, infection, and are receiving antibiotics, all of which can affect theophylline clearance. Thus the dose must be carefully individualized and the serum level maintained within a narrow therapeutic range (10 to 20 mg/l). The usual loading dose is 6 mg/kg of aminophylline with maintenance dosage of 0.5 mg/kg.h.

Corticosteroids

There are now several controlled trials showing benefit of oral corticosteroids in patients with acute exacerbations of COPD. A placebo-controlled study in hospital patients without hypercapnic respiratory failure showed improvement in FEV_1 and reduction in days in hospital in those treated with 30 mg prednisolone daily. A further study of exacerbations treated with prednisolone in the community also showed a positive result.

There is therefore good evidence that corticosteroids are beneficial in exacerbations of COPD, the usual regime being 30 mg prednisolone daily for 2 weeks. The lowest dose that produces benefit requires further study.

Diuretics

In patients with fluid retention as a result of respiratory failure and cor pulmonale, diuretics should be used judicially, as they have the potential to reduce right ventricular end-diastolic volume considerably and hence cardiac output.

Anticoagulants

Pulmonary emboli are probably are under-recognized in severe COPD. It is difficult to diagnose pulmonary emboli in such patients: ventilation/perfusion abnormalities are often present and can lead to false-positive reports of pulmonary thromboembolic disease. Prophylactic subcutaneous heparin is often given to patients with exacerbations of COPD, particularly those who have respiratory failure.

Physiotherapy

There is very little evidence to support the use of physiotherapy to improve expectoration in patients with acute exacerbations of COPD, although some studies suggest that there is some benefit in patients producing large amounts of sputum.

Assessment of recovery from acute exacerbations of COPD

Arterial blood gases should be checked while breathing air, which gives a guide to the need for later formal reassessment for long-term oxygen therapy. Antibiotics need not usually be given for more than 7 days. Respiratory failure in COPD is dealt with in Chapter 17.7.

Surgical treatment in COPD

Bullous emphysema

Exertional dyspnoea is the usual presenting feature in patients with bullous disease, although a single bulla of moderate size is unlikely to produce symptoms when the remaining lung is normal. Bullae may present as a chance finding on a chest radiograph or as a pneumothorax. Occasionally they become infected, in which case

there may be a fluid level, sometimes with surrounding consolidation. Such infection may result in closure of the bronchial connection, shrinkage, or even obliteration of the bulla.

Respiratory function tests may be non-specific and simply reflect COPD. Almost always there is some degree of airway obstruction, which may result from concomitant diffuse emphysema or airways disease, or as a result of the loss of lung elastic recoil that accompanies large bullae. Overinflation is typically present, but is underestimated if measured by the helium dilution technique rather than by plethysmography. Gas exchange is usually impaired as shown by a reduced TL_{CO}. The K_{CO} may reflect the quality of the non-bullous lung if the bullae are non-ventilating, which may be helpful in making a decision concerning surgery.

Treatment

The only treatment that is considered for large bullae is surgical obliteration. This should not be offered to patients who are asymptomatic, since the operation does have an appreciable risk. The principal indication is progressive dyspnoea, but in those with airflow limitation it has been difficult to determine which patients benefit from bullectomy. Many techniques have been used in the past to assess patient's suitability for this procedure, such as bronchography and pulmonary angiography, which have now been essentially replaced by CT scanning. A critical feature is the quality of the non-bullous lung: airflow limitation is determined by the degree of emphysema in the non-bullous lung rather than the extent of the bullous disease. Quantitative perfusion scanning may demonstrate retained perfusion in collapsed peribullous lung, which may improve after operation. Patients with bullae occupying less than 50 per cent of the hemithorax, with an FEV_1 of less than 1 litre, or hypercapnia carry a high risk of a poor response to surgery.

The aims of surgery are to obliterate the bullous space and restore the elastic integrity of the lung. Several techniques have been described, including excision, plication, marsupialization, and intracavity drainage. Most operations are performed by a conventional lateral thoracotomy, but superficial bullae have also recently been dealt with using thoracoscopic and laser techniques. The perioperative mortality in published series ranges from 0 to 20 per cent in patients with a wide range of disability and hence operative risk.

The best functional results occur in younger patients with mild symptoms, with large bullae, relatively well-preserved pulmonary function, and normal surrounding lung. Those with small bullae (less than 1 litre or less than 50 per cent of the hemithorax), poor overall lung function (FEV_1 less than 1 litre), and diffuse emphysema have least functional improvement and in these the improvement has to be weighed against the risk of surgery. Studies of the long-term follow-up of patients after surgery indicate that giant bullae do not recur.

Lung transplantation

It was originally considered that patients with endstage COPD were not suitable for a single lung transplant since perfusion would be preferentially directed towards the transplanted lung because of its lower pulmonary vascular resistance, producing profound ventilation/perfusion mismatch. The current success of a single lung transplant, despite the presence of abnormal mechanics in the native lung, is due in part to improved patient selection, lung preservation, and anaesthetic management. There are problems if residual infection is present in the native lung, and large bullae in the native lung may show gross hyperinflation in the early postoperative period, causing mediastinal shift and compression of the transplanted lung. Hence those patients with recurrent pulmonary infection or bilateral large bullae are considered for heart–lung transplantation or bilateral sequential lung transplantation. For detailed discussion of lung transplantation, see Chapter 17.16.

Lung volume reduction surgery

The growing number of patients with emphysema on waiting lists for lung transplantation has led to a recent re-examination of previous surgical techniques that might give symptomatic relief, particularly the technique of lung volume reduction surgery (pneumonectomy or pneumoplasty). The rationale for this technique is to reduce the volume of overinflated emphysematous lung by 20 to 30 per cent, with the aim of improving the elastic recoil of the lungs, diaphragm configuration, chest wall mechanics, and gas exchange. Persistent postoperative air leaks were overcome by the use of strips of bovine pericardium to buttress the stapling line. The technique is usually performed via a median sternotomy, without the need for cardiopulmonary bypass. Thoracoscopic laser pneumoplasty has been developed as an alternative technique to the more conventional excisional surgery. Careful patient selection is necessary on the basis of a distended thorax, predominantly upper lobe disease demonstrated by CT scanning, and severe functional disability in spite of a programme of pulmonary rehabilitation.

The early results are encouraging: improvements in lung function that have occurred up to 6 months after surgery are impressive and better than can be produced by conventional medical treatment with bronchodilators or corticosteriods. Controlled trials of this technique are underway but have not yet been published.

A recent study compared lung volume reduction surgery with single lung transplant for emphysema: disease severity was greater in the lung transplant group, and their increase in FEV_1 and FVC was greater, but the increase in 6-min walking distant was similar in both groups.

Many questions concerning this technique require answers from future studies, particularly knowledge of the duration of the benefit, the best selection criteria for patients, and the mechanism of the improvement.

17.7 Chronic respiratory failure

P. M. A. Calverley

Introduction

Although respiration is ultimately a biochemical process involving the generation of ATP, the term respiratory failure is used more loosely to describe the failure of gas exchange within the lung to maintain arterial blood gas homeostasis. Defining normal blood gas tensions is harder than it may appear initially as P_aO_2 falls with age and the extent of this is debated. The most commonly applied formula to describe this is:

$$P_aO_2 \text{ (kPa)} = 13.86 - [0.036 \times \text{age (years)}]$$

Thus a P_aO_2 of 10.6 kPa may be abnormal in a man of 24 years but a 'normal' value in a woman of 80. Subnormal levels of arterial oxygenation are described as hypoxaemia, whilst arterial CO_2 tensions, which do not show similar age dependence, are considered to be hypercapnic when they exceed 6.0 kPa (45 mmHg).

Respiratory failure is defined primarily in terms of hypoxaemia and is arbitrarily considered to be present when the arterial P_O_2 (at sea level) is less than 8.0 kPa (60 mmHg). It need not be accompanied by hypercapnia, but when this develops it leads to acidosis due to the accumulation of carbonic acid by the Henderson–Hasselbalch equilibrium. If the acidosis is not rapidly progressive, and in the presence of intact renal compensatory mechanisms that generate bicarbonate ions, it becomes 'chronic'—a compensated state where the arterial pH returns to normal.

In summary, chronic respiratory failure describes a clinical state when the arterial P_O_2 breathing air is less than 8.0 kPa, which may or may not be associated with hypercapnia, but is accompanied by a normal arterial pH and has been present for several days or more. This definition emphasizes the physiological determinants of gas exchange that characterize the problem.

Unlike other forms of organ system failure, such as cardiac or hepatic failure, the clinical symptoms and signs of chronic respiratory failure are relatively undramatic, but its development is equally significant, both as a marker of disease progression and in producing serious complications beyond those normally seen with the underlying disease. This chapter will review the causes, clinical features, and assessment of chronic respiratory failure as well as specific means of treatment. However, to do so logically requires some understanding of the principles underlying the development of this condition, as well as the factors relevant to the selection of the threshold values used in defining this state.

Physiological determinants of blood gas tensions

In health there is a predictable fall in the partial pressure of oxygen from that in the room air to that in mixed venous blood. This reflects the effect of diluting room air with resident gas in the alveoli, the efficiency of pulmonary oxygen exchange, and the consumption of oxygen by metabolizing tissues. Conversely, there is a predictable increase in the amount of CO_2 added to the circulation and subsequently removed from the lungs during expiration. This simple system is reliant on a range of physical processes that differ somewhat for O_2 and CO_2. Within the lungs gas transport is largely by convective bulk transport and in the alveoli by diffusion. In the blood oxygen combines with haemoglobin, which augments transportation to the tissues where diffusion is the final process involved. By contrast, CO_2 transport begins with diffusion from relatively high tissue concentrations and is buffered in solution in the blood. This complex mechanism can be deranged in a number of predictable ways that are discussed below.

In the last 20 years the analysis of pulmonary gas exchange has been revolutionized by the use of the complex multiple inert gas elimination technique in research laboratories around the world. This gives a relatively complete description of the distribution of gas exchange abnormalities within the lungs. However, for an understanding of the general principles involved in disease states the traditional three-compartment model is easier to follow. This assumes that alveolar air within the lungs is either ideally matched to pulmonary arterial blood flow within the pulmonary capillary bed or is totally mismatched, meaning that either the ventilation–perfusion ratio is unity, that is, ventilation without perfusion (physiological dead space, V_D), or this ratio is zero, that is, perfusion without ventilation (venous admixture effect). The physiological dead space includes a component due to dilution of the resident gas in the airways, the anatomical dead space, while the shunt fraction incorporates the very small amount of cardiac output (less than 1 per cent) not passing through the pulmonary capillary bed.

Hypoxaemia

The principal mechanisms leading to arterial hypoxaemia are shown in Table 1. Individuals resident at altitude, for example the high Andes and Himalayas, experience significantly lower inspired oxygen tensions than those at sea level and even individuals with normal lungs can develop clinically significant hypoxaemia, especially during sleep. Even minor degrees of respiratory impairment in these circumstances can produce dramatic changes in blood gas tensions and the early onset of cor pulmonale. Conversely, people with established hypoxaemia at sea level can occasionally experience worsening symptoms when travelling by air where cabin pressurization is 75 per cent of atmospheric. However, in clinical practice, this is relatively infrequent.

Four processes cause arterial hypoxaemia due to inefficient pulmonary gas exchange:

- ventilation–perfusion (V/Q) mismatch
- hypoventilation
- diffusion limitation
- true shunt.

Much the most important of these is ventilation–perfusion mismatching. In many diseases where minute ventilation is increased, the additional inspired gas is distributed to well-perfused areas of the lungs, but when the opposite occurs and perfusion exceeds effective ventilation (low V/Q states), arterial P_aO_2 falls. At first this might seem surprising as most diseases associated with ventilation–perfusion imbalance are of patchy distribution and compensation from areas of high V/Q ratios might be expected. However, this does not occur owing to an important feature of the oxyhaemoglobin dissociation curve (Fig. 1), whose sigmoid shape means

that well-perfused parts of the lung cannot increase the arterial oxygen saturation of the blood leaving them beyond 100 per cent, hence the saturation of the pulmonary venous blood must fall as long as low *V*/*Q* areas are present.

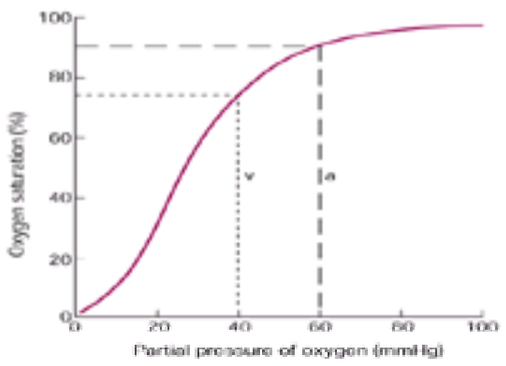

Fig. 1 The haemoglobin–oxygen dissociation curve. a, partial pressure of oxygen of 8 kPa (60 mmHg), which is the definition of arterial hypoxia. v, partial pressure of oxygen of 5.3 kPa (40 mmHg), which is typical of mixed venous blood. Note that once the PaO_2 falls below 8 kPa small further falls dramatically decrease the arterial oxygen saturation.

The second important mechanism contributing to arterial hypoxaemia is alveolar hypoventilation, where the supply of fresh oxygen is globally reduced because of generally inadequate minute ventilation. This process often coexists with ventilation–perfusion mismatching and tends to exacerbate it. In some situations, such as during exercise, total minute ventilation may lie within the normal range but can still be inappropriately low for the subject's metabolic requirements, thereby leading to hypoxaemia.

Two less important mechanisms are anatomical shunting and diffusion limitation. The former occurs predominantly with intrapulmonary arteriovenous malformations. Congenital cardiac anomalies such as ventricular septal defects with reversed flow are often lumped in with this problem, although technically they are extrapulmonary in origin. The failure to increase PaO_2 to greater than 40 kPa (300 mmHg), even when exposed to 100 per cent oxygen, is diagnostic. Diffusion limitation was initially believed to be important in many diseases, the assumption being that passive diffusion of oxygen was reduced to the point where equilibration with haemoglobin during red cell transit of the pulmonary capillaries was incomplete. Detailed studies with modern techniques of gas exchange analysis have largely discredited this, except for small falls in arterial oxygen tension at maximum levels of performance in elderly athletes and possibly during exercise in some forms of interstitial lung disease.

Although not the sole explanation of arterial hypoxaemia, the degree of hypoxaemia can be worsened when the mixed venous arterial oxygen tension is significantly reduced as occurs in low cardiac output states or conditions where peripheral oxygen consumption is increased.

Hypercapnia

Analysis of the pulmonary causes for changes in arterial CO_2 tension is much simpler, the relevant relationship being:

$$PaCO_2 = K \times VCO_2/V_A$$

where VCO_2 is the CO_2 production by the body, V_A is the alveolar ventilation, and K is a constant.

It is easy to see that inadequate alveolar ventilation, due to either low total alveolar ventilation or an inability to increase V_A in response to an increase in metabolic CO_2 production, will increase the arterial CO_2. Alveolar ventilation is influenced by a range of factors, reflecting the balance of the intrinsic capacity of the ventilatory pump and the demands placed on it (Fig. 2).

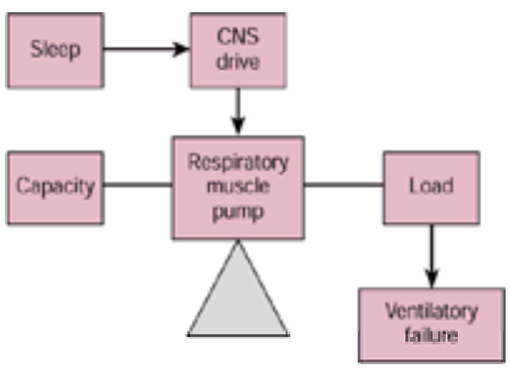

Fig. 2 Alveolar ventilation reflects the balance of the intrinsic capacity of the ventilatory pump and the demands placed on it. A reduced respiratory drive, particularly during sleep, reduces alveolar ventilation but does not produce significant hypercapnia.

The second important mechanism is ventilation–perfusion abnormality, although here the important component is the increased physiological dead space. This can be seen by a rearrangement of the equation above as shown below:

$$PaCO_2 = K \times VCO_2/ V(1–V_D/V_T)$$

where V_D/V_T is the ratio of the physiological dead space to the tidal volume and V is the total minute ventilation.

An increase in V_D occurring when ventilation–perfusion ratios are high can lead to an increase in CO_2 tension. Rather surprisingly, low ventilation–perfusion units are much less important in producing CO_2 retention than they are in producing hypoxia since CO_2 transport from the blood to the alveolar gas is linear (Fig. 3). This means that in areas of normal ventilation–perfusion ratios an increase in overall minute ventilation will increase CO_2 elimination and compensate for the CO_2 that is not excreted from areas of reduced perfusion.

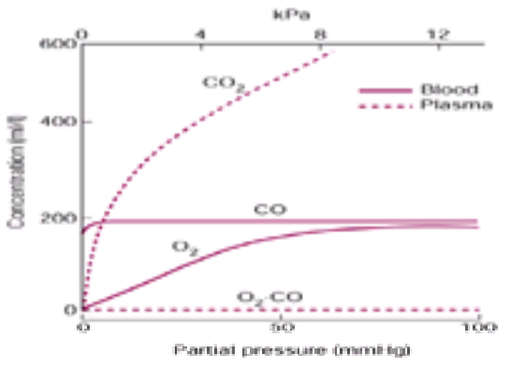

Fig. 3 Concentration of oxygen (O_2), carbon monoxide (CO), and carbon dioxide (CO_2) in blood and plasma at differing partial pressures of these gases.

In most cases of chronic respiratory failure with CO_2 retention, both of these processes operate and the patient is unable to sustain the high overall levels of ventilation needed to maintain CO_2 tensions within the normal range. An important compensatory mechanism in the trade-off between the increased chemical drive to breathing and the mechanical limitations on ventilation is the breathing pattern. In both chronic obstructive and restrictive lung disease a rapid shallow breathing pattern is adopted to minimize respiratory discomfort whilst maintaining minute ventilation. However, the relative fall in tidal volume further worsens the V_D/V_T ratio and can itself contribute to CO_2 retention. Some of these problems are resolved when the buffering capacity of the blood rises as compensation for respiratory acidosis occurs.

Special circumstances

As already noted, residence at altitude and exercise pose particular problems for gas exchange and may induce temporary respiratory failure. There is now a wealth of data indicating that similar changes can occur during sleep. All healthy people show an approximately 15 per cent reduction in minute ventilation in the transition from wakefulness to stable non-REM (rapid eye movement) sleep, and this may be greater still in phasic REM sleep. The ventilatory responses to both hypoxia and hypercapnia decline as sleep deepens and upper airway resistance rises, especially in those who snore. Despite this the blood gas tensions vary little in health during sleep, but dramatic abnormalities can develop during periods of repetitive upper airway obstruction (see Chapter 17.8.2) or when coexisting neuromuscular weakness leads to excessive dependence on muscle groups whose activity declines with sleep (see below).

Gas transport to the tissues

Oxygen delivered to the tissues depends on the oxygen saturation of arterial blood (SaO_2), the haemoglobin concentration (**Hb**), and the cardiac output (**C.O.**), related as follows:

$$\text{Oxygen delivery } (DO_2) = \text{C.O.} \times (\text{Hb} \times 1.34) \times (SaO_2/100)$$

This is influenced only indirectly by the effectiveness of gas exchange. Since oxygen delivery is the clinically relevant outcome of oxygenation, decisions about when and how much to intervene therapeutically will be influenced by this variable. Small changes in saturation become clinically more important in individuals with impaired cardiac function and/or reduced haemoglobin concentration, and a higher SaO_2 should be maintained. In general, there is little to be gained by increasing SaO_2 to the high 90s, especially as this may cause secondary carbon dioxide retention in some diseases. As is clear from Fig. 1, desaturations below 90 per cent only occur when the arterial oxygen tension is below 8.0 kPa (60 mmHg) and this is also influenced by a number of other factors that determine the position of the dissociation curve (see Table 2). This provides the rationale for the choice of 8.0 kPa as the cut-off point for the onset of respiratory failure.

Causes of chronic respiratory failure

The principal causes of chronic respiratory failure are summarized in Table 3. This list is extensive, but the commonest causes are discussed below.

Chronic airflow limitation

This term covers the most important cause of chronic respiratory failure, chronic obstructive pulmonary disease (**COPD**), but is also relevant to diseases such as chronic bronchial asthma, which is now excluded from the definition of COPD, and bronchiectasis, where airflow obstruction is a frequent finding as the disease advances. In all these cases there is a reduction in the forced expiratory volume in 1 s (**FEV_1**) to forced vital capacity (**FVC**) ratio below 70 per cent and a reduction in the FEV_1, which is commonly below 35 per cent predicted before chronic respiratory failure is noted clinically.

In all these cases, hypoxaemia is the first abnormality, which is largely due to ventilation– perfusion mismatching. Early attempts at relating these changes to structural patterns of airway and alveolar disease in COPD have proved unsuccessful. As lung mechanics worsen (commonly when FEV_1 falls below 1.5 litres or 35 per cent of the predicted value), arterial CO_2 increases. This has been related to the development of inspiratory threshold loading (PEEPi) with the onset of chronic hyperinflation, but the degree of CO_2 retention varies between subjects suggesting that individual variations in chemoresponsiveness/perception of ventilatory load contribute to this process. There is no predictable relationship between the severity of impaired lung mechanics below the thresholds indicated and the degree of hypoxaemia or hypercapnia, and many patients who maintain arterial CO_2 tensions within the normal range develop acute CO_2 retention during exacerbations of their disease. These changes can be relatively short lived and the hypercapnia resolves by the time of discharge. Coexisting left ventricular impairment reduces cardiac output and increases venous admixture, which can cause severe hypercapnia and acidosis, which none the less respond rapidly to appropriate treatment.

Patients with COPD in association with persistent hypercapnic respiratory failure have a worse prognosis than those with intermittent hypercapnia during exacerbations (Fig. 4). The pattern in chronic asthma and bronchiectasis appears similar to COPD indicating that lung mechanics rather than individual pathology dictates the severity of the gas exchange disorder.

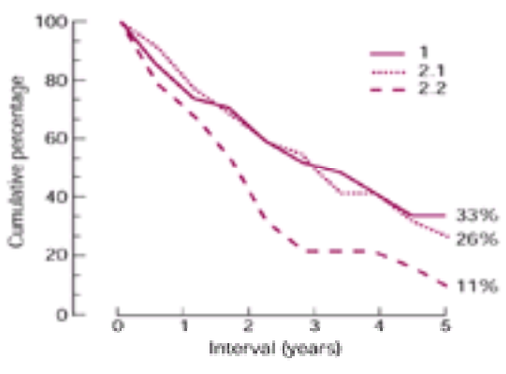

Fig. 4 Survival after index admission in three groups of COPD patients with similar initial spirometry. Group 1 never exhibited CO_2 retention, group 2.1 retained CO_2during the admission but this resolved, while group 2.2 had persistent arterial hypercapnia. (Based on data from Costello *et al*. 1997.)

Interstitial lung disease

Despite the wide range of primary pathologies covered by the term interstitial lung disease they present with a relatively stereotyped physiological picture. A restrictive physiological disorder (FEV_1/FVC greater than 75 per cent with a reduced absolute FEV_1 and FVC) is usual, although patients with sarcoidosis commonly show airways involvement and can present with severe airflow limitation or a mixed physiological pattern. Near normal spirometry can be seen with significant exercise limitation and exercise-induced oxygen desaturation in some patients where COPD and interstitial lung disease coexist. Typically, resting gas exchange is relatively preserved in interstitial lung disease until late in the course of disease, whereas exercise-induced desaturation is an early finding, often seen when spirometric changes are unimpressive. Studies using the multiple inert gas technique have described a bimodal pattern of ventilation–perfusion distribution, with some areas of lung having normal *V*/*Q* relationships and others relatively little ventilation, that is, increased physiological shunting. This situation worsens during exercise. A small number of patients with severe interstitial lung disease develop CO_2 retention in the terminal phase of their illness and cor pulmonale. The physiological mechanisms underlying this are poorly studied but are probably similar to those in COPD.

Chest wall and neuromuscular disease

Here the underlying lung structure and potential for gas exchange are unimpaired, but the ability to maintain adequate alveolar ventilation is reduced. This can be due to increased chest wall stiffness as in kyphoscoliosis, or reduced inspiratory muscle force as in neuromuscular disease. In this latter group the reduction in maximum inspiratory pressure can be global, such as in Duchenne muscular dystrophy, or more specific, such as isolated diaphragmatic weakness, where gas exchange abnormalities may only be present during specific sleep stages. Significant abnormalities of gas exchange at rest only occur with advanced disease and not in every patient. Alveolar hypoventilation is the dominant mechanism of both hypoxaemia and hypercapnia, although secondary changes such as pulmonary microatelectasis may contribute an element of *V*/*Q* mismatching. Assessing exercise hypoxaemia is difficult in these patients due to their generalized muscle weakness. However, sleep-related oxygen desaturation, particularly during REM sleep when the inspiratory system is most dependent on diaphragm function, is a common finding in patients with mild daytime hypoxaemia due to chest wall problems or neuromuscular diseases. Occasionally these changes are dramatic, but in boys with muscular dystrophy the presence of transient hypoxaemic episodes was no better guide to prognosis than was measurement of the vital capacity (Fig. 5). Arterial CO_2 tensions often lie in the high normal range, daytime hypercapnia only being seen in advanced disease.

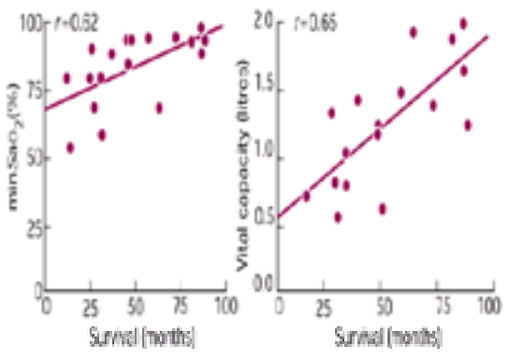

Fig. 5 Survival of boys with respiratory failure due to neuromuscular disease plotted against minimum arterial oxygen saturation recorded during sleep and vital capacity. (Based on data from Phillips *et al*.1999.)

Non-pulmonary disorders

Patients with stable congestive cardiac failure often show mild reductions in PaO_2 and a normal or low $PaCO_2$ due to premature airway closure secondary to pulmonary oedema. Some patients with severe liver cirrhosis develop the so-called hepatorenal syndrome, with otherwise unexplained hypoxaemia due to *V*/*Q* mismatching and true anatomical shunting through arteriovenous communications in the pulmonary circulation. Morbidly obese individuals can develop hypoxaemia and hypercapnia due to profound nocturnal hypoventilation and chemoreceptor resetting. Rather more common are the problems of patients with severe obstructive sleep apnoea who develop daytime hypoxaemia and hypercapnia secondary to recurrent nocturnal upper airway obstruction and oxygen desaturation. Careful review of these 'Pickwickian' patients often shows coexisting hypothyroidism or obstructive lung disease. This diagnosis should be suspected in any patient with COPD with significant respiratory failure and an FEV_1 greater than 1.5 litres. Correction of the sleep apnoea by nasal continuous positive airway pressure can produce significant improvement in daytime blood gases, but in the great majority of patients with obstructive sleep apnoea no significant abnormalities of waking gas exchange are seen.

Pulmonary vascular disease

This is an uncommon cause of hypoxaemia and at the time of diagnosis CO_2 retention is rare. Rather variable changes in D_LCO are reported, but as pulmonary hypertension becomes more advanced, exercise and resting hypoxaemia develops, a significant component being secondary to the reduced cardiac output and increase in mixed venous oxygen tension.

Assessment of chronic respiratory failure

This is relatively straightforward. The diagnosis of mild/moderate hypoxaemia rests on an awareness of the possibility rather than any specific clinical finding. When the arterial PO_2 is below 8.0 kPa, impairment of concentration and memory can be demonstrated, but these features are extremely non-specific. Although tempting to ascribe to hypoxaemia, the principal cause of breathlessness in these patients is usually the underlying disease. Reduction of peripheral chemoreceptor activity by supplementary oxygen can be beneficial, but this is usually secondary to a fall in minute ventilation rather that to any specific 'dyspnogenic' effect of hypoxia itself.

Hypercapnia is equally non-specific, with headache the most commonly attributed symptom. There are no good data to support this in compensated respiratory failure, although a generalized degree of vasodilation is seen in some patients with CO_2 retention, which may be accompanied by a large volume pulse and warm peripheral extremities.

On examination central cyanosis may be apparent as a bluish discoloration of the mucous membranes associated with an increase in the reduced circulating haemoglobin to approximately 5 g/dl. It is an unreliable clinical sign in some ethnic groups and in the presence of artificial illumination. An increased facial colouring due to secondary polycythaemia can occur, whilst the jugular venous pressure may be elevated and ankle swelling can develop in the face of worsening CO_2 retention.

The principal diagnostic steps are listed in Table 4. Measurement of arterial blood gases, preferably breathing air, is the most reliable way of diagnosing chronic respiratory failure. It is essential to know whether the patient was using oxygen when the sample was taken, and if so, at what inspired concentration. Patients with chronic airflow limitation treated with bronchodilators nebulized in oxygen may show unexpectedly high PaO_2 for some time after this treatment. Non-invasive measurement of arterial oxygen saturation using pulse oximetry can be used to screen individuals at risk of chronic respiratory failure and to monitor patients in hospital or overnight, but it is no substitute for assessing blood gas tensions to make the diagnosis correctly.

Treatment of chronic respiratory failure

Managing stable chronic respiratory failure involves several steps:

1. making a firm diagnosis;
2. correction of the underlying disorder;

3. increasing the inspired oxygen concentration; and
4. increasing alveolar ventilation.

Making a firm diagnosis

This is essential for rational management. It is important to remember that more than one process may contribute to the development of chronic respiratory failure; for example, poor left ventricular function due to cardiac disease and chronic obstructive pulmonary disease together. The relative importance of each factor should be determined.

Correction of the underlying disorder

In general, treatment of the primary pathology improves both *V*/*Q* relationships and hence oxygenation, and respiratory system mechanics, which increases ventilatory capacity and lowers the $PaCO_2$. In patients with COPD this usually involves administration of inhaled bronchodilators and corticosteroids (see Chapter 17.6), but marked improvement is the exception rather than the rule in patients where chronic respiratory failure has developed. Medical therapy tends to be ineffective by the time chronic respiratory failure has developed in interstitial lung disease and the neuromuscular disorders.

Specific pulmonary vasodilator treatment has been used to treat pulmonary hypertension, with most evidence of improvement seen after infusion of prostacyclin in primary pulmonary hypertension. Attempts to improve gas exchange in secondary pulmonary hypertension by the use of inhaled nitric oxide, a specific pulmonary arterial vasodilator, have been disappointing and in general, resting gas exchange has deteriorated after this treatment rather than improved.

Increasing the inspired oxygen concentration

Hypoxaemia secondary to *V*/*Q* mismatch or global hypoventilation is relatively easily corrected by supplementary oxygen. In chronic airflow limitation and especially COPD, where respiratory time constants for gas exchange are long, it may take 30 minutes before a new steady state is reached when breathing relatively low concentrations of oxygen. Monitoring of blood gases should be adjusted accordingly.

In the chronic stable state, treatment with oxygen is given to prevent or reverse the chronic consequences of hypoxaemia. The benefits of regular oxygen treatment on breathlessness are marginal and there are no data to suggest that the severity or subsequent progression of breathlessness is influenced by chronic oxygen treatment. Almost all data about oxygen therapy in chronic respiratory failure are based on observations in hypoxaemic COPD, treatment in other conditions being offered by analogy with this more common problem.

Two well-performed randomized clinical trials have shown that regular treatment of patients with COPD and stable hypoxaemia (PaO_2 less than 55 mmHg) prolongs life (Fig. 6(a)). These data suggest that patients using more oxygen (the 'continuous' limb of the Nocturnal Oxygen Therapy Trial Group) do better than either the United Kingdom Medical Research Council treatment group or the North American patients using oxygen only at night. A more recent Polish study found no benefit when patients with COPD with a PaO_2 of 7.3 to 8.8 kPa were treated with oxygen at home for 15 h/day (Fig. 6(b)), emphasizing that chronic oxygen therapy is only of value when the oxygen saturation falls below 90 per cent.

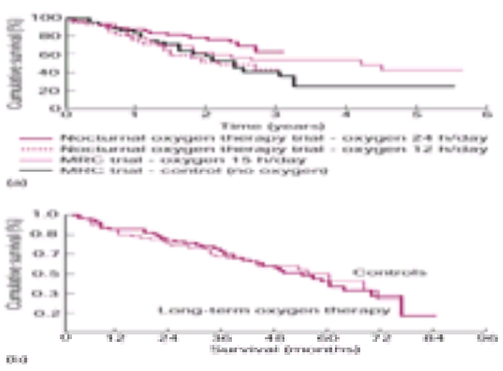

Fig. 6 The effect of regular domicilliary oxygen on survival in COPD. Panel (a) combines data from the MRC and NIH oxygen trial in the United States. Survival is greatest in those receiving oxygen for the whole 24-h day. Panel (b) is based on the study of Gorecka *et al*. for COPD patients with a PaO_2 between 7.3 and 8.5 kPa who were treated with oxygen or normal medical therapy. There was no survival benefit in the oxygen treated group, confirming the importance of the 7.3 kPa threshold in selecting patients for this therapy.

These studies showed that progression of secondary pulmonary hypertension can be halted by regular oxygen treatment and secondary polycythaemia can be corrected. However, secondary polycythaemia in COPD is influenced by the amount of carboxyhaemoglobin from cigarettes and patients who continue to smoke do not show a fall in red cell mass or packed cell volumes with oxygen treatment. Neuropsychological effects of chronic hypoxaemia have been described and may be improved by regular oxygen treatment, although the evidence for this is limited.

Giving oxygen during exercise increases performance and particularly endurance in patients with COPD who are relatively normoxaemic, as well as those with resting hypoxaemia. Again carbon monoxide from cigarette smoking reduces this response, and whether oxygen desaturation during exercise is necessary for the benefit to occur has not been conclusively established, although it is used as a reimbursement criterion for portable oxygen in North America.

Oxygen concentrators are the most cost-effective way of delivering oxygen for near continuous use. These devices have proved reliable and safe and use the ability of zeolite cells to separate nitrogen from room air and so generate an oxygen-enriched inspirate. Liquid oxygen has the advantage of allowing refilling of portable oxygen units relatively easily for use during exercise. Oxygen masks are the most accurate way of delivering oxygen and a range of inspired concentrations (24, 28, 35 per cent) are available. However, they are easily dislodged during sleep and plastic oxygen nasal prongs with a long extension pipe offer an easier system for use in the home. Occasional patients, especially those with severe interstitial lung disease, may have difficulties obtaining a PaO_2 greater than 8.0 kPa with these systems. Transtracheal oxygen delivery may have a role here, but early enthusiasm for this has been tempered by problems with cannula occlusion, infection, and bleeding. A variety of oxygen-conserving devices that deliver oxygen only during inspiration have been developed which increase the time between refills of portable oxygen equipment as well as having financial advantages in some health-care systems.

Improving alveolar ventilation

Mechanical

This is a valuable way of reducing arterial CO_2 in disorders like COPD and can increase arterial oxygen tension as well, especially in conditions such as neuromuscular disease where hypoventilation predominates. The use of tank respirators in neuromuscular weakness has now been superseded by the development of non-invasive nasal positive-pressure ventilation (**NIPPV**), which is normally only needed at night. This therapy is used increasingly in the management of acute on chronic respiratory failure in patients where the primary problem is ventilatory without coexisting pneumonia/acute lung injury. Its chronic use arose from the belief that respiratory muscle fatigue was an important cause of CO_2 retention in COPD and the empirical observation that gas exchange and survival were better in patients with kyphoscoliosis treated with night-time cuirass ventilation. Newer studies have shown that respiratory muscle function is well preserved in COPD when allowance in made for the muscle shortening secondary to pulmonary hyperinflation. Several trials of NIPPV in stable hypoxaemic but normacapnic COPD have reported relatively unimpressive results. By contrast, NIPPV mainly given at night improved blood gases in patients with hypercapnic COPD, as well as leading to benefits in health status. No good randomized trial of this therapy has yet been reported and the role of NIPPV in the treatment of hypercapnic COPD is still controversial.

By contrast, significant symptomatic and blood gas improvements have been demonstrated in patients with kyphoscoliosis, but again no randomized clinical trial data

are available. At present, it appears unlikely that these will be performed given the significant and sustained symptomatic benefits seen clinically. The only study to report prospective data on muscular dystrophy found no effect of regular NIPPV on survival in normocapnic patients, but use of this therapy as supportive treatment in the terminal phases of advanced muscular dystrophy appears to be associated with prolonged survival. It is always important in the face of progressive disease such as muscular dystrophy or motor neurone disease that the patient should be fully informed of the complications of NIPPV and the fact that it is unlikely to influence the underlying progression of the condition. Provided a good dialogue between patient, carer, and physician is established, then reasonable decisions about the use of this ethically difficult treatment are still possible.

Although volume-cycled ventilation was initially preferred, most patients are now managed with a bilevel pressure-cycled patient triggered device. This may have some advantages in obstructive lung disease where small amounts of PEEP can be added to reduce static PEEPi. Adequate peak inspiratory pressure generation, preferably in excess of 20 cmH_2O, is needed in both COPD and kyphoscoliosis, where total respiratory system compliance is reduced. Patient–mask interfaces remain a major problem, especially in patients with unusual craniofacial structure where getting a comfortable mask fit without excessive tightness can be difficult. Progress should be assessed by regular blood gas measurements, and overnight monitoring of oxygenation and CO_2 tensions is useful at the start of therapy. Patience and trained respiratory therapists are the best way of ensuring long-term compliance with treatment.

Specific pharmacological therapy

Whilst mechanical ventilatory support is effective it is also cumbersome, uncomfortable, and restricting, hence a simple drug treatment would be invaluable. Although medroxyprogestrone acetate has non-specific ventilatory stimulant effects and can produce small falls in CO_2 tension in patients with COPD, its oestrogen-like side-effects limit its use. Methylxanthines like theophylline have some chemoreceptor stimulant effects, but are mainly of use for their bronchodilator and anti-inflammatory properties. Almitrine bismethylate is an interesting specific peripheral chemoreceptor stimulant drug, which also modifies intrapulmonary *V*/*Q* matching and increases arterial oxygen while reducing CO_2 tensions in patients with resting hypoxaemia. These properties have led to its use in parts of Europe, but it is associated with the development of peripheral neuropathy and possibly increasing pulmonary artery pressure during exercise, which has limited its more widespread application.

Despite the attractions of a pharmacological approach, concerns over the precipitation of inspiratory muscle fatigue and the recognition that, in most diseases, the central drive to breath is already high, mean that treatment with respiratory stimulant therapy is likely to have only limited clinical application.

17.8.1 Upper airways obstruction

J. R. Stradling

Definition

The trachea and carina are usually included in discussions of upper airways obstruction because many of the conditions that can completely block off the main airway can affect the trachea, presenting in a similar way to those affecting the larynx and pharynx. For convenience, the causes of upper airways obstruction are divided into acute (within minutes or hours) and non-acute, although there is not quite such a clear distinction in clinical practice. Many of the causes of upper airways obstruction (particularly infection) are more common in children, but this section deals with the problem mainly from an adults' physician's perspective.

At resting levels of minute ventilation, the main airway can be reduced to a diameter of 3 mm or so before respiratory distress and stridor occur. Little more narrowing is required to precipitate complete asphyxia. Hence, when upper airways obstruction is suspected, assessment of severity, diagnosis, and treatment must be regarded as a medical emergency. The causes are listed in Table 1 and discussed in more detail below.

Diagnosis

Diagnosis of upper airways obstruction requires a high degree of clinical suspicion. Not all that wheezes is asthma. If upper airways obstruction develops gradually, then it is most likely to be misdiagnosed as asthma or chronic airways obstruction, particularly if, for example, a carcinoma of the trachea coexists with chronic airways obstruction. This is not uncommon, since both are usually caused by smoking. Clues in the history will be a more rapid onset than might be expected for chronic airways obstruction and no previous history of a similar problem. The progression is usually relentless, without fluctuations, although a course of steroids prescribed for 'asthma' may produce temporary tumour shrinkage. At first, stridor or noisy breathing will only be heard on exercise, but it will gradually appear at lower and lower levels of activity. Sometimes the patient is well aware that the blockage is 'somewhere in the neck' and such a complaint should be taken seriously, as should associated haemoptysis. A non-productive cough is often present. A change in the voice in association with shortness of breath indicates the possibility of laryngeal obstruction. Upper airways obstruction is sometimes more symptomatic on lying down.

Examination

In pure upper airways obstruction, the noisy breathing will localize to the airway and tends to be monophonic and stridulous. Stridor may be absent if there is a long segment of obstruction. The only sound at the periphery on auscultation of the chest will be the transmitted noise of the stridor. However, as mentioned above, some patients will have coincidental lower airways obstruction, which should not discourage further investigation of a suggestive history. If upper airways obstruction is extrathoracic, stridor will tend to be worse on inspiration, and the converse may be true when the lesion is intrathoracic. The reasons for this are discussed below.

Tests of lung function

During a forced expiration from total lung volume down to residual volume there is a progressive fall in expiratory flow rate. This is largely due to the fact that the airways become narrower as the lungs become smaller, and this progressively restricts maximum flow rate regardless of the effort made. This can be displayed graphically as a plot of expiratory flow against the volume exhaled from total lung capacity down to residual volume, the so called 'flow–volume' plot or loop (Fig. 1(a)). This fall-off in maximal flow rates with falling lung volume is called 'volume dependence of flow'. However, if a fixed resistance is introduced (such as tracheal stenosis), then the maximal flow rate possible is independent of the lung volume. High flow rates, usually seen at larger lung volumes, cannot be generated and, instead of the normal triangular appearance of the flow–volume plot, it has a squared appearance. At lower lung volumes the normal intrinsic airways resistance may again exceed the abnormal upper airways resistance so that the flow–volume plot may once again follow the normal path (Fig. 1(a)).

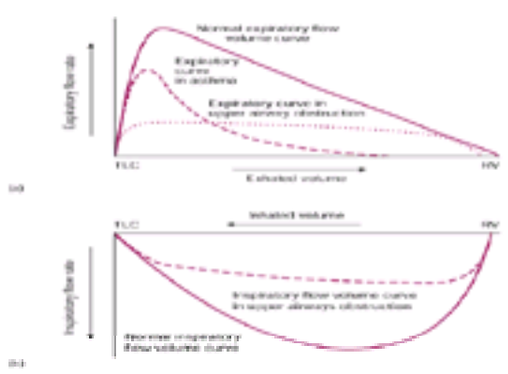

Fig. 1 (a) Expiratory flow–volume loop. The subject exhales with maximum effort from total lung capacity (TLC) until residual volume (RV) is reached. Normally, maximum flow (vertical axis) is reached early on and the flow falls almost linearly with lung volumes thereafter. In lower airways obstruction (e.g. asthma), all flows are reduced, but particularly at lower lung volumes. In upper airways obstruction, the maximum flow is clipped and roughly constant across most of the manoeuvre. (b) Inspiratory volume loop. The subject inhales maximally from residual volume (RV) up to total lung capacity (TLC). Normally, maximum flow is reached at about half-way when there is the best combination of airways size and muscle strength (see text). In upper airways obstruction, maximum flow is determined by the size of the remaining orifice and is roughly constant across the manoeuvre.

If the apparatus required to measure flow–volume plots or loops is not available, a peak expiratory flow (PEF) meter and spirometry plot may be useful. Because the fixed extra expiratory resistance clips the high flow rates predominantly, then the PEF rate will be reduced disproportionately to the forced expiratory volume in 1 s (FEV_1). This is because the FEV_1 is a measure over a longer time period, which includes lower flow rates because of the falling lung volume. This gives rise to a simple index of upper airways obstruction; FEV_1 (ml) divided by the PEF rate (l/min). Normally the value will be less than 10, but as the PEF rate is preferentially clipped (which does not happen when there is increased diffuse airways obstruction such as asthma) it may rise above 10 in upper airway obstruction. However, an index of less than 10 does not exclude upper airways obstruction because the lesion may not be rigid and, if it is intrathoracic, it may also narrow a little as lung volume falls. Another spirometric clue to upper airway obstruction is the shape of the FEV_1 curve. Normally this is curved because flow rate falls with time, but it becomes straighter if flow rate is fixed (Fig. 2(a)).

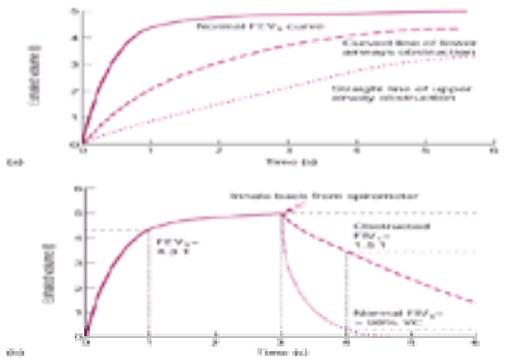

Fig. 2 (a) Curves of forced expiratory volume (FEV) against time. Normally exhalation is rapid, and more than 75 per cent of the final volume (vital capacity (VC)) is exhaled in 1 s (FEV_1). In lower airways obstruction, flows are slower and thus less air is exhaled in 1 s; the line is still curved because flows are falling. In upper airways obstruction, because flows are roughly constant at a low level set by the remaining orifice, the line is nearly straight and FEV_1 is also low. (b) Following a forced exhalation manoeuvre into a spirometer, a forced inhalation can be made. Normally inspiration is fast and the forced inspiratory volume in 1 s (FIV_1) is almost the vital capacity (VC). If there is upper airways obstruction, particularly extrathoracic such as at the vocal cords, then inspiration will be very limited and FIV_1 will be small.

If flow–volume plotting apparatus is available, inspiratory patterns can also be examined. The normal inspiratory limb of the flow–volume loop is almost semicircular (Fig. 1(b)). This is because at residual volume the airways are small and limit flow; towards total lung capacity the inspiratory muscles are reaching their full contraction and power is falling off. Hence maximum flows are achieved in the midrange of lung volume (Fig. 1(b)). Again, if upper airways obstruction is present, this pattern may be replaced by a squarer shape owing to the imposition of a lower maximum flow rate by the fixed resistance (Fig. 1(b)).

Comparison of the inspiratory and expiratory limbs of the flow–volume loop may give a clue as to the location of an upper airways obstruction. If the lesion is extrathoracic and has any variability to its lumen, it will tend to be narrowest during inspiration (walls sucked together) and widest during expiration (blown apart). Conversely, an intrathoracic lesion will tend to be squashed on expiration by the raised intrathoracic pressures, thus presenting a higher resistance than during inspiration when it will tend to be pulled open. Although in theory these statements are correct, in practice flow–volume loops are not always sufficiently characteristic to allow a confident diagnosis about the exact site and presence of an upper airways obstruction. They may be more useful as a tool to follow changes, such as in response to treatment.

Vocal cord paresis due to bilateral recurrent laryngeal nerve damage is often very much worse on inspiration. Simple spirometry can be diagnostic here. The expiratory tracing will be normal as the cords are blown apart. If the patient immediately inhales back from the spirometer (make sure that a new in-line filter is present first) the inspiratory rate will be tortuously slow (Fig. 2(b)). The forced inspiratory volume in 1 s (FIV_1) will often be much smaller than the FEV_1, whereas normally the reverse is true (Fig. 2(b)).

The effect of breathing a low-density gas mixture, such as 21 per cent oxygen in helium (Heliox), on airways resistance has also been used to try to differentiate lower from upper airways obstruction. Flow in small airways is largely laminar and not affected by the density of the intraluminal gas. However, flow at a tight stenosis will be turbulent, and then it becomes dependent on the gas density. Thus airflow resistance will fall on breathing Heliox if the obstruction is in the upper airways, but will remain unchanged when the increased resistance is due to peripheral airways narrowing. This test may be particularly useful when there is evidence of both lower and upper airways obstruction, but proof of a significant contribution from an upper airways lesion is required before considering any further intervention.

For simple monitoring of progress of a patient with known upper airways obstruction on the ward, for example during treatment, sophisticated tests are not required, and measurement of the PEF rate is probably adequate for most purposes.

Specific causes

Acute causes of upper airway obstruction

Aspiration

Upper airways obstruction due to aspiration is usually due to the object lodging in the larynx, since this is the narrowest portion of the airway until two or three divisions down the bronchial tree. The usual culprit is a piece of food, and thus this condition has been colourfully called the 'café coronary'. The patient suddenly becomes distressed, is unable to talk, and apparently unable to breathe. He may point to his throat trying to indicate the problem. Inspiration to provide the air necessary for a good expulsive cough may not be possible. Indeed, lung volume may 'ratchet' down to residual volume.

The Heimlich manoeuvre was invented for this circumstance and its principles should be taught to first-aid workers. If the patient is still upright, then the helper stands behind with his arms clasped around the upper abdomen. A very forceful pull, backwards and upwards, will drive the diaphragm upwards and should provide enough expired air to shift the aspirated food from the cords (Fig. 3). The manoeuvre can be repeated, of course, but a forceful first try is likely to be the most successful. If the Heimlich manoeuvre fails, then it may be possible to dislodge the lump of food with a finger once the patient has become unconscious. The only alternative is an emergency cricothyrotomy which requires a hole to be made in the cricothyroid membrane just below the Adam's apple of the thyroid cartilage and above the cricoid cartilage. Even a small hole (2 mm or so) will allow sufficient ventilation to keep the patient alive. Emergency cricothyroidotomies have been attempted with everything from penknives to ball-point pens: special large-bore curved-needle kits are available for the purpose and are safer than an unskilled attempt at a tracheostomy.

Fig. 3 The Heimlich manoeuvre for the emergency treatment of acute pharyngeal or laryngeal obstruction due to a bolus of food. Two or three sharp thrusts in the direction of the arrow may cause the food to be ejected. (Reproduced with permission from Flenley, 1990.)

Oedema

Acute oedema of the larynx or pharynx is usually either due to allergy (atopic or non-atopic), a hereditary abnormality in the complement pathway, or inhalation of noxious gases.

Allergic oedema

Episodes of upper airways and facial oedema sometimes have no known cause and appear without warning. Often there will be an atopic history with a specific allergy. Some allergic reactions are not based on atopy and IgE, but may occur through IgG or direct activation of other inflammatory pathways. Allergies to nuts, strawberries, etc. may involve this latter mechanism rather than IgE. Insect stings usually produce pharyngeal and glottic oedema via IgE mechanisms.

Treatment of these allergic causes of upper airways obstruction consists of subcutaneous (or intramuscular) adrenaline (1 ml of 1:1000) with antihistamines and steroids (see Section xxx on acute anaphylaxis). Aerosolized adrenaline may also be useful, using 10 ml of 1:10 000 in an ordinary nebulizer.

Hereditary and acquired angioedema

Hereditary and acquired angioedema are due to deficiency of plasma C1 esterase inhibitor. This defect may be caused by impaired synthesis, due to a genetic defect causing failure of protein production, or production of inactive protein (hereditary angioedema), or by increased catabolism (acquired angioedema). The absence of C1 esterase inhibitor means that the enzyme activating the first component of the complement pathway is unchecked, allowing abnormal increase in activity of the whole pathway and production of vasoactive products.

Hereditary angioedema typically presents in infancy. An episode of oral and facial swelling is often precipitated by local trauma, such as a tooth extraction or a blow to the face, and lasts about 48 to 72 h. The skin manifestations do not itch in the way that allergic oedema does. Colicky abdominal pain due to intestinal oedema is an alternative presentation, when pooling of fluid in oedematous bowel can be sufficient to cause hypotension and shock. Diagnosis hinges on the clinical presentation, a positive family history (autosomal dominant), and low levels of C1 esterase inhibitor. In the form where normal amounts of inactive C1 esterase inhibitor are present, it is necessary to demonstrate low C4 levels during an attack.

Acquired angioedema presents in adult life. It is not familial. It may be associated with lymphoproliferative or other malignant diseases (type I) or more commonly with the presence of autoantibodies to C1 inhibitor (type II).

The disease is serious: 25 to 30 per cent of sufferers of hereditary angioedema die from asphyxia. As for cases of allergic upper airway oedema, treatment of the acute attack consists of adrenaline and steroids, but the response is much less satisfactory. Emergency tracheostomy or cricothyrotomy may be necessary. C1 esterase inhibitor plasma concentrate can be used for severe attacks, but very large doses are frequently needed for those with an acquired defect. Fresh-frozen plasma has been reported to work sometimes, but it contains larger amounts of the substrates C4 and C2 which might theoretically provoke worsening oedema.

Attenuated androgens, for example danazol, raise C1 esterase inhibitor levels within a few weeks, probably by increasing hepatic synthesis, and can usually prevent attacks in hereditary angioedema. Acquired angioedema generally fails to respond to this treatment, but can be treated prophylactically with antifibrinolytic agents. If episodes such as tooth extractions are triggers, then C1 esterase inhibitor can be given beforehand.

Smoke inhalation

Inhalation of hot smoke can burn the upper airways and contributes significantly to deaths due to fires. Upper airways obstruction due to heat injury and mucosal swelling usually develops within 24 h of exposure, but stenosis due to scarring can develop later. A hoarse voice, stridor, severe conjunctivitis, burnt nasal hairs, and falling peak flow all suggest significant upper airways damage. Bronchoscopy is then the best tool to establish whether there is significant oedema or mucosal ulceration obstructing the airways.

Management usually consists of simple measures such as elevating the head of the bed and inhaling cool moist air with added oxygen. If peak flow continues to fall, then transfer to an intensive care unit and bronchoscopy with the capability to perform an intubation, guided by direct vision, is the correct approach.

Infections

Upper airway infections rarely cause obstruction in adults, but can do so in infants and young children. Whilst they can present dramatically with upper airways obstruction, prodromal symptoms usually occur. Streptococcal pharyngitis, tonsillitis, and retropharyngeal abscesses are amongst the most important. Croup (due to respiratory syncytial, parainfluenza, and other viruses) is very common, with narrowing of the subglottic trachea, sometimes with a thick purulent coating over the larynx and trachea. Treatment consists of cool mist and supplemental oxygen, with careful monitoring of upper airways function.

Although again more common in children, acute epiglottitis, usually due to *Haemophilus influenzae*, can affect adults. Pyrexia, drooling, hoarse voice, difficulty in breathing, intense sore throat, and stridor are the usual presenting symptoms. Compared with croup, there is usually a faster onset and course. The diagnosis may be missed initially but lateral neck radiographs show swelling of the epiglottis (Fig. 4). Attempts to examine the back of the throat may precipitate further obstruction, particularly in children. Even tipping the head back for a lateral neck radiograph can provoke complete obstruction and be disastrous. Thus, if there is evidence of breathing difficulty with stridor and the clinical diagnosis is epiglottitis, then the correct management for children is immediate transfer to intensive care and intubation for 48 to 72 h whilst the infection is controlled by ampicillin or chloramphenicol. In adults, close monitoring in intensive care is probably adequate and prophylactic intubation is not routinely practised. General use of *H. influenzae* vaccines should make this problem increasingly rare.

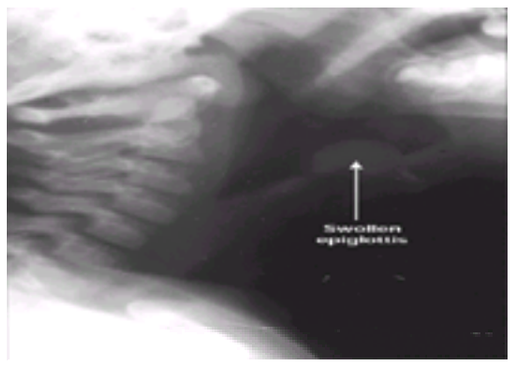

Fig. 4 Lateral neck radiograph of a child with epiglottitis. Note the swollen epiglottis overlying the glottis.

Non-acute causes of upper airway obstruction

Tumours

Laryngeal, and less commonly tracheal, tumours are usually seen in smokers. The dominant cell type is squamous. Spread of a primary bronchial carcinoma into the base of the trachea is probably the commonest cause of upper airways obstruction in pulmonology practice.

Laryngeal tumours nearly always present with hoarseness, or voice change, and cough. Large airways tumours are commonly not diagnosed until far advanced. This is because they mimic lower airways obstruction, as mentioned earlier, and chest radiography is often normal. Tumours may also respond to asthma therapy, showing temporary shrinkage with steroids, which may further mask the real diagnosis.

If history, examination, and lung function tests suggest an upper airways obstruction, then some form of imaging is required. CT is the least invasive approach and therefore least likely to disturb the airway and make matters worse, but will provide no histology. Plain films (posteroanterior and lateral) may show tracheal narrowing

but can be very deceptive. Direct visualization is usually necessary for diagnosis, biopsy, and to aid future therapy.

There is some disagreement as to whether fibreoptic or rigid bronchoscopy should be the investigation of first choice. Rigid bronchoscopy requires anaesthesia and sometimes this precipitates acute obstruction, when the bronchoscope then has to be passed quickly and forced through the obstructing tumour. This 'core-out' can reduce tumour bulk, with control of haemorrhage possible under direct vision, and improvement in the airway may buy time while other treatments such as radiotherapy are employed. Flexible fibreoptic bronchoscopy may be possible without disturbing the tumour, although coughing and increased secretions can precipitate complete occlusion. Direct application of adrenaline may help as an initial emergency treatment, and in theory cocaine (a vasoconstrictor) would be preferable to lignocaine as a local anaesthetic. If stenosis reduces tracheal diameter to less than 4 mm or so, it is best left alone during flexible bronchoscopy and should certainly not be biopsied (Fig. 5). In cases that are likely to be difficult, it can be helpful to pass an endotracheal tube over the flexible bronchoscope before it is introduced. This allows a guided intubation in an emergency, using the bronchoscope as a guidewire.

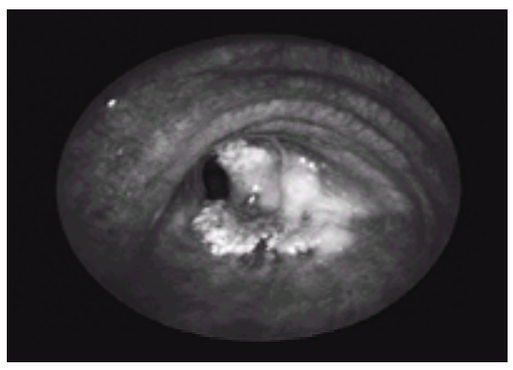

Fig. 5 Bronchoscopic view of a tracheal carcinoma blocking most of the lumen. (By courtesy of Dr P. Stradling.)

Aside from intubation or tracheostomy (when appropriate), emergency treatment of tumours compromising the upper airway consists of dexamethasone (12 mg daily), nebulized adrenaline (10 ml of 1:10 000 up to six times daily), humidification of inspired air, and breathing Heliox (21 per cent oxygen in helium). Improvement in the airway may then be achieved by treatment of the tumour with chemotherapy or radiotherapy. Sometimes, however, these can initially provoke swelling of the tumour, so that steroids are usually prescribed first, with emergency treatments kept close to the hand (Heliox, adrenaline). If these therapies do not help, then palliation can be achieved with the use of bronchoscopically guided laser therapy or cryotherapy, which literally either burn or freeze away tumour tissue with a low incidence of serious haemorrhage. Laser therapy is a laborious procedure, currently only available in a few specialist centres. Cryotherapy is quicker and safer, and can be performed down a flexible bronchoscope. These techniques are only of use with intraluminal tumours and cannot be applied when the narrowing is due to external compression. Another approach is the use of silicon or metal endobronchial stents. Some of these can be inserted via a flexible bronchoscope; others require surgery. They are particularly useful when external compression is present, and can produce dramatic resolution of symptoms. It is rarely appropriate to 'debulk' a malignant tumour at thoracotomy in an attempt to improve large airway patency.

Unfortunately, upper airways obstruction from a tumour becomes a terminal event in many cases. Powerful sedation is indicated to make the patient unaware that he or she is asphyxiating and choking to death.

Some rare, non-malignant tumours can obstruct the trachea, and rarely granulomatous conditions such as sarcoid and Wegener's granulomatosis may mimic tumour.

Tracheal stenosis

Tracheal stenosis usually develops following prolonged intubation or after a tracheostomy has been allowed to close following tube removal (Fig. 6). This scarring may appear some time after the initiating event. Again, radiology or bronchoscopy will usually confirm the diagnosis, already strongly suspected from the history. Temporary relief may be obtained by dilating the stricture at rigid bronchoscopy. Definitive treatment involves resection of the stenosed portion and reanastomosis.

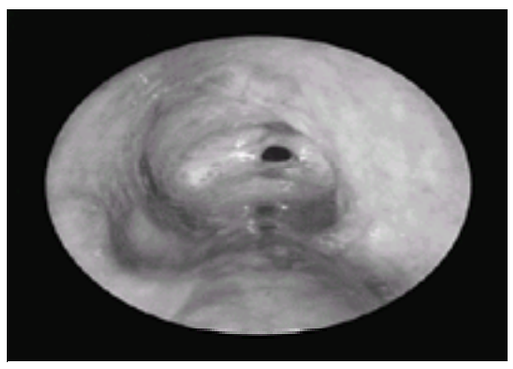

Fig. 6 Bronchoscopic view of a post-tracheostomy tracheal stricture. The remaining hole is about 2 to 3 mm in diameter. (By courtesy of Dr P. Stradling.)

Tracheal compression

Tracheal compression (Fig. 7) may be due to malignant or non-malignant conditions. External compression by malignant tumour (primary or secondary) has been covered in the previous section. Non-malignant causes include thyroid enlargement, aortic aneurysm, sclerosing mediastinitis, mediastinal neurofibroma, and Castleman's disease. If definitive treatment is not possible, then stenting the airway is the only option available. When thyroid enlargement leads to tracheal obstruction, surgical removal may not solve the problem completely. Prolonged pressure on the trachea can lead to tracheomalacia, so that the tracheal wall collapses when unsupported by the thyroid. Temporary use of an endotracheal stent is then appropriate.

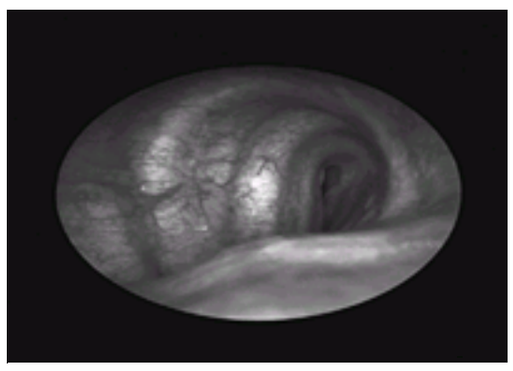

Fig. 7 Bronchoscopic view of external tracheal compression by right-sided paratracheal malignant nodes. (By courtesy of Dr P. Stradling.)

Tracheal abnormalities

Tracheomalacia may be secondary to prolonged external compression (see above) or a primary abnormality that presents in childhood. It is essentially a weakness or deficiency of the supporting cartilages. It is sometimes seen secondary to a long history of chronic airways obstruction. Normally the anteroposterior diameter of the trachea decreases by up to about 10 per cent during a cough. In tracheomalacia, collapse during coughing is over 50 per cent and sometimes is complete. The symptoms of this are usually stridor, shortness of breath, and paroxysms of coughing. In addition, inefficient coughing can lead to recurrent pneumonia and bronchiectasis.

A 'scabbard trachea' is said to be present when the lateral dimensions of the trachea are significantly narrower than the anteroposterior dimensions. This deformity, usually present along the whole intrathoracic trachea, is normally associated with chronic airways obstruction. It rarely causes severe upper airways obstruction and on a plain chest radiograph there is obvious tracheal ring calcification.

Tracheobronchiomegaly (or Mounier–Kuhn disease) is probably an inherited structural abnormality of the trachea presenting in adult life as apparent chronic airways obstruction. The trachea is dilated from the larynx to the second- or third-generation airways. There is atrophy of both cartilage and muscle. It is usually misdiagnosed as chronic airways obstruction, but the presence of prolonged but ineffectual coughing and harsh upper airway sounds should lead to lung function tests which then show evidence of an expiratory (intrathoracic) upper airway resistance. Radiological examination will show the dilated airways.

Tracheobronchopathia osteochondroplastica is a very rare condition characterized by cartilaginous and bony excrescences growing into the large airway lumina. This can lead to significant upper airways obstruction, but is more often a post mortem finding which is unsuspected in life.

Relapsing polychondritis is an 'autoimmune' systemic disorder affecting cartilage all over the body (ribs, trachea, ear lobes, nose, joints) and may be associated with systemic lupus erythematosus, Wegener's granulomatosis, and cryptogenic liver cirrhosis. Large airways involvement is a frequent cause of death in this condition. There is irregular narrowing of the trachea and main airways, with flaccidity of the tissues sometimes allowing marked collapse on expiration. The diagnosis can be hard to make: involvement of other cartilaginous sites is the critical feature to look for. The condition is often difficult to treat. Aside from local surgical or stenting procedures, steroids and other immunosuppressive therapies are usually given.

Laryngeal dysfunction

Damage to one recurrent laryngeal nerve usually causes a weak voice that improves a little with time as the opposite cord 'learns' to compensate by moving slightly across the midline to improve apposition. As the recurrent laryngeal nerve is invaded or compressed (usually by tumour at the left hilum), differential effects on abductors and adductors may be seen. For example unopposed adduction may occur prior to complete paralysis.

Bilateral recurrent laryngeal nerve paralysis produces flaccid cords that lie passively midway between full abduction and adduction. Abduction is very poor, such that rapid inspiration will draw the cords together and produce stridor, thus limiting exercise tolerance. Inspiratory stridor may initially be present only during sleep, when general decrease in muscle tone reduces any residual laryngeal abductor activity. Although this may be labelled as snoring, careful questioning of a witness will identify whether snoring or the machinery-like screech of inspiratory stridor is present (particularly if the physician can imitate the two noises!).

The usual clinical history is of voice change following thyroidectomy some years before. This may have been quite subtle, such as difficulty in singing, but with speech relatively unaffected. Nocturnal stridor and reduction in exercise tolerance then develop over a period of years. Eventually the obstruction at night can be sufficient to produce obstructive apnoea and respiratory failure. These events may be due to involvement of the previously damaged recurrent laryngeal nerves in scarring at the thyroidectomy site. Sometimes bilateral paralysis can occur for no apparent reason, and it is assumed that the aetiology is similar to Bell's palsy or the diaphragmatic palsy of neuralgic amyotrophy. A very rare differential diagnosis is an Arnold–Chiari malformation causing brain stem compression and presenting with sleep-related stridor in association with ventilatory failure.

Laryngeal surgery could prevent inspiratory cord closure, but would do so at the expense of the voice. Thus a tracheostomy with a speaking tube is the usual approach. However, if the night-time obstruction is the main problem (with sleep disruption and daytime sleepiness), nasal continuous positive airway pressure therapy will usually keep the cords apart during sleep.

Damage to the superior laryngeal nerves supplying the cricothyroid (a vocal cord tensor) causes only a weak voice. Speech is still possible because the main adductors still function

Apart from laryngeal paralysis, laryngeal destructive conditions such as rheumatoid arthritis can lead to poor abduction with inspiratory stridor, particularly at night. In Parkinson's disease with autonomic involvement (Shy–Drager syndrome) or more generalized brain atrophy (multisystem atrophy) there can be a fairly specific wasting of the laryngeal abductors. This also presents with inspiratory stridor (or apnoea) at night and can progress to respiratory failure.

Functional laryngeal abnormalities, with narrowing during inspiration and/or expiration, can occur. These may be due to psychological problems, but the syndrome blends with reflex laryngeal dysfunction in patients with asthma. Expiratory laryngeal wheezing can occur in response to emotional pressure even in well-controlled asthma. In this situation, the laryngeal component of the increased airways resistance can be considerable. Inhalations of histamine can sometimes mimic this, which might therefore be due to a reflex originating from afferent receptors. Why this should happen is not clear, but it may be activation of the laryngeal braking mechanism to help raise functional residual capacity.

Functional inspiratory stridor is not particularly related to asthma, but may follow a respiratory tract infection. There is some evidence that techniques used by speech therapists can help with this problem.

17.8.2 Sleep-related disorders of breathing

J. R. Stradling

Introduction

This chapter discusses the disorders of breathing that appear only during sleep. This rapidly expanding subspecialty within respiratory medicine now provides about 10 to 15 per cent of the speciality's referrals. Following its first proper description in 1967 as a medical curiosity, obstructive sleep apnoea and its variants are now thought to significantly impair the functioning of about 0.5 to 1 per cent of the population. Most general hospitals will have some form of monitoring system for the diagnosis of sleep apnoea syndromes, although tertiary centres tend to provide most of the treatment. The diversity of symptoms produced by these disorders means that all physicians need to have an understanding of them and are likely to come across many cases during their professional life.

Normal physiology of breathing during sleep Table 1)

Sleep can be divided into two very different states. The dominant sleep stage is non-rapid eye movement (NREM) sleep (Fig. 1 and Fig. 2). This phase of sleep, which is preferentially reclaimed following sleep deprivation, appears to be when the brain shuts down and is necessary for maximum daytime alertness and continuing cognitive function. NREM sleep shows a continuum from drowsy down to very deep sleep, arbitrarily subdivided into stages 1, 2, 3, and 4. The awake electroencephalogram (EEG) is characterized by low voltage, high frequency activity, with the only dominant frequency being the so-called alpha activity (approximately 10 Hz), present when the eyes are closed. As sleep supervenes, the alpha activity disappears, overall EEG frequency falls, muscle tone (usually measured from a chin electromyogram (EMG)) falls, and the eyes begin to roll from side to side. This transition phase is called stage 1. Stage 2 is defined by the appearance of K complexes (isolated large waves) and sleep spindles (bursts of about 13 Hz activity). As sleep deepens further, increasing amounts of large, slow waves (approximately 1 Hz) appear. These stages are called 3 and 4, or slow-wave sleep.

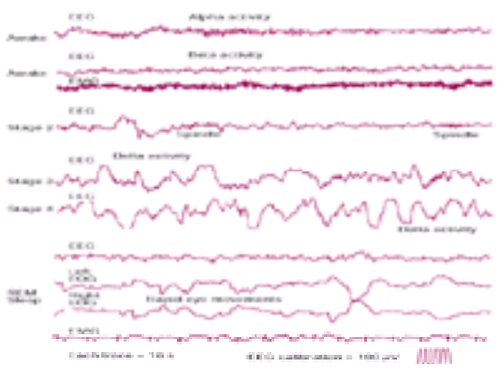

Fig. 1 Examples of electrical brain activity (EEG), eye movements (EOG), and chin muscle tone (EMG) during wakefulness and the different sleep stages.

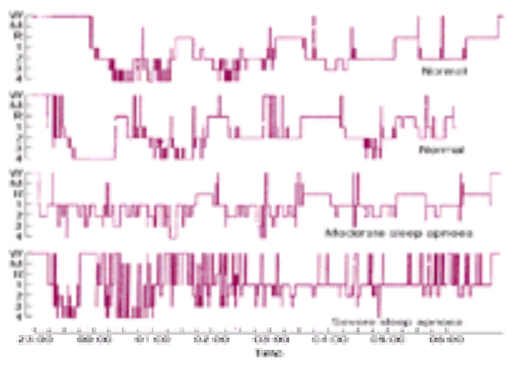

Fig. 2 Examples of all-night hypnograms (based on 20-s epochs) in two normal subjects and two patients with sleep apnoea. Note the reduced deep sleep (stages 3 and 4) in the patients, but no indication that they are waking up hundreds of times a night. W, awake; M, movement (awake); R, REM sleep; 1 to 4, stages 1, 2, 3, 4 of non-REM sleep.

The other main phase of sleep is rapid eye movement (REM) sleep or dreaming sleep. This stage is characterized by a return of the EEG to a pattern resembling wakefulness. The EMG tone falls to very low levels and there are bursts of rapid eye movements, mainly from side to side, under closed eyelids. Effectively the cortex is 'awake' again, processing images and able to integrate outside noises or other stimuli into complex dreams. The fall in EMG tone is because the rest of the body's muscles have been 'cut off' from the brain and paralysed, hence the fall in EMG tone. This paralysis (or atonia) is under active control from a centre in the pons that hyperpolarises the lower motor neurones via inhibitory reticulospinal pathways. Cats in whom this centre has been destroyed no longer show atonia during REM sleep, and as a consequence they may get up and walk around or appear to chase phantom birds, presumably reflecting their dream content. The function of this atonia centre may therefore be to prevent the dreaming brain from influencing the rest of the body. Paralysis during REM sleep occurs dominantly in muscles that normally have a tonic postural activity; thus the diaphragm is spared although pharyngeal, intercostal, and accessory muscles are all affected to differing extents.

The normal pattern of the oscillation between NREM and REM sleep is shown in Fig. 2. This 'hypnogram', as it is called, is constructed by classifying successive 30-s epochs from tracings of EEG, EMG, and eye movement data into either awake, movement, REM sleep, or stages 1–4; thus 960 epochs are obtained in an 8-h night.

During wakefulness breathing is influenced by a variety of pathways, some conscious and voluntary, others entirely automatic and involuntary. Classic responses to hypoxia, hypercapnia, and vagal afferents (integrated in the brainstem) can be overruled by cortical signals to subserve functions such as talking. These two types of control are separate and can be damaged separately by disease processes. The presence of wakefulness itself provides an input to the respiratory centre, almost equivalent to the amount of ventilation seen at rest. Thus, following a period of hyperventilation, a normal subject will go on breathing at just below normal levels, despite hypocapnia and hyperoxia, until the carbon dioxide rises, when normal ventilation is re-established. This is not true during NREM sleep, when hypocapnia will produce apnoea until the $PaCO_2$ rises back to a critical threshold level.

Another component of wakefulness is the high muscle tone that holds the body in the required posture. This 'awake' input into the anterior horn cells means that other inputs, such as those from the respiratory centre, can further activate muscles, including the intercostals and pharyngeal. The withdrawal of this 'awake' tone with the onset of sleep means that a certain respiratory centre output to the relevant anterior horn cells is less able to raise membrane potentials to firing threshold, such that respiratory muscle activity falls with sleep onset, minute volume typically reduces by about 10 to 15 per cent, and $PaCO_2$ rises by 3 to 8 mmHg. Reduction of pharyngeal muscle tone narrows the lumen, and thus there is normally a rise in upper airway resistance. This reduction in ventilation has trivial effect on the arterial oxygen saturation (SaO_2) in the normal circumstance when SaO_2 is on the flat part of the haemoglobin dissociation curve, but dramatic falls in saturation will be apparent when SaO_2 starts below 92 per cent, the steep part of the curve. If ventilatory responses to carbon dioxide or hypoxia are measured during NREM sleep, the slopes are flatter and right shifted, indicating a reduced overall sensitivity. Exactly why this occurs is not known, but reduced tone of the respiratory muscles, the withdrawal of awake drive, increased upper airway resistance, and (probably) true reduction in central sensitivity to carbon dioxide or $[H^+]$ could all contribute. If, as a consequence of respiratory disease, compensatory mechanisms are already employed to cope with the extra work of breathing, then these seem to be particularly reduced during sleep as well.

During REM sleep, overall ventilation stays much the same as in NREM sleep, but the breath-to-breath variability increases considerably, sometimes with apnoeas during the actual periods of eye movements, and compensatory increases in between. Sensitivities to carbon dioxide and hypoxia were originally thought to be further reduced, but they are hard to measure in the presence of spontaneously variable breathing and more recent evidence suggests they may not change much at all. What is far more important is the atonia of postural muscles. The hyperpolarization of the anterior horn cells greatly reduces the efficacy of respiratory signals to the intercostal, accessory, and pharyngeal muscles. This will not matter in a normal subject with an efficient diaphragm and a non-compromised pharynx. However, if the subject is dependent on muscles other than the diaphragm for breathing, or has a narrow compromised pharynx, then REM sleep may powerfully interfere with ventilation with consequent hypoxaemia and hypercapnia.

Also of relevance to breathing during REM sleep are the reduced arousal responses to respiratory stimuli compared with non-REM sleep. The arousal responses to some ventilatory stimuli (hypoxia, hypercapnia, extra resistive load) are believed to be mediated mainly by the perception of the ventilatory effort made in response, rather than the specific ventilatory stimulus itself. If a ventilatory response to hypoxia is measured during REM sleep, then the subject will usually tolerate a much lower SaO_2 before arousing compared to NREM sleep. Furthermore, if the drive to sleep is high, such as after sleep deprivation, arousal will be delayed still further.

It can be seen from the above that, although sleep is not a problem for those with normal respiratory systems, once abnormalities are present there is potential for a damaging interaction between sleep and breathing, particularly during REM sleep.

Obstructive sleep apnoea

Definition

Sleep apnoea was first properly documented in neurophysiological sleep laboratories using techniques that had been developed for the investigation of conditions such as insomnia, narcolepsy, and depression. It was realized that hundreds of episodes of breath cessation, or apnoea, usually due to upper airway obstruction with associated snoring, were related to marked sleep disturbance. Because simple oronasal flow detectors were used, the critical event was defined as an episode of apnoea. Because it was easy to measure, an arbitrary definition was made, and breath cessation for longer than 10 s became an official apnoea. Early work suggested that normal, young people rarely had more than about 30 apnoeas per night, so that the standard definition of 'sleep apnoea syndrome' became more than 35 apnoeas per night, or more than five per hour of sleep, each lasting for 10 s or longer. This definition has existed long beyond its clinical usefulness: it is quite clear that recurrent partial obstruction to the upper airway can fragment sleep just as severely with no actual apnoeas or hypopnoeas developing at all. A more pragmatic and clinically useful definition might now be 'a sleep disruption syndrome that is due to a respiratory problem engendered by sleep itself, sufficient to cause symptoms when awake. Usually this is upper airway incompetence during sleep, but may also be due to problems of respiratory drive'. As the pathogenesis of sleep apnoea is explained, this shift in emphasis, with the inclusion of symptoms, will become clear.

Aetiology (Table 2)

The upper pharyngeal airway has to serve two functions, swallowing and breathing, which require different design features. When used for swallowing the pharynx has to behave like the oesophagus, and when used for breathing it has to remain an open tube like the trachea. These dual functions are achieved by having a floppy and collapsible muscular tube that is also capable of being held open rigidly by dilator muscles. The muscles responsible for this dilator function are discussed in the section on the structure and function of the upper respiratory tract (see Chapter 17.1.1). All these muscles have reduced activation during sleep, so that some pharyngeal narrowing occurs normally. There are, then, additional factors that determine whether this reduction leads to significant upper airflow obstruction in a particular individual. There are various theories as to these additional factors, but essentially they divide into two groups. Firstly, there may be abnormalities of the activation of the pharyngeal dilator muscles, perhaps due to defective or unstable central control. Secondly, there may be anatomical abnormalities that allow significant obstruction to occur even with the normal sleep-related reduction in muscle tone.

Neuromuscular function

Early investigations of EMG activity in pharyngeal muscles found reductions in tone with sleep during obstructive apnoeas. However, it was very difficult to show that these reductions were truly abnormal. Recent evidence shows that there is in fact an increase in activity of these muscles, both awake and asleep, in response to factors provoking pharyngeal collapse. In some patients with primary neuromuscular problems (from brainstem lesions to myopathies) there can be associated obstructive sleep apnoea, and pharyngeal muscle involvement seems a probable explanation. However, the majority of patients with obstructive sleep apnoea do not show evidence of any other neuromuscular problems.

During inspiration, pharyngeal dilator activity has to be synchronized with diaphragmatic activity and be adequate to overcome negative intrapharyngeal pressure. It has been suggested that a lack of co-ordination between diaphragmatic and pharyngeal activation may allow the pharynx to collapse. For example normal subjects breathing against an inspiratory resistance can be made to have a few obstructive apnoeas by artificially inducing periodic breathing during sleep. The gradual return of respiratory drive, following the nadir of ventilation, seems to activate the diaphragm first, leaving the pharynx unbraced. The presence of an inspiratory resistance then 'challenges' the pharynx and allows collapse for a few breaths before pharyngeal tone returns and restores patency.

Although instability of respiratory control during sleep has been postulated as a cause of obstructive sleep apnoea, following treatment with nasal continuous positive airway pressure therapy (see later) there is no evidence of a premorbid underlying respiratory instability, nor does altering respiratory drive have a useful effect. More convincing is the suggestion that there may be failure of normal reflex protective mechanisms in the pharynx, whereby receptors in the pharynx detect falls in pressure that distort the airway and provoke protective increases in pharyngeal dilator tone (see Section 17.1.1). Snoring itself may also be one of the stimuli that activate this dilator reflex, and it is conceivable that interruption of this reflex arc can occur, perhaps through years of pharyngeal trauma from snoring, mucosal oedema, or toxic agents such as cigarette smoke and alcohol.

Anatomical causes

Anatomical abnormalities influence pharyngeal function in a variety of ways. Simple encroachment of the pharyngeal lumen, for example with tonsillar hypertrophy, means that the normal fall in pharyngeal dilator tone with sleep can lead to critical narrowing and obstruction. Alternatively, there are abnormalities which 'load' the

upper airway, requiring increased dilator muscle action that is then lost during sleep (for example high nasal resistance or increased external compression from neck obesity). Finally, there may be mechanical problems such that muscular activity fails to dilate the pharyngeal lumen effectively.

There are many case reports of obvious anatomical abnormalities provoking obstructive sleep apnoea, for example tonsillar hypertrophy, pharyngeal oedema, tumours, acromegaly, mucopolysaccharidoses, and mandibular or maxillary underdevelopment. These reports show that pharyngeal narrowing (asymptomatic whilst awake) can provoke obstructive sleep apnoea, but such diagnoses represent only a small proportion of cases.

The majority of patients with obstructive sleep apnoea are overweight. In many clinics the average obesity index is well over 30 kg/m ^{2}, equivalent to being about 30 per cent overweight, for example 95 kg (15 stone) at a height of 1.78 m (5 ft 10 in). Weight loss can certainly cure obstructive sleep apnoea, and all studies identifying risk factors have found obesity to be dominant, accounting for up to 40 per cent of the variance in severity.

Most groups have found neck circumference to be a better predictor of severity of obstructive sleep apnoea than obesity itself, suggesting that it is neck obesity and external pharyngeal loading that is important. Animal studies have shown that only a small amount of extra external pressure over the pharynx is required to collapse it during sleep, and recent imaging studies have suggested that quite small amounts of extra fat do occur either side of the pharynx in patients with obstructive sleep apnoea, together with larger amounts subcutaneously.

Although general obesity is related to neck obesity, the overall correlation is only about 0.75. This is because fat distribution varies considerably between individuals. The 'female' distribution tends to be in the lower body and the 'male' distribution is more central. Thus a man who is not particularly overweight can have a large neck and vice versa.

As mentioned earlier, there is evidence that some of the upper airway dilator muscles (e.g. genioglossus) of obese patients with obstructive sleep apnoea are actually working harder than normal, perhaps as compensation for the added external loading from neck obesity. Compensations by the respiratory system for other types of extra loading have been shown to be much less active during sleep.

In summary, overall the evidence suggests that most obstructive sleep apnoea in adults is due to loading of the upper airway caused by obesity. This external loading can be fended off during wakefulness but not during sleep, when the withdrawal of postural muscle tone allows the pharyngeal dilators to be overwhelmed, leading to excessive narrowing or collapse of the airway, with consequent apnoea.

However, not all adult sleep apnoea can be explained by obesity or intrapharyngeal anatomical abnormalities. The significance of marked retro- or micrognathia for obstructive sleep apnoea was recognized early on, particularly in children (Pierre–Robin syndrome). Careful cephalometric studies of facial and skull morphology have revealed that some patients with obstructive sleep apnoea have longer faces, retropositioning of the mandible (measured as a more acute angle between the sella to nasion and nasion to supramentale planes), a downward movement of the hyoid, elongation of the soft palate, and a narrower anteroposterior distance behind the tongue. Some, or all, of these changes may be secondary to many years of sleep apnoea rather than part of the cause. However, the retropositioning of the mandible may be contributory, and surgery to advance the mandible may be curative in carefully selected cases.

P>Retropositioning of the mandible may be a legacy from childhood. There is good evidence that nasal blockage and mouth breathing very early in life alter facial development (the so-called 'adenoidal facies'), and one feature of this is mandibular retropositioning. Following early adenoidectomy and resumption of nasal breathing, the mandible can return to its normal position. One theory is that mandibular underdevelopment and obesity are two relatively common independent risk factors for obstructive sleep apnoea that together may be synergistic.

Other factors provoking obstructive sleep apnoea

Alcohol is a potent reducer of muscle tone, and can further reduce pharyngeal dilator muscle tone during sleep. It is well known that alcohol worsens snoring, but it can also convert snoring to full apnoea. Other sedatives, such as the benzodiazepines, barbiturates, and opiates, can do the same, and this has important consequences for anaesthesia in such patients. Sleep deprivation itself can reduce upper airway muscle tone during subsequent sleep, provoking a vicious circle, whereby apnoea causes sleep disruption, causing worsening apnoea.

Nasal blockage can contribute to the tendency of the pharynx to collapse by lowering intrapharyngeal pressure. If extra effort has to be made to inspire through a high nasal resistance, there will be a greater vacuum effect in the pharynx, increasing its tendency to collapse. Once collapse occurs, flow ceases, pharyngeal pressure returns to atmospheric, the lumen opens, and the cycle repeats. This certainly leads to snoring, but may no longer be very important when there is full apnoea. However, nasal obstruction may contribute long term to sleep apnoea by damaging the pharynx through years of snoring, making it more collapsible, but improving nasal patency rarely cures obstructive sleep apnoea.

Hypothyroidism is associated with obstructive sleep apnoea, but the mechanism s not clear. It may be through weight gain or through tissue or fluid deposition in the pharynx. Alternatively, a low thyroxine level may interference directly with muscle function.

Immediate consequences of sleep apnoea

Upper airway narrowing, sometimes with complete apnoea, usually commences as sleep passes from awake to stage 2. Once significant obstruction occurs there will be increasing respiratory effort to try and overcome it. The length of such events is highly variable, ranging from only a few seconds to well over a minute. At some point arousal occurs, with an improvement in upper airway resistance, resolution of any asphyxia, and then a return to sleep, whereupon the cycle repeats (Fig. 3, Fig. 4, and Fig. 5). Hypoxaemia and mild hypercapnia usually accompany these periods of obstructed breathing. If there is complete apnoea, the rate of fall of $Sa{O_2}$will depend mainly on the amount of oxygen stored in the lungs. This depends on the functional residual capacity since apnoeas occur at end-expiration, preventing inspiration. The length of the apnoea also determines how low the $Sa{O_2}$ will fall, and varies considerably between patients. The consequences of such hypoxaemia and hypercapnia are not clear. Because the blood gas derangements are so transient they may do little harm, unless there is already ischaemic heart disease, for example.

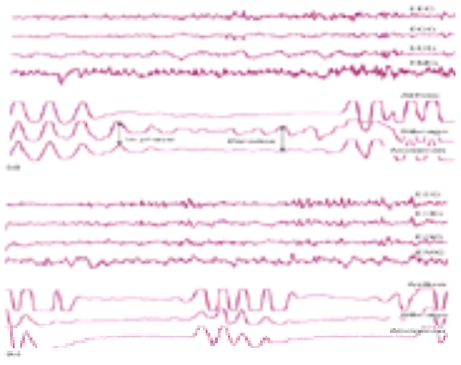

Fig. 3 Obstructive (a) and central (b) apnoeas (16-s traces): (a) airflow ceases, but rib-cage and abdominal movements persist and become paradoxical; (b) rib-cage and abdominal movements cease as well as airflow.

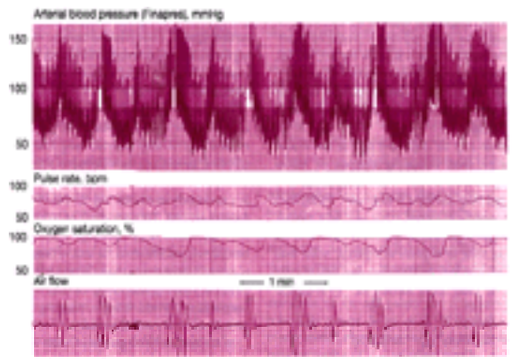

Fig. 4 Five-min tracing from a patient with obstructive sleep apnoea. The rises in blood pressure (top trace) and heart rate (second trace) coincide with the cessation of each apnoea and an arousal. During each apnoea (evident from the bottom airflow trace) each frustrated inspiratory effort is accompanied by a fall in blood pressure (pulsus paradoxus).

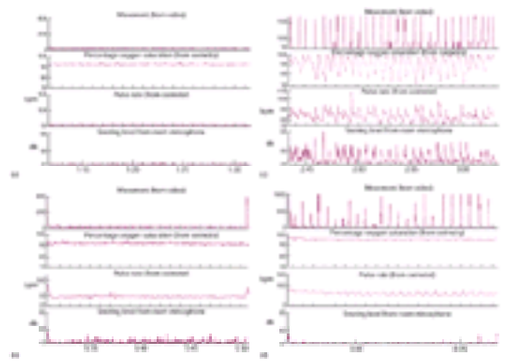

Fig. 5 Short sleep tracings of body movement, SaO_2, pulse rate, and snoring level in four different subjects. (a) Normal subject (no fluctuations in any signals), 20 min. (b) Patient with continual low level snoring and almost no arousals, 20 min. (c) Patient with classical obstructive apnoeas, evident from the snoring–silence–snoring pattern together with movements and oscillations in the pulse and SaO_2, 20 min. (d) Patient with periodic movements of the legs during sleep, recurrent arousal (oscillations in pulse and body movements), but no evidence of a respiratory cause (no snoring or SaO_2 dips), 10 min. A video recording of the whole night is always available and can be viewed when the exact cause of abnormal signals is not immediately obvious.

Hypoxaemia was believed to play an important part in the arousal response that saves the patient from continuing asphyxia. In animal models, removal of the carotid body abolishes significant ventilatory response to hypoxaemia during sleep and there is no arousal. Giving extra added oxygen does prolong apnoeas to a small extent and delay arousal. However, recent evidence suggests that the main arousal stimulus is the actual respiratory effort being made in response to asphyxia, rather than the asphyxia per se. Normal subjects tend to wake when they have to make respiratory efforts about three times above the normal (10–20 cmH_2O pleural pressure swings). This degree of effort is easily reached in obstructive sleep apnoea, when pressures down to –80 cmH_2O can be recorded during the frustrated inspiratory efforts. Such pressures can also be reached by heavy snorers, even if they do not develop hypoxaemia, and this also leads to arousals.

In terms of symptoms, the most important consequence of sleep-induced upper airway narrowing is sleep fragmentation. The original methodology of sleep analysis, using coarse 30-s epochs to stage sleep, effectively glossed over the multitude of transient arousals that are the main consequence of obstructive sleep apnoea. Superficially, a sleep hypnogram in a moderately severe case (Fig. 2) could look almost normal despite hundreds of arousals. The importance of trying to measure these has recently been appreciated, and technology to measure arousals automatically is being developed. However, the level of sleep disruption (number and 'size' of arousals) necessary to cause daytime symptoms is not known. There is a clear, but variable, relationship between increasing sleep disruption and deteriorating daytime function, meaning that there is no clear cut off between normality and abnormality.

In addition to blood gas disturbances and sleep disruption, there are many other consequences of obstructive sleep apnoea. During the apnoea there is activation of the diving reflex that produces bradycardia, particularly when there is associated hypoxaemia. Upon arousal there is a sudden pulse rate and blood pressure rise, probably due to activation of the sympathetic nervous system as part of the arousal process itself. During the actual frustrated inspiratory efforts, blood pressure falls with each reduction in intrathoracic pressure (pulsus paradoxus) and, in conjunction with the blood pressure rise on arousal, produces a very characteristic trace (Fig. 4). As well as increased nocturnal catecholamine secretion in patients with obstructive sleep apnoea, there is also a suppression of growth hormone and testosterone levels. There is marked polyuria during sleep (a reversal of the normal relative oliguria), but the mechanism is not clear. It may be related to the recurrent arousals, or to increased atrial natriuretic peptide (ANP) production following right atrial distension due to large inspiratory efforts.

It will be clear from this account that there are grey areas of uncertainty regarding definition and measurement of significant aspects of sleep apnoea. We discussed earlier that original definitions centred on the actual obstructive event. There has now been a shift towards trying to look more closely at the most important result—sleep fragmentation. This is particularly necessary now we know that 10-s apnoeas are not the only result of upper airway narrowing during sleep that can provoke multiple arousals and daytime sleepiness. Since heavy snorers can have considerable sleep fragmentation without significant falls in SaO_2, examining blood gas abnormalities (for example with an oximeter) is not always good enough either. The implications for this in terms of investigations are discussed later. A considerable amount of effort is being put into establishing which variable, measured during a sleep study, best defines the severity of the disorder. At present there is no clear answer and therefore there remain many different approaches to diagnosis and management.

Symptoms and presentation

The main symptom of obstructive sleep apnoea is daytime hypersomnolence, and this correlates broadly with the degree of sleep disruption. Early in the development of the disorder the daytime sleepiness is little more than often experienced by normal people after a few disturbed nights. Whilst occupied there is little difficulty in concentrating and staying awake, but once activities become more boring, unwanted sleepiness intervenes. Initially this may be viewed as normal, such as falling asleep in front of the television every evening. As the sleep disruption worsens there will be interference with an increasing number of activities. Of particular importance is sleepiness whilst driving. Sleepiness can be devastating, particularly on long motorway journeys after dark, when sensory stimulation is low. Initially there will be lane wandering with sudden arousal and correction. Accidents involving driving off the road, or driving into vehicles in front, are more common in patients with obstructive sleep apnoea. Sleepiness also impinges greatly on work performance and home life. The patient will develop a reputation for slothfulness and lack of interest.

It is important to ask the right questions to assess sleepiness. It is not the same as tiredness, which is a lack of energy or desire to get up and do anything, without a desire to sleep. Because of the insidious onset of obstructive sleep apnoea, any sleepiness may be regarded as normal by the patient, and thus situational questions need to be asked such as 'how often do you have to pull off the road whilst driving owing to sleepiness?' rather than just 'are you sleepy?' A well validated and simple way to do this is with the Epworth Sleepiness Scale (Fig. 6). Objective sleepiness can be assessed in the sleep laboratory by measuring how long the patient takes to fall asleep on a number of occasions across the day. This is useful for research purposes but adds little to the clinical management of such patients. A list of other symptoms seen in obstructive sleep apnoea is given in Table 3. It is sad to say, but the corrosive effect of sleepiness on all aspects of a patient's life has often been present for years before someone (usually not a doctor) tumbles to the diagnosis.

EPWORTH SLEEPINESS SCALE

Fig. 6 Questionnaire scale to assess subjective sleepiness. The scores for each answer (0–3) are summed to give a range from 0 (no sleepiness at all) to 24 (maximally sleepy). The upper limit of normal is about 9, and most patients with symptomatic obstructive sleep apnoea are in the middle teens.

A typical case history would be that of a middle-aged man complaining of increasing daytime sleepiness. It is usually some specific event that prompts initial consultation, such as falling asleep whilst driving, operating machinery, or during an important board meeting. There will be a long history of gradually worsening snoring with apnoeas, possibly witnessed by the spouse, who will probably have moved out of the bedroom owing to the noise. There is likely to have been a weight gain over the last few years with an obesity index of greater than 30 kg/m^2 and a collar size of 17 inches or more. There is usually a history of fairly high alcohol intake and smoking. On examination there may be nasal stuffiness, evidence of a small lower jaw (such as teeth crowding or several extractions for this problem), and a small pharynx with mucosal bogginess and wrinkling. Of course, it should be stressed that not all these features are likely to be present in one individual.

Part of the history and examination of patients with possible obstructive sleep apnoea should be directed towards precipitating factors such as hypothyroidism and acromegaly. Other diagnoses such as mucopolysaccharidosis, pharyngeal tumours, tonsillar hypertrophy, neurological disorders, and significant retrognathia will be more obvious.

Diagnosis

Following the history and examination, further outpatient tests may be appropriate, for example thyroxine or growth hormone estimations. Blood gases and simple lung function tests may be necessary if associated diurnal respiratory failure is suspected. A raised haemoglobin may also signify diurnal respiratory failure, as will a raised venous bicarbonate. Obstructive sleep apnoea tends to go with the findings that constitute the so-called 'syndrome X', namely hypertension, obesity, and insulin resistance. Blood pressure and blood sugar should be measured.

Unless the presenting problem turns out not to be sleep related, some form of sleep study will be required. In the past, the usual procedure was to employ full polysomnography, which measured sleep state and respiratory variables (Fig. 2 and Fig. 3). This investigation and its analysis is expensive and time consuming, particularly if all recurrent arousals are documented. The primary requirement is to assess sleep fragmentation, establish if a respiratory problem is responsible, and decide if upper airway obstruction is the primary cause. Full polysomnography, properly interpreted, will usually allow this, with the EEG and EMG giving good information on sleep disruption, and aspects of respiration deduced from rib-cage/abdominal movement transducers, oronasal airflow, and snoring and continuous oximeter recordings. However, there is considerable signal redundancy in such recordings, and the essential derivatives—sleep disruption and respiration—can be assessed in much simpler ways (Fig. 5). Most clinical respiratory sleep laboratories have abandoned routine, conventional polysomnography because of its unnecessary expense.

Sleep fragmentation can be inferred from a variety of signals. The most sensitive appears to be autonomic markers of brainstem activation, such as blood pressure and pulse rate rises. In addition, since most abnormal respiratory events will end in some form of arousal, counting body movements provides some guide to the degree of sleep fragmentation, and may be most predictive of daytime symptoms. Upper airway obstruction can be inferred from snoring, a particular inspiratory pattern on a nasal flow tracing (flow limitation), paradoxical ribcage/abdominal movements, and from pulsus paradoxus visible on a beat to beat blood pressure tracing (now easily obtainable non-invasively, Fig. 4). Many simple, commercial monitoring systems can be used to record these signals and to assess the extent of the sleep fragmentation and whether upper airways obstruction is the likely cause. Recent work suggests that these simpler measures can predict sleepiness in obstructive sleep apnoea, and its response to treatment, at least as well as EEG-based approaches, which are clearly not the gold standard they were once thought to be. The attention paid to each signal, and perhaps the exact sleep study system used, will depend to some extent on the condition under investigation. Figure 5 shows data provided by the system in routine use in our laboratory, designed primarily to identify obstructive sleep apnoea and its variants, but it will also identify central sleep apnoea (see below) and non-respiratory problems such as periodic movements of the legs during sleep.

Because of the imprecise relationship between the number of abnormalities on a sleep study and the severity of symptoms, trying to count them exactly is pointless, particularly given that there can be considerable night to night variation. Hence, the reporting of sleep studies tends to be more qualitative than previously, with divisions simply into mild, moderate, and severe. The reporter is essentially trying to see if there is an adequate and understandable explanation for the patient's symptoms.

Treatment

Once it is established that the patient's symptoms are likely to be due to sleep disruption from sleep-induced upper airway obstruction, then therapy has to be tailored to symptom severity.

Mild symptoms may resolve with simple treatments and advice (Table 4). Weight loss is undoubtedly effective, but often very difficult to achieve. If sleep disruption only occurs whilst supine, when upper airway obstruction tends to be worst, then learning to lie on one's side may be helpful. Stopping sedatives and evening alcohol can help. Initial enthusiasm for the tricyclic antidepressants has waned, although they may slightly improve mild cases. They are believed to work through REM sleep suppression and by improving upper airway tone. No other drug has shown any consistent effect.

If symptoms are severe, there is one effective therapy—nasal continuous positive airway pressure (NCPAP). This treatment involves wearing a small mask (Fig. 7) over the nose whilst asleep, kept above atmospheric pressure by a pump. Pressures in the region of 10 cmH $_2$O are enough to splint open the pharynx and resist collapse, allowing unobstructed breathing and undisturbed sleep (Fig. 8). The response is dramatic, in terms of both physiology and daytime symptoms. These resolve rapidly, even after one night of treatment. There are several randomized, placebo-controlled trials proving beyond doubt the symptomatic benefit. The unpleasantness and unaesthetic appearance of this treatment initially repels patients, but once the benefits have been experienced, acceptance is high. Off-the-shelf systems, with comfortable soft masks, are now available for home use at about £300 each. Such equipment will last for years and represents extraordinary value for money given the enormous improvement in patient functioning that they produce. NCPAP machines have recently been introduced that hunt automatically the pressure required by the patient to overcome their obstructive sleep apnoea. These are mainly used in the sleep laboratory as there is no evidence to support their more general use.

Fig. 7 A soft silicone nasal mask and its head gear, used in the treatment of obstructive sleep apnoea.

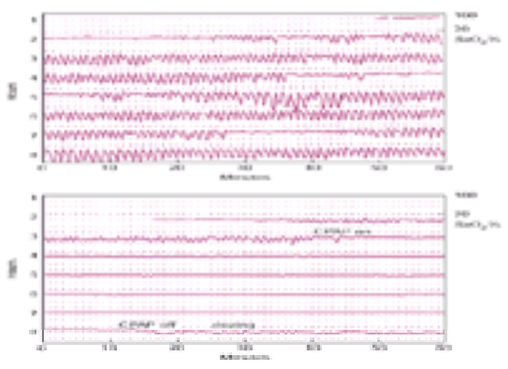

Fig. 8 Two all-night oximetry tracings from a patient with obstructive sleep apnoea, before treatment and during his first night on nasal CPAP. Each tracing starts top left and finishes bottom right. Each tracing is continuous for 8 h with the vertical axis for each individual line scaled 70–100 per cent SaO_2.

Much effort is put into helping patients to become established on NCPAP, through attentive education and comfort-improving measures such as humidification. Once established on NCPAP, a patient with obstructive sleep apnoea is likely to require it for life unless he can lose a significant amount of weight. This may only be achieved through gastric surgery, such as silastic ring gastroplasty to reduce food consumption. Another surgical treatment, whose popularity is decreasing, is uvulopalatopharyngoplasty, which consists of removing part of the soft palate and any residual tonsils, and 'tightening up' the sidewalls of the pharynx. Although it can reduce snoring, its success rate at treating obstructive sleep apnoea is not good: approximately 50 per cent of patients experience a 50 per cent improvement in the number of apnoeas per hour. Attempts to improve the selection of patients have had very limited success, although thin patients with large soft palates, residual tonsils, and milder disease do the best. The operation may have a more significant role in the treatment of snoring-induced arousals than full apnoeas, although this is not established.

Other operative techniques involving advancement of the mandible (and sometimes the maxilla) may be appropriate in highly selected cases. Tracheostomy was the first therapy ever tried and was (of course) very effective. It may still be appropriate in occasional patients.

A newer approach has been the use of mandibular advancement devices, worn in the mouth at night (Fig. 9). These hold the lower jaw closed and forward, thus increasing the space behind the tongue and hence pharyngeal volume. They are undergoing extensive trials in a variety of situations, but the situation is complicated by the plethora of such devices available. The current conclusion is that they do work, but less so as the severity of the obstructive sleep apnoea (and usually therefore the obesity) increase. Their main use currently is in the control of unacceptable snoring.

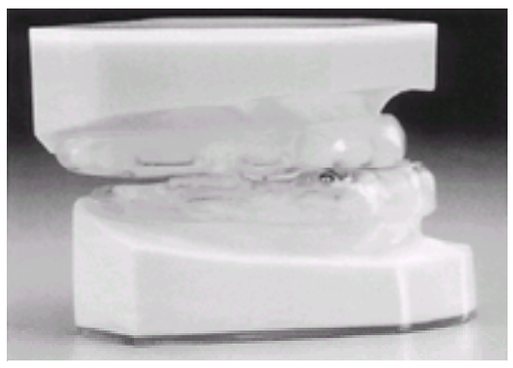

Fig. 9 Example of a mandibular advancement device, worn in the mouth at night. These hold the lower jaw forward and closed, thus increasing pharyngeal dimensions. They are used extensively for the control of snoring but they are not very effective in any more than mild obstructive sleep apnoea.

Epidemiology

Given difficulties over definition, the prevalence of symptomatic obstructive sleep apnoea is hard to establish, and will depend on where an arbitrary cut-off is drawn. In an early study, about 0.3 per cent of men aged 35 to 65 years clearly had severe, symptomatic obstructive sleep apnoea, requiring nasal continuous positive airway pressure (NCPAP) therapy and responsive to such treatment. However, about 5 per cent had more than five dips of more than 4 per cent SaO_2 per hour, one suggested threshold for normality. However, most of these subjects were not obviously symptomatic and would not have wanted a treatment such a NCPAP. Overall in this study, sleepiness correlated with snoring, and more sleepiness seemed to be due to snoring than classical sleep apnoea. Other studies in Israel, the United States, and Italy have found prevalences of 'significant' sleep apnoea in the 0.5 to 2 per cent range.

Predictors of sleep apnoea in these prevalence studies have been obesity, snoring, age, self-reported sleepiness, and alcohol consumption. Snoring is more common in men than women, and obstructive sleep apnoea syndrome itself is about five to ten times more common in men. The prevalence in women probably increases after the menopause with redistribution of body fat to a more male-like, upper body, distribution.

If these prevalence studies are correct, then obstructive sleep apnoea is more common than sarcoidosis and fibrosing alveolitis combined; and every chest physician in the United Kingdom should have about 100 patients on NCPAP.

Prognosis and long-term complications

Although the main reason for treating obstructive sleep apnoea is to relieve the daytime symptoms, mainly sleepiness, there is also limited evidence that these patients have an increased cardiovascular mortality (Fig. 10). Two studies have looked at the long-term survival of patients with treated obstructive sleep apnoea and compared them with some form of untreated control patients. Both found an increased mortality due to cardiovascular events such as myocardial infarction and stroke in the untreated group. The cause of this is not clear and a variety of hypotheses have been advanced. The main problem is that, because a variety of cardiovascular risk factors also contribute to the production of obstructive sleep apnoea (central obesity, smoking, alcohol), it is difficult to identify the real contribution made independently by obstructive sleep apnoea to cardiovascular deaths. Possibilities include sustained hypertension, intermittent nocturnal hypertension, increased catecholamine release, hypoxia-induced cardiac arrhythmias, insulin resistance, hyperlipidaemia, and left ventricular hypertrophy. As yet, most of these risk factors have not been shown to differ between patients with obstructive sleep apnoea and well-matched controls. The exception are the episodic blood pressure rises that occur with each apnoea, a very small increase in diastolic blood pressure (about 2 mmHg), and a small carryover of the raised systolic nocturnal blood pressure into the first few hours of wakefulness (Fig. 4 and Fig. 11). These nocturnal surges in blood pressure may be harmful to the vascular system, and absence of the usual nocturnal fall in blood pressure is said to be a marker of cardiovascular morbidity. Treatment with nasal NCPAP prevents these surges in blood pressure by abolishing the apnoea-induced arousals, and this may be the mechanism by which NCPAP improves mortality in obstructive sleep apnoea, although there are many other possible explanations.

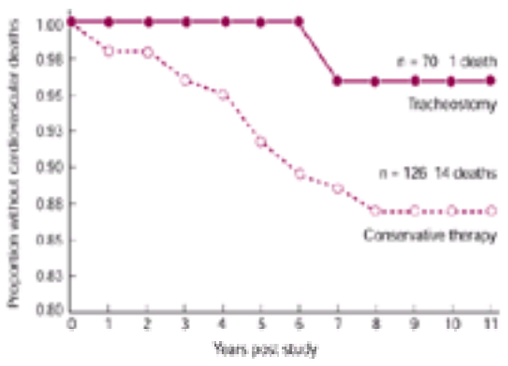

Fig. 10 Long-term survival without a cardiovascular death of 196 patients with obstructive sleep apnoea. The two groups consisted of one with 70 patients who accepted the definitive treatment then available of tracheostomy, and one with 126 patients who declined such therapy and merely attempted weight loss. (Reproduced with permission from C. Guilleminault and M. Partinen (1990). *Obstructive sleep apnoea syndrome*. Raven Press, New York.)

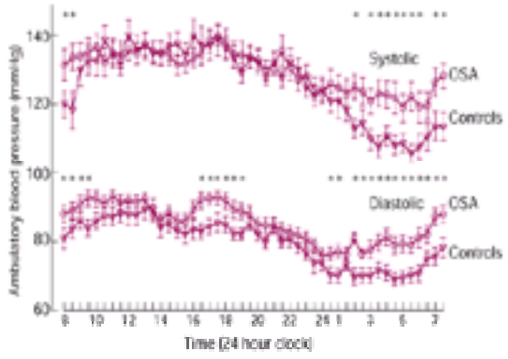

Fig. 11 Twenty-four-h blood pressure records (half hourly) from a group of patients with obstructive sleep apnoea, and individually matched control subjects. The asterisks indicate the times when there were significant differences between the groups. Note the higher systolic and diastolic pressures at night in the patients with obstructive sleep apnoea, with persistence of this into the early morning after awakening, and a generally higher diastolic for much of the day. (Reproduced from Davies C, *et al* (2000). *Thorax*, **55**, 736–40, with permission.)

Nasal CPAP produces a demonstrable improvement in vigilance and sleepiness, which in a randomized, controlled trial was reflected in improved performance on a driving simulator. There is also some evidence that the higher car accident rate in patients falls after treatment. In the 3 years prior to diagnosis, health care utilization by patients with obstructive sleep apnoea, compared to matched controls, is about twice as high. Recent data suggest that this too falls following treatment.

Conclusions

There has been a move away from considering obstructive sleep apnoea to be a condition that one either has or does not have. There is a continuum from light intermittent snoring through to severe, all-night, obstructive sleep apnoea. An analogy can be drawn with hypertension, where there is also a continuum of severity, variability in the measurement, only moderate correlation between the measured abnormality and the physiological consequences, uncertainty over the most relevant way to measure it (one-off versus 24-h blood pressure monitoring), and the target organ damage (e.g. atheroma) may not just be due to the blood pressure. In addition, benefits of treatment have to be weighed against any side-effects. Sleep-induced upper airway obstruction should really be viewed in a similar way.

Sleep-induced hypoventilation and central sleep apnoea

So far we have discussed the sleep-related disorders of breathing that are due to sleep-induced narrowing of the upper airway. Breathing during sleep may also decrease, not because of upper airway obstruction, but because of a reduction in central output to the respiratory muscles—so-called central, rather than obstructive, apnoea (Fig. 3). There are many causes for central sleep apnoea or hypoventilation, and Table 5 shows one way of classifying them. Some of the central apnoeas disturb sleep and present with daytime sleepiness, whereas others tend to present with symptoms of respiratory failure, such as morning headaches with cyanosis and confusion, ankle oedema, and shortness of breath on exertion.

Absent ventilatory drive

Brainstem abnormalities may damage the areas responsible for automatic chemical control of ventilation. Whilst awake, the wakefulness-related ventilatory drive may be adequate to maintain PaO_2 and $PaCO_2$ levels, but on falling asleep, drive falls or even disappears with marked hypoventilation (or apnoea) and hypoxaemia. Arousal is then necessary to restore the blood gases. This failure of brainstem automatic control (known as Ondine's curse) can be congenital, or may be acquired as the result of a stroke, infection, surgical damage, multiple sclerosis, or compression by a tumour or syrinx.

Reduction of chemical drive can occur as a secondary problem when ventilation is reduced by mechanical problems such as chronic airways obstruction or weak respiratory muscles. It appears that chronic underventilation can lead to blunting of ventilatory drive, perhaps through alteration in acid–base buffering in the brainstem, and can also lead to marked falls in ventilation during sleep.

Unstable ventilatory drive

The wakefulness-related ventilatory drive stabilizes ventilation and prevents it from falling below a certain level. If reasons for ventilatory instability exist then, by removing this stabilizing effect, sleep will allow periodic respiration to develop. The usual provoker of instability is an increased drive to breathe. Control theory shows that increasing the gain in any feedback system causes instability through overshoot and undershoot. A good example of this is the hypoxaemia of altitude, which accentuates the response to change in arterial carbon dioxide tension, promoting instability. When sleep occurs there is the usual fall in ventilation. This leads to increased hypoxaemia and a rise in carbon dioxide tension, causing increased ventilation, both provoking arousal. This provides extra awake ventilatory drive, which restores the blood gases, and the cycle repeats. Thus, periodic breathing with recurrent arousals is very common at altitude, with the expected daytime consequence of sleepiness and complaints of insomnia. Acetazolamide produces a metabolic acidosis and increases ventilation overall, the hypoxaemia is relieved, and thus the ventilatory response to carbon dioxide becomes less steep. Both these factors restore stability and reduce periodic respiration.

In left ventricular failure there is also extra ventilatory drive, mainly due to stimulation of interstitial lung receptors by the raised pulmonary venous pressure. In conjunction with the longer circulation time seen in heart failure, this also provokes instability with waxing and waning of the ventilation. This periodic breathing, or Cheyne–Stokes respiration, is quite common in heart failure, and through sleep disruption produces daytime sleepiness and complaints of nocturnal dyspnoea (Fig. 12). The patient is usually aware that on arousal the dyspnoea disappears within a few seconds, unlike the paroxysmal nocturnal dyspnoea of pulmonary oedema which usually takes at least 15 min or so to abate following getting out of bed. Treatment with either overnight oxygen or acetazolamide can sometimes reduce the periodicity and improve both sleep quality and symptoms. There has been some recent interest in NCPAP as a treatment for left ventricular failure and periodic breathing. The mechanism of any action is unknown, and at present the evidence does not justify its general use.

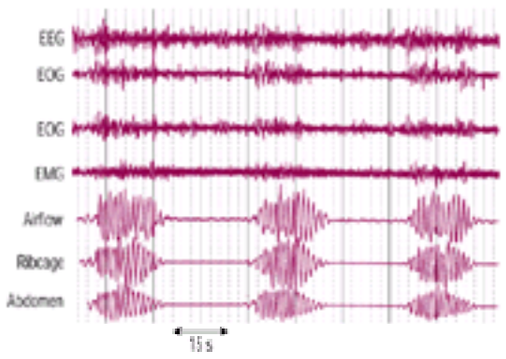

Fig. 12 Tracing of Cheyne–Stokes respiration from a patient with poor left ventricular function but no radiological or clinical evidence of current pulmonary oedema. With each return of respiration there is arousal from sleep (not clearly visible with this compressed EEG tracing).

Instability of respiratory control can also occur in normal subjects in the early stages of sleep or if sleep is disturbed for other reasons. This is because sleep depth is oscillating back and forth between drowsy wakefulness and light sleep, with the ventilatory drive oscillating as well.

REM sleep apnoeas

During normal REM sleep the phasic bursts of eye movements are associated with transient falls in ventilation, and even the occurrence of apnoeas. The rib-cage muscles are affected most, but diaphragmatic excursion can also fall. Such periodicities are entirely normal.

As discussed earlier, the REM sleep inhibition of most muscles (apart from the diaphragm) can greatly reduce overall ventilation when the accessory muscles of respiration are needed for breathing. Thus on entering REM sleep there can be profound falls in ventilation and $Sa\mathrm{O}_2$ in patients with neuromuscular diseases, chest-wall abnormalities, and chronic airways obstruction.

Generalized neuromuscular diseases tend to involve the respiratory muscles in concert with other muscles. However, in some disorders the respiratory muscles, particularly the diaphragm, may be involved very early on, at a time when other muscles are virtually normal. A particular example of this is adult-type acid maltase deficiency, where patients may present in respiratory failure whilst still able to walk normally. REM-sleep-related hypoxaemia may be the first sign that there are problems, and it is not known whether this actually accelerates the onset of eventual diurnal respiratory failure, or is merely a marker that respiratory failure will soon follow. Sometimes there may be associated upper airway obstruction during REM sleep, leading to even larger falls in $Sa\mathrm{O}_2$. Overnight oximetry studies will indicate the degree of hypoxaemia but will not establish if there is additional upper airway obstruction.

There has been great interest in the REM-sleep-related hypoxaemia seen in chronic airways obstruction. It was thought possible that these hypoxic episodes might be the reason why some patients developed respiratory failure but others did not. However, it appears that REM sleep hypoventilation and a fall in $Pa\mathrm{O}_2$ is fairly universal in this group of patients. If the patient is initially well oxygenated and on the flat part of the haemoglobin dissociation curve, the fall in $Sa\mathrm{O}_2$ (which is usually what is monitored) is not particularly dramatic; however, if the patient is initially poorly oxygenated and on the steep part of the curve, similar hypoventilation will produce dramatic falls in $Sa\mathrm{O}_2$. As yet there is no evidence that these REM sleep falls in $Sa\mathrm{O}_2$ contribute to the morbidity and mortality of patients with chronic airflow obstruction, although some centres have shown that overnight oxygen therapy reduces arousals, thus improving sleep quality. The main problem is that the falls in $Sa\mathrm{O}_2$ can look superficially like obstructive sleep apnoea leading to an erroneous diagnosis and the inappropriate use of NCPAP.

Reflex apnoea

Central respiratory output can be modified by a number of reflexes from receptors in the upper airway. There is a reflex from the pharynx that inhibits inspiratory flow when the pharynx is being sucked in and collapsed. This makes teleological sense, as a slowing of inspiratory flow would reduce the tendency to collapse. There are some patients with pharyngeal collapse who, instead of struggling to inspire against the blocked airway, simply stop breathing until they finally arouse, presumably due to the fall in $Pa\mathrm{O}_2$ and rise in $Pa\mathrm{CO}_2$. This then appears as a central apnoea, despite the aetiology being pharyngeal collapse. This tends to happen when the patient is supine, with snoring or ordinary obstructive apnoeas when decubitus. If the pharynx is anaesthetized experimentally, then inspiratory attempts return, suggesting that superficial receptors are responsible. These patients usually present with typical histories of obstructive sleep apnoea, respond to NCPAP, and can be managed in the same way.

Apparent central apnoea

The diagnosis of central apnoea depends on demonstrating the absence of respiratory effort when airflow at the nose and mouth stops. Surface measurements of rib-cage and abdominal movement are usually employed as evidence of continuing respiratory effort. However, in two circumstances, marked obesity and muscular weakness, the surface transducers may fail to register that inspiratory efforts are still being made (although more sensitive measures of inspiratory effort, such as oesophageal pressure tracings, will usually do so). Obesity lessens the sensitivity of surface transducers, and with muscle weakness the inspiratory muscles may not be able to move the chest wall detectably against a closed upper airway.

Overnight ventilation for central sleep apnoea or hypoventilation

The chronic ventilatory failure associated with some neurological disorders (e.g. acid maltase deficiency, postpoliomyelitis syndrome, motor neurone disease, Duchenne dystrophy) usually progress rapidly to death, even when quality of life is otherwise very good. The same is true of chest-wall restrictive disorders such as scoliosis, as well as the ventilatory failure that can develop many years after extensive thoracoplasty. However, supporting breathing overnight can fully reverse ventilatory failure, and the response to treatment can be dramatic, with resolution of all symptoms and restoration of normal blood gases, even when off the ventilator during the day. The mechanism by which supporting breathing at night corrects ventilatory failure is not clear and there are various possibilities. Firstly, it may simply be that the respiratory muscles are rested so that they can respond better to the demands of the respiratory centre during the day. Secondly, it may be that improving the blood gases at night, and preventing the marked REM sleep deteriorations, leads to resetting of the respiratory centre back towards normal, that reverses an acquired blunting of drive. Tricyclic antidepressants such as protriptyline can virtually abolish REM sleep periods and their associated hypoxaemia and have been shown to improve daytime blood gases temporarily, suggesting that simply abolishing these periods of particular hypoxia can help. Thirdly, by increasing chest-wall and lung excursion (tidal volumes in excess of the voluntary vital capacity are sometimes obtained) overall respiratory compliance may improve, allowing the muscles to work more efficiently. Whatever the explanation, there is no doubt that this is a life-saving therapy that in certain conditions can add decades of active life.

Most of the original techniques to support ventilation overnight evolved from the iron lung that was developed to support poliomyelitis victims. Evacuating the air from around the chest expands the lungs, recreating the normal way of breathing. A range of devices involving airtight jackets and shells over the chest were developed, but required much attention to detail and often individual, tailor-made systems. Unfortunately a specific complication, resulted from the abolition of spontaneous ventilatory drive to the diaphragm and pharyngeal muscles, upper airway collapse can occur during the mechanical inspiratory phase and greatly limit efficacy. The recent development of comfortable nasal and face masks has revolutionized the overnight ventilation of these patients. Positive pressure ventilation can be used via a face mask, or more comfortably via the nasal masks used for NCPAP (Fig. 7). Although there are still many problems to be overcome when establishing patients on such equipment (particularly mask comfort and air leaks through the mouth when using nasal masks), the systems can be bought off the shelf ready to use (current cost approximately £3500). Most units now use positive pressure ventilation in preference to the negative pressure systems.

Electrical pacing of the diaphragm is occasionally used for supporting ventilation in conditions where the phrenic nerve and diaphragm are intact and the problem is central. This involves the implantation of bilateral phrenic electrodes and induction coils under the skin that are activated by external induction coils.

Conclusions

Ventilatory failure should not be viewed as a diagnosis. It is a finding that requires a specific explanation. Many of the causes become most obvious at night, when they produce dramatic falls in the level of SaO_2 due to further failure of ventilatory drive mechanisms. Specific treatments aimed at reversing these sleep-related failures of ventilatory drive can produce rapid and satisfactory resolution of symptoms, as well as prolongation of life.

17.9 Bronchiectasis

D. Bilton

Introduction

The definition of bronchiectasis is based on morbid anatomy first described by Laennec, who in 1819 found abnormal chronic dilatation of the bronchi in an infant who died following whooping cough. The word itself is from the Greek *bronchion* (wind pipe or tube) and *ektasis* (stretched out or extension). By 1891 it was recognized in a textbook of medicine that bronchiectasis was 'not a separate disease' but 'a result of various affectations of the bronchi', hence bronchiectasis is not a final diagnosis but a final pathology of a number of causes which may require their own specific treatment.

Prevalence

Up to 1953, estimates of the prevalence of bronchiectasis in the United Kingdom varied from 0.77 to 1.3 per 1000 population, but it seems that the prevalence has since fallen, at least of severe disease, as judged by a reduction in hospital admissions and deaths. This follows the introduction of antibiotic therapy for pulmonary infection, the control of tuberculosis, and effective vaccination for whooping cough and measles. However, the figures quoted may be an underestimate of the true prevalence of bronchiectasis: the diagnosis depends on demonstrating the cardinal feature of abnormal chronic dilatation of one or more bronchi, and it is likely that many people with chronic sputum production are mislabelled as 'bronchitic'. Indeed, recent CT scanning studies of patients with so-called 'chronic bronchitis' suggest that this is the case, and only the application of non-invasive imaging in large community surveys would tell us the true prevalence of the disorder. Bronchiectasis is regarded as a common problem in less developed countries where antibiotics are less readily available, socio-economic conditions are poor, and the prevalence of both tuberculosis and HIV are high.

Pathology

Macroscopic inspection of bronchiectatic lung reveals permanent dilatation of subsegmental airways that are inflamed, tortuous, and often partially or totally obstructed with secretions. The process also includes bronchioles, and at endstage there may be marked fibrosis of small airways. In allergic bronchopulmonary aspergillosis the changes are predominantly in proximal airways. Bronchiectasis caused by cystic fibrosis is likely to be more marked in the upper lobes. There is a spectrum of disease that ranges from cylindrical, where there is uniform dilatation, to saccular, where there may be gross terminal dilatation of the bronchi (saccules or cyst). An intermediate form is termed varicose bronchiectasis.

Microscopic features

The overall appearance is of chronic inflammation in the bronchial wall with inflammatory cells and mucus in the lumen. There is destruction of the elastin layer of the bronchial wall with a variable amount of fibrosis. Neutrophils are the main cell population in the bronchial lumen, whereas the commonest cells in the bronchial wall are mononuclear. The label follicular is applied when there is lymphoid follicle formation as part of extensive mural inflammation, which in subepithelial sites may cause finger projections blocking the bronchial lumen.

Aetiology and pathogenesis

There is a broad spectrum of causes and underlying conditions associated with bronchiectasis. These are summarized in Table 1.

The pathogenesis of bronchiectasis requires the combination of an infective insult with impaired clearance mechanisms that may result from local obstruction, impaired local structural defences, or defective immune defences. This is supported by work in animal models, which also show that the infection must be active, with damage to the airway wall occurring as a result of direct microbial insult or the secondary effects of the host inflammatory response.

The term 'vicious cycle' has been proposed to explain the development of bronchiectasis in a predisposed individual following a trigger insult, as shown in Fig. 1, which also demonstrates the key role played by neutrophil elastase. Neutrophils are recruited as part of the natural defences, but the inflammation is not self-limiting and in patients with bronchiectasis neutrophils persist in the airway secretions, with free neutrophil elastase activity usually present. Elastase, a neutrophil-derived serine proteinase, is known to inhibit ciliary beating, damage epithelia, act as a mucus secretagogue, and inhibit opsonophagocytosis via cleavage of immunoglobulins. All these actions contribute to persistence of bacteria in the respiratory tract and long-term tissue damage. Figure 1 illustrates that whenever a patient enters the pathway, for example in primary ciliary dyskinesia (which inhibits mucociliary clearance), or with immunoglobulin deficiency (which favours persistence of microbes in the bronchial tree), the vicious cycle becomes self-perpetuating with the final outcome of airway damage.

Fig. 1 The vicious cycle of infection and inflammation leading to progressive tissue damage in bronchiectasis.

Developmental defects

The congenital forms of bronchiectasis frequently show deficiency of elements of the bronchial wall that are necessary to prevent collapse and hence 'obstruction' of the airway. In Williams–Campbell syndrome there is deficiency of the bronchial cartilage. The Mounier–Kuhn syndrome or tracheobronchomegaly is the 'adult equivalent' of congenital deficiency of bronchial cartilage. Pulmonary sequestration predisposes to bronchiectasis because of decreased pulmonary clearance of the affected segment.

Mechanical obstruction

Bronchiectasis confined to a single lobe may be the result of local mechanical obstruction, either in the lumen (intrinsic), for example by a tumour or foreign body, or originating outside the lumen (extrinsic), for example by lymph node enlargement from tuberculosis or a tumour.

Disorders of mucociliary clearance

The disease cystic fibrosis provides the archetypal model of a genetic predisposition for the development of bronchiectasis. In this disorder (described in Chapter 17.10) there is dysfunction of the cystic fibrosis transmembrane regulator, a transmembrane chloride channel and ion transport regulatory protein. The resulting abnormal salt and water transport across respiratory epithelia predisposes to respiratory infection and the effects of the vicious cycle are clearly demonstrated as a structurally normal lung suffers progressive airway damage and the development of bronchiectasis.

Primary ciliary dyskinesia describes a group of inherited disorders in which mutation of several different genes may give rise to non-functional cilia. It is generally considered to be an autosomal recessive disorder with variable penetrance. The diagnosis is made by demonstrating abnormality of the cilia on electron microscopy. In the largest subgroup of this syndrome, and the form first described, the cilia lack dynein arms, which are the structures responsible for movement of cilia or spermatozoa. Subsequently it has been appreciated that a variety of components of the cilia are affected.

The intriguing observation that about 50 per cent of all subjects with immotile cilia syndrome have situs invervus is true for most subgroups, apart from those who have absent cilia or those whose main characteristic is lack of the two central microtubules. When ciliary dyskinesia is associated with abnormal situs the condition is labelled Kartagener's syndrome after the paediatrician who described four patients with the association of dextrocardia, sinusitis, and bronchiectasis in 1933.

Young's syndrome seems to represent an acquired defect of mucociliary clearance in which obstructive azoospermia is associated with sinusitis and bronchiectasis. The condition may occur after a man has successfully fathered a child, and may be associated with mercury poisoning from 'tooth powders' used in infancy (Pink's disease).

Secondary ciliary dyskinesia refers to the situation in which cilia are intrinsically normal but ciliary beating is reduced because of toxic damage from neutrophil or bacterial products. Tobacco smoke and other environmental pollutants have also been implicated in reducing ciliary beat frequency.

Postinfective bronchiectasis

The true incidence of postinfective bronchiectasis is difficult to establish because studies have been retrospective, relying on histories obtained 'second hand' from parents. The micro-organisms known to cause infection likely to progress to bronchiectasis are *Bordetella pertussis*, measles virus, adenoviruses, *Trypanosoma cruzi*, and *Mycobacterium tuberculosis*.

As mentioned above, the pattern of bronchiectasis has changed since the introduction of vaccinations and widespread availability of antibiotics in the developed world. A population with cylindrical bronchiectasis has superseded the gross saccular bronchiectasis associated with severe repeated childhood respiratory infections in the pre-antibiotic era. This may be associated with a childhood history of a chesty cough, with a long period of remission of symptoms through the teens and twenties, followed by the onset of symptoms of productive cough of purulent sputum and/or sinusitis in the third or fourth decade of life. Some of these patients may report having whooping cough or measles in childhood, but it is not appropriate to label them as postinfective unless symptoms have been persistent, without remission since childhood.

Immune deficiency

Immune deficiency is an important cause of bronchiectasis because treatment with intravenous immunoglobulin (where appropriate) will correct the defect and should prevent progression of disease.

Bronchiectasis presenting in childhood should trigger an extensive assessment of phagocytic and cellular immune defences. The rare disorder, X-linked hypogammaglobulinaemia, presents early in life and bronchiectasis is a frequent complication if untreated.

Adult-onset acquired panhypogammaglobulinaemia frequently presents with recurrent respiratory infection and is complicated by bronchiectasis if untreated. Selective deficiencies of IgG and IgM, and of IgG subclasses, are also treatable causes of bronchiectasis. Moreover, functional antibody deficiencies and failure to mount and maintain adequate responses to antigen challenge (for example pneumococcal vaccine) may be present despite normal total immunoglobulins, hence subtle humoral deficiency, a treatable cause of bronchiectasis, can be easily missed.

Immune defects may be secondary to malignancy or be related to treatment with immunosuppressive agents. Bronchiectasis is now a recognized complication of HIV disease.

Excessive immune response

Figure 1 illustrates the mechanism by which damage may occur as a result of the host response to chronic airway infection. Allergic bronchopulmonary aspergillosis is a condition in which the excessive reaction to a 'non-infecting' organism seems to be the major factor in producing the associated characteristic proximal upper lobe bronchiectasis. The appearance of obliterative bronchiolitis and subsequent bronchiectasis in lung transplant rejection further highlights the role of a damaging immune response in the development of bronchiectasis.

Toxic insult

In some patients there is a clear history of an inhalation accident or exposure to hot gases, for example in a fire victim. Aspiration of gastric contents is another

important cause of bronchiectasis insomuch as treatment to prevent aspiration will prevent further airway damage.

Associated conditions

The association of rheumatoid arthritis with bronchiectasis is well recognized. Treatment of bronchiectasis in patients with rheumatoid arthritis can be difficult, reflecting the need to achieve the right balance of immunosuppression, which helps the underlying inflammatory disease process but can simultaneously impair antimicrobial defences. The association of inflammatory bowel disease with bronchiectasis also highlights the issue of immunosuppression: some patients with both conditions report an improvement in chest symptoms when they take systemic corticosteroids for flares of inflammatory bowel symptoms.

Rhinosinusitis

About 80 per cent of patients with bronchiectasis have upper respiratory tract symptoms, with postnasal drip being the most common problem. Some 30 per cent of patients have chronic sinus sepsis, with fewer having recurrent ear infections. In ciliary dyskinesia, however, ear infections are almost invariably present.

Idiopathic bronchiectasis

The underlying cause of bronchiectasis remains unknown in 40 to 60 per cent of patients, even in specialist bronchiectasis clinics.

Clinical features

History

Bronchiectasis should be suspected when there is a history of persistent cough productive of mucopurulent or purulent sputum throughout the year. Patients have frequently been treated for recurrent chest infections and labelled as 'bronchitic', often despite the absence of a history of smoking.

Patients may produce mucoid sputum early in their disease, developing purulent sputum when they suffer an exacerbation associated with viral upper respiratory tract infection. Such exacerbations may be associated with pleuritic chest pain, haemoptysis, fever, and sometimes wheeze. Those presenting as adults often recall a 'chesty cough' or 'wheezy bronchitis' associated with upper respiratory tract infections in childhood, followed by complete resolution of symptoms in the teens and early adult life before these return after a viral trigger. Upper respiratory tract symptoms such as postnasal drip are common, and in about 30 per cent of cases there is a history of chronic sinusitis.

Patients with bronchiectasis also suffer from undue tiredness, which many find more troublesome than the productive cough.

Examination

Severe 'classic' cases of bronchiectasis seen in the pre-antibiotic era or in less developed countries are associated with obvious clinical signs including finger clubbing and widespread course crackles. Nowadays it is much more likely for clinical examination to be normal. The absence of clubbing or lung crackles does not exclude bronchiectasis.

Investigation

Radiological imaging

The chest radiograph may be normal in at least 50 per cent of patients with CT or bronchographic evidence of bronchiectasis. If it is abnormal the findings relate to thickened and dilated bronchi, which produce tram-line opacities and ring shadows. Retained mucus may be seen as tubular opacities, and there may be associated volume loss of the affected lobe.

The gold standard for the diagnosis of bronchiectasis is thin section, high-resolution CT (**HRCT**) of the chest, which has replaced the more invasive investigation of bronchography. The diagnostic criteria for bronchiectasis on HRCT depend on finding both dilatation and thickening of the affected bronchi, dilatation being present if the internal diameter of the bronchus is greater than the diameter of its accompanying pulmonary artery. The classic appearance of a cross-section of a thick-walled dilated bronchus next to the accompanying pulmonary artery is the 'signet ring' sign, as shown in Fig. 2. Bronchial dilatation is also recognized when airways are seen in longitudinal section on CT and there is a failure of tapering as the bronchus courses towards the periphery.

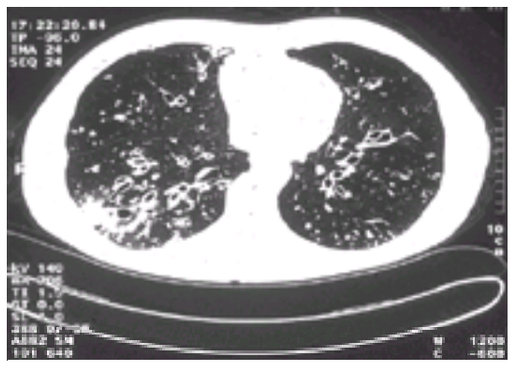

Fig. 2 CT scan of patient with bronchiectasis showing characteristic signet-ring sign.

There is a morphological spectrum of bronchiectasis, with cylindrical bronchiectasis forming one group, cystic or saccular bronchiectasis at the other end of the spectrum, and an intermediate group termed 'varicose' bronchiectasis. The CT appearances of this spectrum are well described. In cylindrical bronchiectasis there is uniform dilatation of the bronchi as they extend towards the periphery. By contrast, varicose bronchiectasis produces a beaded appearance, best shown when bronchi are imaged in the plane of the scan. Cystic bronchiectasis is recognized by rings representing markedly dilated bronchi, which may be clustered together and may contain air–fluid levels.

In addition to defining the extent of bronchiectasis, CT scanning may suggest the need for a bronchoscopy; for example if there is a bronchial obstruction, perhaps due to a foreign body or tumour.

Other tests

Once HRCT has proved the presence of bronchiectasis, investigations are directed towards defining the status of the disease and at attempting to establish an underlying cause. Table 2 highlights the minimum required to assess the current state of disease. Examination of a sputum specimen is crucial, it being important to document its character—mucoid or purulent—and to determine the colonizing organism, typical organisms being non-typeable *Haemophilus influenzae*, *Moraxella iatarrhalis*, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa. H. influenzae* is the most common (40 to 60 per cent). *P. aeruginosa* is usually associated with worsening symptoms and more severe lung disease. (See Chapter 17.3.3 for further information on the microbiological investigation of patients with lung disease.)

As the sputum microbiology may alter over time it is helpful to obtain repeated samples to ensure that an appropriate antibiotic management plan is in place. Measurement of inflammatory markers allows an assessment of the patient's current 'inflammatory burden'. Many have come to accept persistent purulent sputum over a period of time and may not complain of being particularly unwell. A raised erythrocyte sedimentation rate and/or C-reactive protein would weight the argument

in favour of early antibiotic intervention.

Table 3 outlines the investigations required to tie down a cause of bronchiectasis, some of which will then require specific treatment, for example immunodeficiency. Allergic bronchopulmonary aspergillosis is an important treatable cause: corticosteroid therapy produces substantial improvements in symptoms and well being, restores lung function, and prevents the development of further bronchiectasis. Similarly, the appreciation that chronic aspiration is the precipitant of lung damage can lead to appropriate therapeutic manoeuvres aimed at prevention of further damage.

Cystic fibrosis/bronchiectasis overlap

The diagnosis of cystic fibrosis should be considered in any patient with unexplained bronchiectasis, but particularly in the presence of upper lobe bronchiectasis, colonization with *Staphylococcus aureus* and *Pseudomonas aeruginosa*, or male infertility. A normal sweat test no longer excludes a diagnosis of cystic fibrosis as mutations occur which produce mild disease and a normal sweat test. If doubt exists, then the patient should be referred to specialist centre for further investigation (see Chapter 17.10).

Management

The principles of management of bronchiectasis are outlined in Table 4. The medical approach is two-pronged, with close attention given to treatment of any underlying cause whilst also treating the established bronchiectasis.

Sputum clearance

Since mucociliary clearance is reduced in bronchiectasis it seems sensible to aid sputum clearance by employing physiotherapy. Physiotherapy does not simply prevent mucus retention, but also allows a patient to expectorate sputum at a chosen convenient time rather than coughing throughout the day or night. There are no controlled trials to prove or disprove its usefulness in terms of disease modification or survival.

The use of mucolytics in bronchiectasis is controversial. The success of recombinant human DNAase in cystic fibrosis was not repeated in bronchiectasis that was not due to cystic fibrosis, when patients did not derive benefit in terms of lung function. A recent Cochrane review concluded that there is insufficient evidence to evaluate the routine use of mucolytics for bronchiectasis.

Antimicrobial therapy

There are two approaches to the use of antimicrobial therapy in bronchiectasis. The first involves the treatment of acute exacerbations. The second is based on the vicious cycle hypothesis, suggesting that chronic targeted antimicrobial therapy should reduce bacterial numbers, thereby reducing the host response and hence the potential for further lung damage. Whilst the latter approach has theoretical merits it has not been proved to be better than the former in randomized controlled trials.

In practice, the modern approach to antimicrobial treatment in bronchiectasis has been derived from regimens used in cystic fibrosis, which have yielded impressive improvements in survival (see Chapter 17.10). This depends on knowledge of a patient's colonizing organism, but there are some issues that apply regardless of the bacterial species. First, high doses of antibiotics are often required. These are necessary to penetrate scarred, thickened bronchial walls and the tenacious secretions that act as a physical barrier to antibiotic penetration to the microbes, which may also be harbouring drug-inactivating enzymes such as b-lactamases. Second, to avoid a high oral dose of an antibiotic that may result in unacceptable side-effects, the nebulized or parenteral route may be employed to achieve high levels of drug in the bronchial wall and secretions. Third, to determine the best treatment regimen for a patient it is worth assessing their initial response to an agent appropriate for the colonizing organism and then assessing the rapidity of return of purulent sputum. If purulent sputum becomes mucoid after a 14-day course of oral antibiotics and remains mucoid until the next viral trigger, then one is likely to recommend 'exacerbation only' treatment. However, if sputum returns to purulent within a few days of treatment finishing, then it is likely that chronic suppressive therapy will be required.

Figure 3 suggests an approach to the treatment patients with bronchiectasis depending on the characteristics of their sputum and the colonizing organism, but it must be pointed out that there has not been a systematic study of the benefits of this approach in the management of this condition.

Fig. 3 Guide to therapy for patients with bronchiectasis.

Bronchodilator therapy

Patients with bronchiectasis can have a restrictive or an obstructive picture. Some may have significant reversibility, and it is therefore worth assessing each individual for their response to b_2-agonists and anticholinergic agents.

Anti-inflammatory therapy

The vicious cycle hypothesis would suggest that the addition of anti-inflammatory therapy to antibiotics should be of benefit in patients with bronchiectasis. In cystic fibrosis, trials of oral corticosteroids have shown significant benefit in terms of lung function. Short-term trials of inhaled corticosteroids have been carried out in bronchiectasis, but evidence supporting long-term use (summarized in a Cochrane review) is limited and further trials are required. However, a trial of oral steroids is warranted whenever there is reversible airflow obstruction: if there is a documented improvement in lung function after a 2-week course, then introduction of inhaled steroids is justified.

Monitoring response to treatment

As each patient requires a tailored management plan it is critical that both the patient and physician agree defined criteria for assessing response. Measurement of lung function clearly produces an objective measure of response to corticosteroids, whereas the introduction of antibiotics may not alter lung function to a great degree but does improve sputum colour, volume, and consistency, and may also produce improvement in general well being. Studies have confirmed the validity of grading sputum colour as a marker of the microbial and inflammatory load in these patients, and diary cards documenting these parameters have proved helpful. This approach also facilitates patient education and self-management plans.

Surgery

Surgery represents the only 'curative' treatment for a select group of patients and should be carefully considered. Resection of bronchiectatic areas of lung was common in the pre-antibiotic era and provided a successful treatment at the time. Physicians' judgment regarding surgery may be unduly coloured by the bias of

patients returning to chest clinics with a recurrence of symptoms some years after resection, and the finding of bronchiectasis in other areas of the lung on CT scanning. These patients highlight the need for full assessment of the extent of bronchiectasis and a careful search for an underlying cause. If bronchiectasis is isolated to a single lobe and is the result of a localized obstruction, then surgery provides a cure and removes the need for lifelong treatment. However, surgery is unlikely to effect a cure if bronchiectasis is present in several lobes, and lobar resection is only indicated in two instances. First, if there is uncontrolled bleeding unresponsive to bronchial artery embolization. Second, if it is felt—after failure of aggressive antimicrobial therapy—that a particular lobe is acting as a 'sump' of infection which prevents good control of symptoms with medical therapy.

Lung transplantation

Lung transplantation provides an effective treatment for endstage bronchiectasis providing an underlying cause has been carefully assessed, treated, and is unlikely to jeopardize the transplanted organs. Patients with immunoglobulin deficiencies are not discounted from transplant assessment providing they are receiving adequate immunoglobulin replacement therapy. (See Chapter 17.16 for further discussion.)

Complications

Infective exacerbations are the most common complications to precipitate hospital admissions in patients with bronchiectasis. It is not common for patients to experience chest pain localized over an area of bronchiectasis, which may become pleuritic in nature during an infective exacerbation. Massive haemoptysis is rare nowadays: it is managed by embolization or, if that fails, by resection of the affected lobe. Minor haemoptysis is a common occurrence associated with infective exacerbations. Metastatic spread of infection rarely occurs in the developed world with good control of pulmonary infection with antibiotics. For similar reasons empyema is now very rare. Amyloidosis is often quoted as a classic complication of bronchiectasis, but is now extremely rare in the United Kingdom. Arthropathy is seen as a complication of bronchiectasis: this seems to flare in association with the chest disease, when active antimicrobial treatment will often result in remission of joint pain. Some patients may suffer vasculitic skin lesions in association with flares of bronchiectasis.

Prognosis

It was reported in 1940 that 70 per cent of 400 patients with bronchiectasis were dead before the age of 40. The situation is clearly different now: in the developed world we do not see the florid postinfective saccular type of bronchiectasis, but more commonly see patients presenting in their fourth and fifth decade of life with symptoms developing after a trigger illness and CT findings of cylindrical bronchiectasis. In 1981 a study following 116 patients for 14 years revealed that 20 per cent of patients treated medically and 17 per cent of surgically treated patients died at a mean age of 53 years. A Finnish study published in 1997 used the national hospital discharge register from 1982 to 1986 to identify newly diagnosed cases of bronchiectasis: 842 such patients were age and sex matched with individuals with chronic obstructive pulmonary disease or asthma discharged at the same time. Over a 10-year follow-up the prognosis for those with bronchiectasis was better than for those patients with chronic obstructive pulmonary disease, but poorer than that for patients with asthma. Bronchiectasis was the main cause of death in 13 per cent of the patients with this condition.

Further research

Further studies are required to identify the major factors that affect prognosis. For example, chronic colonization with *Pseudomonas* sp. may be a bad prognostic factor, but this may be negated by aggressive antimicrobial therapy. Study of homogeneous groups of patients (with respect to aetiology and colonizing organisms) should help assess various management regimens with regard to their effect on decline in lung function and survival. It is likely that a careful search for genetic factors that affect lung defences will yield new causes of bronchiectasis and allow the current so-called idiopathic group to be assigned a cause. We may then be able to define an at-risk population and aim to prevent development of bronchiectasis.

17.10 Cystic fibrosis

Duncan Geddes and Andy Bush

Definition

Cystic fibrosis is a recessively inherited disease caused by mutations in the cystic fibrosis gene located on the long arm of chromosome 7. The classical clinical picture is a combination of pancreatic insufficiency, suppurative lung disease, and high sweat sodium concentration, presenting in childhood and progressing to early death from respiratory failure. However, genetic analysis has identified many patients with less severe disease and cystic fibrosis mutations are also associated with male infertility and idiopathic pancreatitis, so expanding the clinical spectrum of cystic fibrosis lung disease. In general, carriers are healthy.

The genetic defect

The cystic fibrosis gene codes for a 168-kDa membrane protein named the cystic fibrosis transmembrane regulator protein (CFTR). CFTR is primarily an ATP responsive chloride channel but it also influences other cellular functions such as sodium transport across the respiratory epithelium, cell surface glycoprotein composition, and normal antibacterial defences. The protein is expressed in organs involved in cystic fibrosis disease—lungs, pancreas, sweat gland, etc.—but also in some places that do not seem to be affected clinically, such as the choroid plexus, heart, and renal tubules.

More than 900 disease-related mutations of the cystic fibrosis gene have been described. Their distribution in relation to the cystic fibrosis gene and its related protein are shown in Fig. 1. The mutations have been classified according to their impact at a cellular level—type 1: no protein; type 2: disordered trafficking; type 3: defective regulation; type 4: defective channel function; type 5: reduced protein synthesis. The understanding of these abnormalities is valuable as a basis for the design of new potentially corrective treatments, as illustrated in Fig. 2.

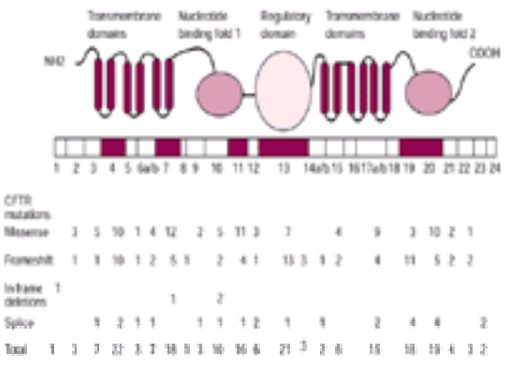

Fig. 1 Distribution of mutations within different regions of the CFTR gene. (Reproduced from Santis G. Basic molecular genetics. In: *Cystic fibrosis* (ed. Hodson ME,

Geddes DM), p. 25. Chapman and Hall, London, with permission.)

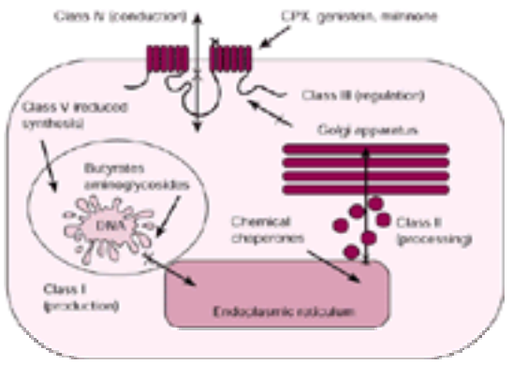

Fig. 2 Five categories of cystic fibrosis mutation with possible corrective treatments. (Reproduced from Rosenstein BJ, Zeitlin PL (1998). Seminar on cystic fibrosis. *Lancet*, **351**, 278, with permission.)

Most mutations are very rare; the commonest in European populations is †F508 which is found on 70 per cent of affected chromosomes. Most genetic laboratories restrict routine testing to the commonest six to eight mutations which account for over 90 per cent within a given population. Genotype–phenotype correlations have shown linkage of so called severe mutations, such as †F508, to pancreatic insufficiency and a tendency to more severe lung disease, while mild mutations go with pancreatic sufficiency and a tendency to less severe lung disease. However, in general, the correlation between genotype and the severity of lung disease is poor. All disease-associated mutations are linked with congenital absence of the vas deferens, resulting in male infertility, while rarer mutations are linked with isolated male infertility with no other evidence of cystic fibrosis disease.

Pathogenesis

Sweat duct

The primary secretion of the sweat duct is normal in volume and electrolyte concentration. However, as this secretion passes along the sweat duct mutant CFTR fails to absorb chloride ions, which therefore remain in the lumen and secondarily impair sodium absorption. The resultant sweat has high concentrations of both sodium and chloride which is useful for diagnosis but can lead to salt depletion in hot weather.

Pancreas

The synthesis and secretion of pancreatic enzymes in the acinus is normal, but disordered ion transport—primarily chloride and secondarily bicarbonate—results in relative dehydration of pancreatic secretions. This in turn leads to low flow and stagnation of secretions in the pancreatic ducts with subsequent autodigestion. The clinical consequences are that low volumes of bicarbonate-depleted pancreatic secretions reach the duodenum, with consequent malabsorption and progressive destruction of the pancreas with cyst formation. Although the islet cells are relatively unaffected at first, they too are progressively destroyed leading to insulin deficiency.

Biliary tract

Intrahepatic biliary secretions are probably normal in cystic fibrosis, but disordered electrolyte transport across the bile duct results in reduced water movement into the lumen. The bile is therefore concentrated, and the volume depleted, leading to plugging and chronic local damage. This eventually causes biliary cirrhosis and associated extrahepatic biliary stenoses. There are secondary changes in bile acids.

Gut

Gastric secretions have decreased volume with increased viscosity and sodium levels. The chloride transport defect similarly leads to altered fluid movement across large and small intestine. These changes are worsened by the addition of dehydrated biliary and pancreatic secretions, as well as by alterations in the osmotic load in the lumen secondary to pancreatic exocrine failure. The resulting deficiency of intraluminal water contributes to meconium ileus in neonates and the distal intestinal obstruction syndrome in adults.

Respiratory tract

The epithelium in the nose, paranasal sinuses, and intrapulmonary conducting airways is disordered in cystic fibrosis, while alveolar function is normal. Defective chloride transport is associated with increased sodium absorption from the lumen. This has two important consequences. Firstly, net surface electrical charge is altered from a normal of –20 mV to cystic fibrosis levels of –40 mV, which can be used for diagnosis. Secondly, increased sodium absorption takes water with it and dehydrates the airway surface liquid, reducing mucociliary clearance and favouring bacterial colonization. In addition, local antibacterial defences—including lactoferrin, lysozyme, and the cationic antibacterial peptides such as the b-defensins—may be impaired by local changes in salt concentration, and bacterial adherence to epithelial cells is increased by changes in cell surface glycoproteins. The net effect is to promote bacterial colonization and to reduce bacterial clearance, with subsequent inflammatory lung damage.

One consequence of bacterial colonization of the lower respiratory tract is an exuberant neutrophilic inflammatory response involving especially interleukin-8 (IL-8) and neutrophil elastase. The combination of elastase and other inflammatory mediators, while initially providing a useful antibacterial defence, is thought to contribute to lung damage and speed the progression of bronchiectasis and small airway narrowing.

Heterozygote advantage

The high frequency of the carrier rate in European populations (1:25) has led to a number of suggested advantages for the carrier, none of which are proven. These range from reduced susceptibility to infections such as cholera (reduced gut chloride secretion) and typhoid (reduced ingestion of bacteria by gut epithelium) to increased fertility among cystic fibrosis carriers.

Epidemiology

Genotype

The prevalence and distribution of the 900 disease-related mutations in the cystic fibrosis gene vary with ethnic origin. †F508 is commonest in northern European populations, accounting for 82 per cent of cystic fibrosis chromosomes in Denmark but only 32 per cent in Turkey. The W1282X mutation is common in Ashkanazi Jews (48 per cent of cystic fibrosis chromosomes) but rare in other populations. All disease-associated mutations are rare in African and almost unknown in Chinese populations.

Phenotype

Birth incidence varies with country of origin from 1:2000 to 1:100 000 as listed in Table 1. Prevalence figures are few and less reliable. In the third world, cystic

fibrosis is likely to be under-diagnosed since early childhood malnutrition, diarrhoea, and chest infections are so common. There are at least 6000 people in the United Kingdom and 30 000 in the United States with cystic fibrosis and numbers are increasing along with life expectancy.

Survival

From 1938 to 1960, most children with cystic fibrosis died before the age of 10. Since 1968, the first year mortality (chiefly from meconium ileus) has fallen from 18 per cent to 4 per cent and survival curves are linear thereafter, showing progressive improvement over succeeding decades. In 1986, the median survival was 25 years and in 1999 about 30 years. Cohort survival analysis shows continuing improvement and estimated survival for a child born with cystic fibrosis in the late 1990s is 40 to 50 years. Age specific mortality rates for females are a little worse then males, although this difference is narrowing and the world record for both sexes is now over 70 years.

Microbiology

People with cystic fibrosis have no detectable immune deficiency and, except for the respiratory tract, have no increased susceptibility to infection. The lungs show evidence of inflammation very early in childhood and thereafter become chronically colonized, characteristically by *Staphylococcus aureus* and *Haemophilus influenzae*, followed some years later by *Pseudomonas aeruginosa*. Many other organisms have been implicated, especially in advanced disease, including *Burkholderia cepacia* and *Stenotrophomonas maltophilia*. *Aspergillus fumigatus* is frequently isolated, but is associated with allergic rather than invasive disease, and atypical mycobateria are occasionally found. Viral, chlamydial, pneumococcal, and other respiratory infections are not more common or severe in cystic fibrosis, but the consequences of these infections may be more important in the damaged and permanently colonized cystic fibrosis lung. The microbiology of the nose and sinuses is the same as for the lung, but the clinical consequences are usually less important.

Staphylococcus aureus

This is the commonest colonizing organism in childhood, with a prevalence of over 50 per cent in children aged 0 to 9. The predeliction of *Staph. aureus* for cystic fibrosis lungs has been ascribed to high electrolyte content of airway surface liquid or enhanced retention in the airways. No phage type predominates and the organism usually remains sensitive to flucloxacillin in spite of prolonged antibiotic treatment. Resistance to tetracycline or erythromycin is relatively common but multiple antibiotic resistance is rare. The prevalence falls in adult life when *Pseudomonas aeruginosa* colonization predominates.

Pseudomonas aeruginosa

This is the commonest colonizing organism after the age of 10 years, with reported prevalence varying between 40 and 80 per cent. Enhanced adherence to cystic fibrosis airways promotes colonization but prior antibiotic treatment may play a part. No particular phage type predominates, but siblings with cystic fibrosis often carry the same type, and environmental sources have been identified in cystic fibrosis centres, dentistry equipment, hydrotherapy pools, and nebulizers. After some months or years of colonization, *Pseudomonas aeruginosa* produces mucoid alginate as a protective biofilm and the organisms live in mucoid microcolonies. This mucoid variant is associated with a worse prognosis and greater antibiotic resistance. Most colonizing *Pseudomonas aeruginosa* are sensitive to antibiotics at first but over the years and in associated with antibiotic treatment multiple resistance to most antibiotics (except colomycin) develops.

Haemophilus influenzae

Non-capsulated *H. influenzae* is a relatively frequent colonizing organism with prevalence of up to 30 per cent, although it may not be isolated due to over-growth of *Staph*. or *Pseudomonas*. Antibiotic resistance is seldom a problem.

Burkholderia cepacia

The overall prevalence of this organism is low, at 3 to 5 per cent, but it poses a particular problem due to occasional cross-infection with a virulent epidemic form that can cause rapid deterioration in patients previously only mildly affected. More usual is chronic asymptomatic carriage or progressive deterioration in the late stage of lung disease. Multiple antibiotic resistance is characteristic.

Diagnosis

Introduction

A consensus document on diagnostic criteria for cystic fibrosis has recently been published. The vast majority of patients with cystic fibrosis can be diagnosed by a sweat test (more than 98 per cent of 19 992 in the United States Cystic Fibrosis Foundation Registry). The occasional patient, particularly with a mutation giving rise to a mild or atypical clinical phenotype, may require more sophisticated testing. However, the major difficulty is usually not in confirming the diagnosis but in thinking of it in an appropriate context (below, and Table 2). Conversely, false positive diagnoses are not rare, and a new referral of a cystic fibrosis patient to the adult clinic should prompt a full review of the diagnosis.

Presenting features

The various age-related problems that can lead to a diagnosis of cystic fibrosis are given in Table 2. Paediatric presentations are relevant to adult life in that if an adult with atypical respiratory disease turns out to have a family history of a child with cystic fibrosis or an illness shown in Table 2, then cystic fibrosis should be considered in the adult. The new diagnosis of cystic fibrosis in a younger relative will also prompt cascade screening (below), usually aiming to discover carriers, but occasionally someone with a clinically mild cystic fibrosis phenotype is discovered. The United States Cystic Fibrosis Foundation Registry data show that as many as 10 per cent of cystic fibrosis patients are not diagnosed until adult life.

Less than 5 per cent pancreatic function is necessary for normal digestive function, and those presenting with cystic fibrosis in adult life are clinically pancreatic sufficient. The main presentation is with respiratory problems, usually recurrent lower respiratory infections with chronic sputum production. Some patients have prior a diagnosis of bronchiectasis, atypical asthma, nasal polyposis, or allergic bronchopulmonary aspergillosis. A new cystic fibrosis diagnosis has been described even in adults in their seventh decade. Depletion of sodium, chloride, and potassium due to excessive sweating, and secondary renal chloride retention, may result in presentation with dehydration and heat exhaustion in an otherwise apparently completely fit adult.

Another important mode of presentation is male infertility due to azoospermia because of congenital bilateral absence of the vas deferens (CABVD). CABVD exists in different forms: firstly, in association with congenital malformations of the upper urinary tract, in which case there is no increased incidence of cystic fibrosis mutations; secondly, as part of classical cystic fibrosis; and thirdly, as a truly isolated forme fruste of cystic fibrosis, with only a single cystic fibrosis mutation and ion transport abnormalities overlapping with, but different from, true cystic fibrosis. Portal hypertension secondary to macronodular cirrhosis in adult life may also be the first presentation of cystic fibrosis.

There is considerable debate as to the status of adults with single organ manifestations characteristic of, but not confined to, cystic fibrosis—for example pancreatitis or allergic bronchopulmonary aspergillosis. Some series report a higher than expected incidence of cystic fibrosis mutations, and the occasional unsuspected cystic fibrosis compound heterozygote. In practice, although cystic fibrosis should be excluded as far as possible by appropriate investigations in the patient with a possible single organ disease, most will not have the traditional clinical cystic fibrosis disease as it is currently defined.

Sweat testing

The test must be performed by someone who is experienced. Techniques include the classical pilocarpine iontopheresis of Gibson and Cooke, and more recently the macroduct collection. For the diagnosis to be established, tests should be performed in duplicate. The normal concentrations of sweat sodium and chloride increase with age. To diagnose cystic fibrosis in a child, the sweat chloride concentration should be greater than 60 mmol/l, and the sweat sodium concentration less than that of chloride. A sweat chloride of less than 40 mmol is normal in older children and adults, and intermediate concentrations are equivocal. However, there are undoubted cases of cystic fibrosis with normal sweat electrolytes, and the sweat test should always be interpreted in the light of the whole clinical picture. If the sweat

test is equivocal, consider repeating it the day after giving fludrocortisone 3 mg/m ^{2} for 2 days. In cystic fibrosis patients, sweat electrolyte concentrations fail to suppress into the normal range. There are a few rare conditions which also cause elevation in sweat electrolyte concentration, but these are rarely a serious diagnostic consideration in practice (Table 3).

Nasal electrical potential difference

The abnormal potential difference across mucosal surfaces can be measured by passing a soft catheter under the inferior turbinate, referencing it to an electrode placed on the abraded skin of the forearm. Normal values are –10 to –30 mV, the cystic fibrosis range –34 to –60 mV. The test is unreliable if the patient has an upper respiratory tract infection. The diagnosis can be further refined by perfusing the nose with solutions of amiloride to block sodium transport, and isoprenaline/low chloride to stimulate CFTR. Nasal potentials require extensive experience if results are to be accurate.

Ion transport can be measured directly from intestinal biopsies in an Ussing chamber, but this remains a research technique only.

Cystic fibrosis genotype

More than 900 different mutations causing cystic fibrosis have been reported. Testing for all is not currently practical. Thus DNA analysis can confirm the diagnosis if two mutations are found, but not exclude it. Linkage analysis can be used for antenatal diagnosis if a couple have already had an affected child, even if the actual mutations are not known.

Other investigations

In doubtful cases, evidence of subclinical organ dysfunction may be sought. Pancreatic dysfunction may be manifest by elevation in 3 day faecal fat excretion, low stool elastase, or abnormal results of pancreatic stimulation tests. CT scan of the chest or bronchoscopy may be used to discover minor bronchiectatic changes or infection with typical cystic fibrosis organisms. Azoospermia is strongly supportive of the diagnosis of cystic fibrosis. But note that it is important not to place too much diagnostic weight on clinically minor changes.

Conclusions

The diagnosis of cystic fibrosis is usually easy to confirm with a properly performed sweat test. There remain a few atypical cases which defy a firm diagnosis. In that event, clinical organ dysfunction should be treated appropriately, and the patient followed up very carefully: often time will clarify the diagnosis.

Screening

Introduction

Screening tests can be used to make an early diagnosis of cystic fibrosis in populations in order for early treatment to be instituted, and to detect cystic fibrosis carriers to allow antenatal diagnosis and the option of termination of affected pregnancies. In both areas there is controversy as to the indications and methods to be used. Currently neither is routinely available.

Methods

In the past, crude tests on meconium have been used, but these lacked accuracy and have been superseded by tests carried out on the routine heel prick blood sample collected from all babies in the first few days of life. These include immunoreactive trypsin, often combined with PCR for one or more common abnormal genes, or pancreatitis-related protein. If routine neonatal screening is to be instituted, it will probably be with immunoreactive trypsin and PCR. Pancreatitis-related protein screening may perform equally well, and obviates the need for genetic testing, which may be an advantage in some cultures.

Carrier screening is by PCR for several of the common cystic fibrosis genes on a blood or mouthwash sample. In principle, this sort of screening may be offered to relatives of known cystic fibrosis patients (cascade screening), by written invitation to the general population, or opportunistically at routine antenatal clinic visits or the GP surgery. It is generally considered that carrier testing at birth will not be useful because of the time lag between obtaining and utilizing the information.

Results

The evidence for the value of screening for the disease has come from a number of retrospective trials, all showing benefit, but with the disadvantage of using historical controls. There has been one prospective, randomized trial of neonatal screening from Wisconsin, United States in which 650 341 babies were screened. Of those in whom the diagnosis of cystic fibrosis was made, in 56 the diagnosis was communicated to the parents, and in 40 the diagnosis was suppressed until it emerged on clinical grounds. There were small but clear-cut nutritional benefits in the group in which the screening diagnosis was communicated, persisting to 10 years of age. The benefits were clearest early in life, at the time when growth is at its most rapid.

In general, carrier screening is poorly taken up when done by invitation, and at antenatal clinics it may be difficult to obtain a sample from the putative father. Cascade screening is generally better utilized, and should be offered at the time of making a new diagnosis.

Conclusions

Any screening test has false positives, which engender unnecessary anxiety, and false negatives, which may result in complacency. The balance of evidence is clearly in favour of neonatal screening so that early treatment can be given, and antenatal diagnosis offered for future pregnancies. The anxiety about false positives seems transient and deemed by the parents to be an acceptable price for subsequent reassurance. Carrier screening other than by cascade is more difficult, and, unless combined with wider public education, is unlikely to have a major impact.

Respiratory management

Introduction

Most of the morbidity and mortality of cystic fibrosis is due to respiratory disease. Much of the treatment is therefore devoted to preventing chronic infection and inflammation, which lead to bronchiectasis, progressive airflow obstruction, cor pulmonale, and ultimately death.

Typical physical findings are finger clubbing, cough with purulent sputum, together with crackles and occasional wheezes, chiefly in the upper lobes. Clinical scoring systems include the comprehensive Schwachman and simpler Taussig scores. The chest radiograph shows thickened bronchial walls and small areas of consolidation which start in the upper lobes and may progress to involve the whole lung (Fig. 3(a)). A variety of radiographic scoring systems have been proposed, for example Crispin–Norman or Brasfield score. Lung function tests show obstruction with relatively well preserved gas transfer. The forced expiratory volume in 1 s (FEV1) is conventionally used to assess the extent and progression of lung disease. Exercise tolerance and arterial blood gases are well maintained until there is extensive lung damage, when hypoxaemic respiratory failure supervenes. Carbon dioxide retention occurs late.

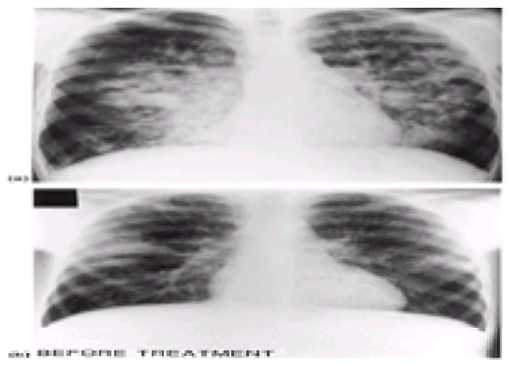

Fig. 3 (a) The typical chest radiograph appearances of advanced cystic fibrosis lung disease. There is also a right pneumothorax. (b) The chest radiograph in an adolescent child with cystic fibrosis complicated by allergic bronchopulmonary aspergillosis. Note the large wedge-shaped shadow.

Infection

Oral antibiotics

The use of prophylactic antistaphylococcal antibiotics is controversial: most would use continuous twice daily oral flucloxacillin if there is evidence of chronic colonization. Minor exacerbations of respiratory symptoms in the patient not colonized with *Pseudomonas* should be treated with a 1-month course of a high-dose antibiotic which will cover *Staph. aureus* and *Haemophilus influenza*.

Ciprofloxacin is used at the time of first isolation of *Pseudomonas aeruginosa*, combined with nebulized antibiotics (below) to try to prevent chronic colonization: the duration of therapy is controversial. Ciprofloxacin is also used to cover exacerbations of symptoms in the *Pseudomonas* colonized patient; however, ciprofloxacin resistance soon becomes common.

Nebulized antibiotics

Nebulized colomycin combined with oral ciprofloxacin is indicated at the time of first isolation of *Pseudomonas aeruginosa*. This approach has been shown in a randomized trial to delay chronic colonization. Once *Pseudomonas aeruginosa* colonization is established, randomized controlled trials have shown benefit from long-term nebulized antibiotics. In Europe, colomycin is the drug most often used. In the United States, nebulized tobramycin is preferred. No comparision of the two has been reported. Occasional patients bronchoconstrict with nebulized antibiotics: a test dose should therefore be given, and if necessary pretreatment with a bronchodilator prescribed.

Intravenous antibiotics

Infective exacerbations not responding to oral antibiotics, particularly those of *Pseudomonas aeruginosa*, are usually treated with a combination of an intravenous aminoglycoside and a semisynthetic antipseudomonal penicillin or cephalosporin. These are frequently given at home. Unlike the circumstance of the febrile patient with neutropenia, there is no evidence to support the use of single daily doses of aminoglycoside in the patient with cystic fibrosis. Drug metabolism in the cystic fibrosis patient is very different from normals and other patient groups. Some centres recommend 3-monthly courses of intravenous antibiotics, irrespective of symptoms, for all cystic fibrosis patients colonized with *Pseudomonas aeruginosa*. A randomized trial in the United Kingdom, although underpowered, did not support this approach.

Cross-infection issues

Fear of nosocomial acquisition of resistant organisms is widespread in the cystic fibrosis community. The apparent increase in prevalence of *Pseudomonas aeruginosa* in specialized clinics probably reflects more assiduous bacterial culture techniques. However, some centres advocate separate clinics for cystic fibrosis patients with and without *Pseudomonas aeruginosa*. Strict cohorting has also been advocated with regard to more resistant organisms such as *Burkholderia cepacia*, but it has subsequently been realized that not all of these organisms are of equal virulence, and cohorting has actually resulted in cystic fibrosis patients acquiring a virulent organism.

Sensible guidelines should be applied to all cystic fibrosis patients: these include diligent handwashing, no sharing of physiotherapy equipment, and the use of single cubicles for inpatients with difficult organisms. Communal physiotherapy and keep fit sessions should be discouraged, and there is no doubt that conferences for cystic fibrosis patients can result in transmission of infection. Careful microbiological surveillance is essential, and special measures may be needed if there is a true epidemic strain within a particular clinic.

Importance of viral infections

Viral infections, trivial in themselves, have been implicated in causing transient reduction in airway defences and an increased risk of *Pseudomonas aeruginosa* acquisition. Most physicians would at least give oral antibiotics (above) to cover viral exacerbations. Annual influenza immunization is advisable.

Atypical mycobacteria

These organisms are often harmless commensals: unlike *M. tuberculosis*, evidence of tissue invasion is generally held to be required to diagnose infection. This evidence cannot often be sought in cystic fibrosis, and decisions as to whether to treat are difficult. Evidence from autopsy studies suggests that atypical mycobacteria should they be treated only if they are repeatedly found in sputum.

Airway clearance

Chest physiotherapy should be performed twice daily as a routine, increasing at times of infective exacerbation. Different groups advocate different techniques (for example active cycle of breathing, autogenic drainage; and mechanical devices, such as the positive expiratory pressure (PEP) mask, flutter, and external oscillation jacket). There are no good comparisons between these approaches, and none has emerged as best. Physical exercise such as swimming supplements, but should not replace formal airway clearance sessions.

Reduction of mucus viscosity

Mucolytics have their advocates but, in general, are not useful. Human recombinant DNase *in vitro* reduces sputum viscosity. In the largest, randomized, controlled trial in the literature, once daily nebulized human recombinant DNase resulted in small but sustained improvement in lung function and reduction in infective exacerbations. Individual responses are very variable, and the treatment is expensive. A carefully monitored n=1 trial is recommended before long-term therapy.

Oxygen and other respiratory support

By analogy with the Medical Research Council and Nocturnal Oxygen Treatment Trial (NOTT) trials of oxygen in COPD, one would anticipate that long-term oxygen would be beneficial to the chronically hypoxic cystic fibrosis patient. The only trial of this approach was underpowered and thus inconclusive. Oxygen is usually prescribed for symptoms only. Nasal ventilation may be a useful short-term expedient while transplantation is awaited.

Bronchodilatation

Bronchial hyper-reactivity is common. Troublesome wheeze may need treatment with short-acting bronchodilators. However, b $_2$-agonists may cause paradoxical bronchoconstriction, and should be used cautiously. Long-acting b $_2$-agonists should only be given if there is clear-cut evidence of benefit. Persistent recurrent wheeze, particularly in the atopic cystic fibrosis patient, may be treated with inhaled or oral corticosteroids.

Aspergillus, including allergic bronchopulmonary aspergillosis

Evidence of exposure to *Aspergillus fumigatus* is common in cystic fibrosis (e.g. positive skin prick test, RAST, IgG precipitins, and sputum culture) but clinical disease is relatively rare. The prevalence of allergic bronchopulmonary aspergillosis is disputed, but is probably around 10 per cent. The major diagnostic criteria for this condition are also common features of cystic fibrosis. Sophisticated immunological testing has been used to try to refine the diagnosis, but an abrupt four-fold rise in total IgE, often in association with IgG precipitins to aspergillus, is the simplest and most reliable investigation. By contrast to typical infective exacerbations of cystic fibrosis, large fleeting radiographic shadows are typical (Fig. 3(b)). Treatment is with oral corticosteroids; the role of itraconazole is controversial.

Anti-inflammatory therapy

The pathogenesis of cystic fibrosis lung disease includes an exuberant IL-8 driven, neutrophil mediated, inflammatory response (see above), which, via the release of neutrophil elastase, may cause much of the tissue damage in the airways. This has lead to the seemingly paradoxical proposal that patients with chronic bronchopulmonary sepsis should be iatrogenically immunosuppressed. Various approaches have been tried, although none are in wide clinical use.

Oral corticosteroids

Usage in severe airway obstruction and allergic bronchopulmonary aspergillosis are discussed above. Long-term routine use was assessed in a multicentre, double-blind trial comparing prednisolone 2 mg/kg on alternate days, 1 mg/kg on alternate days, and placebo. This showed: (a) no benefit, except in patients colonized with *Ps. aeruginosa*; (b) sustained improvement in lung function in colonized patients; (c) unacceptable side-effects (growth failure, cataract, glucose intolerance), necessitating stopping the higher dose after 2 years and the lower dose after 4 years. Although in some patients, regular alternate-day steroids may be considered for up to 2 years, their routine use cannot be justified.

Inhaled corticosteroids

Since oral steroids are beneficial, but at the cost of unacceptable side-effects, it would seem logical to use long-term inhaled corticosteroids. Unfortunately there is no satisfactory trial confirming benefit: only small, relatively short-term studies have been done. Currently, inhaled corticosteroids can only be recommended for persistent wheeze, particularly in the atopic cystic fibrosis patient.

Ibuprofen

A multicentre, double-blind, placebo-controlled trial of ibuprofen showed a slowing of the rate of decline of lung function, particularly in young patients. However, ibuprofen is not widely used. This may be because: (a) not all age groups benefited; (b) there are theoretical reasons for believing that lower doses may actually be harmful, meaning that ibuprofen levels need to be measured and a high dose given; and (c) if intravenous aminoglycosides have to be administered for an acute exacerbation of chest disease, there is a significant risk of nephrotoxicity.

Other anti-inflammatory approaches

Although anti-inflammatory defences are normal in cystic fibrosis, they are overwhelmed by the burden of neutrophil elastase. Boosting the natural defences (a_1-antitrypsin, secretory leukoprotease inhibitor) by nebulizer has been the subject of small and inconclusive trials. Further safety and efficacy data are awaited.

Cytotoxics

There are anecdotal reports of the successful use of methotrexate, cyclosporin, and intravenous immunoglobulin in cystic fibrosis, particularly in those with severe, non-bronchiectatic airflow obstruction. There are no large trials of these approaches.

Haemoptysis

Blood streaking of sputum is common in cystic fibrosis and requires no special treatment. Massive haemoptysis is variously defined, usually as the expectoration of more than 250 ml of blood in 24 h, and is a frightening emergency which does require active management. It is usually a complication of quite severe lung disease, and the source is from hypertrophied bronchial arteries. The patient should be admitted, given antipseudomonal intravenous antibiotics, and any clotting abnormalities corrected. Careful chest physiotherapy should be continued. Trasylol and vasopressin are sometimes used to try to control haemorrhage. If bleeding does not settle, or recurs, then bronchial artery embolism should be considered. All sizeable bronchial arteries should be occluded. Preoperative bronchoscopy does not influence management, and often fails to define the side of bleeding in any case. The major risk of embolization is inadvertent occlusion of a major spinal artery, resulting in paraplegia. Lobectomy is rarely necessary, and carries a high risk in these patients, who are often very compromised.

Pneumothorax

This is usually a complication of late-stage lung disease. Shallow pneumothoraces require no special measures; more severe air leaks are initially treated with tube drainage. Careful physiotherapy must be continued, and intravenous antibiotics given. If there is a continued air leak, pleurodesis should be undertaken. However, it is important to consult with the local transplant service before doing this, because aggressive pleurectomy is seen by some to be a contraindication to subsequent transplantation.

Upper airway disease

Nasal polyps are seen in up to 50 per cent of adults with cystic fibrosis. Treatment is with nasal steroids in the first instance. If medical management fails, surgical polypectomy is indicated, but 50 per cent will require a second procedure within 2 years. Abnormal sinus radiographs are universal, but symptomatic sinusitis relatively rare. If present, sinusitis should be treated medically with prolonged antibiotics, nasal steroids, and possibly decongestants in the first instance; surgery is rarely needed. Rarely, surgery is needed for mucocele of the frontal sinuses.

Gastrointestinal management

Pancreatic insufficiency needs to be treated in 85 per cent of cases; meconium ileus or distal intestinal obstruction syndrome affects up to 30 per cent; symptomatic liver disease occurs in about 5 per cent, but in general the gastrointestinal manifestations of cystic fibrosis are less important than the lung disease. For a few patients, however, they are the dominant problem.

Pancreatic insufficiency

This is usually present from birth with low levels of bicarbonate and lipolytic and proteolytic enzymes in pancreatic secretions. Those with clinical pancreatic sufficiency secrete low but adequate levels of enzymes. Some develop pancreatic insufficiency later in life. The usual presentations are neonatal meconium ileus or failure to thrive with associated steatorrhoea and malnutrition. Consequences can include anaemia, vitamin deficiency, and occasionally oedema; complications include rectal prolapse, intussusception, volvulus, and distant intestinal obstruction.

The diagnosis is confirmed by estimation of stool elastase, demonstration of unsplit fat globules in the stool, or increased faecal fat on a 2 or 3-day stool collection. Formal testing of pancreatic function is seldom required.

Treatment with pancreatic enzyme and vitamin supplementation is usually straightforward and successful. Enteric coated enzyme preparations are taken before meals and the quantity adjusted to achieve normal stools. Most adults need four to eight capsules with main meals and two to four with snacks and learn to adjust the dose according to the fat content of the meal. The commonest cause of failure is poor compliance, although occasionally lactose intolerance, inflammatory bowel disease, coeliac disease, or bowel infection/infestation may coexist. A few patients need to take H_2 blockers, proton pump inhibitors, or antacids to achieve complete control of symptoms. Large bowel strictures have developed in some patients (usually children) taking high-strength enzyme preparations, probably as a toxic effect of the coating rather than the enzymes themselves.

Nutrition

Vitamin supplementation should be given to all patients to cover fat soluble vitamin deficiency. Multivitamin tablets contain vitamins A and D, but vitamin E needs to be given separately to maintain adequate intake. The diet should otherwise be normal, with a high calorie intake, usually 130 per cent of recommended daily allowance. Patients unable to maintain weight in spite of optimal dietary advice can be helped by enteral feeding, which is better tolerated by gastrostomy than by a nasogastric tube in the long term.

Distal intestine obstruction syndrome

Constipation and a loaded colon are relatively common in cystic fibrosis and usually respond to modification of the diet, pancreatic supplements, and a high fluid and roughage intake; occasionally lactulose or cisapride are helpful. Severe constipation merges into the distal intestine obstruction syndrome with pain, palpable faecal masses, and complete obstruction with faecal material in the distal ileum or ascending colon. The cause is multifactorial with imbalance of pancreatic enzymes and diet, disturbed fluid and electrolyte transport, faecal dehydration, and abnormal intestinal mobility all playing a part.

Patients present with chronic intermittent pain or episodes of complete obstruction. Although the differential diagnosis is wide and includes common conditions such as appendicitis, most patients improve with medical treatment and surgery should be avoided unless there is clear evidence of another diagnosis. Treatment with a balanced intestinal lavage solution, 500 to 1000 ml/h by nasogastric tube, usually moves the faecal blockage within 4 to 6 h. Alternatives are gastrografin by mouth or enema, or oral n-acetylcysteine. Occasionally, removal of inspissated faeces at colonoscopy is needed.

Other gastrointestinal complications

Pancreatitis is rare but should be excluded in cases of abdominal pain. It usually affects those who are clinically pancreatic sufficient. Treatment is conventional, with special attention to pulmonary infections, because the pain of pancreatitis may interfere with physiotherapy. Gastro-oesophageal reflux is common, sometimes with overt vomiting, and may be associated with coughing, physiotherapy, and bronchodilators which may relax the oesophageal sphincter. Aspiration of stomach contents is seldom a clinical problem. Although peptic ulcer disease might be expected in view of the low pancreatic bicarbonate secretion, there is only one report of an increased frequency of ulceration. *Helicobacter pylori* infection is uncommon, perhaps because of antibiotic treatment. Lactose intolerance, coeliac disease, and inflammatory bowel disease occur with the expected or slightly increased frequency in the cystic fibrosis population, but symptoms may be misattributed to cystic fibrosis and diagnosis therefore delayed. Both giardiasis and *Clostridium difficile* gut infection have been reported as being more frequent in cystic fibrosis but are not common clinical problems.

Liver disease

Liver disease causes problems in 5 per cent and death in 2 per cent of people with cystic fibrosis, but abnormal liver function tests are very common and up to 50 per cent have biliary cirrhosis demonstrable at post mortem. With increasing survival, liver disease may become more important.

Although liver enlargement and jaundice occasionally occur in early childhood, liver disease is usually signalled by hepatosplenomegaly or abnormal liver function on routine testing. Decompensation with jaundice, ascites, or encephalopathy are rare and occur late. Variceal bleeding only occurs in a minority of those with established chronic liver disease. Minor or modest elevations of aminotransferase, gamma glutamyl transpepddidase, or alkaline phosphatase levels are very common but do not correlate with established liver disease unless the enzyme levels are greater than four times normal. Routine ultrasound detects fatty change or multilobular cirrhosis: the finding of portal vein dilatation, splenomegaly, or colateral vessels indicating portal hypertension. Cholangiography is occasionally needed for treatment of gall stones: this may reveal irregularities of the intrahepatic ducts, suggesting chronic liver disease, and significant strictures of the common bile duct may also be seen. Liver biopsy is seldom needed.

No treatment has been shown to modify the course of chronic liver disease in cystic fibrosis, although clinical and biochemical improvements have been shown following treatment with ursodeoxycholic acid. This bile acid stimulates bile flow, may protect the hepatocyte from toxicity of bile acids, and is helpful in primary biliary cirrhosis. Many hepatologists therefore recommend its use in cystic fibrosis.

Jaundice must be investigated to exclude drug hepatotoxicity or treatable obstructive cause, but is otherwise a late event with poor prognosis. Variceal bleeding is treated with injection sclerotherapy or banding ligation, and in the short-term balloon tamponade or vasoconstrictor drugs may buy a little time. Surgical treatment is hazardous due to lung disease and in a few patients the insertion of a transjugular intrahepatic portal systemic shunt may be an alternative. Prophylactic treatment of varices has not been shown to help and may be detrimental. Ascites and encephalopathy are rare and are usually preterminal events to be managed conventionally.

In most cases of complicated chronic liver disease, management is made more difficult by the presence of lung infection that must be aggressively treated. Respiratory failure may develop concurrently. When this occurs, intubation and ventilation are seldom successful.

Diabetes

Glucose intolerance in cystic fibrosis increases with age, being rare under 10 years, affecting 14 per cent by 15 years, and over 65 per cent at 25 years, by which age 32 per cent are frankly diabetic. Even when glucose tolerance is normal, reduced insulin secretion is frequent. This is caused by gradual and progressive loss of beta cell mass in line with pancreatic fibrosis. Peripheral insulin sensitivity is normal and autoimmune factors are not involved.

Diagnosis is based on conventional WHO recommendations. Some recommend annual oral glucose tolerance tests, but screening for diabetes in a cystic fibrosis clinic is usually done by measurement of HBA1c, together with random or fasting blood sugar levels. Diabetes is usually diagnosed at such screening, but a few patients present with weight loss and increased frequency and severity of chest infections, although polyuria and polydipsia occasionally develop first. It has been suggested that the onset of diabetes is a marker of general deterioration, but many patients return to their previous level of health when diabetes is controlled. Oral hypoglycaemic agents provide control in a minority of patients for a limited time: insulin replacement is usually necessary. Control of blood sugar is relatively simple, with slow release preparations given twice daily. Ketoacidosis and insulin resistance are almost unknown.

The dietary management of diabetes in cystic fibrosis differs from that of other forms of diabetes: high dietary intake is maintained and insulin adjusted to fit the diet rather than the other way round. The usual recommendations are an energy intake of 150 per cent of normal with frequent balanced meals.

Early microangiopathy has been shown in cystic fibrosis patients with diabetes, but retinopathy, neuropathy, and nephropathy are very rare. This is due in part to the mildness of the diabetes and in part to short survival. Nevertheless, cystic fibrosis patients with diabetes tend to have excess morbidity and slightly increased rate of decline in weight and lung function.

Other organ systems

Reproduction

Almost all cystic fibrosis males have obstructive azoospermia with otherwise normal sexual function. This is due to absence of the vas deferens, and although there are no sperm in the ejaculate there is normal spermatogenesis and Leydig cell function. Counselling about infertility should be done by the time of puberty, ideally before permanent relationships develop. Most men opt to confirm the azoospermia by a sperm count. *In vitro* fertilization using aspirated sperm has been successful and there are now many cystic fibrosis fathers.

Early reports of reduced fertility in cystic fibrosis women have not been confirmed and most can conceive normally. The child must carry one mutation from the mother: the risk of cystic fibrosis is therefore 1 in 50 in a Caucasian populations with a carrier frequency of 1 in 25. Counselling and paternal genotyping allows reassurance for the majority of cystic fibrosis pregnancies and identifies a 1 in 2 risk when the father is a carrier. Successful pregnancies have been completed by many hundreds of cystic fibrosis women, but women with severe lung disease may not be able to complete a pregnancy safely, the risks rising with impaired lung function and especially when the 1 s FEV1 is less than 30 per cent predicted. Children born have been healthy, without an increased frequency of birth defects despite the mothers' extensive drug treatment. Lactation is normal.

Vaginal candidiasis secondary to antibiotic treatment is relatively common in cystic fibrosis, but otherwise there are no specific gynaecological problems. Sexual behaviour in both genders may be inhibited by low weight, delayed puberty, cough, sputum, haemoptysis, breathlessness, and indwelling catheters, but most people adapt well and persistent problems are few.

H4>Skin and joints

Clubbing is almost universal in those with significant lung disease and regresses after successful lung transplantation. Hypertropic osteoarthropathy is rare. Episodic arthritis, predominantly affecting the large joints, is quite common and is associated with chest infections. Erosive arthritis is rare. Pain responds to non-steroidal anti-inflammatory drugs and steroids or immunosuppression are seldom needed. Systemic vasculitis has occasionally been reported but is surprisingly rare considering the extent of immune activation, the frequency of circulating immune complexes, and the number of drugs taken.

Kidneys

Glomerulonephritis has been reported but is probably no more frequent than in the normal population. Drug-induced renal damage is rare and is usually associated with higher than recommended aminoglycoside levels. Very large numbers of aminoglycoside treatments appear to be safe when serum levels are well controlled. Renal stones are commoner in cystic fibrosis, probably due to excess oxylate absorption secondary to altered bowel bacterial flora. Systemic amyloidosis has occasionally been reported secondary to prolonged pulmonary infection.

Central nervous system

Ototoxicity occasionally results from aminoglycoside treatment but is not seen when serum levels are well controlled. Cerebral abscess rarely complicates lung sepsis. Vitamin E deficiency leads to a cerebellar syndrome combined with peripheral neuropathy.

Osteoporosis

Reduced bone mineral density is common in cystic fibrosis, with a prevalence among adults of up to 60 per cent. This is partly due to general malnutrition as well as vitamin D malabsorption, but relative immobility is sometimes a factor. An increased rate of fractures has been reported and rib fractures from coughing can interfere with adequate physiotherapy. Vertebral compression fractures are fortunately rare. Regular bone mineral density measurements are recommended with extra vitamin D and calcium supplementation when low. Bisphosphonates can cause bone pain and have not yet been fully evaluated.

Management of respiratory failure

Recurrent and persistent chest infection leads to progressive decline in lung function with eventual respiratory failure in the vast majority of patients; in about 2 per cent the liver fails first. At this stage palliation of symptoms should replace aggressive treatment unless there is a realistic prospect of a lung or liver transplant. If this is feasible, then preoperative work-up, counselling, surgical assessment, and placement on the waiting list should take place 2 years before the predicted date of death.

Lung transplantation (see also Chapter 17.16)

Selection criteria are listed in Table 4. The timing of assessment is judged on the level and rate of decline of lung function, arterial blood gases, and the frequency and severity of chest infections. Patients on the waiting list must be managed optimally to maintain lung function and nutrition, usually with gastrostomy feeding. Non-invasive ventilatory support can provide a bridge to transplantation for patients with progressive respiratory failure but intubation and conventional ventilation are not recommended. Donor organs are scarce and at least 50 per cent of listed cystic fibrosis patients never receive a transplant. The results for lung transplantation are the same as for other lung diseases with a survival of 70 per cent at 1 year and 50 per cent at 3 years.

Liver transplantation is appropriate for the occasional patient dying of liver failure with relatively good lung function: survival at 1 year is 40 per cent. For patients with respiratory failure and severe liver disease combined lung and liver transplantation is a possibility but with poor survival and with limited organ availability the operation is difficult to justify.

Terminal care

The timing of the decision to switch to palliative care is difficult and should be made in conjunction with the patient and relatives. The most distressing symptoms are cough, sputum retention, breathlessness, and exhaustion. Small doses of morphine are usually well tolerated and only seldom worsen respiratory failure.

The cystic fibrosis team

As with many chronic diseases, the purely medical care of cystic fibrosis is relatively straightforward. Proper holistic care requires a team approach, and without such a team, care will be second rate. Typically, the core of the team is formed by a specialist nurse, a physiotherapist, a dietician, a psychologist, and a social worker, together with a specialist doctor. It is unrealistic to expect every hospital to provide this, and so close contact with a tertiary centre is advisable. Many of the physical issues (airway clearance, nutritional management) have been discussed above. Equally important are many of the psychological problems springing from the presence of a chronic disease.

The normal tasks of adolescence include rebelling and breaking free of parental care. In those with cystic fibrosis this may never have been achieved, because the parents have wanted to keep control of treatment regimens, and have been reluctant to allow independence. Although the paediatric clinics should have established a pattern of the adolescent coming into the consulting room alone, frequently this does not happen, and the adult physician is confronted with parents who resent the idea that their now grown-up child should be seen on their own. Conversely, the consequences of a full-blown adolescent revolt (no treatment done, abuse of cigarettes, alcohol, and soft and hard drugs) may be particularly catastrophic in the cystic fibrosis patient. The authors know of no easy answer to adolescence and its aftermath.

Knowledge of fertility issues is notoriously poor amongst adult men with cystic fibrosis: these may need to be tackled tactfully. The issues surrounding pregnancy in the cystic fibrosis girl, who may herself be severely breathless, but desperately wishing for a child, also require sensitive handling. Further education and employment are also difficult issues in the setting of chronic physical disability, but skilled help may allow the cystic fibrosis patient to maximize their potential. A fuller account of the many and complex psychosocial issues surrounding care can be found elsewhere: appreciation of these issues is just as important as knowing the correct management of the physical problems of cystic fibrosis.

Future prospects

The growth in basic scientific understanding of cystic fibrosis will lead to a number of new treatments directed at the mutant CFTR gene or protein. These include gene therapy, which has already reached preliminary clinical trials, protein replacement therapy, and drug therapy to correct the molecular defect (as illustrated in Fig. 2). Research into correction of the disordered electrophysiology with sodium channel blockers, such as amiloride, or promoters of chloride transport, such as UTP, is already well advanced. There is, therefore, a real prospect of new fundamental treatments to prevent the development of cystic fibrosis disease and lead to improved health, prolonged survival, and reduction in life-long supportive therapy.

17.11.1 Diffuse parenchymal lung disease: an introduction

R. M. du Bois

Definition

The definition of diffuse parenchymal lung disease has become confused. This is due to a combination of muddled nomenclature, the overuse of synonyms, and a lack of precision in defining the individual diseases that come under this 'umbrella' term.

Diffuse parenchymal lung disease used to be known as interstitial lung disease. The change of terminology recognized that it was not just the parenchyma but also the airspace components of the acini that are involved in the diffuse parenchymal lung diseases. Infective pneumonias and some malignancies involve the acinar regions of the lung but are excluded from the classification by convention, although they must be considered as part of a differential diagnosis when diffuse parenchymal lung diseases are being considered.

Each specific disease will be considered in subsequent chapters and this introduction will focus on the approach to the classification of the diffuse lung diseases and their diagnosis and management.

Classification

Diffuse parenchymal lung diseases can be subdivided into five major groupings:

- associated with systemic diseases including rheumatological disease;
- diseases caused by environmental triggers or drug-ingestion;
- granulomatous diseases;
- idiopathic interstitial pneumonias;
- other diffuse lung diseases.

The majority of the environmentally and drug-induced lung diseases and granulomatous lung diseases are of known cause. Diffuse parenchymal lung diseases occurring in the context of systemic disease have known associations but are generally of unknown cause. The majority of the heterogeneous group of 'other' diffuse parenchymal lung diseases is of unknown cause as are, by definition, the idiopathic interstitial pneumonias. Table 1 and Fig. 1 illustrate the diseases of known and unknown cause that fall within each of the above broad headings, and Table 2 illustrates disorders that present more acutely, an important distinguishing feature.

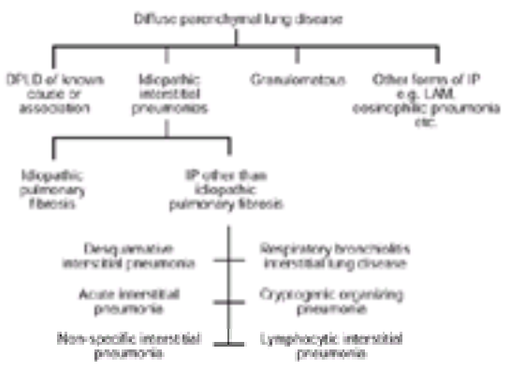

Fig. 1 Classification of diffuse parenchymal lung disease. DPLD, diffuse parenchymal lung disease; IP, interstitial pneumonia; LAM, lymphangioleiomyomatosis.

Idiopathic interstitial pneumonias

The group of diseases known together as the 'idiopathic interstitial pneumonias' are those that have produced most confusion in terms of nomenclature and understanding. This is largely because pathological pattern descriptions have been used interchangeably with disease 'labels' without consistency. Over the last five decades, two parallel processes—clinical and histopathological—were used to define diseases that are now included within the idiopathic interstitial pneumonias.

Clinical

In 1944, Hamman and Rich described four patients who died of a rapidly progressive process; the histopathological appearances showed interstitial pneumonia and fibrosis. Subsequently, similar disease patterns occurring over a more chronic time frame were identified. All of these were characterized by the presence of progressive breathlessness, crackles heard on auscultation of the chest, chest radiography which showed reticulonodular patterns of abnormality in the periphery and the bases of the lung fields, and a restrictive ventilatory defect on lung function testing. Similar but less acute disorders were subsequently described. Together all of these disorders have been loosely labelled as 'cryptogenic fibrosing alveolitis' or 'idiopathic pulmonary fibrosis' in the United States and elsewhere. Bronchoalveolar lavage was later introduced as an investigative tool and the presence of excess neutrophils and/or eosinophils helped to confirm this diagnosis. More recently, high resolution computed tomography has been used to define patterns of disease, helping to identify a number of quite distinct patterns that had previously been included under the single diagnostic 'label' of 'cryptogenic fibrosing alveolitis'.

Histopathological

In 1975, Liebow described five interstitial pneumonias that could be associated with clinical disease that mimics 'cryptogenic fibrosing alveolitis':

- usual interstitial pneumonia (UIP);
- desquamative interstitial pneumonia (DIP);
- bronchiolitis obliterans with usual interstitial pneumonia (BIP);
- lymphoid interstitial pneumonia;

- giant cell interstitial pneumonia.

Over subsequent years it became clear that not all of these interstitial pneumonias were idiopathic. Lymphocytic interstitial pneumonia was generally due to lymphoproliferative disorders, rheumatological disease, or AIDS-related disease. Giant cell interstitial pneumonia was found to be due to the exposure to the alloy hard metal (cobalt, tungsten carbide, titanium salts).

This resulted in a revision of the classification such that the interstitial pneumonias, defined histopathologically, of known cause, were removed. The idiopathic group now included UIP and DIP from the original classification. To these were added respiratory bronchiolitis–interstitial lung disease (RB-ILD), diffuse alveolar damage (DAD), and non-specific interstitial pneumonia (NSIP). BIP was renamed 'organizing pneumonia.'

Usual interstitial pneumonia

Usual interstitial pneumonia is by definition, the pattern seen in cryptogenic fibrosing alveolitis. The hallmark of usual interstitial pneumonia is a patchy distribution of interstitial fibrosis, chronic inflammatory cells, cystic airspaces (honeycomb lung), and areas of relatively normal lung. This pattern of pathology has a non-uniform appearance, best visible under low microscopic power, suggesting that the pathological process is at different stages of evolution throughout the biopsy (i.e. temporally heterogeneous), a feature that distinguishes usual interstitial pneumonia from other interstitial pneumonias. Another key feature is abundant fibroblastic foci.

Desquamative interstitial pneumonia

The characteristic feature of desquamative interstitial pneumonia is the diffuse accumulation of alveolar macrophages within the airspace in a rather monotonous, uniform pattern. There may be some interstitial inflammation and fibrosis but this is minor by comparison with the intra-alveolar inflammation. This pattern of disease is found almost exclusively in cigarette smokers.

Respiratory bronchiolitis–interstitial lung disease

The histopathological features of respiratory bronchiolitis–interstitial lung disease are very similar to those of desquamative interstitial pneumonia. They are differentiated by being less profuse, with pigmented macrophages accumulating in the airspaces around the bronchioles, which are themselves inflamed. The similarity of alveolar macrophage accumulation between desquamative interstitial pneumonia and respiratory bronchiolitis–interstitial lung disease (which also occurs almost exclusively in cigarette smokers) has led some to believe that these histopathological patterns are both part of the same spectrum of disease, but this view is not held unequivocally.

Diffuse alveolar damage

Diffuse alveolar damage is uncommon and the histopathological changes suggest an acute insult. This is the pattern of disease seen in both the adult respiratory distress syndrome and acute interstitial pneumonia (effectively, the adult respiratory distress syndrome of unknown cause). It is characterized by the presence of hyaline membranes lining damaged alveoli and, in more subacute states, the presence of buds of organization in the alveoli of those acini that have been damaged and are undergoing the healing process.

Non-specific interstitial pneumonia

This is arguably the least satisfactory histopathological entity and 'label'. Despite its name, there are specific features that define this histopathological pattern. There are varying degrees of interstitial inflammation and fibrosis within the interstitium but, unlike usual interstitial pneumonia, with which it is most likely to be confused (see Table 3), the appearances are uniform with none of the temporal heterogeneity of usual interstitial pneumonia and significantly less of the fibroblastic foci that are hallmarks of usual interstitial pneumonia.

American Thoracic Society and European Respiratory Society consensus statements on the nomenclature

Over the last few years these parallel clinical and histopathological approaches to the differentiation of the idiopathic interstitial pneumonia subgroup of the diffuse parenchymal lung diseases have become more integrated. The American Thoracic Society and European Respiratory Society have met to provide a consensus statement on the nomenclature of these diseases, which is summarized in Table 4. This classification attempts to provide a disease nomenclature that incorporates clinical, radiological, and histopathological patterns and to separate this from a pure histopathological classification that describes only the pattern of disease down the microscope without taking into account the clinical pathway that the disease has taken to reach that pathology. This is an important point because different insults could result in similar histopathological patterns. For example asbestos exposure can produce a usual interstitial pneumonia pattern of disease but, because it is of known cause, it is not included within the idiopathic interstitial pneumonias. Similarly, exposure to environmental agents to produce extrinsic allergic alveolitis can result in a non-specific interstitial pneumonia pattern, but this is clearly a distinct disease from that of a patient who presents with features similar to cryptogenic fibrosing alveolitis, who may have a similar histopathological pattern on lung biopsy.

The key issue that has emerged from the idiopathic interstitial pneumonias nomenclature debate, therefore, is that all clinical, radiological, and histopathological data must be taken into account before a diagnostic 'label' is applied to an individual patient. This new approach now allows a more precise definition of those diseases that are included within the idiopathic interstitial pneumonias.

Cryptogenic fibrosing alveolitis

The American Thoracic Society and European Respiratory Society consensus statement on this disease now recommends that cryptogenic fibrosing alveolitis (synonymous with idiopathic pulmonary fibrosis in the United States and elsewhere) must have the usual interstitial pneumonia pattern of pathology, or the appropriate clinical features, high resolution computed tomography pattern, and a bronchoalveolar lavage or transbronchial biopsy that excludes other disease (Table 5).

This is arguably the most contentious of the disease definitions in that there is a distinct subgroup of individuals who have all of the clinical, radiological, and bronchoalveolar lavage features of cryptogenic fibrosing alveolitis but who are found to have the non-specific interstitial pneumonia pattern of histopathology. At present it would be best to define these as the non-specific interstitial pneumonia variant of cryptogenic fibrosing alveolitis.

Desquamative interstitial pneumonia and respiratory bronchiolitis–interstitial lung disease

These diseases bear the same name as the histopathological classification because the idiopathic variants appear to be fairly uniform in their clinical and radiological features. Both are rare and it is possible that idiopathic variants may emerge.

Acute interstitial pneumonia

This disease resembles the adult respiratory distress syndrome in mode of onset, radiological and histopathological features, sharing the diffuse alveolar damage pattern of histopathology. Acute interstitial pneumonia is distinguished from adult respiratory distress syndrome by the absence of a known trigger. This nomenclature should not be used in the context of the rheumatological diseases in which a similar pattern of pathology can be seen.

Non-specific interstitial pneumonia

There are a number of clinical and radiological pathways that lead to a similar pattern of histopathology. However, once known causes and associated diseases have been excluded there appear at present to be no disease entities that have this histopathological variant other than the cryptogenic fibrosing alveolitis variant described above. Future studies are needed to validate this conclusion.

Cryptogenic organizing pneumonia

This disease was first defined in 1983 and was then redesignated 'bronchiolitis obliterans organizing pneumonia' in the United States in 1985. This nomenclature was so similar to 'bronchiolitis obliterans' that confusion ensued. Bronchiolitis obliterans organizing pneumonia is a pneumonic-like illness whereas bronchiolitis obliterans is an airway disease with distinct clinical, radiological, physiological, and histopathological appearances. It has therefore been decided to rename this disease cryptogenic organizing pneumonia to make the distinction between bronchiolitis obliterans quite clear and to define this disease as having the histopathological pattern of organizing pneumonia.

Lymphocytic interstitial pneumonia

This is included for completeness because this histopathological pattern can be seen in patients with rheumatological disease that can mimic the idiopathic interstitial pneumonias. It is likely that this will be included in the future within the non-specific interstitial pneumonia classification because the majority of diseases that have this pattern on biopsy are either lymphoproliferative or AIDS-associated.

Diagnostic approach

There are more than 200 entities included within the diffuse parenchymal lung disease group. A logical approach to diagnosis and management helps to avoid the major pitfalls that can be encountered in making a firm diagnosis. This approach can be considered in two phases:

- Phase 1
  - clinical history
  - clinical examination
  - chest radiography
  - pulmonary function tests
  - selective blood tests
- Phase 2
  - high resolution computed tomography
  - bronchoalveolar lavage
  - lung biopsy

This two-phase approach to diagnosis is summarized in Fig. 2.

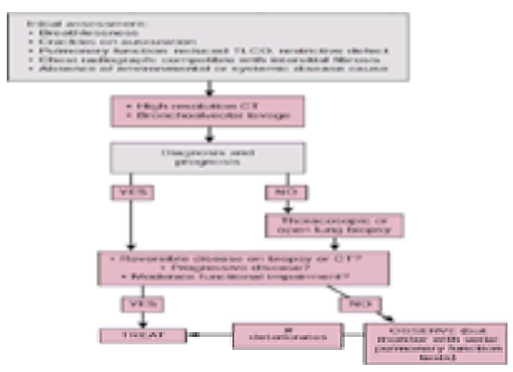

Fig. 2 Algorithm for the diagnosis, assessment, and management of suspected idiopathic interstitial pneumonia.

Clinical history

Most patients present with slowly progressive breathlessness, with or without a cough that is usually dry and non-productive. Duration and speed of onset are important: disease presenting acutely narrows down the differential diagnosis considerably (see Table 2).

The presence of wheeze is discriminatory as this implies that the diffuse lung disease process has an airway component that narrows the differential diagnosis. Examples of this include lymphangioleiomyomatosis or Langerhans cell histiocytosis. Other respiratory symptoms are uncommon and when present may also help to focus diagnosis. Pleurisy may occur in the rheumatological diseases and drug-induced disease, but never in cryptogenic fibrosing alveolitis or extrinsic allergic alveolitis. Haemoptysis may suggest alveolar haemorrhage that can be due to a variety of causes. A history of pneumothorax suggests peripheral lung cysts, which occur most commonly in Langerhans cell histiocytosis and lymphangioleiomyomatosis.

The past medical history can provide crucial information, particularly if there is a history of rheumatological disease, other systemic disease such as systemic vasculitis, or previous diseases that have required long-term drug therapy.

A complete occupational and domestic environmental history is necessary. The occupational history should include all occupations from school-leaving because many diseases caused by occupational environmental exposure occur after a lag period. The environmental dusts that are of relevance are those that are respirable, that is can penetrate the acinar regions of the lungs. The environmental conditions in which such dusts are found involve most commonly the sawing, grinding, drilling, or other working of materials that produce dusts of the appropriate size. A comprehensive occupational history therefore requires knowledge of the materials that are processed in particular job definitions and also of materials that can produce chronic lung inflammation. Organic dusts that provoke disease are most commonly those that occur in the context of fungal contamination of materials such as hay (as in farmers lung) or avian proteins found on the bloom and in the excreta of domestic birds such as budgerigars, pigeons, and hens (producing extrinsic allergic alveolitis). Table 1 includes diseases that need to be considered.

A history of foreign travel is also important because this may suggest the possibility of parasitic infection that can produce pulmonary eosinophilia.

A history of cigarette smoking will help to define predisposition to Langerhans cell histiocytosis, desquamative interstitial pneumonia, respiratory bronchiolitis–interstitial lung disease, and can provoke acute exacerbations of lung vasculitis as in Goodpasture's syndrome. By contrast, smoking appears to 'protect' patients from sarcoidosis and extrinsic allergic alveolitis.

A drug ingestion history also needs to be comprehensive. The list of drugs that can produce a diffuse parenchymal lung disease is increasing rapidly. A good source of drug-induced pulmonary adverse effects can be found on the web site listed at the end of this chapter.

Clinical examination

This is often unrewarding in the respiratory tract. Digital clubbing is common in cryptogenic fibrosing alveolitis but much less so in the other diffuse parenchymal lung diseases. Showers of fine end inspiratory crackles are typical of fibrosing alveolitis but more sporadic crackles can be found in many diffuse parenchymal lung diseases. Expiratory wheeze helps to define associated airway disease, which can be discriminatory.

More helpful is the examination of the rest of the systems to identify ocular disease (suggesting sarcoidosis or vasculitis), skin disease (that might support a diagnosis of sarcoidosis or rheumatological disease), musculoskeletal signs suggesting rheumatological disease, neurological disease (such as mononeuritis multiplex in

vasculitis), or a variety of central and peripheral neuropathies (in sarcoidosis).

Chest radiography

Chest radiography is one of the key components in the process of diagnosis of diffuse parenchymal lung disease. Five features should be noted:

- lung size;
- distribution of abnormalities;
- size and nature of nodular and/or reticular abnormalities;
- presence of confluent shadows;
- presence of pleural disease or lymphadenopathy.

Lung size

Patients with fibrosing lung diseases will generally have small lungs on chest radiography. Pitfalls include patients who have failed to take a full inspiration and patients with neuromuscular and other extrathoracic lesions that preclude full inspiration. This can mimic a fibrosing lung disease and needs to be considered if the small lungs appear to have normal parenchyma.

If other clinical features have suggested a diagnosis of fibrosing alveolitis, normal or large-size lungs indicate the coexistence of emphysema and fibrosing alveolitis: this admixture of disease processes is not uncommon as both are associated with cigarette smoking.

Other causes of large or normal sized lungs on chest radiography occurring together with nodular or reticular shadowing include Langerhans cell histiocytosis, lymphangioleiomyomatosis (a disorder involving smooth muscle proliferation that occurs only in women of childbearing age), tuberous sclerosis, of which lymphangioleiomyomatosis is believed by some to be a *forme fruste*. Chronic sarcoidosis can also feature large lungs, but this is usually associated with severe upper zone fibrosis causing a retraction of the hilar shadows towards the apices. Idiopathic bronchiectasis or cystic fibrosis can also be mistaken for diffuse parenchymal lung disease but the history of regular purulent sputum production will discriminate.

Distribution of abnormalities

The distribution of the abnormalities is always helpful. Fibrosing alveolitis occurring alone, in association with rheumatological diseases, or due to asbestos exposure produces reticular or reticulonodular abnormality predominantly in the basal zones, but also visible in the periphery of the lung, obscuring the diaphragm and the right and left heart borders. Predominantly upper zone disease, particularly involving loss of lung volume with an upward shift of the hilar shadows denoting upper zone fibrosis, occurs in chronic sarcoidosis and tuberculosis, extrinsic allergic alveolitis in its chronic stage, bronchopulmonary aspergillosis (almost always in the presence of asthma), and occasionally in Langerhans cell histiocytosis.

Predominant mid-zone abnormalities occur in sarcoidosis, extrinsic allergic alveolitis in its acute and chronic forms, and Langerhans cell histiocytosis.

Size and nature of nodular and reticular abnormalities

The size and shape of the abnormalities are helpful pointers to diagnosis. Very small 'granular' nodules less than 1 mm in size are seen in conditions such as idiopathic pulmonary hemosiderosis, miliary tuberculosis, and alveolar microlithiasis. Nodules up to 5 mm in diameter are seen in sarcoidosis, extrinsic allergic alveolitis, and silicosis. Shadows greater than 5 mm in size are present in Wegener's granulomatosis, rheumatoid arthritis, lymphoma, and other malignancies. Nodules of differing size and shape are highly suggestive of metastatic malignancy, and nodules that cavitate raise suspicion of Wegener's granulomatosis, other necrotizing granulomas, and rheumatoid nodules. Necrotizing squamous cell carcinomas and multiple staphylococcal abscesses need to be excluded. Lower zone reticulonodular shadowing is the pattern in fibrosing alveolitis of whatever cause.

Confluent shadowing

Confluent shadowing denotes airspace opacification. The presence of air bronchograms is very helpful in defining consolidation. All conditions that have predominant alveolar-filling histopathology will produce this pattern of radiographic change. These disorders include pulmonary alveolar proteinosis, diffuse alveolar haemorrhage, pulmonary eosinophilia (in which the confluent shadowing is often peripheral, as it frequently is in cryptogenic organizing pneumonia). Infection, particularly opportunistic infection in the immunosuppressed patient, alveolar cell carcinoma, and lymphoma must be differentiated, particularly as all of these can be complications of diffuse lung disease or its treatment.

Pleural disease and lymphadenopathy

The presence of pleural disease (with or without effusion) helps to exclude certain diagnoses such as extrinsic allergic alveolitis and cryptogenic fibrosing alveolitis. It is a common feature of the rheumatological diseases, particularly rheumatoid arthritis and systemic lupus erythematosus. It is also a feature of drug-induced lung disease, may occur in sarcoidosis, and is relatively common in Churg–Strauss granulomatosis and Wegener's granulomatosis.

Symmetrical hilar lymphadenopathy is usually due to sarcoidosis. Tuberculosis and lymphoma (and other malignancies) must always be considered, and these are more likely if the changes are unilateral. Lymphadenopathy is rarely observed on chest radiography in other diffuse lung diseases, with the notable exception of silicosis. Hilar calcification occurs in sarcoidosis and silicosis in addition to tuberculosis.

Radionuclide imaging

Gallium scanning has now fallen out of favour as a diagnostic tool for diffuse lung disease. Ventilation perfusion scanning as a means of identifying thromboembolic disease produces frequent false positives in the presence of diffuse lung disease and should not be used in this circumstance, spiral computed tomography being preferred. ^{99m}Tc-DTPA clearance from the lungs has been used in some centres as a tool for early detection of diffuse lung disease and as a predictor of outcome. In patients with fibrosing alveolitis occurring alone or in the context of rheumatological disease, sarcoidosis and other diffuse lung diseases, rapid clearance predicts disease that is more likely to be progressive.

Pulmonary function testing

In the majority of patients with diffuse parenchymal lung disease, lung function tests reveal a restrictive pattern of ventilatory defect with reduced gas transfer (DL_{CO}). Arterial oxygen tensions (PaO_2) may be normal or low and $PaCO_2$ may also be normal or low. In more subtle disease with normal gas transfer at rest, exercise tests can unmask abnormality: PaO_2falls and the alveolar–arterial oxygen gradient (A–a gradient) widens, indicating abnormalities of gas exchange usually due to ventilation–perfusion mismatch, but with an increased diffusion component on exercise. The anatomical dead space to tidal volume ratio (V_D/V_T) falls on exercise in the normal individual but remains the same or increases in restrictive lung disease.These investigations of pulmonary function can confirm the presence of disease but cannot discriminate between the different causes.

In disorders in which an airway component is associated with the diffuse parenchymal lung disease, a mixed obstructive–restrictive ventilatory defect is observed. This occurs in Langerhans' cell histiocytosis and more advanced sarcoidosis, both of which are bronchocentric disease processes. Evidence of subtle airway disease can sometimes be seen in less chronic sarcoidosis and also in early extrinsic allergic alveolitis. Combined pathologies may coexist; in patients with fibrosing alveolitis who have been cigarette smokers, a mixed obstructive–restrictive process is present due to a combination of emphysema and fibrosing alveolitis.

Blood tests

Routine haematology and biochemical tests are not of any discriminatory value in the diffuse lung diseases. Peripheral blood eosinophilia (above 1.5×10^{9}/l) is a

prerequisite for diagnosis of pulmonary eosinophilia. This is particularly helpful in the chronic forms of pulmonary eosinophilia, when total IgE levels are low, as this can discriminate between the allergic forms of disease that can affect the lung in which IgE levels match eosinophil levels.

Angiotensin converting enzyme concentrations are helpful in sarcoidosis but are not diagnostic. Their main value is in monitoring the burden of disease if found to be elevated at presentation. Routine immunoglobulin estimates are of no diagnostic value.

By contrast, autoantibody testing is important. The finding of a positive antinuclear antibody, with particular specific extractable nuclear antigen profiles, or of rheumatoid factor, may indicate that lung disease is the first manifestation of a systemic rheumatological condition. This form of presentation is reported increasingly and has important implications in terms of the precise diagnosis of the diffuse parenchymal lung disease and prognosis. Good examples of this include: the anti-DNA topoisomerase autoantibody, which is associated with fibrosing alveolitis in systemic sclerosis; the anticentromere antibody, which is associated with pulmonary vascular disease in systemic sclerosis; the anti-t-RNA synthetase autoantibodies, which occur when polymyositis is found in association with diffuse parenchymal lung disease; anti-Sm in systemic lupus erythematosus; SS-A and SS-B in Sjögrens syndrome; and the anti-RNP autoantibody in mixed connective tissue disease.

Antineutrophil cytoplasmic antibody (ANCA) is particularly helpful if the pattern is cytoplasmic, suggesting that the diffuse parenchymal lung disease is a manifestation of Wegener's granulomatosis or microscopic polyangiitis. The perinuclear (pANCA) pattern is much less discriminatory and is found in elevated titre in a wide variety of disorders, including rheumatological disease.

Bronchoalveolar lavage

When this technique was first employed, roughly 20 years ago, it was hoped that it could replace surgical biopsy in providing precise diagnostic information. This has proved not to be the case. It was also hoped that serial bronchoalveolar lavage might be a better monitoring tool than other indices of change. This has also been disproved. Nonetheless, bronchoalveolar lavage does still have a role in the diagnosis of diffuse lung diseases. It provides very helpful confirmatory evidence of diffuse lung disease in patients who cannot (for reasons of comorbidity or disease severity) or will not consent to a surgical biopsy following initial investigations. It is also helpful in excluding infection or malignancy.

The pattern of inflammatory cell infiltrate will differentiate the fibrosing lung conditions (characterized by neutrophils and/or eosinophils) from the granulomatous or drug-induced lug diseases (characterized by an excess of lymphocytes with or without granulocytes). Furthermore, the patterns of bronchoalveolar lavage are beginning to become helpful in differentiating the different idiopathic interstitial pneumonias: granulocytes in cryptogenic fibrosing alveolitis; granulocytes and lymphocytes together with 'smoker's inclusions' in macrophages in desquamative interstitial pneumonia; neutrophils, often in very high numbers, in acute interstitial pneumonia; granulocytes and lymphocytes in non-specific interstitial pneumonia and organizing pneumonia; and lymphocytes in lymphocytic interstitial pneumonia.

Bronchoalveolar lavage can provide diagnostic material in some of the rarer lung disorders, such as: pulmonary alveolar proteinosis (milky effluent; PAS-positive material; phospholipid, membrane-like structures under electronmicroscopy; biochemistry); Langerhans cell histiocytosis (increased numbers of Langerhans cells identified by CD1a staining); mineral dust exposure (energy dispersive analysis by X-rays, asbestos bodies); iron-laden macrophages (alveolar haemorrhage). Other very helpful appearances include the bizarre multinuclear giant cells obtained from patients exposed to the alloy hard metal and the proliferative response of T-cells obtained from the lungs of patients with beryllium exposure, confirming a diagnosis of chronic berylliosis.

High resolution computed tomography

High resolution computed tomography provides a three dimensional anatomical reconstruction of the whole of both lungs. This provides a number of significant advantages over plain chest radiography in the diagnosis and discrimination of the different parenchymal lung diseases, and some patterns are pathognomonic (Table 6).

The major advances that computed tomography has provided is in the earlier detection of suspected lung disease, when chest radiography is often normal; the differentiation of one diffuse lung disease from another; an estimate of the likely reversibility of the disease process—in general a 'ground glass' appearance favours reversibility in response to therapy, or sometimes spontaneously, whereas a coarse reticular pattern of abnormality is generally irreversible and indicates fixed fibrosis. Other irreversible features include the thin cystic structures seen in Langerhans cell histiocytosis and lymphangioleiomyomatosis. Less definitive patterns include variably sized nodules of varying density, linear opacification, and more subtle reticular change. Thickening of the interlobular septa or around the bronchovascular bundles imply a lymphatic component of the disease process. This degree of anatomic precision is the reason why high resolution computed tomography increases sensitivity, specificity, predictive value and, most importantly, confidence of diagnosis in the diffuse lung diseases. An assessment of the degree of reversibility also allows a better estimate of prognosis.

In patchy disease, the location of the best site for a surgical biopsy can be identified using high resolution computed tomography and more subtle pleural disease and airway disease can be identified. These additional features, in the context of the features of diffuse parenchymal lung disease, also help in the differential diagnosis. Good examples include the combination of airway and diffuse disease in rheumatological disorders such as rheumatoid arthritis and the subtle combination of patchy parenchymal disease together with pleural tags in drug-induced disease.

Computed tomography provides a better correlation with functional abnormalities than any other index, including surgical biopsy. In this regard, the extent of disease on computed tomography best matches measures of gas exchange and survival. The availability of high resolution imaging has therefore reduced the need for surgical biopsy in patients with diffuse lung disease considerably, but not removed it entirely.

Lung biopsy

It is imperative that a precise diagnosis is made from the large number of potential causes of diffuse parenchymal lung disease. The advantage of having a firm diagnosis is that the appropriate treatment can be instituted, treatment changed if that which has been started is inappropriate, a balance of cost–benefit to the patient can be better established, and, most importantly, the patient can be better informed about outcome, both with and without treatment. The oft used empirical approach of a trial of treatment—and if that fails then biopsy—is flawed. The major flaws being firstly that treatment will modify the disease process, making diagnosis more difficult with a subsequent biopsy, and secondly, the patient may have deteriorated during this waiting period, making biopsy more risky, and side-effects consequent upon treatment may also complicate the process. It is therefore recommended that, if there is any doubt about diagnosis after using all investigative tools other than biopsy, biopsy should be advised.

There are two types of biopsy. Transbronchial biopsy is used where the disease process is centred around the small airways, allowing access to the transbronchial approach, and when the diagnosis can be made on small biopsies, meaning that the pathological appearances must be so characteristic on small biopsies that there is no doubt. The best examples of this are the granulomatous diseases such as sarcoidosis or malignant diseases such as lymphangitis carcinomatosa.

For the more difficult diffuse lung diseases, particularly the idiopathic interstitial pneumonias, a surgical biopsy is necessary so that the overall pattern of disease can be appreciated. This does require a larger sample. The surgeon is also able to take samples from more than one site, thereby increasing the likelihood of obtaining representative tissue. Two approaches have been used: the limited thoracotomy approach or the more recently introduced video-assisted thoracoscopic surgical technique. The latter is a less invasive approach that is now preferred, providing equivalent sized samples to the more open technique but with some evidence of lessened morbidity. For choice of biopsy procedure in particular diseases see Table 7.

17.11.2 Cryptogenic fibrosing alveolitis

R. M. du Bois

Introduction

The first description of what we currently recognize as fibrosing alveolitis was in 1907. Since then nomenclature has been confused; multiple synonyms have been used, including Hamman–Rich syndrome. With the advent of a new histopathological classification and the recognition of particular patterns of disease on high resolution computed tomography, it is now possible to define cryptogenic fibrosing alveolitis very specifically

Definition

The International Consensus Statement on cryptogenic fibrosing alveolitis (idiopathic pulmonary fibrosis in the United States) has defined the disease as a specific form of chronic fibrosing interstitial pneumonia, requiring, in the presence of a surgical biopsy showing the usual interstitial pneumonia pattern of pathology (see Chapter 17.11.1):

- the exclusion of other known causes of interstitial lung disease such as drug toxicities, environmental exposures, and rheumatological disease;
- abnormal pulmonary function studies that include evidence of restriction (reduced vital capacity (VC) often with an increased FEV_1/FVC ratio) and/or impaired gas exchange (increased alveolar–arterial oxygen gradient ($P(A–a)O_2$) at rest or on exercise or decreased carbon monoxide transfer factor ($DLCO$));
- typical features on chest radiography or high resolution computed tomography scans.

In the absence of a surgical lung biopsy, the diagnosis of cryptogenic fibrosing alveolitis is less certain. However, in the immunocompetent adult, the presence of all of the following major diagnostic criteria as well as at least three of the four minor criteria increases the likelihood of a correct clinical diagnosis of cryptogenic fibrosing alveolitis:

- Major criteria
  - exclusion of other known causes of diffuse lung disease such as certain drug toxicities, environmental exposures, and rheumatological diseases;
  - abnormal pulmonary function studies that include evidence of restriction (reduced VC often with an increased FEV_1/FVC ratio) and impaired gas exchange (increased $P(A–a)O_2$at rest or on exercise or decreased $DLCO$);
  - bibasilar reticular abnormalities with honeycombing and minimal or no ground glass opacities on high resolution computed tomography scans;
  - transbronchial lung biopsy or bronchoalveolar lavage showing no features to support an alternate diagnosis, such as granulomas on biopsy or an excess of lymphocytes on bronchoalveolar lavage.
- Minor criteria
  - age more than 50 years;
  - insidious onset of otherwise unexplained dyspnoea on exertion;
  - duration of illness more than 3 to 6 months;
  - bibasilar, inspiratory crackles on chest auscultation.

Aetiology

Epidemiology

Cryptogenic fibrosing alveolitis may occur in any decade of life but is most commonly seen between the ages 50 to 60 years; children do not get the disease, although they can develop a diffuse lung disease that mimics the condition but does not have the usual interstitial pneumonia pathology. Cryptogenic fibrosing alveolitis occurs in males slightly more frequently than females. There is no geographic variation. Prevalence and incidence rates (approximately 5 per 100 000) are only estimates in the United Kingdom and elsewhere, but are increasing based on evidence from mortality statistics for England and Wales. A registry-based study from the United States estimated a prevalence of 20.2 cases per 100 000 for males and 13.2 cases per 100 000 for females and an incidence of 10.7 cases per 100 000 per year for males and 7.4 cases per 100 000 per year for females.

Possible trigger factors

By definition there is no known aetiology. Multiple factors are likely to be involved. The disease is more common in patients who have a history of cigarette smoking. Viruses, particularly Epstein–Barr virus, have been implicated as trigger factors but this is not proven. More recently, an increased occupational exposure to metal dusts, wood fires, and antidepressant medication has been associated with excess cryptogenic fibrosing alveolitis by comparison with control populations.

In most patients, there is no family history of fibrosing alveolitis but, in a small subgroup a familial pattern is observed. The inheritance pattern is unpredictable and it is likely therefore that transmission involves variable penetrance. The clinical features of the familial and sporadic variants are identical. There are, as yet, no known

predisposing immunogenetic factors, unlike other diffuse lung diseases that can produce lung fibrosis such as the Hermansky–Pudlak syndrome (a condition characterized by oculocutaneous albinism and abnormal platelets), the diffuse lung disease of systemic sclerosis (associated with the anti-DNA topoisomerase I autoantibody, in turn highly associated with an excess of the HLA DRB1*II and DPB1*1301 class II MHC alleles), and sarcoidosis.

Pathogenesis

The pathogenetic processes that give rise to cryptogenic fibrosing alveolitis involve lung injury, an immunological and inflammatory response, and fibrogenesis. All four components appear to be occurring in parallel and this is reflected in the heterogeneity of the histopathological appearances. The various trigger agents implicated in the disease are likely to be the causes of injury, complemented by an adverse imbalance in the oxidant–antioxidant profile within the lung, together with the release of tissue-damaging enzymes from macrophages and granulocytes.

The inflammatory response is variable and its relationship to fibrogenesis is unclear. In brief, all of the cellular and molecular biological mechanisms that determine immune and inflammatory cell recruitment and activation have been shown to operate in the lungs of patients with cryptogenic fibrosing alveolitis. Key components appear to be the up-regulation of tumour necrosis factor-a, chemokines, notably interleukin 8, and growth factors, most notably transforming growth factor-b and connective tissue growth factor. Whether up-regulation of the mechanisms that result in inflammatory cell traffic is pathological or a physiological response to injury is not clear.

The evidence that the fibrogenetic response has become autonomous (i.e. not a simple tissue repair mechanism) is strong. In gene over-expression animal models, the transient over-expression of transforming growth factor-b resulted in a progressive fibrosing lung disease that mimicked cryptogenic fibrosing alveolitis, with a histopathological appearance that was indistinguishable from usual interstitial pneumonia.

Pathology

Usual interstitial pneumonia is the pattern seen in patients with cryptogenic fibrosing alveolitis. The hallmark of usual interstitial pneumonia is a patchy distribution of interstitial fibrosis, chronic inflammatory cell infiltrate, enlarged cystic air spaces (honeycomb lung), and normal lung (Fig. 1 and Plate 1). Inflammation is often mild and the fibrosis characterized by acellular collagen bundles with foci of proliferating fibroblasts. This non-uniform appearance, which is often visible under low microscopic power, suggests the pathological processes are at different stages of development (temporal heterogeneity), a feature that distinguishes usual interstitial pneumonia from other interstitial pneumonias.

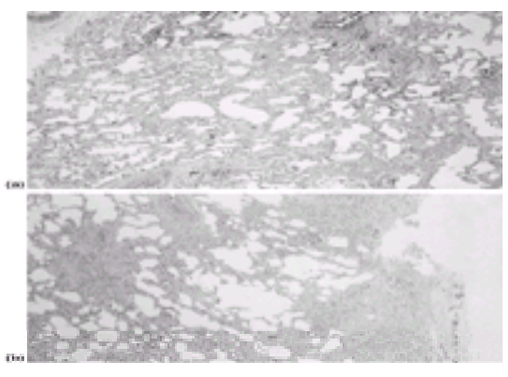

Fig. 1 Histopathological appearance of cryptogenic fibrosing alveolitis and the non-specific interstitial pneumonia 'mimic'. (a) Usual interstitial pneumonia, the histopathological pattern seen in cryptogenic fibrosing alveolitis. Note the pale, fibroblast foci that are the hallmark of usual interstitial pneumonia. (b) The non-specific interstitial pneumonia 'mimic' of cryptogenic fibrosing alveolitis. This is much less common than usual interstitial pneumonia. Note the uniformity of the pathology throughout the section. (See also Plate 1.)

Clinicopathological correlations

Correlations between clinical and physiological indices of disease and lung biopsy appearances have, in general, proved to be disappointing. This is probably a reflection of the fact that biopsy samples a small area of the peripheral (and most involved) part of the lung, whereas other indices reflect the function of the whole of both lungs. Despite this, it has been shown that the degree of lung involvement can be correlated with lung function indices. More recent studies have utilized high resolution computed tomography (that 'samples' the anatomy of the whole of both lungs) instead of biopsy and have shown better correlations with lung function indices, especially gas transfer, and have concluded that high resolution computed tomography provides a more accurate prediction of outcome.

Clinical features

History

A history of progressive breathlessness on exertion in the absence of wheeze is typical. A dry cough may be present, but sputum production is unusual until the later stages of the disease. Haemoptysis is uncommon and should suggest the development of lung malignancy that occurs with a 7 to 14-fold relative risk in cryptogenic fibrosing alveolitis. Chest pain is uncommon. Constitutional symptoms such as weight loss and lethargy are recognized.

A full occupational and domestic environmental exposure (from school leaving), and drug ingestion history, are necessary to identify diseases that can mimic cryptogenic fibrosing alveolitis (see Table 1). A history of other diseases, particularly the rheumatological disorders, is important because the diffuse lung disease in this context can mimic, but is quite different from, cryptogenic fibrosing alveolitis.

Examination

Digital clubbing is present in 70 to 80 per cent of patients. On auscultation, very fine crackles are heard at the lung bases and in the midaxillary line, occurring at the end of inspiration in early cases but becoming paninspiratory in more advanced disease. In the presence of more subtle disease, the crackles may disappear as the patient leans forward, but usually they persist in the midaxillary line.

At more advanced stages of disease, central cyanosis may be evident, also signs of pulmonary hypertension and right ventricular failure. In addition, general examination may reveal non-pulmonary features that would suggest alternative, systemic diseases, such as arthropathy, vasculitis, skin disorders, and peripheral lymphadenopathy.

Investigations

Imaging

Chest radiography

A typical chest radiograph of a patient with cryptogenic fibrosing alveolitis is characterized by small lung fields and reticulonodular shadowing, particularly at the periphery of the lung and at the bases, obscuring the right and left heart borders and making the diaphragmatic surfaces irregular (Fig. 2). Even in more subtle examples of fibrosing alveolitis, this distribution of radiographic abnormality should suggest the diagnosis. In more advanced cases, all lung zones are involved, at which point evidence of honeycomb shadowing may be present.

Fig. 2 Chest radiograph of a patient with cryptogenic fibrosing alveolitis. This shows the typical features of the disease with peripheral, predominantly basal, reticulonodular changes obscuring the heart borders and diaphragms.

Lymphadenopathy is rarely observed on chest radiography and the presence of pleural disease should suggest an alternative diagnosis. Cardiomegaly and prominent pulmonary arteries indicate secondary pulmonary hypertension.

High resolution computed tomography

The use of high resolution computed tomography over the last 10 years has revolutionized the approach to diffuse lung disease. The pattern of abnormality may be characteristic in a number of diffuse lung diseases (see Chapter 17.11.1) and is virtually pathognomonic in cryptogenic fibrosing alveolitis. Typical early changes are of a peripheral rim of reticular change at the bases, posteriorly (Fig. 3). As disease becomes more extensive, these changes are observed in the other lung zones and more centrally. Computed tomography confirms that pleural disease is not present in cryptogenic fibrosing alveolitis but, by contrast to the observation on plain chest radiography, mediastinal lymphadenopathy is commonly present. In more subtle cases, it is important to perform prone as well as supine scans to exclude the contribution of gravity to the radiographic appearances due to vascular and interstitial pooling in the dependent areas.

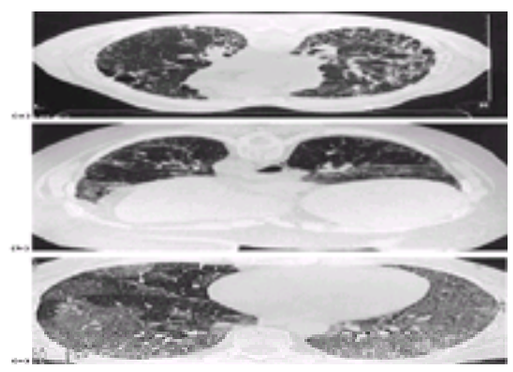

Fig. 3 High resolution computed tomography of patients with diffuse lung diseases that can mimic cryptogenic fibrosing alveolitis. (a) The predominantly peripheral, coarse honeycombing is characteristic of cryptogenic fibrosing alveolitis. (b) More fine fibrotic change is seen in non-specific interstitial pneumonia. Note the absence of honeycombing and the less clear-cut peripheral distribution of disease. (c) Desquamative interstitial pneumonia showing widespread, ground glass opacification with maintenance of the fine architecture of the lung and no evidence of fibrosis.

Radionuclide imaging

Ventilation–perfusion scans

Ventilation–perfusion scans show mismatching of perfusion to ventilation in cryptogenic fibrosing alveolitis, making the test unreliable in excluding thromboembolic disease in this situation. This is important because there is an increased incidence of pulmonary embolus in this disease and the diagnosis of pulmonary embolus will therefore rely on the clinical features, identification of the venous source of emboli, and, in some instances, spiral computed tomography to identify vascular occlusion in the more proximal arteries.

Gallium scanning

Gallium scanning is a highly sensitive but non-specific test, being positive in a wide range of diffuse processes that involve macrophage activation. It has no role in the diagnosis or management of cryptogenic fibrosing alveolitis.

^{99m}Tc-diethylinetriamine pentacetate (DTPA) clearance

Clearance from the lung of inhaled ^{99m}Tc-diethylinetriamine pentacetate (DTPA) is of value in identifying early disease and is a helpful test in prognosis; patients with a persistently normal clearance run a more stable, non-progressive course. Cigarette smoking will produce increased clearance rates and the test is therefore only of value in non-smokers or those who have given up smoking for at least 1 month prior to assessment. The role of DTPA clearance studies in routine clinical management is not yet clear.

Lung function tests

Fibrosing alveolitis is characterized by a restrictive ventilatory defect of mechanical function resulting in reduced pulmonary compliance, vital capacity, and total lung capacity. Residual volume is usually decreased unless there is coincident airflow obstruction due to cigarette smoking and lung recoil pressure is increased.

Carbon monoxide transfer factor (*DL*CO, a measure of diffusion capacity) is reduced and may be the only abnormality in early disease. In most patients the gas transfer measurement adjusted for alveolar volume (*K*CO) is also reduced, but less than *DL*CO, indicating that the capacity to exchange gas is impaired in lung that has not been destroyed. If there is significant coexisting emphysema, lung volumes will be well preserved in the face of a disproportionately depressed gas transfer measurement in both *DL*CO and *K*CO. Gas transfer is reduced by both the emphysematous and the fibrosing processes, whereas lung volumes will tend to be increased by emphysema but reduced by fibrosis and these two opposing influences result in relatively normal-sized lungs radiographically and physiologically.

Typical blood gas measurements will reveal a reduced PaO_2 value with a normal or low $PaCO_2$ measurement. In more advanced cases, the $PaCO_2$ will be reduced because of the increase in ventilatory drive in a patient with more severe lung stiffening due to fibrosis, but in terminal stages CO_2 may rise. The low PaO_2 is largely attributable to ventilation–perfusion mismatching. On exercise, hypoxaemia is exacerbated and a widening of the alveolar–arterial (A–a) gradient is observed. Infrequently, these abnormalities on exercise testing are the only physiological abnormalities, but usually by the time the patient seeks advice there is already some abnormality in the gas transfer measurement at rest.

Lung function measurements (to include gas transfer) should be made sequentially to assess the progression of the disease process. Spirometry alone or, worse, peak flow measurements, are inadequate. It is sensible to plot out serial lung function studies to visualize more gradual change that may be missed if results are

compared only with the previous set of measurements.

Blood tests

Blood tests are of little value in the diagnosis of cryptogenic fibrosing alveolitis. In severe cases, secondary polycythaemia may be observed and a high neutrophil count may indicate superadded infection. Corticosteroid therapy will elevate total white count to around 13 to 14 × 10^{9}/l, sometimes even higher.

Elevations in one or more classes of immunoglobulins, particularly IgG and IgM, may be seen and rheumatoid factor or antinuclear antibody may be present in abnormal titres in approximately 45 per cent of patients, but none of these immunological assessments is specific. The titres of autoantibodies do not approach those seen in the rheumatological diseases. In cases where there is a history of significant antigen exposure, or when there is doubt about relevant exposures, it is helpful to perform precipitin tests against the fungal antigens which produce diseases such as farmer's lung or the avian antigens which can provoke budgerigar or pigeon fancier's lung.

Bronchoalveolar lavage

Bronchoalveolar lavage is valuable in excluding infection and as confirmation that the histopathological pattern is likely to be the usual interstitial pneumonia pattern in patients who cannot or will not tolerate surgical biopsy. In a typical patient with cryptogenic fibrosing alveolitis, bronchoalveolar lavage would produce an increase in total cell returns of three to six fold (up to 6 × 10^{5}/ml of fluid return), and of these up to 20 per cent may be neutrophils or eosinophils. A large excess of lymphocytes suggests an alternative diagnosis such as granulomatous or drug-induced causes of lung disease. Serial bronchoalveolar lavage is of no value in monitoring disease.

Lung biopsy

The only lung biopsy technique that provides useful information is surgical lung biopsy, either through minithoracotomy or video-assisted thoracoscopic biopsy (the most common procedure). The surgeon will biopsy at least two sites to ensure representative sampling and the biopsy can be divided into parts that will be stored, if necessary, for immunohistochemical, molecular, and electron microscopical analysis in addition to the more routine histopathological evaluation.

Transbronchial biopsy cannot be used for diagnosis of cryptogenic fibrosing alveolitis and is only helpful in excluding other conditions such as granulomatous disease. The specimens produced are small, and do not allow an assessment to be made of the individual patterns that are important in differentiating the different idiopathic interstitial pneumonias.

Treatment

Established drug regimens

There have been no prospective, placebo-controlled, randomized trials of treatment in this condition. Most information on drug efficacy is derived from individual comparative series. Many of these have been retrospective. Assessment of efficacy is further complicated by recent knowledge that historic series probably included patients whose disease had the histopathological appearances of interstitial pneumonias other than usual interstitial pneumonia. These qualifications mean that the level of evidence base on which recommendations are made is low. However, world-wide experience, coupled with the recently published American Thoracic Society/ European Respiratory Society statement on cryptogenic fibrosing alveolitis, suggests that a combination of low-dose prednisolone (dosage varies between centres internationally but 20 mg on alternate days is the author's preference) together with azathioprine at 2.5 mg/kg per day up to a maximum of 150 mg/day should be the first-line treatment (Table 2). Azathioprine treatment should be commenced at 50 mg/day for 1 month with weekly full blood count monitoring to ensure that the individual does not have the methyltransferase deficiency that predisposes to enhanced toxicity. Provided blood counts are stable at 4 weeks, dosage can be increased to the maximum. Full blood count and liver function tests need to be performed 6 to 8-weekly.

An alternative to azathioprine is cyclophosphamide at 2 mg/kg per day up to a maximum of 150 mg per day. In addition to the potential bone marrow toxicity, haemorrhagic cystitis and bladder neoplasm are complications. Regular dipstick analysis for blood is recommended by some, ideally at weekly intervals. There is no place for high-dose corticosteroid treatment in the routine management of cryptogenic fibrosing alveolitis.

Other treatment regimens

Other drugs that have been used to treat this disease are colchicine (which has a similar efficacy to corticosteroids alone but with less side-effects), cyclosporin (very little data and no justification for use of this agent), penicillamine (no evidence of efficacy), pirfenidone (possible disease stabilization during corticosteroid reduction in a small subset of patients, but not commercially available), and interferon-g (small study with reservations that the subgroup studied was not representative of cryptogenic fibrosing alveolitis as defined above). None of the approaches other than colchicine are recommended for the reasons indicated.

Acute exacerbations or accelerated disease

Sudden deterioration can occur. Supervening infection, heart failure, and thromboembolism must be excluded. If accelerated disease is believed to be the cause of the deterioration, intravenous corticosteroids (1 g/day methylprednisolone for 3 days) together with intravenous cyclophosphamide (600 mg/m^{2} as a single dose, repeated at roughly 2-week intervals if blood counts are satisfactory) should be considered.

Transplantation

Single lung transplantation is now the organ replacement therapy of choice for end-stage fibrosing alveolitis. The procedure has not been used for a sufficiently long period to provide information about long-term survival, but approximately 60 per cent are alive at 3 years.

Supportive therapy

When all treatment options have failed, supportive therapy is necessary. Supplemental oxygen may be required and this can be provided in the home through oxygen concentrators. Diuretics may be necessary and infection should be treated promptly. In the terminal phases, small dosages of opiates have been shown to suppress the sensation of extreme breathlessness that occurs as the lungs become much less compliant.

This chronic, often relentlessly progressive, disease has a disabling affect on the patient and their close family. Full support by medical and non-medical health-care professionals should be involved in the patient's care; medical social workers, physiotherapists, occupational therapists, and rehabilitation programmes for patients form an important part of supportive management.

Monitoring of treatment

Immunosuppression can take 3 to 6 months, and sometimes longer, to produce a maximal effect. Patient monitoring with full lung function tests at 3-monthly intervals during the first year is recommended. If the disease becomes stable or improvement is seen, treatment should be continued until the disease has stabilised for a total of 1 year. A tapering, with a view to complete withdrawal of immunosuppression, should be tried at this point. If function deteriorates, alternative drug therapies need to be tried. Once lung function is less than 30 per cent predicted, consideration for transplantation is required. The age limit imposed by some transplantation centres needs to be taken into account when planning management.

Prognosis

Historically, survival was thought to be roughly 50 per cent at 4 years. More recent studies comparing survival of incident cases as opposed to prevalent cases, and with a more rigid definition of cryptogenic fibrosing alveolitis as outlined above, have shown the prognosis is even more desperate, with median survival being less than 3 years and 10-year survival of 5 to 10 per cent. These appalling survival figures highlight the need for early detection, early introduction of treatment, and early

consideration of transplantation in patients who fail to respond to therapy.

Areas of uncertainty

What is the cause?

It is unlikely that a single aetiology will be identified and, even if it were, removal of that cause is unlikely to be curative. Multiple trigger factors are likely to operate in conjunction with some form of genetic predisposition resulting in disease. Patients often expect clinicians to be able to identify a cause that results in a cure and they need to be told that this will not happen.

Should all patients undergo surgical biopsy?

Decisions about biopsy need to take into account the degree of certainty of diagnosis using all of the investigations outlined above, particularly high resolution computed tomography and bronchoalveolar lavage. If there is any doubt about diagnosis, then surgical biopsy is needed to confirm the diagnosis. These decisions must always take into account the individual patient and need to be made in the context of other potentially complicating, comorbid conditions and whether there is a likelihood of an increased complication rate. Chronological age should not be a factor but clearly biological age is.

When should treatment be commenced?

It is a mistake to wait until a patient has limiting breathlessness before commencing treatment. At this stage at least 50 per cent of lung function is likely to have been lost and the patient will have little reserve. Many studies have shown that treatment is more likely to be successful if commenced early. The key issue is the likelihood of improving or stabilizing disease against the likelihood of side-effects. This has to be related to the individual. Factors that predict likely response to therapy are ground glass appearances (indicating cellularity) on high resolution computed tomography and comorbid conditions such as hypertension and diabetes mellitus that will increase the risk of corticosteroid-induced side-effect.

It is also important to remember that functional deficit caused by lung damage and scarring cannot be reversed; it is only the more recent, inflammatory pathological response that is responsive to currently used treatment. Improvement in lung function is seen in only 5 to 10 per cent of cases. Therapeutic response, if it occurs, more probably results in disease stability. The patient, and some clinical colleagues, need to be told this. This emphasizes the importance of attempting to stabilize disease at a level of function that is acceptable to the patient.

How long should treatment continue?

Optimal duration of therapy is not known. An approach to the management of immunosuppressant drugs is described above under 'Treatment'. The issue with regard to corticosteroids is less clear-cut. There is anecdotal evidence that complete corticosteroid withdrawal can result in a rebound of disease activity, which cannot then be controlled. It is therefore reasonable to attempt to reduce corticosteroids to approximately 10 mg every other day and, if disease remains stable at this level, then this dosage of drug should be continued indefinitely. The likelihood of significant side-effects on such a small dosage is low set against the possibility of disease flare-up on complete withdrawal of treatment.

Areas for future research

The major areas of future research involve a clarification of epidemiological issues and a resolution of the issue of possible immunogenetic predisposition and the relationship between environmental exposures and immunogenetic predisposition. Differences in the evolution of fibrogenesis in different patterns of idiopathic interstitial pneumonia need to be studied and this will probably involve a better appreciation of different functional phenotypes of fibroblasts, with particular regard to their connective tissue matrix products. Prospective, properly controlled, double-blind studies of treatment efficacy, using cohorts of patients with the usual interstitial pneumonia histopathological pattern, are of paramount importance to identify optimal treatment. This will require an international collaborative effort.

17.11.3 Bronchiolitis obliterans and organizing pneumonia

R. M. du Bois

Introduction

The bronchioles are defined as airways that have no cartilaginous support and comprise the terminal bronchioles and the respiratory bronchioles leading to the alveolar ducts. In many diffuse parenchymal lung disorders, the small bronchioles are involved in the histopathological process and bronchiolar disorders are often included in the classification of diffuse parenchymal lung diseases. The nomenclature of bronchiolitis has become confused. This is because pathological and clinical descriptions have been used interchangeably. There are three main histopathological patterns (Fig. 1 and Table 1):

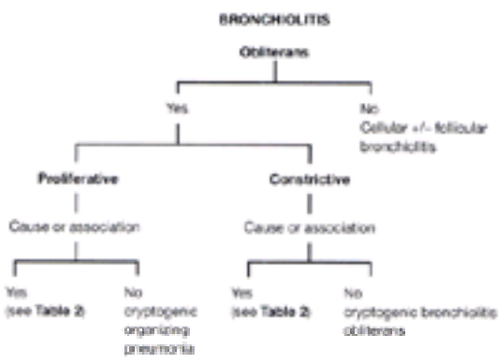

Fig. 1 Algorithm for the classification of bronchiolitis.

- proliferative bronchiolitis;
- constrictive bronchiolitis;
- cellular/ follicular bronchiolitis.

Proliferative and constrictive bronchiolitis patterns both cause obliteration of the bronchioles—'bronchiolitis obliterans'—but are associated with distinct clinical patterns of disease. Both may be the result of a known or unknown cause or association (see Table 2).

Nomenclature

Bronchiolitis obliterans is a term that has been used for many years to denote a relentless fibrosis of the bronchioles that results in severe, generally irreversible, airflow obstruction, and is characterized by obliteration of the terminal bronchioles by fixed fibrosis. In 1983, Davison *et al*. described a group of patients who presented with pneumonic-like features, but without evidence of infection, and in whom histopathological appearances were those of intra-alveolar organization spreading proximally to the terminal bronchiole. This disorder also obliterated the bronchioles, but with intraluminal loose, fibrous tissue, quite different from that seen in bronchiolitis obliterans. No cause was found for this condition and it was termed cryptogenic organizing pneumonitis. In 1985, Epler *et al*. rediscovered the entity, reporting the results of analysis of a large number of histopathological specimens, and gave the disease the name bronchiolitis obliterans organizing pneumonia. This confusion of nomenclature resulted in bronchiolitis obliterans and organizing pneumonia being regarded as synonyms.

An American Thoracic Society/ European Respiratory Society nomenclature committee has now redefined the diffuse lung diseases, including organizing pneumonia. It recommended that the idiopathic (or cryptogenic) variant of organizing pneumonia should be known as cryptogenic organizing pneumonia, with the histopathological features of organizing pneumonia. It must be noted that this disease and these pathological features are synonymous with idiopathic bronchiolitis obliterans organizing pneumonia, a term that will undoubtedly still appear in the literature. Bronchiolitis obliterans should be the term for the irreversible airway disease.

Bronchiolitis obliterans

Introduction

As with every form of bronchiolitis, attempts should be made to identify a potential trigger (see Table 2). Once all known triggers and associations have been excluded, the disease can be considered cryptogenic. Occasionally, the initial presentation of rheumatological disease is with the pulmonary manifestation, and it is therefore important to exclude this as far as possible through a full clinical history and examination, and also by testing for autoantibodies.

This disease is the result of progressive obliteration of the terminal bronchioles with connective tissue matrix. It is a relentless condition that is usually non-responsive to therapy. The pathogenesis is unknown.

Histopathology

The terminal bronchioles are predominantly involved with some extension into the proximal respiratory bronchioles. The lumens are significantly narrowed and often obliterated by a mixture of cellular inflammation and fibrosis–constrictive bronchiolitis (Fig. 2 and Plate 1). In advanced stages, the airways are occluded by dense, relatively acellular connective tissue matrix.

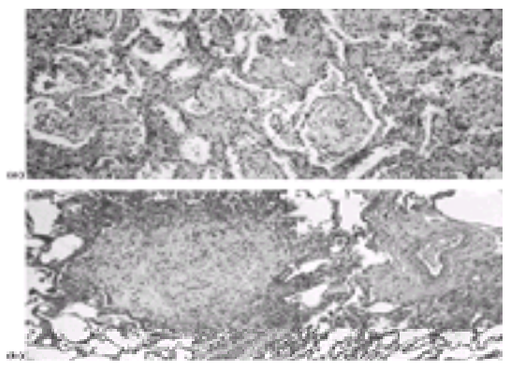

Fig. 2 Histopathology. (a) Proliferative bronchiolitis. (b) Constrictive bronchiolitis. Note the loosely packed granulation tissue in (a) in contrast to the more established scarring in (b). (See also Plate 1.)

Clinical features

The most striking clinical feature is progressive breathlessness, often with little wheeze despite this being predominantly an airway disease. Cough may occur, but is rarely productive, and haemoptysis is not a feature. Chest pain is uncommon but chest tightness may be described. Clinical examination of the respiratory system is unremarkable. Occasionally an inspiratory 'squeak' is heard, which is very characteristic of small airway disease. Examination of other systems may identify subtle rheumatological disease.

Investigations

Imaging

Chest radiography shows large lung fields with some loss of vascular markings but no evidence of infiltration.

High resolution computed tomography is more informative (Fig. 3). There is a patchiness of attenuation, described as 'mosaicism'. This represents variable degrees of lung perfusion caused by patchy vasoconstriction in affected areas, this being due to reflex hypoxic vasospasm in response to airway obliteration. The mosaic pattern is enhanced on expiratory CT because gas trapping enhances the differences between perfused and non-perfused lung.

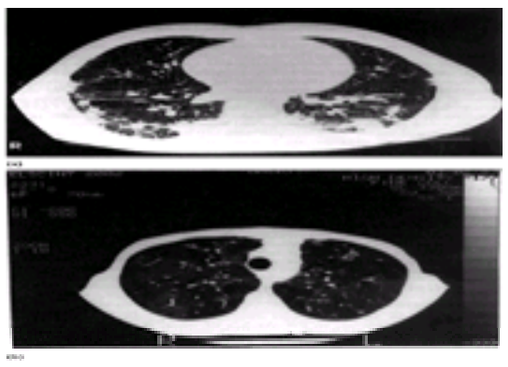

Fig. 3 High resolution computed tomography. (a) Organizing pneumonia. Peripheral consolidation is the classic feature. Histopathology is proliferative. (b) Bronchiolitis obliterans. The attenuation of the lung fields varies from grey (normal perfusion) to black (reduced perfusion due to hypoxic vasoconstriction resulting from airway obliteration). Histopathology is constrictive.

Lung function tests

Lung function tests show fixed airflow obstruction with an increase in residual volume and total lung capacity measured by plethysmography. Total gas transfer for carbon monoxide (*DL*CO) is reduced, but the gas transfer index (total gas transfer corrected for alveolar volume) is preserved. This is an important distinguishing feature from airway diseases that cause obliteration of the vascular bed, such as emphysema. The arterial partial pressure of oxygen (PaO_2) is relatively well preserved until disease is severe.

Other investigations

Blood tests are unhelpful, with the exception of assays for autoantibodies that might suggest rheumatological disease. Bronchoalveolar lavage is not normally indicated and may be dangerous if disease is severe. However, when performed, an excess of neutrophils is characteristic.

Differential diagnosis

Cryptogenic bronchiolitis obliterans should be distinguished from other forms of chronic airflow obstruction, such as asthma, chronic obstructive pulmonary disease (COPD), and known causes or associations that result in bronchiolitis obliterans. The relatively well-preserved gas transfer index is an important feature distinguishing this condition from emphysema. The appearances on high resolution computed tomography (particularly the expiratory scan) are characteristic of obliterated small airways. In exceptional circumstances, surgical biopsy is needed to confirm the diagnosis. If this is undertaken, the characteristic airway abnormalities can sometimes be elusive. Multiple sectioning throughout the whole block is required to obtain regions that would allow a correct diagnosis to be made.

Treatment

Treatment response is generally poor. It is important to give a trial of corticosteroids to exclude reversibility. A reasonable approach would be to give 40 mg of prednisolone per day for 4 weeks, measuring pulmonary function before and after, paying particular attention to changes in residual volume and gas transfer. If there is significant objective response, steroid dosage should be tapered and maintenance inhaler therapy given. This should consist of inhaled corticosteroids and, possibly, a long-acting b_2-adrenoceptor agonist such as salmeterol or eformoterol. Immunosuppressants, typically azathioprine, have been tried but with limited success.

In the younger patient, lung transplantation should be considered. However, the most common long-term problem encountered with lung transplantation is an obliterative bronchiolitis. Counselling of the patient is particularly important in this situation.

Organizing pneumonia

Introduction

Known causes of, and associations with, organizing pneumonia should be identified (see Table 2). In the absence of these, the term cryptogenic organizing

pneumonia is used. Clinical features are very similar for the cryptogenic and non-cryptogenic disease.

Histopathology

The most striking abnormality is the filling of the airways distal to the terminal bronchiole and the alveoli with granulation tissue in a peribronchiolar distribution, comprising buds of loose collagen and connective tissue matrix cells with a uniform appearance (Fig. 2). There may be some surrounding chronic inflammation. The intra-alveolar granulation tissue may spread from one alveolus to another thorough the pores of Kohn.

Clinical features

The disease presents subacutely with a history of, usually, 2 to 3 months' non-productive cough, shortness of breath, and the systemic features of fever, weight loss, and malaise. It affects men and women equally and occurs predominantly in the fifth and sixth decades. Digital clubbing is rare. A few crackles may be heard on auscultation, but this is not invariable. Features of systemic disease may suggest that the lung problems are secondary.

Investigations

Imaging

Chest radiography shows, most commonly, a bilateral, predominantly peripheral, and often basal, pattern of consolidation. Very occasionally there is an interstitial pattern reminiscent of fibrosing alveolitis, and even more rarely the pattern is of a single nodule. Cavitation can occur but is uncommon. Pleural disease is rare.

High resolution computed tomography defines the pattern more clearly and often shows the disease as more extensive than would be suspected from plain chest radiography (Fig. 3). The predominantly peripheral pattern of confluent disease with air bronchograms may be confirmed. A rarer variant, with a very marked peribronchovascular bundle distribution, can be associated with changes suggestive of fibrosis. This more interstitial variant is less likely to resolve.

Lung function tests

Lung function tests show a restrictive ventilatory defect with reduced gas transfer. $Pa{O_2}$ is well maintained unless disease is severe.

Other tests

Blood tests are non-specific, suggesting an inflammatory process with a leucocytosis, elevated erythrocyte sedimentation rate, and C-reactive protein. A seasonal variant of disease (occurring between February and May) has been reported in one series and this was associated with abnormal liver function tests.

Bronchoalveolar lavage

Typical features are in increase in lymphocytes together with neutrophils and/or eosinophils. The CD4:CD8 ratio is low. Foamy macrophages are characteristic. Occasionally, mast cells and plasma cells may be seen.

Differential diagnosis

All other causes of consolidation visible on imaging need to be considered. These include infection, eosinophilic pneumonia, alveolar haemorrhage, alveolar proteinosis, alveolar cell carcinoma, vasculitis, and lymphoma. Patients who have atypical features or who have not responded to treatment as completely as would be expected should have the alternative diagnoses considered.

Diagnosis is most cases will require a surgical biopsy. In exceptional circumstances, the diagnosis may be made in the context of the classical (consolidation) form of disease on the basis of typical bronchoalveolar lavage findings, together with a transbronchial biopsy that is consistent. It is noteworthy, however, that areas of organization are seen on histopathological examination of biopsies from a variety of disorders such as vasculitis, eosinophilic pneumonia, and malignancy, but in these circumstances they are minor features and not the dominant pathology. Unfortunately, a transbronchial biopsy may only sample these minor features, thereby resulting in misdiagnosis.

Treatment

Corticosteroids usually work extremely well. It is usual to commence with a dosage of 0.75 mg/kg per day orally for a month and then gradually taper whilst monitoring symptomatic, radiological, and physiological improvement. It is usually possible to discontinue corticosteroids after 6 to 12 months. Relapses can occur at any time but usually respond to a reintroduction of corticosteroids. Rarely, immunosuppressants, such as azathioprine or cyclophosphamide, need to be used as steroid-sparing agents or in more resistant disease.

Occasionally patients present with respiratory failure due to very extensive disease and in this situation pulsed intravenous methylprednisolone at 500 to 1000 mg daily for 3 days can be life saving. It is very unusual to have to use mechanical ventilation.

Prognosis

The prognosis is generally very good. Indices of a poor prognosis include organizing pneumonia that is secondary to rheumatological or other systemic disease, an imaging pattern that shows an interstitial or mixed pattern of disease, and a bronchoalveolar lavage that has no lymphocytes. Estimates of 5-year survival are 73 per cent for primary disease compared to 44 per cent for disease that occurs secondary to other disorders. Deaths due to organizing pneumonia are uncommon and in various series range from 3 to 13 per cent of cases.

17.11..4The lungs and rheumatological diseases

R. M. du Bois and A. K. Wells

Introduction

Lung involvement can occur in all rheumatological diseases, with different patterns of respiratory pathology predominant in different diseases. The frequency and best management of these problems is often uncertain because, although common, they have been less well documented than the more obvious rheumatological features. Respiratory involvement may be subclinical, symptoms often being masked by exercise limitation due to musculoskeletal factors.

In some patients, diffuse lung disease is the presenting feature of the rheumatological disease, when typical computed tomography appearances together with autoantibody studies will point to the correct diagnosis.

Imaging

Chest radiography will identify the predominantly reticulonodular pattern of the diseases that mimic fibrosing alveolitis (see Chapter 17.11.1 and Chapter 17.11.2), the consolidation of organizing pneumonia and alveolar haemorrhage, the ground glass pattern of acute pneumonitis, the hyperinflation of bronchiolitis obliterans, and the presence of pleural disease.

High resolution computed tomography will enhance the sensitivity, precision, and accuracy of diagnosis. It will also reveal combinations of patterns that suggest specific rheumatological diseases. In fibrosing alveolitis, there is a reticular pattern that is initially basal and peripheral with honeycombing. More extensive disease progresses upwards and anteriorly. Ground glass changes are found in more cellular disease; mosaicism (alternating regions of increased and decreased attenuation) is typical of small airway disease. Bronchiectasis and pleural changes are seen more clearly than on chest radiography. Prediction of reversibility is much more precise than with chest radiography.

Lung function

Lung function testing does not discriminate in terms of precise pulmonary diagnosis but will differentiate obstructive ventilatory defects, characteristic of airways disease, from the restrictive pattern with reduction in gas transfer that is seen in all forms of diffuse lung disease. Lung function testing is the gold standard measure of extent of disease. Exercise tests will unmask more subtle disease, often subclinical, but are not routine requirements. A measure of gas transfer, however, is always needed.

Clinical features of lung disease in particular autoimmune rheumatic disorders

Systemic sclerosis

The criteria for classification of systemic sclerosis are described in Chapter 18.11.3. Pulmonary involvement has emerged as the major cause of excess morbidity and mortality in this disorder. The patterns of lung disease with which systemic sclerosis may present are variable and are shown in Table 1.

Fibrosing alveolitis

Clinical features

Lung disease may be the first manifestation of systemic sclerosis, and dyspnoea occurs in roughly 55 per cent of patients with this condition. Cough is a less frequently reported symptom, but when it occurs is dry and non-productive; haemoptysis indicates complicating carcinoma or bronchial telangiectasia. Pleuritic chest pain is uncommon. A history of Raynaud's phenomenon is often present. Digital clubbing is rare because of the poor vasculature of the digits. Fine crackles are heard at the bases and are of 'velcro' character. Capillaroscopy, digital thermography, and a positive antinuclear antibody can be helpful in suggesting the correct diagnosis. Lung fibrosis occurs more commonly in patients with the Scl 70, anti-DNA topoisomerase autoantibody. Chest radiographic series have identified diffuse lung disease in up to 67 per cent of patients. Oesophageal dilatation may be seen on chest radiography and is almost universally present on high resolution computed tomography. ^{99m}Tc-diethylinetriamine pentacetate clearance has been used in some centres to identify early disease and to predict prognosis—persistently normal clearance predicts lung function stability. Lung function abnormalities are found in up to 90 per cent of patients; scleroderma of the chest wall may rarely cause extrathoracic restriction. Bronchoalveolar lavage is of value in excluding complicating infection and malignancy and in suggesting the most likely histopathological pattern, but it is of no value in monitoring disease. In non-specific interstitial pneumonia (NSIP, see Chapter 17.11.1), the most common histopathological pattern, granulocytes and lymphocytes may be present in excess; usual interstitial pneumonia is less common, associated with excess of neutrophils with or without eosinophils on lavage.

Prognosis

The prognosis of fibrosing alveolitis in systemic sclerosis is dependent upon the extent of disease at presentation, but it is much better than in cryptogenic fibrosing alveolitis. Significant improvements can be achieved in response to therapy, despite the prevalent view held by many (Fig. 1). Worse lung function, particularly vital capacity and gas transfer (*DL*CO), indicates a poorer outcome, and similar observations have been made using extent of disease on computed tomography as the criterion. Crude mortality rates are 3.9 per cent per year for males and 2.6 per cent per year for females with systemic sclerosis, with lung disease the commonest cause of death. There is also an increased risk of lung cancer.

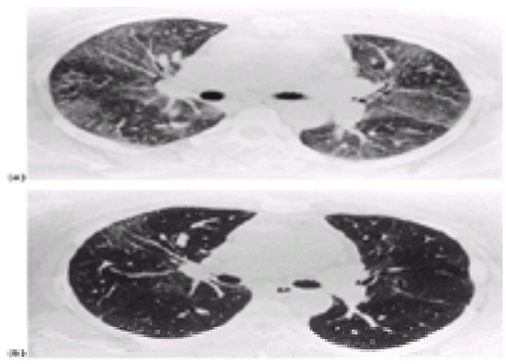

Fig. 1 CT scans of a patient with the fibrosing alveolitis of systemic sclerosis, demonstrating a non-specific interstitial pneumonia pattern of disease. (a) Before treatment. Note the widespread ground glass pattern of disease, with some areas in which the airways have been distracted demonstrating fine fibrosis. (b) After treatment. The residual, more fibrotic areas remain, but much of the abnormality has cleared.

Pulmonary vascular disease in systemic sclerosis

Unlike the other rheumatological diseases, vascular involvement in systemic sclerosis is caused not by vasculitis but by concentric fibrosis replacing the normal intima and media of small arterioles. Isolated pulmonary vascular disease occurs mainly in the limited form of systemic sclerosis (including the CREST syndrome—calcinosis, Raynaud's phenomenon, oesophageal dysmotility, sclerodactyly, telangiectasiae) and in individuals with the anticentromere autoantibody. Chest radiography, high resolution computed tomography, and bronchoalveolar lavage are all normal. Lung function studies show an isolated fall in DL_{CO} and gas transfer index (K_{CO}). When damage to the pulmonary vascular bed is extensive (gas transfer <50 per cent predicted) the risk of pulmonary hypertension increases. Mortality rates are increased with increasing pulmonary hypertension, for which Doppler echocardiography is a good screening test.

Other pulmonary complications

Aspiration pneumonia is uncommon, particularly considering the prevalence of oesophageal dysfunction in systemic sclerosis. Pleural disease is also uncommon. Rarely, the extent of skin tightness over the chest wall produces an extrinsic restriction of ventilation. Occasionally, the first manifestation of pulmonary parenchymal disease is organizing pneumonia

Polymyositis/dermatomyositis

The defining criteria for polymyositis and dermatomyositis are described in Chapter 18.11.7.

Pulmonary complications occur in up to 64 per cent of patients in combined series and are the most frequent cause of death. The main manifestations of lung disease are summarized in Table 1.

Diffuse lung disease

Diffuse lung disease is the commonest problem encountered in the context of dermatomyositis/ polymyositis. The pattern of diffuse lung disease often mimics that of fibrosing alveolitis, but a rapidly progressive form of acute pneumonitis can occur. Organizing pneumonia may also be the presenting feature. A recent report has described an acute presentation of pulmonary capillaritis with alveolar haemorrhage in association with polymyositis.

Clinical features depend upon the nature of the lung process. Breathlessness on exertion without wheeze is a common presenting symptom and, if the myopathy is severe, orthopnoea can be striking. Haemoptysis may occur if there is capillaritis. Pleural disease is uncommon. Computed tomography can be particularly helpful; a combination of patchy consolidation with a peripheral reticular pattern being highly characteristic. In recent alveolar haemorrhage or marked myopathy, there may be a disproportionate preservation of gas transfer index (K_{CO}). It must be remembered, however, that acute haemorrhage can occur in the context of previous chronic disease and so the K_{CO} may be normal or subnormal, but elevated from the baseline level. Autoantibodies to aminoacyl-tRNA synthetases are often found when inflammatory myopathies coexist with diffuse lung disease—Jo-1 (antihistidyl tRNA synthetase) is the most common. This occurs in 20 to 30 per cent of patients with inflammatory myopathy, but in 50 to 100 per cent of cases of inflammatory myopathy and diffuse lung disease, in contrast to less than 5 per cent of patients without diffuse lung disease.

Other pulmonary manifestations

Aspiration pneumonia needs to be considered if there is upper airway/ pharyngeal muscle weakness. The predilection for the posterior lung segments may suggest this diagnosis. Respiratory muscle weakness may be present in the absence of parenchymal lung disease and requires studies of muscle function for confirmation.

Rheumatoid arthritis

The American Rheumatism Association revised criteria for the classification of rheumatoid arthritis (rheumatoid arthritis) are described in Chapter 18.8. Pleuropulmonary manifestations are summarized in Table 1.

Fibrosing alveolitis

The fibrosing alveolitis of rheumatoid arthritis has a male predominance (male:female 3:1), is associated with HLA-B8 and HLA-Dw3 positivity, and is histologically similar to cryptogenic fibrosing alveolitis, but some patients may have non-specific interstitial pneumonia rather than usual interstitial pneumonia. Minor pulmonary fibrosis is common; in one open lung biopsy series pulmonary fibrosis was seen in 60 per cent of patients. Smoking is a risk factor for the development of overt pulmonary fibrosis and has also been associated with subclinical disease. High titres of rheumatoid factor and the presence of rheumatoid nodules are also associated with an increased prevalence of diffuse lung disease.

The most frequent symptom is exertional dyspnoea, although this may be masked by a general loss of mobility due to systemic disease. The clinical picture is usually identical to cryptogenic fibrosing alveolitis with bilateral, predominantly basal crackles and tachypnoea. Digital clubbing is more prevalent than in other rheumatological diseases. Reductions in carbon monoxide diffusing capacity are found in up to 40 per cent of unselected rheumatoid arthritis patients, but radiologically overt pulmonary fibrosis is found in only 1 to 5 per cent of cases (based on three large chest radiographic series).

Organizing pneumonia

The clinical presentation of organizing pneumonia is similar to infective pneumonia with systemic features of fever and weight loss, multifocal consolidation on chest radiograph and computed tomography, a restrictive functional defect, and generally a good response to corticosteroids. Histopathology shows acini filled with loose connective tissue and a variable inflammatory infiltrate. Organizing pneumonia is more common in rheumatoid arthritis than in other rheumatological diseases, with the possible exception of polymyositis.

Bronchiolitis obliterans

The clinical presentation is of progressive breathlessness. Clinical signs reveal hyperinflation of the chest, often with an inspiratory 'squeak'. Chest radiography confirms hyperinflation with no infiltration. High resolution computed tomography shows a 'mosaic' pattern of variable perfusion as a result of the hypoxic vasoconstriction that results from the airway occlusion. Lung function is often a mixed obstructive/restrictive pattern, with obstruction predominating; gas transfer index

(K_{CO}) is preserved. Bronchiolitis obliterans is characterized histologically by destruction of the terminal bronchiolar wall by granulation tissue, effacement of the lumen, and eventual replacement of the bronchiole by fibrous tissue. There is great heterogeneity in the speed of progression, with some patients having indolent disease.

The association of the use of penicillamine with obliterative bronchiolitis was first reported in the late 1970s. Following a number of case reports and small series, obliterative bronchiolitis was identified in a large cohort study in 3/133 rheumatoid arthritis patients using penicillamine, compared to 0/469 who were not using this drug. Obliterative bronchiolitis has, however, been reported in many rheumatoid arthritis patients not using penicillamine, and the relationship of the drug to this airways obliteration is unclear.

Bronchiectasis

The prevalence of bronchiectasis is higher in rheumatoid arthritis than in other rheumatological diseases. A recent literature review identified 289 patients with bronchiectasis associated with rheumatoid arthritis reported since 1928. Although associated with long-standing rheumatoid arthritis in one study, bronchiectasis was found on computed tomography in 30 per cent of 50 rheumatoid arthritis patients with normal chest radiographs on prospective evaluation. Bronchiectatic changes (often subtle) are easily visualized on computed tomography, and a combination of diffuse lung disease and airway disease on computed tomography should raise the suspicion of rheumatological disease, especially rheumatoid arthritis or Sjögren's syndrome, in patients whose lung disease may be the first manifestation of their rheumatological disorder (Fig. 2).

Fig. 2 High resolution computed tomography of a patient with rheumatoid arthritis. There are areas showing reticular changes consistent with fibrosing alveolitis. In addition, in areas where there is no fibrosis, there is evidence of bronchial wall thickening and bronchiectasis. This combination of computed tomographic features is highly characteristic of rheumatoid arthritis.

Pulmonary vasculitis

Pulmonary vasculitis is a potential but uncommon complication of rheumatoid arthritis, given the relatively high prevalence of systemic vasculitis in the disease. Similarly, diffuse alveolar haemorrhage is a rare complication of rheumatoid arthritis.

Pulmonary rheumatoid nodules

These may be single (when distinguishing from malignancy can be impossible, especially in the cigarette smoker) or multiple, and are found on chest radiography in less than 1 per cent of patients with rheumatoid arthritis, usually in association with rheumatoid nodules elsewhere in the body. They may vary in size according to underlying rheumatoid activity, and can be as much as 7 cm in diameter. Nodule cavitation occasionally causes haemoptysis, and pneumothorax can result from the rupture of subpleural nodules, but generally these are found as asymptomatic abnormalities on chest radiography. Caplan's syndrome is the association of single or multiple nodules with coal-miner's pneumoconiosis.

Pleural disease

Pleural disease is seen at autopsy in approximately 50 per cent of patients with rheumatoid arthritis and 20 per cent give a history of pleuritic chest pain. Pleural effusions are found in less than 5 per cent, usually in males, and are frequently asymptomatic, often being identified on routine chest radiography. In a minority, pleuritic pain and fever are prominent and the exclusion of empyema (which may be more prevalent in rheumatoid arthritis) is required. Occasionally, effusions may develop acutely in association with pericarditis or exacerbations of arthritis; more typically, radiographic abnormalities are chronic, often remaining unchanged for years. The fluid is an exudate, with a low glucose level (correlating poorly with serum glucose), a low pH, and, usually, a predominant lymphocytosis (although a neutrophilia is occasionally found).

Other pulmonary manifestations

Other pulmonary complications of rheumatoid arthritis are rare. Lower respiratory tract infection is increased in frequency, bronchopneumonia is a common terminal event, accounting for 15 to 20 per cent of deaths.

Sjögren's syndrome

The defining features of Sjögren's syndrome are described in Chapter 18.11.6. Pulmonary involvement is common, with objective evidence of pulmonary abnormalities in approximately a quarter of cases. This usually consists of lymphocytic infiltration producing diffuse lung disease and tracheobronchial disease.

Diffuse lung disease

Although often asymptomatic, diffuse lung disease in Sjögren's syndrome may present with cough, dyspnoea, crackles on auscultation, reticular or reticulonodular abnormalities on chest radiography, and a restrictive pattern of functional impairment. Interstitial involvement can be classified as fibrosing alveolitis or lymphocytic interstitial pneumonia in up to 10 per cent of patients with primary Sjögren's syndrome. Lymphoma may be a complicating problem and can mimic organizing pneumonia**.**Organizing pneumonia (bronchiolitis obliterans organizing pneumonia, BOOP) has been reported in Sjögren's syndrome, but occurs less frequently than in rheumatoid arthritis or polymyositis.

Tracheobronchial disease

Tracheobronchial disease may take the form of loss of mucus secretion in the trachea (xerotrachea), chronic bronchitis, or small airways disease. Xerotrachea occurs in up to 25 per cent of patients with primary Sjögren's syndrome and consists of atrophy of tracheobronchial mucous glands in association with a lymphoplasmocytic infiltrate, manifesting clinically as a relentless dry cough and endobronchial inflammation at bronchoscopy. It is likely that similar histological abnormalities in bronchi and bronchioles account for an increased prevalence of bronchial hyper-responsiveness, reported in 40 to 60 per cent of patients with primary and secondary Sjögren's syndrome. The evaluation of airflow at low lung volumes in unselected patients with primary and secondary Sjögren's syndrome has demonstrated a high prevalence of small disease.

Systemic lupus erythematosus (SLE)

The 1982 revised ACR criteria for the diagnosis of systemic lupus erythematosus are described in Chapter 18.11.2. Pleuropulmonary manifestations of this condition

are shown in Table 1.

Diffuse lung disease

The prevalence of diffuse lung disease on lung biopsy or at autopsy is highly variable (4–70 per cent). Only 3 per cent of systemic lupus erythematosus patients have clinical evidence of diffuse lung disease at the onset of systemic disease, and a disease resembling fibrosing alveolitis develops during follow-up in less than 5 per cent. The clinical presentation (dyspnoea, cough, predominantly basal crackles, a restrictive lung function defect or isolated reduction in carbon monoxide diffusing capacity, basal infiltrates on chest radiography) is typical of rheumatological fibrosing alveolitis. However, features not typical of cryptogenic fibrosing alveolitis include variably associated pleuritic pain, a paucity of patients with morphologically extensive or functionally severe lung fibrosis, and the frequent presence of enlarged peribronchiolar lymphoid follicles at lung biopsy (although other histological findings are indistinguishable from cryptogenic fibrosing alveolitis).

Acute lupus pneumonitis, seen in less than 2 per cent of systemic lupus erythematosus patients, is life-threatening with a mortality rate despite treatment of over 50 per cent once respiratory failure has developed. It must be distinguished from organizing pneumonia.

Extrapulmonary restriction

Extrapulmonary restriction is a well-recognized complication of systemic lupus erythematosus that results in exertional dyspnoea, a restrictive functional defect, and marked elevation of K_{CO}. The 'shrinking lung syndrome' was first described in patients with severe restriction and a marked reduction in lung volume on chest radiography, and is generally ascribed to respiratory muscle weakness. There is no treatment of proven efficacy, although some patients have improved with corticosteroid or immunosuppressive therapy.

Diffuse alveolar haemorrhage

Although seen more frequently than in other rheumatological disorders, diffuse alveolar haemorrhage is rare in systemic lupus erythematosus. The typical presentation of acute dyspnoea and extensive pulmonary infiltrates on chest radiography may mimic acute lupus pneumonitis, especially in the absence of haemoptysis. Diffuse alveolar haemorrhage is often life-threatening, with a mortality similar to acute lupus pneumonitis.

Pulmonary hypertension

Pulmonary hypertension was once considered rare in systemic lupus erythematosus, but is now reported with increasing frequency, and has a 2-year survival of less than 50 per cent in severe disease. Abnormalities indicative of subclinical pulmonary hypertension are found on echocardiography in 10 per cent of patients, usually in association with Raynaud's phenomenon, and thus it is likely that pulmonary hypertension results from vasoconstriction, rather than pulmonary vasculitis (which is seldom identified in systemic lupus erythematosus even at autopsy). An important alternative mechanism for pulmonary hypertension is thromboembolism, which has a high prevalence in systemic lupus erythematosus, especially in patients with antiphospholipid antibodies.

Pleural disease

Pleural disease is the most common pulmonary manifestation of systemic lupus erythematosus. Clinical or radiographic evidence of pleural involvement is seen in 20 per cent of patients at the onset of systemic disease and occurs in at least 50 per cent at some time (with pleural abnormalities at autopsy in 50–100 per cent). Pleural disease is often asymptomatic, but pleuritic pain may be recurrent or intractable. Pleural fluid is usually serosanguinous (but occasionally haemorrhagic) and exudative, with a neutrophilia in patients with pleurisy but a predominant lymphocytosis in chronic effusions.

Relapsing polychondritis

Relapsing polychondritis is described in Chapter 17.8.1. Respiratory involvement probably accounts for around 10 per cent of deaths in this condition. Pulmonary parenchymal disease is rare, but vasculitis may occur. Destruction and obstruction of the glottis, trachea, and bronchi lead to airway stricture, collapse, and distal infection. Lung function testing shows diminution in maximal inspiratory (large, extrathoracic airways) and expiratory flow (smaller, intrathoracic airways) rates, suggesting airway collapse while static recoil pressures are preserved. Chest radiography may suggest bronchiectasis, with airway thickening and dilatation being confirmed on high resolution computed tomography. Dynamic computed tomography scanning showing collapse of the larger airways on inspiratory manoeuvres can help to localize disease. Treatment is by mechanical stenting. Immunosuppression may be helpful.

Ankylosing spondylitis

Ankylosing spondylitis is described in Chapter 18.7. Fibrotic lung disease on chest radiography, largely or entirely confined to the upper zones, is the main pulmonary complication of this condition; diffuse reticulonodular infiltrates in the upper zones are usually symmetrical and are seldom extensive, except in patients with severe spinal disease or a long history of the disorder. This is uncommon, seen in only 1 to 2 per cent of a series of 2080 patients with ankylosing spondylitis. However, on high resolution computed tomography, limited interstitial lung disease, bronchiectasis, or paraseptal emphysema are present in the majority of patients, even when chest radiographic appearances are normal. There is no proven treatment to prevent the development of apical fibrosis; resistance to corticosteroid therapy being the rule. Cavities may develop within distorted fibrotic apical tissue and are sometimes colonized by mycobacteria or fungi, especially *Aspergillus fumigatus* that are isolated in up to 60 per cent of patients with apical cavitation. Life-threatening haemoptysis is an occasional complication of mycetoma formation within cavities; this may be controllable by bronchial artery embolization, the resection of a mycetoma being a treatment of last resort, due to the high prevalence of postoperative bronchopleural fistula or empyema.

Extrapulmonary restriction due to immobilization of the chest wall (costovertebral ankylosis) is an occasional complication of ankylosing spondylitis, associated with surprisingly little impairment in pulmonary function, perhaps because the diaphragm is able to make a major contribution in the presence of a high resting volume.

Mixed connective tissue disease

This syndrome is defined by the presence of features of systemic lupus erythematosus, systemic sclerosis, and polymyositis (Sjögren's syndrome may also be seen) in association with high titres (>1:1600) of autoantibody directed against the extractable nuclear antigen U1-RNP (see Chapter 18.11.2 for discussion).
Pleuropulmonary complications occur in 20 to 85 per cent of patients, most commonly diffuse lung disease. Pulmonary involvement, investigations, and treatment are as for the individual rheumatological disease.

Treatment of lung disease in particular autoimmune rheumatic disorders

Treatment is directed at the type of lung disease, irrespective of the rheumatological disease in which it is found (Table 2). Opportunistic infection and pulmonary side-effects caused by treatment of the rheumatological disease can mimic pulmonary complications of the rheumatological disease and must be excluded. Similarly, carcinoma and lymphoma are complications of diffuse lung disease in rheumatological lung disease that must be differentiated.

17.11.5 The lung in vasculitis

R. M. du Bois

Introduction

The nomenclature of vasculitis has been confused. This is because there is overlap between clinical and histopathological features in a group of disorders of unknown aetiology. It is useful to subdivide pulmonary vasculitides into primary systemic or secondary, and to differentiate them from non-vasculitic disorders that can affect the pulmonary circulation (Table 1). The secondary and non-vasculitic diseases are discussed in other chapters: Table 2 summarizes the primary vasculitides, indicating those in which the lung is involved.

Clinical manifestations of pulmonary vasculitis

Lung involvement in vasculitic disease can manifest as:

1. diffuse alveolar haemorrhage or
2. isolated gas transfer for carbon monoxide (*DL*CO) deficit with or without pulmonary hypertension.

Other features of the underlying or associated disease may be present, and the pulmonary disorder may present as part of a pulmonary–renal syndrome, of which Goodpasture's disease is the best-known example.

Diffuse alveolar haemorrhage

The presenting features of diffuse alveolar haemorrhage often mimic infective pneumonia. The patient may give a history of fever, weight loss, and other systemic symptoms pointing towards the underlying diagnosis, but cough, breathlessness, and clinical signs suggestive of pneumonia are the main respiratory features. Indeed, if pneumonia is suspected on clinical and radiological grounds, but no organism is found, then other explanations need to be considered, including alveolar haemorrhage. A history of previous haemoptysis is helpful but not invariable: the first manifestation of diffuse alveolar haemorrhage can be acute.

Chest radiography shows consolidation, typically resolving within a matter of days, quite unlike the pattern seen in infective pneumonia, a point that can be helpful retrospectively if alveolar haemorrhage is not suspected at presentation. High-resolution computed tomography may reveal more subtle ground-glass partial alveolar filling. An acute fall in haemoglobin can occur; chronic iron-deficient anaemia suggests chronicity.

In the absence of a history of haemoptysis, confirmation of alveolar haemorrhage can be obtained by bronchoalveolar lavage that will reveal frank blood-staining in sequential lavage in the acute presentation, or the presence of numerous macrophages containing iron, identified by Perl's stain, in more chronic disease. The gas transfer corrected for alveolar volume (*K*CO) is elevated in acute haemorrhage, but where this has occurred on a background of small, previously undetected, haemorrhage, the interstitial fibrosis consequent upon this chronic haemorrhage may have reduced gas transfer such that an elevation above normal is not observed. If diagnosis remains elusive, surgical biopsy may be necessary to make the diagnosis and reveal the aetiology if vasculitis is responsible.

If a diagnosis of alveolar haemorrhage is suspected, investigations shown in Table 3 should be considered. Diffuse pulmonary haemorrhage occurring without identifiable cause or association is known as idiopathic pulmonary haemosiderosis (see Chapter 17.11.8). Pulmonary vasculitis can be primary or secondary.

Treatment is for the underlying cause. Prognosis can be poor in certain situations, most notably alveolar haemorrhage in rheumatological disease.

Isolated gas transfer deficit with or without pulmonary hypertension

A patient with an abnormality of the pulmonary vasculature, but in the absence of alveolar haemorrhage, will present with breathlessness on exertion. Clinical examination of the respiratory system will be normal, as will routine lung imaging. Lung function tests will show relatively well-preserved lung volumes, but with a reduced gas transfer factor (*DL*CO and *K*CO). Exercise testing will demonstrate a fall in PaO_2, a drop in oxygen saturation, and widening of the alveolar–arterial (A–a) gradient, with a high ventilatory reserve. In severe pulmonary vascular disease, clinical features of pulmonary hypertension may be observed. This is most easily confirmed by echocardiography, particularly if tricuspid regurgitation is present, when a Doppler estimate of pulmonary artery pressures can be obtained. Right heart catheterization may be required to confirm the diagnosis. Other causes of vascular compartment abnormality such as systemic sclerosis, primary pulmonary hypertension, or coagulation abnormalities must be excluded.

Specific disorders

Churg–Strauss syndrome

This disease, first described by Churg and Strauss in 1951, is defined by the presence of numerous eosinophils and granulomatous inflammation in the respiratory tract, together with a necrotizing vasculitis affecting small to medium-sized vessels, and associated with asthma and eosinophilia. It is a rare disorder, mainly affecting adults around the age of 40 years, but has been reported in individuals from ages 7 to 74 years. In combined series there is roughly a 2:1 prevalence for males to females. There is little information about geographical variation.

Aetiology and pathogenesis

This is not known, but thought to be an eosinophilic granulomatous response to a foreign antigen, akin to the eosinophilic granulomatosis seen in schistosomiasis. In this regard, immunological stimuli in the form of vaccination or immunotherapy have been reported as a trigger for the disease, but the pauci-immune nature of the histopathology raises doubts about this trigger mechanism.

More recently the introduction of antileukotriene therapy for asthma has resulted in an apparent increased incidence of Churg–Strauss syndrome. Two possible reasons have been advanced for this finding. First, that the drug has been a trigger for Churg–Strauss syndrome in predisposed individuals. Second, that the withdrawal or reduction of corticosteroids that has been possible with the introduction of non-steroid therapy has 'unmasked' the underlying condition. However, some

individuals who have never been on corticosteroids have developed Churg–Strauss syndrome with the introduction of one of these drugs.

The relationship of antineutrophil cytoplasmic antibodies (**ANCA**) to disease pathogenesis is unclear. There have been studies demonstrating an up-regulation of the receptor for ANCA on the surface of neutrophils at disease sites, and ANCA can also interact with endothelial cells, causing injury and coagulation.

Clinical

Two sets of criteria have been used to define the disease clinically: Lanham's criteria and the criteria of the American College of Rheumatology. In addition to systemic features such as fever and weight loss, Lanham defined the disease as requiring the presence of the following:

1. asthma;
2. eosinophilia greater than 1.5×10^9/l in the peripheral blood; and
3. evidence of systemic vasculitis in two or more non-lung organs.

The American College of Rheumatology defined Churg–Strauss syndrome as requiring four of the following six criteria:

1. the presence of asthma;
2. eosinophilia greater than 10 per cent in the peripheral blood;
3. evidence of a neuropathy in a vasculitic pattern (e.g. mononeuritis multiplex);
4. transient pulmonary infiltrates;
5. a history of sinus disease; and
6. evidence of extravascular eosinophilia on biopsy.

The disease is considered to evolve in three phases, the first (prodromal) consisting of a long history of rhinitis with nasal polyps that slowly progresses (often over years) to late-onset asthma, which is frequently difficult to treat. The second phase is of increasing peripheral blood and tissue eosinophilia that can wax and wane. The third and final phase is the manifestation of systemic vasculitis. This pattern of disease evolution has been shown in studies to be greater than 95 per cent specific and sensitive for Churg–Strauss syndrome. Table 4 illustrates the major pulmonary manifestations.

Other organ involvement

Skin lesions

These are seen in about 60 per cent of patients, generally manifesting as palpable purpura or subcutaneous nodules. Skin infarcts may also been seen.

Cardiac involvement

The heart may be involved diffusely, producing congestive cardiac failure or restrictive cardiomyopathy. Coronary artery inflammation may also be present, as can pericardial effusion. Cardiac disease is the most common cause of death in Churg–Strauss syndrome.

Renal disease

This is much less common than in Wegener's granulomatosis or microscopic polyangiitis, but the histopathology is very similar, consisting of a focal segmental necrotizing glomerulonephritis. Renal disease is generally mild, but endstage renal failure is reported.

Central nervous system

Mononeuritis multiplex is the most common manifestation, occurring in up to 75 per cent of patients. Cranial nerve involvement is less common, but cerebrovascular disease may occur.

Gastrointestinal involvement

Vasculitis of the mesenteric vessels may produce bowel abnormality, including perforation. Less commonly, eosinophilic infiltration may cause obstruction.

Musculoskeletal system

Arthritis is relatively common, as are myalgias.

Pathology

Lung biopsy shows a necrotizing angiitis, granulomas, and tissue eosinophilia. Giant cells and fibrinoid necrosis are present. It is not unusual to find only some of these features in a single biopsy and there can be overlap with the histopathological appearances of Wegener's granulomatosis and microscopic polyangiitis.

Investigations

Chest radiography shows areas of infiltration in the lung in up to 77 per cent of patients; pleural disease is seen in up to 50 per cent, and pericardial disease may occur with effusions sufficiently severe to cause tamponade. Computed tomography adds greater resolution to the imaging: nodules are uncommon and the main abnormalities are areas of ground-glass infiltrate, particularly if there is alveolar haemorrhage, which may also produce areas of consolidation.

There is a peripheral blood eosinophilia, matched by a marked eosinophilia on bronchoalveolar lavage. Antineutrophil cytoplasmic antibodies are found in roughly two-thirds of cases and are usually of the p-ANCA pattern.

Treatment

Initial treatment depends upon severity of presentation and the organs involved. In isolated pulmonary disease, the first-line treatment of choice is prednisolone at 1 mg/kg per day (up to a total of 60 mg/day) orally or, in more urgent situations such as alveolar haemorrhage, up to 1 g of methylprednisolone intravenously on each of three successive days. Response is usually good.

In more severe disease, particularly life-threatening situations when mechanical organ support is required, cyclophosphamide is added. This is given either orally at 2 mg/kg per day up to a maximum usually of 150 mg/day, or intravenously as a bolus of 600 mg/m^2 as frequently as weekly in more severe disease. It is thought that intravenous administration of cyclophosphamide is less likely to provoke the major complica-tion of cyclophosphamide therapy—haemorrhagic cystitis and subsequent malignancy—that are seen with prolonged oral use of this drug. Other immunosuppressive approaches have been tried, including azathioprine, methotrexate, and mycophenolate mofetil: the evidence in support of these treatments is less firm.

Because of the long-term side-effect profile of cyclophosphamide, especially bladder tumours, arguably the best approach to therapy would be to induce remission with either prednisolone alone or, in more severe presentations, prednisolone and pulsed intravenous cyclophosphamide, before maintaining that remission with prednisolone and one of the other immunosuppressant drugs. There is strong evidence that plasma exchange has no place in this or any other pauci-immune pulmonary vasculitis. Prophylactic co-trimoxazole (trimethoprim 160 mg/sulphamethoxazole 800 mg) three times a week is often used to reduce the risk of *Pneumocystis carinii* opportunistic infection.

Prognosis

Prognosis is generally good for those with isolated intrathoracic disease, but worsens with two or more extrapulmonary complications, particularly proteinuria greater than 1 g/day, renal insufficiency (creatinine greater than 140 µmol/l), cardiomyopathy, gastrointestinal disease, or central nervous system involvement. Five-year mortality for two or more of these complicating factors is 46 per cent, compared with 26 per cent with one and 12 per cent with none of the extrapulmonary features: recognition of this is useful in helping to determine initial therapy. Main causes of death are cardiac disease followed by renal failure, cerebrovascular involvement, and gastrointestinal disease. Lung disease accounts for 10 per cent of deaths.

Wegener's granulomatosis

The main description of Wegener's granulomatosis occurs elsewhere (see Chapter 20.10.3). It is a granulomatous inflammation due to necrotizing vasculitis affecting small to medium-sized vessels, typically involving the respiratory tract (both upper and lower) and often causing necrotizing glomerulonephritis.

Incidence

Wegener's granulomatosis is the third most common systemic vasculitis after giant-cell arteritis and rheumatoid arthritis. In 90 per cent of cases involvement of the upper and/or lower respiratory tract is the first manifestation, and in various series up to 85 per cent of patients have lung involvement at some stage of the disease. Males and females are affected equally.

Pulmonary presentation

In 34 per cent of cases lung involvement is asymptomatic. The main manifestations in the lung are (see Table 4):

1. one or more nodules which can cavitate;
2. localized or diffuse infiltrates (pleural effusions may be seen);
3. alveolar haemorrhage that may be part of a pulmonary–renal syndrome; and
4. large and small airway disease.

There is often a history of rhinosinusitis, often pre-dating other manifestations but seen at some stage of the disease in up to 92 per cent of cases. Presentations of lower respiratory tract involvement include the non-specific symptom of cough, with or without purulent sputum and haemoptysis. There is often fever, weight loss, and the systemic features of non-respiratory disease.

Chest radiography will show the presence of nodules or consolidation, the latter possibly due to inflammatory infiltrate or alveolar haemorrhage. Pleural effusion may be present. High-resolution computed tomography will show these features with greater resolution and is the better modality to identify the number of nodules and determine whether they are cavitating. It is also very helpful in identifying tracheal and bronchial abnormality, including frank bronchiectasis. Characteristic airway involvement includes subglottic stenosis and stenosis of the main airways. Subtle parenchymal fibrosis may be seen as a reticular subpleural process mimicking fibrosing alveolitis.

Fibre-optic bronchoscopy may confirm airway disease, showing evidence of tracheobronchitis including ulceration and 'cobble-stoning' of the mucosa with, in more chronic situations, cicatricial narrowing of the airways with scar tissue. Bronchoalveolar lavage returns an excess of neutrophils and usually of eosinophils (with diffuse infiltrates) or lymphocytes (more interstitial disease), but the most important use of this procedure is to exclude an infective complication of the disease or its treatment, or alveolar haemorrhage. Transbronchial biopsy can be hazardous, resulting in major haemorrhage, and should be avoided. If lung biopsy is necessary to confirm the diagnosis, a surgical approach should be used, but usually it is possible to obtain a histological diagnosis from other tissue, particularly skin or kidney.

Haematological and biochemical investigations reflect the inflammatory process. The presence of c-ANCA is highly specific for this disease (up to 95 per cent in some series) and can be diagnostic in the right clinical context.

Pathology

The histopathological appearances of Wegener's granulomatosis include a necrotizing vasculitis, granuloma formation, necrosis, and surrounding inflammation with a combination of acute and chronic inflammatory cells. This and other non-pulmonary features are discussed in Chapter 20.10.3.

Treatment

First-line treatment is a combination of prednisolone at 1 mg/kg per day (usually up to a maximum of 60 mg), together with cyclophosphamide given either orally up to 150 mg/day or intravenously at 600 mg/m^{2}at intervals dependent on disease severity. The hazards of cyclophosphamide given long-term and the alternative treatments are as for Churg–Strauss syndrome (see above). Co-trimoxazole therapy has been efficacious in this disease for localized upper respiratory tract or minor lower respiratory tract disease, but is not recommended for more systemic disease, although it appears to have a role in the maintenance of remission.

Prognosis

Since the introduction of combination immunosuppression the mortality from this disease has improved from a mean survival of 5 months to a 75 per cent complete remission. However, relapse occurs in up to 50 per cent of cases: long-term follow-up is needed.

Microscopic polyangiitis

The main description of microscopic polyangiitis occurs elsewhere (see Chapter 20.10.3). It is a necrotizing vasculitis that affects small vessels, with few or no immune complex deposits. Lung disease is said to occur in between 34 and 55 per cent of cases.

Pulmonary presentation (see Table 4)

The major presentation in the lung is diffuse alveolar haemorrhage, which can have a poor prognosis. Pulmonary capillaritis may be associated with evidence of disease outside the lung, particularly necrotizing glomerulonephritis, mononeuritis multiplex, and skin lesions. It may be difficult to distinguish microscopic polyangiitis from Wegener's granulomatosis without a biopsy, but if this is performed then the key issue is whether or not granulomas are present. Granulomas are not found in microscopic polyangiitis, whilst they are characteristic of Wegener's granulomatosis. Renal biopsies can be identical in the two conditions. Microscopic polyangiitis also needs to be distinguished from polyarteritis nodosa that, by definition, only affects arteries, rarely arterioles, and never small vessels. Renal vasculitis with microaneurysm formation occurs in polyarteritis nodosa but not microscopic polyangiitis, and diffuse alveolar haemorrhage does not occur in polyarteritis nodosa.

Other diseases

Other primary systemic vasculitides may occasionally present with respiratory features.

Takayasu's arteritis

This arteritis affects predominantly the aorta and its main branches but can involve the pulmonary arteries in up to 50 per cent of patients, presenting with features of pulmonary vascular occlusion.

Giant-cell arteritis

There is rarely objective evidence of lung involvement, but 25 per cent of patients with giant-cell arteritis have associated cough, hoarseness, and sore throat at presentation.

The other systemic vasculitides that feature in the Chapel Hill International consensus nomenclature, but which rarely if ever present with lung disease, are Henoch–Schönlein purpura and essential cryoglobulinaemia.

Behçet's disease

This occurs predominantly in Mediterranean countries and can produce pulmonary vascular inflammation affecting all sizes of vessels and resulting in pulmonary arterial aneurysms, arterial and venous thrombosis, pulmonary infarcts, and pulmonary haemorrhage. It is crucial to differentiate haemorrhage from thrombosis because of the treatment implications.

Pulmonary veno-occlusive disease

This is a disorder of unknown cause that manifests with progressive occlusion of the post-capillary venules, resulting in features similar to those of pulmonary oedema. There is no known effective treatment. Differentiation from cardiogenic causes of raised pulmonary venous pressure must be made.

Lymphomatoid granulomatosis

This has been included historically within the category of pulmonary vasculitis but is now believed to be a lymphoproliferative disease.

Sarcoidosis

Robert P. Baughman and Elyse E. Lower

The aetiology of sarcoidosis is unknown. It is characterized by the presence of non-caseating granulomas in at least two organs. Patients may experience a variable course ranging from spontaneous remission to severe chronic disease and occasionally death.

Historical introduction

The disease was first recognized in 1869 by Jonathan Hutchinson, who treated a man with skin lesions that appeared unrelated to tuberculosis or any other process that he had encountered. Initially, most reports described patients with skin lesions. Since the disease is often self-limiting, pathological information was scarce. Schaumann in Sweden was one of the first to recognize the multiorgan nature of the disease, with the common pathological feature of granulomas. His original thesis was written in 1914, but not published until 1936.

After the Second World War, the use of routine screening radiography identified asymptomatic patients with abnormal chest radiographs. Lofgren described a group of patients with erythema nodosum, uveitis, and hilar adenopathy. Others began to appreciate the unique aspects of sarcoidosis compared with tuberculosis. Interestingly, as tuberculosis becomes less frequent in a country, sarcoidosis becomes more obvious. The observation that sarcoidosis is a disease of industrial nations and temperate climates may reflect this phenomenon. However, several groups have reported series of patients with sarcoidosis in India, Thailand, and China.

Pulmonary sarcoidosis can be evaluated by chest radiography. Scadding in Scotland and Wurm in Germany described a staging system based on the appearances seen on the chest radiograph, and this became a useful method of describing the extent of lung involvement. It also has prognostic significance and has been used for 40 years as the method of choice for characterizing lung involvement with sarcoidosis.

Newer radiological techniques have been evaluated in sarcoidosis. The chest CT scan provides more detailed information regarding adenopathy, but has not replaced the prognostic information available from the chest radiograph. A gallium scan will reveal increased uptake in areas of inflammation, such as lung and mediastinum. Magnetic resonance imaging (**MRI**) and positron emission tomography (PET) have brought new methods for evaluating extrapulmonary disease.

Bronchoalveolar lavage has provided a new method for sampling lower airway secretions, and it soon became apparent that the lavage findings from patients with sarcoidosis are distinctly different from normal subjects, providing insights into the true inflammatory response of the lung.

The definition of sarcoidosis had been the subject of much debate. An international sarcoidosis group began meeting in 1958. Currently this group, the World Association of Sarcoidosis and Other Granulomatous Diseases (WASOG), is chaired by D. Geraint James and tries to provide order from what was chaos. By consensus, the definition of sarcoidosis has been established and further refined over the years. The group now meets every 2 years and stresses the international aspects of the disease.

Aetiology

The cause of sarcoidosis remains obscure. One hypothesis is that sarcoidosis is an inflammatory response to an environmental agent (including infectious) which occurs in a susceptible host. Susceptibility is determined on the basis of genetic predisposition.

Several potential infectious agents have been proposed as causes of sarcoidosis. The granulomatous reaction reminds many of tuberculosis, and much effort has been expended trying to identify a mycobacterial cause. Several studies using polymerase chain reaction (PCR) and similar molecular biological techniques have been employed, but there is still no convincing evidence that *Mycobacterium tuberculosis* causes most cases of sarcoidosis. It may lead to an occasional case of sarcoid-like reaction. Other mycobacteria have been identified in some cases. Cell wall-deficient mycobacteria have been grown from the blood of patients with sarcoidosis. However, a recently completed control trial failed to demonstrate a difference in the incidence of cell wall-deficient mycobacteria between those with sarcoidosis and controls.

Epidemiology

Sarcoidosis is a worldwide disease. It has been reported to have a higher prevalence in Scandinavian countries as well as in Ireland. Table 1 summarizes the relative frequency of sarcoidosis per 100 000 people around the world. In the United States, a higher incidence of sarcoidosis has been reported in African-American people.

The disease presentation varies in different parts of the world. Table 1 also lists some of the more frequent patterns seen with various ethnic groups. For example, lupus pernio is common among African-American and West Indian people who have migrated to Great Britain, while erythema nodosum is common among Scandinavians. Cardiac disease has been reported at a higher frequency in Japanese patients with sarcoidosis than for other groups. HLA studies have suggested that there may be certain genetic patterns associated with particular manifestations of the disease.

Occupational exposures have been studied as a possible cause of sarcoidosis. Beryllium is a metal used in certain industries (ceramics, nuclear processing) which can cause a reaction in the lung and skin indistinguishable from sarcoidosis. Besides clinical history, the distinguishing feature about berylliosis is that lymphocytes are stimulated to replicate when exposed to beryllium salts. The lymphocyte stimulation test of blood, or the more sensitive bronchoalveolar lavage, is a reliable way of detecting which patients are reacting to beryllium.

There are other occupations associated with sarcoidosis. These include health-care workers, who have been found to be at increased risk. In one study, the odds ratio of a health-care worker acquiring sarcoidosis was 64 times the rate of the general population. Such a high rate could be due to work-related exposures (medications, disinfectants), or be due to an infectious agent. Clusters of sarcoidosis have been reported among firemen and aircraft-carrier personnel.

Obviously, none of these occupational exposures encompass all cases of sarcoidosis. One possible cause of sarcoidosis is that it is the common reaction to several

possible agents.

Pathogenesis

Sarcoidosis is defined by its immunological reaction, the granuloma. Original immunological studies stressed a lack of systemic immune response by the patient with sarcoidosis. This includes anergy, which is a common feature of active sarcoidosis. A reduction in circulating leucocytes, especially lymphocytes, is an important feature of the disease.

In the 1970s, new techniques helped us understand sarcoidosis better. The most important tool introduced at the time was bronchoalveolar lavage, which provided a sample of the inflammatory cells in the lower respiratory tract. In normal lavage fluid, alveolar macrophages are the usual resident inflammatory cell retrieved; lymphocytes and neutrophils are found much less frequently. In lavage fluid from patients with active sarcoidosis, the preponderance of T lymphocytes is usually increased. These lymphocytes are often T-helper/inducer cells (CD4+), and the ratio of CD4 to CD8 lymphocytes is increased from that normally found in the blood, often to greater than 3.5.

The CD4 lymphocyte is a crucial cell in cell-mediated immunity. The CD4 lymphocytes are activated and release several cytokines, including interleukin 2 (**IL-2**) and g-interferon. The T lymphocyte can mount either a T_{H1} or T_{H2} response. The T_{H1} response is associated with granuloma formation, while T_{H2} is associated with an eosinophilic response and fibrosis. The initial response of sarcoidosis follows a T_{H1}pattern. The lymphocytes release IL-2 spontaneously, and g-interferon is released by both lymphocytes and macrophages. An increase in IL-12 and lower levels of IL-10 have also recently been described, consistent with a T_{H1} response.

The alveolar macrophage is also activated in sarcoidosis, and increased levels of IL-1, tumour necrosis factor, and oxygen free radicals are released by macrophages retrieved by bronchoalveolar lavage. During the evolution of the disease, the macrophages and other resident cells may release factors associated with fibrosis. For example, IL-8 is found in the bronchoalveolar lavage fluid of some patients with sarcoidosis, and this increase in IL-8 is associated with the finding of fibrosis in the lung.

The resolution of sarcoidosis has also been studied with serial lavages. The T lymphocytes remain elevated for some time, but the proportion of CD4 to CD8 decreases to the ratio in blood (0.8 to 2.2). The amount of cytokines released also decreases. This return to normal of the inflammatory response has been shown to occur during treatment of sarcoidosis with corticosteroids or methotrexate.

Clinical features

Patients with sarcoidosis may have a variety of presentations. Commonly affected organs include the lung, skin, and eyes. Less commonly, the liver, heart, and brain are affected by the disease. Individual organ involvement by sarcoidosis can be proved by a biopsy showing non-caseating granuloma. Presumed organ involvement is assumed if certain criteria are met. Table 2 lists some of the criteria suggested for definite or probable organ involvement for some of the more commonly affected organs in sarcoidosis.

Lung

Respiratory involvement has been described in more than 90 per cent of patients. The lung involvement includes both the lymph nodes and the lung parenchyma. Scadding and Wurm independently described four stages of the chest radiograph: stage 1 is hilar adenopathy alone (Fig. 1), stage 2 is adenopathy and parenchymal disease, stage 3 is parenchymal disease alone (Fig. 2), and stage 4 is fibrosis. The interstitial disease usually has a diffuse reticulonodular appearance, but confluent patches of disease (alveolar sarcoidosis) have been described. Fibrotic changes due to sarcoidosis are usually in the upper lobe, with retraction. The staging system has proved useful in standardizing reports of pulmonary level of involvement. It has also proved a useful prognostic measure. Patients with stage 1 disease have a 90 per cent rate of resolution within 2 to 3 years, while patients with stage 3 disease possess only a 30 per cent chance of resolution. However, it does not predict the degree of extrapulmonary disease. The choice of the term 'stage' is therefore unfortunate. However, it is so standard that it will not be easily replaced.

Fig. 1 Chest radiograph showing stage 1 sarcoid.

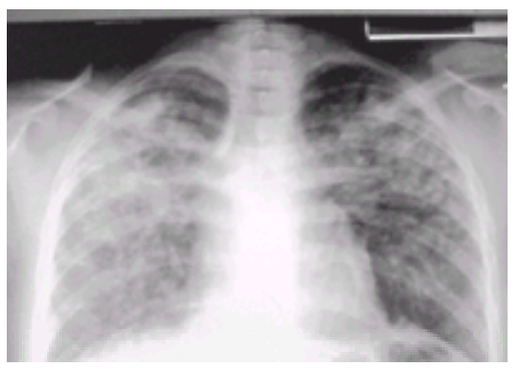

Fig. 2 Chest radiograph showing stage 3 sarcoid.

Table 3 lists the other diseases to be considered in the differential diagnosis based on the chest radiograph pattern. The presence of mediastinal adenopathy alone (stage 1 disease) is certainly consistent with lymphoma or metastatic cancer. It has been pointed out that symmetrical bilateral adenopathy with right paratracheal adenopathy in an asymptomatic individual is almost always sarcoidosis. Asymmetrical adenopathy raises the question of lymphoma, and a tissue diagnosis is usually required. For patients with diffuse infiltrates, adenopathy points one toward sarcoidosis. However, several other conditions may have some adenopathy, including hypersensitivity pneumonitis and idiopathic pulmonary fibrosis. The larger the adenopathy, the more likely is sarcoidosis.

The use of the CT scan has changed our evaluation of many interstitial lung diseases. In sarcoidosis, peribronchial thickening is often seen in the upper lobe. Adenopathy is usually seen in sarcoidosis, making the staging system only applicable for plain radiographs. The CT scan may identify adenopathy in a patient with possible extrapulmonary sarcoidosis. This may help in deciding where to proceed with a tissue diagnosis (brain biopsy or mediastinoscopy).

Pulmonary function studies in patients with sarcoidosis classically demonstrate a restrictive pattern, with reduction of lung volumes. The transfer factor is usually reduced out of proportion to the loss of lung volume, as one would expect in an interstitial lung disease. In advanced cases, the oxygen level will be reduced,

especially during exercise. Obstructive disease can also occur in sarcoidosis. This can be due to airway involvement by the sarcoidosis or associated with cough, a common complaint in the condition.

Skin

The skin is the second most commonly affected organ in sarcoidosis. There are six major manifestations. Hyperpigmentation, hypopigmentation, and keloid reaction may demonstrate granulomas on biopsy. However, their appearance is not always specific. Waxy, maculopapular lesions, which occur on the extremities, back, and face, are usually raised, with the majority less than 2 cm in diameter. When these occur on the face, especially on the cheeks and nose, they are called lupus pernio. Erythema nodosum—red nodular lesions on the extremities—usually involves the legs. The constellation of erythema nodosum, arthritis (in the ankles), hilar adenopathy, and uveitis is referred to as Lofgren's syndrome and is a diagnostic manifestation of sarcoidosis. It is associated with a good prognosis. Interestingly, the skin lesions from erythema nodosum do not contain granulomas, but are felt to be due to circulating immune complexes from the disease.

Eye

The eye can be affected in more than 20 per cent of patients with sarcoidosis. The most common findings are uveitis and lacrimal gland involvement. Anterior uveitis is often self-limiting, and can be treated topically; however, posterior uveitis is a more chronic form of the disease and may require injections of corticosteroids or systemic therapy. Sicca (dry eyes) and glaucoma are long-term complications which are encountered in patients often years after other sarcoidosis symptoms have resolved. They are consequences of the fibrotic changes in the lacrimal glands and eye. They do not respond to anti-inflammatory therapy. Optic nerve involvement can be seen with sarcoidosis, with idiopathic disease and multiple sclerosis being the other major causes of this sight-threatening complication. Retinal disease has also been reported. Fortunately, blindness from sarcoidosis is rare, and usually a consequence of untreated uveitis, retinitis, or optic neuritis.

Neurological

Neurological disease from sarcoidosis includes cranial nerve, central nervous system, and peripheral nerve involvement. Bell's palsy (seventh cranial nerve) is a common complaint in neurosarcoidosis. Central nervous system lesions can lead to a lymphocytic meningitis. Hypothalamic involvement is a characteristic finding, with diabetes insipidus as a resulting complaint. The use of contrast-enhanced magnetic resonance imaging is the most sensitive method for detecting central nervous system disease. The lumbar puncture is complementary, with increased protein and lymphocytes often seen in active disease. Detection of angiotensin-converting enzyme in the spinal fluid is suggestive but not diagnostic of neurosarcoidosis.

Other manifestations

Liver and spleen involvement may be found in over half of patients with sarcoidosis. However, symptomatic disease occurs in less than 10 per cent of patients. Often, elevated liver function tests (especially the alkaline phosphatase and g-glutamyl transferase) are seen, suggesting an obstructive pattern. Hyperbilirubinaemia is relatively rare, but implies extensive disease and is usually an indication for therapy. Massive splenomegaly can occur, and occasionally splenectomy is performed to avoid rupture.

Hypercalcaemia and hypercalcinuria are seen with sarcoidosis. The mechanism is related to the effect of the granuloma on vitamin D_3. The granuloma itself converts the vitamin D_3 to the biologically active form 1,25-D_3. This form of the vitamin has immunological activity as well as enhancing calcium absorption from the gastrointestinal tract. In some patients with sarcoidosis, the 1,25-D_3 can leak into the bloodstream and produce a systemic effect. Increased sunlight exposure also increases the levels of 1,25-D_3. In America, hypercalcaemia is far more common in Caucasian than African-American individuals. Because of the effect of increased calcium absorption, urolithiasis may also be seen in patients with sarcoidosis. Recently, it has been appreciated as a marker for chronic disease.

A less common, but serious complication of sarcoidosis is cardiac involvement. Direct involvement of the heart can lead to arrhythmias such as heart block and ventricular ectopy. This can lead to sudden death. If the problem is recognized, the use of an implanted defibrillator may reduce this risk. Cardiomyopathy is also seen, and cardiac sarcoidosis should be considered in a young patient who presents with unexpected heart failure. Endomyocardial biopsy rarely makes a diagnosis, since the granulomas are patchy. The technetium scan showing non-segmental fixed defects is the most sensitive test. Gallium uptake of the heart is more specific than a thallium scan.

Sarcoidosis granulomas can involve virtually any organ of the body. Rare manifestations include bone cysts, usually in the distal portion of the fingers, sinus invasion, pleural disease, breast disease, and ovarian or testicular masses.

The multiorgan involvement of sarcoidosis distinguishes it from other diseases. Lymphoma and tuberculosis are two diseases often considered in the differential diagnosis of patients with possible sarcoidosis. Table 4 summarizes the common features in all three of these diseases and points out those features that can be used to separate them.

Pathology

The non-caseating granuloma is the characteristic pathological feature of sarcoidosis (Fig. 3). The centre of the granuloma includes macrophages and giant cells which are of the Langerhans type and can contain over 10 nuclei. This core of cells is surrounded by two rings of lymphocytes, the larger inner component of CD4 helper cells, while the outer ring can be CD8 suppressor cells. The granulomas tend to be well formed, and in lung biopsies are often well demarcated from normal tissue. The central area will occasionally contain a Schaumann body, formed of crystallized material (calcium phosphate). This is different in appearance from foreign bodies or caseation, which can be seen in other granulomatous diseases. Occasionally the granuloma will have a necrotic area, but the majority of the granulomas do not.

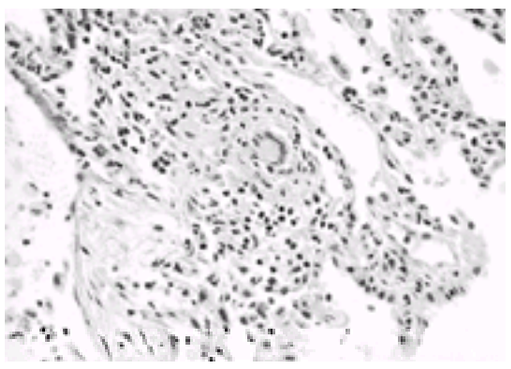

Fig. 3 Transbronchial biopsy demonstrating a non-caseating granuloma in the centre of the field. A multinuclear giant cell is seen within the granuloma. (Haematoxylin and eosin stain, original magnification ×40.)

Because the cause of sarcoidosis is unknown, one can never be absolutely confident of the diagnosis, which is always one of exclusion. However, the finding of non-caseating granulomas in two or more organs is considered diagnostic. Cultures and special stains for tuberculosis and deep-seated fungal infections should be taken to rule out infection as the cause of granulomas. Close examination should also be made for foreign bodies and malignancy, both of which can lead to a granulomatous reaction.

Laboratory diagnosis

Serum angiotensin-converting enzyme (ACE) levels

In 1976, Lieberman reported that ACE level was elevated in the blood of some patients with sarcoidosis. Mild elevations have also been reported in diabetes mellitus and osteoarthritis. High levels have been detected in patients with infectious granulomatous diseases such as tuberculosis, histoplasmosis, and coccidioidomycosis; but also in Gaucher's disease, leprosy, and hyperthyroidism. Because ACE is measured using a biological assay, patients on ACE inhibitors may have low levels.

In those with granulomatous disease, the source of the ACE is not the lung (the usual source), but the granulomas themselves. It appears that ACE has immunoregulatory properties.

Determining the significance of the ACE level in sarcoidosis can be difficult for a variety of reasons. Sixty per cent of patients with acute disease will have elevated values, whilst only 10 per cent of patients with disease for more than 2 years will continue to have an elevated level. The ACE level will decrease in response to treatment or disease resolution, and it has therefore been proposed as a marker for disease activity. However, corticosteroids independently suppress ACE levels, and reducing the dose of corticosteroids may lead to a rise in ACE level without a clinical worsening of disease. Furthermore, since ACE levels are elevated in only a small proportion of those with chronic disease, decreases observed with serial measurement may simply reflect the long-standing nature of the disease.

There is a genetic polymorphism for ACE, with an insertion (I) or deletion (D) of a genomic DNA fragment. There appears to be no difference in the distribution of the alleles in patients with sarcoidosis compared with the general population. Interestingly, ACE levels are higher in DD patients, and this needs to be considered when one is measuring the serum ACE level. There is some evidence that the DD allele is associated with a worse prognosis in patients with sarcoidosis, and it is interesting to note that DD alleles have also been associated with a worse outcome in patients with coronary artery disease.

The serum lysozyme can also be elevated in sarcoidosis in the same way as ACE. However, it is elevated in a smaller proportion of patients and not routinely used in clinical practice.

Tests of the lung

Bronchoalveolar lavage findings can be characteristic in sarcoidosis. The finding of increased lymphocytes, especially an increased CD4 to CD8 ratio, has been interpreted by some groups as enough to make the diagnosis of sarcoidosis, and in a patient with a compatible clinical history and no evidence for infection or malignancy, the lavage findings may be considered sufficient. A more definitive answer from bronchoscopy includes a transbronchial biopsy showing non-caseating granulomas. In over 60 per cent of patients with a stage 1 chest radiograph the biopsy should be positive, rising to 80 per cent in patients with stage 2 or 3 disease. Transbronchial needle aspiration has recently been used to sample hilar lymph nodes, but raises the problem of incomplete sampling in patients with a malignancy and granulomatous response to the lesion. Mediastinoscopy and video-assisted thoracoscopy provide a minimally invasive method to obtain more tissue.

The gallium scan can reveal increased activity in patients with sarcoidosis. The activated macrophage has increased levels of transferrin receptors on its surface and this results in an increase in gallium uptake. Unfortunately, interpreting the uptake in the lung may be difficult as it is non-specific and occurs with other inflammatory lung diseases. It also rapidly returns to normal with corticosteroid therapy. On the other hand, the uptake in the parotid and conjunctiva (the 'panda' sign) and the uptake in the hilar nodes (the 'lambda' sign) are fairly characteristic for sarcoidosis and are useful confirmation in difficult cases.

Other tests

The Kveim–Siltzbach agent is a suspension of spleen tissue from a patient with confirmed sarcoidosis. Six weeks after an intradermal injection of the agent, the site is inspected for a reaction, which will occur in over 60 per cent of patients with acute sarcoidosis. On biopsy, the reaction will show non-caseating granulomas, consistent with sarcoidosis. Properly prepared Kveim–Siltzbach agent has a less than 1 in 500 chance of causing a false positive. However, because of the difficulties in preparing the agent and concerns regarding the risk of transmission of an infectious agent, the test is rarely used except in those centres with a well established reagent.

Other laboratory tests may support the diagnosis of sarcoidosis or be useful in monitoring the level of disease activity. The erythrocyte sedimentation rate can be elevated in sarcoidosis and fall with remission of the disease, but one-third of patients will have a normal sedimentation rate, so it is not specific or sensitive.

Serum calcium is elevated in 10 per cent of cases and is supportive of the diagnosis, but hypercalcaemia can be seen in other conditions which mimic sarcoidosis, such as malignancy. Hypercalcaemia due to sarcoidosis should be associated with a normal to low serum phosphorus. In patients with significant hypercalcaemia, renal failure may occur, reversible in many cases with lowering of the serum calcium.

Hypergammaglobulinaemia is also a feature of sarcoidosis. Activated T lymphocytes in the lung are capable of stimulating circulating peripheral blood B cells, leading to the polyclonal gammaglobulin response. As a result of this non-specific reaction, serological markers for some diseases may be falsely elevated. This includes antifungal antibodies and antinuclear antibodies. Hypergammaglobulinaemia is more common in African-American than Caucasian individuals.

Liver involvement occurs in over half of patients with sarcoidosis. In some cases the liver blood tests are entirely normal, but the majority of patients with liver involvement have elevated serum enzymes. Usually the pattern is obstructive, with a rise in the serum alkaline phosphatase, but in some an elevation of the transaminases is seen. Elevation of the serum bilirubin is less frequent and associated with more extensive liver involvement. Rarely, lymphadenopathy at the porta hepatis can lead to biliary obstruction.

Haematological abnormalities are common in sarcoidosis. Lymphopenia is frequently seen, and is probably due to sequestration of lymphocytes into the area of inflammation, such as the lung. Anaemia has been reported in about 20 per cent of patients. The mechanism is multifactorial, including a high proportion of patients with iron deficiency. Other causes include direct bone marrow invasion by granulomas. Cytokines such as IL-2 may also result in suppression of the bone marrow.

Treatment

The natural course of sarcoidosis is unclear, since corticosteroids are normally used to treat symptomatic patients. For the patient with no symptoms on presentation, the prognosis is often good. Spontaneous resolution commonly occurs within a year or two of diagnosis, but the disease can also take a chronic form, with symptoms for many years. The concept of acute disease, which lasts for less than 2 years, as opposed to chronic disease has been a useful method for considering patients, especially in terms of therapy. Table 5 lists several factors associated with resolution within 2 to 5 years as well as those predicting chronic disease. Acute disease is associated with erythema nodosum, hilar adenopathy, anterior uveitis, and Bell's palsy. Whereas chronic disease includes such manifestations as lupus pernio, stage 4 chest radiograph, posterior uveitis, and bone cysts. Most chronic disease is controllable by therapy, but there is a refractory form of the disease which often involves the cardiac and central nervous systems. Mortality from sarcoidosis occurs, but is less than 5 per cent in most series.

The major indication for therapy in sarcoidosis is symptoms. Hypercalcaemia should be treated, even if the patient is asymptomatic. An eye examination should be performed in all patients with sarcoidosis. Uveitis may be misdiagnosed as sicca (dry eyes). The former will require anti-inflammatory agents, while the latter will only need a wetting agent.

If possible, treatment should be topical. Corticosteroid creams and eye drops are effective if inflammation is superficial. The effectiveness of inhaled steroids is less clear-cut. The higher-potency steroids such as budesonide appear to have a role in reducing the dosage of systemic corticosteroids. Several randomized trials have indicated a role for this drug as maintenance therapy for a patient who has received systemic therapy for 3 months to induce remission.

It is not clear whether corticosteroids change the natural course of the disease. Early randomized trials found no difference in the long-term outcome of patients who received corticosteroids compared with controls. A British Thoracic Society randomized study did demonstrate a small benefit for corticosteroids over placebo for patients with persistent, but not severe, disease. One of the difficulties in assessing this and other trials is that the more severely affected patients were treated with corticosteroids and excluded from the study.

Figure 4 summarizes the use of systemic corticosteroid therapy at three large centres over a period of several years. The genetic background of each group varies,

with the Iowa group being mostly of Scandinavian descent, Philadelphia being African-American, and Milan being Italian. In general, 30 to 60 per cent of patients never required therapy. However, once therapy was instituted, in 18 to 53 per cent of the patients it could not be withdrawn. In patients who were tapered off corticosteroids, one group found that 80 per cent eventually relapsed and required reinstitution of therapy. The differences in rate of continued therapy and relapse between the centres could be due to either the genetic background of the patients or the bias of the treating physicians.

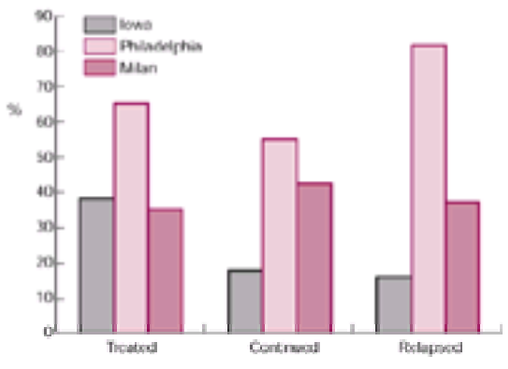

Fig. 4 The results of corticosteroid therapy from three medical centres. The first set of columns demonstrates the percentage of patients treated. The second set of columns represents the percentage of patients who required therapy to be continued beyond 2 years. The last set of columns reports the subgroup of people initially treated with corticosteroids and tapered off treatment who subsequently required reinstitution of therapy.

Once systemic steroids are initiated, one has to remember that a prolonged course is usually necessary. In the beginning, doses may be changed every 1 to 3 months, but after a patient tolerates a lower dose (equivalent to less than 10 mg of prednisolone per day), tapering may be prolonged. The use of alternate-day corticosteroids is strongly advocated by some, but others are less enthusiastic. Rarely will alternate-day therapy be sufficient for initial control of the disease.

The toxicity of corticosteroids is well known. These include weight gain, diabetes mellitus, hypertension, and mood swings. Avascular necrosis and osteopenia are significant problems with prolonged use. Some patients with sarcoidosis will have lost weight as part of their disease. However, the weight gain with treatment often surpasses the amount of weight loss. The longer a patient is on corticosteroids, the greater the risk of problems. Unfortunately, most patients will require more than a year of treatment.

Several alternatives to systemic corticosteroids have been proposed over the years. These are summarized and compared with corticosteroids in Table 6. We include the usual doses, commonly encountered toxicities, an estimate of response rate, and the usual indications for use.

The commonly prescribed antimalarial agents chloroquine and hydroxychloroquine possess anti-inflammatory activity with their major toxicities being eye and gastrointestinal. Because hydroxychloroquine, especially at 400 mg a day or less, is unlikely to cause eye toxicity, it is more frequently prescribed. However, some experts feel chloroquine is a more effective agent. These drugs concentrate in the skin and are most efficacious for skin disease and hypercalcaemia. They are less successful in the treatment of pulmonary disease. A recent report described some utility in patients with neurological disease.

Methotrexate is an antimetabolite chemotherapy used for various solid tumours. Over 30 years ago it was first noted as an immunosuppressant for the treatment of rheumatoid arthritis. In that disease, it prevents joint destruction and is often used to avoid steroid toxicity. In sarcoidosis, methotrexate has been most studied as a treatment for chronic disease. This probably reflects the fact that it may require 6 months for the drug to become effective. The usual dose is 10 to 15 mg orally each week, adjusted if this proves toxic. Acute toxicity including mucositis and nausea can be minimized with supplements of folic acid at 1 mg/day. Leucopenia can also occur, but is usually insignificant unless the patient is already leucopenic from sarcoidosis or the patient has renal insufficiency. We have successfully treated patients with doses as small as 2.5 mg of methotrexate a week. The long-term toxicity of methotrexate can include hypersensitivity pneumonitis and cirrhosis. The latter is a concern, because 50 per cent of patients with chronic disease will have sarcoid granulomas in a liver biopsy, and we recommend liver biopsies every 2 years for patients requiring the drug long term. Methotrexate is teratogenic, but current data suggest it is not carcinogenic.

The response rate to methotrexate in chronic sarcoidosis is 60 to 80 per cent. Most patients who respond can be treated with methotrexate alone. Approximately 20 per cent of patients will require additional low-dose corticosteroids. In most patients skin lesions can be easily controlled with methotrexate, but studies have also reported benefit for disease in the lungs, eyes, and nervous system.

Azathioprine has been used for many years as an immunosuppressant for patients receiving solid-organ transplants and those with idiopathic pulmonary fibrosis. However, its use in sarcoidosis has been more sporadic, usually reserved for chronic cases. Its major side-effects are gastrointestinal and haematological.

Other drugs have been used for refractory sarcoidosis. Cyclophosphamide is used in the treatment of many vasculitic diseases and has been reported as very useful in neurological and cardiac sarcoidosis, but it has more gastrointestinal, haematological, and bladder toxicity than methotrexate or azathioprine.

Case reports suggest that thalidomide may be useful in treating sarcoidosis. It has severe teratogenic effects and may cause peripheral neuropathy and drowsiness. Cyclosporin has been used with limited success in some neurological cases. A recent randomized trial failed to show additional benefit over corticosteroids alone in patients with pulmonary sarcoidosis. The drug is relatively expensive, causes hypertension and renal failure, and requires blood levels to be monitored. Pentoxyfylline has been shown by one centre to provide some benefit in acute sarcoidosis. It is associated with significant gastrointestinal toxicity, which is dose dependent.

There is no single treatment for all patients with sarcoidosis. Figure 5 summarizes our clinical approach. The first step is to determine whether the patient requires treatment. The decision to treat is usually based on the patient's symptoms. The clinician needs to determine the extent of the symptomatic disease and whether the disease is acute or chronic. Asymptomatic or minimally symptomatic patients with hypercalcaemia, cardiac, or central nervous system disease may require therapy to prevent life-threatening complications. The use of systemic therapy usually means corticosteroids first. However, over time, the patient and the physician may need to seek alternatives.

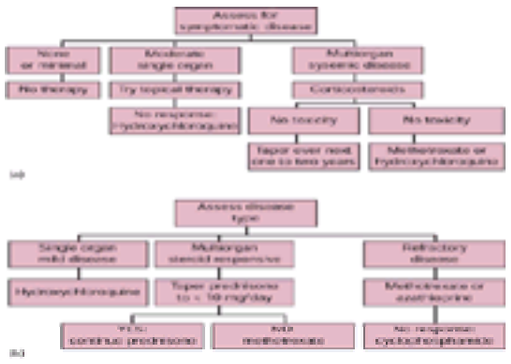

Fig. 5 The approach to treatment of patients with sarcoidosis at the Interstitial Lung Disease Clinic at the University of Cincinnati. Patients are initially classified as having either acute (a) or chronic (b) disease. Further evaluation depends on their symptoms and response to therapy.

Prognosis

Sarcoidosis will resolve within 2 to 5 years in the majority of cases. Approximately 25 per cent of patients will develop residual fibrosis. In a minority of patients, the disease will become chronic and persist for more than 5 years.

For the patient with chronic disease, treatment can usually palliate the symptoms. However, organ failure—including eye, liver, cardiac, or respiratory—can occur as a result of disease.

Most series from referral centres report a 5 per cent mortality from sarcoidosis, most commonly due to respiratory failure, but with cardiac, neurological, and hepatic failure as other causes. Respiratory failure leading to death can be predicted from pulmonary function tests. For example, one study found that of those with a vital capacity persistently less than 1 litre, a third died of respiratory failure, whereas no patient with a vital capacity of over 1.5 litres did so. The 5 per cent mortality reported from referral centres is higher than that encountered in a non-referral setting, where the mortality approximates 1 per cent. Organ transplantation has been performed successfully in patients with sarcoidosis. Although sarcoidosis lesions can occur in the new organ, organ failure due to recurrent sarcoidosis is unlikely.

Special problems

Endstage lung disease is the most common problem for patients with severe sarcoidosis. The fibrotic disease leads to cor pulmonale and respiratory distress. In addition, cavitary lesions can lead to bronchiectasis or become colonized with aspergillus. Aspergillomas can cause fatal haemoptysis. Their treatment can be difficult because most patients are not good surgical candidates. Embolization has been used for life-threatening bleeding.

Steroid-induced osteopenia is a significant problem with long-term corticosteroid therapy. Because of the risk of hypercalcaemia, patients are often not given calcium supplements, but this should be considered if a patient requires long-term systemic steroids. Monitoring serum calcium during therapy is usually sufficient to avoid complications. The use of nasal calcitonin or oral bisphosphonates should also be considered.

Areas of uncertainty/controversy

Some clinicians have proposed the use of bronchoalveolar lavage as the exclusive diagnostic test for sarcoidosis. This is based on the rationale that in the appropriate clinical setting, bronchoalveolar lavage findings of increased lymphocytes and a CD4 to CD8 ratio of greater than 3.5 represents a granulomatous process. In patients with cultures negative for tuberculosis and fungal infection, sarcoidosis is most likely and no further diagnostic testing may be needed. The percentage of patients with increased lymphocytes and CD4 to CD8 ratio varies from centre to centre. In our institution, at least 50 per cent of patients with sarcoidosis will meet these criteria. However, the use of bronchoalveolar lavage does not provide an absolute diagnosis of sarcoidosis. As previously noted, transbronchial needle aspirate may also be useful in making a diagnosis; however, the finding of a granuloma does not guarantee the diagnosis. One way to interpret the bronchoalveolar lavage or tissue results is to consider each as complementary in making the diagnosis of sarcoidosis.

The use of corticosteroids for the treatment of sarcoidosis remains controversial. In the patient with minimal symptoms, treatment can be withheld or topical agents used. If the disease spontaneously resolves, no therapy is indicated. However, if the patient becomes symptomatic, corticosteroids will probably be useful. The treatment of the patient with persistent, mild disease is unclear. The British Thoracic study suggests that these patients should receive corticosteroids, but others argue that the benefits are small and do not justify the use of these agents.

Areas needing further research

The cause of sarcoidosis remains unknown. The newer techniques of molecular biology may provide additional insight into a causative agent or the underlying genetic predisposition for the disease.

Patients with chronic disease represent a disproportionate number of cases with increased morbidity and need for medical services. The use of corticosteroids alone is not adequate for many of these patients. Research into whether other agents are truly steroid sparing and associated with a good clinical outcome are still necessary.

Pneumoconioses

A. Seaton

Most lung diseases are caused or provoked at least in part by the inhalation of harmful material. A wide range of lung conditions, including cancer (exposure to asbestos, radon daughters in mines, polycyclic aromatic hydrocarbons, nickel refining, chloromethyl ethers), pneumonia (legionnaire's disease in hospitals), asthma (flour, isocyanates, epoxy resins), allergic alveolitis (farmer's lung, maltworker's lung), and toxic pneumonitis (silo-filler's disease, chlorine poisoning, cadmium poisoning), may occur as a result of workplace exposure. When exposure to mineral dust in the workplace results in a diffuse, usually fibrotic, reaction in the lung acinus, the condition is called a pneumoconiosis.

The distinction between tuberculosis and a specific effect of dust in the causation of respiratory disease was made in the mid-nineteenth century. By this time silicosis, often complicated by tuberculosis, was widespread amongst metal miners, tunnellers, potters, and cutlers. The Industrial Revolution stimulated the need for coal, and the production of this fuel resulted in increasing numbers of sufferers from coal-worker's pneumoconiosis. This in turn was not distinguished from silicosis until the late 1940s, and in some countries the two conditions are still referred to by the one name.

In the United Kingdom, and generally in the West, dust control in mines and decline of traditional industries have resulted in a reduction in the numbers of workers suffering from these two diseases. By contrast, industrialization of developing countries has stimulated the need for indigenous coal and minerals, and in China, South America, and India several million workers are employed in mining, often in conditions which ensure a high incidence of pneumoconiosis. At the same time, the rise of the asbestos and chemical industries has added new problems for society in weighing the benefits of the product against the cost in terms of human morbidity. Fortunately, these problems are potentially soluble by application of preventive measures, as emphasized in the following sections.

Coal-worker's pneumoconiosis

Coal-worker's pneumoconiosis is caused by inhalation of coal-mine dust, a complex mixture of coal, kaolin, mica, silica, and other clay minerals. It is now uncommon in the United Kingdom, and good dust control together with reductions in the workforce imply that the disease may disappear in the next few years. Nevertheless, the strategic importance of coal as a long-term source of fuel supply and as a chemical feedstock means that it will continue to be needed, and any relaxation of dust control in mines will be followed by the reappearance of pneumoconiosis. There has also been a reduction in the incidence of coal-worker's pneumoconiosis in other Western countries, but in China the disease is widespread and in India it afflicts about 1 to 2 per cent of the current workforce of 800 000.

Aetiology and pathology

The pathogenicity of coal dust differs in different areas. If lung damage is to occur, the dust must be inhalable to acinar level within the lung. Thus the particles must have aerodynamic characteristics that make them equivalent to a sphere of unit density between 0.5 and 7 µm in diameter. Once inhaled, the particles must be able to overcome the lung's defences. Some, containing a high proportion of quartz (crystalline silicon dioxide), are toxic to macrophages and cause their disruption after phagocytosis. Such particles are cleared predominantly to the lymph nodes where they remain and set up a fibrotic reaction that ultimately destroys the node. However, some remain in the peribronchiolar and perivascular parts of the acinus, where whorled fibrosis occurs leading to the typical silicotic nodule. The mechanisms of quartz-induced fibrosis are discussed further in the silicosis section. However, since most coal dust contains relatively little quartz and is not particularly toxic to macrophages *in vitro*, some other explanation for its harmfulness must be sought. *In vivo* studies in rats have shown that inhalation of relatively low concentrations of coal dust, comparable with those occurring in United Kingdom mines in the recent past, cause inhibition of macrophage migration and provoke an inflammatory response, mediated *inter alia* by interleukin 1 (**IL-1**) and tumour necrosis factor, resulting in the release of elastase and the degradation of fibronectin. It seems likely that these toxic effects *in vivo* on macrophages are fundamental to the pathological processes in coal-worker's pneumoconiosis, including the concomitant centriacinar emphysema.

The total amount of dust inhaled is also a critical factor in the development of pneumoconiosis. Epidemiological studies have shown clear relationships between cumulative dust exposure and radiological evidence of disease. However, this is not straightforward, as some coal dusts are clearly more toxic than others, and it is not always possible to characterize this toxicity by the relative mineralogical composition of the coal dust. There is evidence that the different minerals in coal dust interact and that some clays may reduce its overall toxicity, perhaps by blocking the surface activity of the toxic fraction. As a general rule, the higher the combustibility (rank) of the coal, the more likely is its dust to cause pneumoconiosis (Fig. 1).

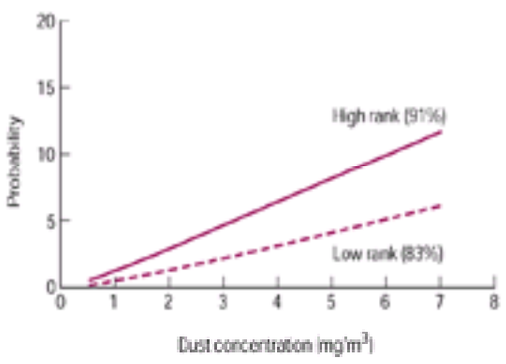

Fig. 1 Relationship between risk of category 2 or 3 radiological simple pneumoconiosis and daily exposure over a working lifetime to different concentrations of coal dust. The greater risk in association with exposure to dust from coals of higher combustibility (rank) should be noted.

Pathologically, coal-worker's pneumoconiosis is characterized by the presence of multiple centriacinar and interlobular foci of dust, inflammatory cells, macrophages, and reticulin or collagen—the coal macule (Fig. 2). In miners exposed to relatively high proportions of quartz, the lesions have a greater resemblance to the silicotic nodule. The presence of small discrete nodules is known as simple pneumoconiosis, and when sufficient numbers of these lesions are present they become visible on a radiograph. Complicated pneumoconiosis, or progressive massive fibrosis, is present by definition when one or more of these lesions is greater than 1 cm in diameter (Fig. 3). This occurs either by aggregation of several, usually collagenous, smaller nodules or by a more diffuse accumulation of dust associated with dead cells and ischaemic necrosis of lung tissue. The former, less common, mechanism occurs particularly in relation to relatively high quartz exposures, while the latter seems more frequent with exposure to high carbon dusts. With either type, and with intermediate types, there is a tendency for the lesions to grow and to be associated with surrounding bullous emphysema, ultimately being responsible for destruction of large volumes of the lung.

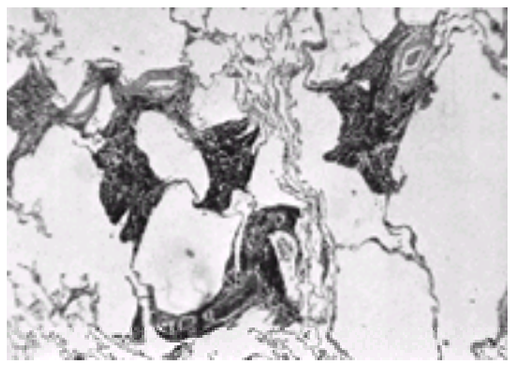

Fig. 2 Simple coal macules, showing accumulations of dust and cells around centre of lobule with associated emphysema.

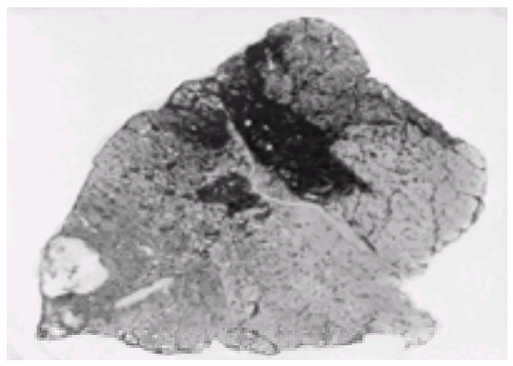

Fig. 3 Whole-lung section of a coal-miner's lung showing progressive massive fibrosis.

The aetiology of progressive massive fibrosis is not completely understood. It is more common in the upper lung zones and in taller men, suggesting a relationship to failure of lung clearance. High carbon or high quartz dusts are particularly liable to cause progressive massive fibrosis, and the higher the dust exposure, the greater is the risk (Fig. 4). Tuberculous infection is no longer an important factor in the developed world, although it may have been in the past. The rheumatoid diathesis is responsible for initiating a rare type of progressive massive fibrosis (Caplan's syndrome), but this is not an important factor overall. For further discussion of the aetiology of progressive massive fibrosis, see the section on silicosis below.

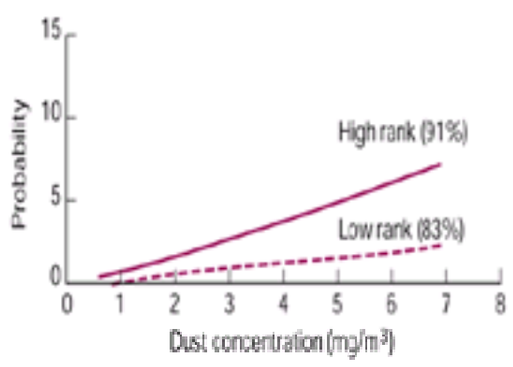

Fig. 4 Relationship between risk of progressive massive fibrosis and exposure to dust over a working lifetime. Again, greater risk in association with exposure to dust from coals of higher combustibility (rank) should be noted.

Clinical features

The people most at risk of coal-worker's pneumoconiosis are those working in the dustiest areas, such as face-workers cutting coal, drilling for shot-firing, developing headings, and drilling bolts into the roof to prevent it falling. Open-cast miners rarely work in such dusty circumstances, except in hot dry countries such as India where loading operations may be extremely dusty. Simple coal-worker's pneumoconiosis causes no symptoms or physical signs, nor any important physiological abnormality. This fact is of importance, as symptoms of respiratory disease in a miner with this condition are due to some other cause, such as bronchitis, heart failure, or asthma, which may be treatable. Radiological progression or regression of simple pneumoconiosis occurs only very rarely after dust exposure ceases, apparent regression sometimes being associated with the development of emphysema.

The danger associated with simple pneumoconiosis is that it predisposes to progressive massive fibrosis, a risk directly related to the profusion of simple pneumoconiosis on the radiograph. Progressive massive fibrosis may occur during working life or appear for the first time after (sometimes many years after) dust exposure ceases, even when there is no apparent simple pneumoconiosis on the radiograph. Progressive massive fibrosis usually progresses and causes a mixture of restriction of lung volumes and, owing to associated emphysema, airflow obstruction. Ultimately it may lead to cor pulmonale and death. However, the rate of progression is very variable. In general, the earlier progressive massive fibrosis develops in a person's life, the more rapidly progressive and thus the greater a threat to health it is.

The patient with progressive massive fibrosis may complain of shortness of breath and symptoms of cor pulmonale. An unusual, but pathognomonic, symptom is melanoptysis—the expectoration of the black contents of a cavitated lesion. Haemoptysis and finger clubbing suggest lung cancer and should not be attributed to pneumoconiosis. Abnormal signs in the chest, if present, relate to the presence of bullae, although sometimes lobar collapse can occur.

Coal-worker's pneumoconiosis is not associated with an increased risk of tuberculosis or lung cancer, although obviously these diseases can occur in coal miners and should be suspected if unusual progression of radiological changes occurs. The association between pneumoconiosis and emphysema has been controversial, but there is now clear evidence of a parallel association between dust exposure and two effects—pneumo-coniosis and airflow obstruction. The more dust that a miner

has been exposed to, the greater are his risks of pneumoconiosis on the one hand, and productive cough, reduction in forced expiratory volume in 1 s (FEV_1), and presence of centriacinar emphysema on the other. Of course, the latter risks are also related to cigarette smoking, and the effect of dust exposure is additive.

The radiological lesions in simple pneumoconiosis are predominantly rounded opacities between 1 and 5 mm in diameter, although small irregular and linear opacities and Kerley B lines are frequently present also. The round opacities tend to be more profuse in the upper and middle zones, whereas the irregular lesions predominate in the lower zone (Fig. 5). Progressive massive fibrosis almost always starts in an upper zone, gradually increasing in size until it may occupy up to a third of the lung. Such lesions are frequently multiple. They are often shaped like short fat sausages, with their outer border curved with the chest wall and separated from the pleura by bullous emphysema (Fig. 6). Calcification is not a feature, but cavitation of progressive massive fibrosis may occur. Caplan's syndrome is the name given to the combination of rheumatoid disease and several round nodules (usually 1 to 5 cm in diameter) in the lungs of a coal miner. The lesions have a rheumatoid histology and rarely cause any serious pulmonary impairment; they often cavitate and disappear. The radiological features of all pneumoconioses are properly described in terms of a set of standard radiographs produced by the International Labour Organization, and use of these standards is mandatory for epidemiological studies.

Fig. 5 Radiograph of a coal miner showing small round lesions of simple pneumoconiosis. Some irregular shadows are also present in the lower zones.

Fig. 6 CT scan of miner, showing central progressive massive fibrosis and surrounding bullous emphysema.

Prevention and management

Epidemiology has shown an exposure–response relationship between the total mass of respirable coal dust to which miners have been exposed and their risks of developing simple pneumoconiosis. This has allowed standards to be set for coal-mine dust levels, which have resulted in falls in the prevalence of the disease in coal mines in the West. Their success depends on regular monitoring of the respirable dust by gravimetric sampler, constant attention to dust suppression by ventilation and the use of water at points of dust production, and regular radiography of the workforce to detect early signs of dust retention. The incidence of progressive massive fibrosis is largely controlled by preventing miners from contracting simple pneumoconiosis, and working conditions in British mines are currently such that this disease is now very rare indeed. The present British standard is 7 mg/m^3, measured in the air returning from the coalface.

If a miner develops simple pneumoconiosis late in his career, no action normally needs to be taken, apart from (in the United Kingdom) advising him to apply to the Respiratory Diseases Board via the Benefits Agency for assessment of disablement and possible benefit payments. A younger man, with several years of further dust exposure ahead, should be advised to work in an area of approved low dust conditions. This advice should be given in the United Kingdom by the employer's occupational health service. Men with more than the earliest stages of radiological change are entitled to disablement benefits from the Benefits Agency, the value of these depending on the extent of disability. Since simple pneumoconiosis *per se* does not disable, these benefits are often small. Payment of benefits for airflow obstruction as an associated effect of coal dust exposure are also made in the United Kingdom if the miner has worked underground for a minimum of 20 years and his FEV_1 is a litre below that predicted. The presence of associated radiological change is no longer necessary.

Silicosis

Silicosis is a fibrotic disease of the lungs due to inhalation of crystalline silicon dioxide, usually in the form of quartz. Such a disease has occurred in metal miners and masons since ancient times, but assumed particular importance in the cutlery and pottery trades in the nineteenth century. Silicosis may affect anyone involved in quarrying, carving, mining, tunnelling, grinding, or sandblasting, if the dust generated contains quartz. In the United Kingdom the traditional trades that caused the disease (pottery, cutlery, flint knapping, sandblasting, tin and iron mining, and slate quarrying) have either introduced safe substitute materials or have declined, so that true silicosis is now quite rare. Between 50 and 60 cases are diagnosed in the United Kingdom each year, usually in the production of slate or granite, among miners cutting through rock, and in fettlers in foundries. However, the author has seen a series of severe cases in British workers who had been employed in circumstances where the risks had been forgotten or were being ignored.

Aetiology and pathology

Crystalline silica is present in the earth's crust usually as quartz, although other forms such as crystobalite and tridymite occur occasionally. All are extremely toxic to macrophages. quartz seems to be most toxic when freshly fractured, suggesting that surface properties are important in toxicity. This concept is supported by experimental evidence that various clay minerals and other chemicals which occlude the surface reduce the toxicity of inhaled quartz when inhaled simultaneously in mixtures of dust. The quartz content of dust from different types of stone may vary considerably from some sandstones which are 100 per cent quartz to shales and slates which may contain less than 10 per cent.

Inhaled particles of quartz small enough (generally less than 7 µm aerodynamic diameter) to reach the acinus are engulfed by macrophages and cause disruption of the phagosome, probably by peroxidation of membrane lipids. Before macrophage death, other reactions occur leading to release of inflammatory mediators, including IL-1, various growth factors, tumour necrosis factor, and fibronectin, largely from interstitial rather than alveolar macrophages. Silica is probably transported across the alveolar epithelium by migrating macrophages and by endocytosis by type 1 alveolar cells, and it is clear from the distribution of pathological lesions that quartz is transported widely in the lung via lymphatics, much of it ultimately being deposited in hilar nodes, which it destroys. This destruction of the nodes is very likely to be responsible for blockage of the exit route for further inhaled dust, and therefore for its retention in the lung and the developmnent of progressive massive fibrosis or, rarely, accelerated or even acute silicosis.

Macroscopic inspection of silicotic lungs shows fibrous pleural adhesions, enlarged lymph nodes that contain fibrotic, often calcified, nodules, and grey nodules throughout the lung. These nodules vary from a few millimetres to several centimetres in diameter and are more profuse in the upper zones (Fig. 7). They may be calcified, and they have a typical whorled appearance when cut across (Fig. 8). The largest lesions consist of many such nodules that have become confluent, and, as

in coal-worker's pneumoconiosis, this progressive massive fibrosis may undergo ischaemic necrosis and cavitate. Under the microscope the silicotic nodule consists of concentric layers of collagen surrounded by a zone of doubly refractile silica particles, macrophages, and fibroblasts. The nodule may contain the remnants of the respiratory bronchiole and arteriole, destroyed by fibrosis. The mechanisms responsible are destruction of macrophages leading to inflammation and laying down of collagen, release of the quartz, further macrophage attraction, and repetition of the cycle. This presumably occurs first in nodes on the drainage pathway, and as these become progressively blocked the process is repeated in the lung. As the quartz never gets removed thereafter, the process continues indefinitely and severity of disease depends on the mass inhaled and retained.

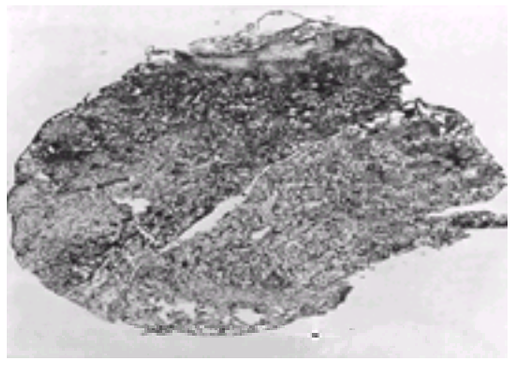

Fig. 7 Whole-lung section from a coal miner whose work had been predominantly in hard rock, showing silicotic nodules in upper parts of upper and lower lobes.

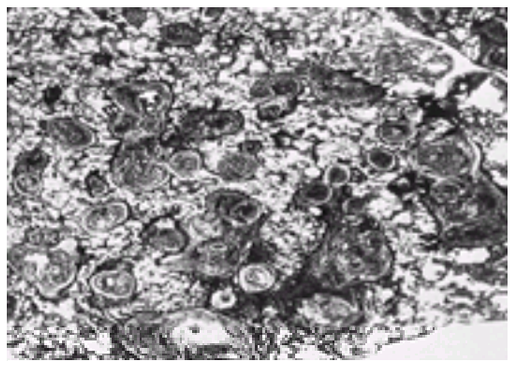

Fig. 8 Silicotic nodules, showing the typical whorled appearance.

Macroscopically, acute silicosis appears like pulmonary oedema. Under the microscope, the alveoli are filled with eosinophilic fluid and the alveolar walls contain plasma cells, lymphocytes, fibroblasts, and silica. In the author's experience, this condition first requires hilar node destruction by the inhaled quartz.

Clinical features

Silicosis presents a spectrum of clinical appearances depending on the circumstances in which it is contracted. The most severe, acute silicosis, may be acquired after very heavy exposure over only months, such as may occur in sandblasting without respiratory protection. Such patients become intensely breathless and die within months. The radiograph shows appearances resembling pulmonary oedema. Less heavy exposure causes progressively less dramatic symptoms, ranging from a progressive upper lobe fibrosis with slowly increasing exertional dyspnoea over several years (accelerated silicosis) to radiographic nodular change similar to coal-worker's pneumoconiosis unassociated with any symptoms or physical signs. The latter type of silicosis is the most common, and is usually associated with exposure to dust containing 10 to 30 per cent silica over a prolonged period. Simple nodular silicosis differs from coal-worker's pneumoconiosis in that the lesions tend to be larger (3 to 5 mm) and that it is progressive even after dust exposure ceases. Lesions increase in size and become more profuse. Moreover, extensive simple silicosis may be associated with some restriction of lung volumes. Simple silicosis rarely seems to be associated with emphysema, unlike coal-worker's pneumoconiosis, but silicotic progressive massive fibrosis is commonly associated with bullous disease. Curiously, it has only recently been recognized that acute enlargement of hilar nodes mimicking sarcoidosis may be an early feature of silicosis. Accelerated silicosis and progressive massive fibrosis cause lung restriction and lead to cor pulmonale and cardiorespiratory failure.

Apart from evidence of cardiac failure or distortion of lung architecture by extreme degrees of massive fibrosis, physical signs are not prominent. Clubbing and crackles are not seen. Diagnosis depends on a history of exposure and the radiographic appearances. The most characteristic of these are nodules between 3 and 5 mm in diameter, predominantly in the upper zones, and eggshell calcification in the hilar nodes (Fig. 9). The latter is virtually a pathognomonic feature, only occurring otherwise, very rarely, in sarcoidosis. All forms of silicosis are liable to be complicated by tuberculosis, usually due to reactivation of a quiescent lesion.

Fig. 9 Radiograph of a hard rock miner, showing massive fibrosis in right mid-zone and eggshell calcification of hilar nodes.

Other mycobacterial diseases (*Mycobacterium kansasii* and *Mycobacterium avium-intracellulare*) also occur more frequently than would be expected in those with silicosis. There is now evidence of a weak association between silicosis and lung cancer, even when exposures to cigarette smoke and other occupational carcinogens have been accounted for. The evidence is sufficient for lung cancer to have been recognized as an occupational disease in patients with silicosis in the United Kingdom. Pneumothorax is an occasional complication of silicosis, as it is of any disease associated with lung fibrosis.

Subjects with silicosis, particularly of the accelerated type, seem to be at increased risk of the development of autoantibodies and of rheumatoid disease, scleroderma, and systemic lupus erythematosus; these conditions have been described in about 10 per cent of some series of patients with silicosis. Focal glomerulonephritis has also been described in silicosis, but the cause of this is unknown.

Prevention and management

The epidemiological evidence suggests that workers exposed to levels of respirable silica in excess of 1 mg/m ^{3} have a high risk of silicosis, and that a risk may still

exist even at levels of around 0.1 mg/m^3. The United Kingdom maximum exposure limit is 0.3 mg/m^3, and industry is obliged to keep exposures of workers below this level as far as practicable, by appropriate ventilation, extraction, and other dust suppression measures. For historic reasons, quartz exposures in coal mining are controlled by total dust levels rather than the silica component of the dust. If higher levels are inevitable, the worker should wear appropriate respiratory protection, although this must be regarded as a second-best and potentially risky procedure. Once a worker has developed the disease, he should be prevented from working with silica again. The only medical management necessary is regular sputum examination for tubercle bacilli, as tuberculosis accelerates the lung damage but responds normally to modern chemotherapy. Acute silicosis would nowadays be an indication for consideration of transplantation. In the United Kingdom, workers with silicosis (whether or not complicated by lung cancer) should apply to the Respiratory Diseases Board of the Benefits Agency for industrial injuries benefits.

Asbestosis

Asbestosis is pulmonary fibrosis caused by exposure to fibres of asbestos. It was originally described in the 1900s and its importance as an occupational disease was recognized by epidemiological studies in the 1930s. However, in the first century AD, Pliny recorded that the weavers of wicks for the lamps of the vestal virgins wore masks for respiratory protection, and so some recognition of its hazards goes back to antiquity.

Asbestos is mined principally in Canada, South Africa, and the former Soviet Union. It is a generic term for a group of fibrous silicates, the most important being chrysotile (white), crocidolite (blue), and amosite (brown). Chrysotile has a serpentine configuration and breaks up into microfibrils, while the other types (amphiboles) are straight and less liable to longitudinal fracture (Fig. 10). All types are resistant to physical and chemical destruction, which gives them their commercial value in fireproofing, insulation, reinforcement of cement, weaving into cloth, bonding in brake linings and plastics, and so on. The asbestos is obtained by crushing the rock to release the fibres, which are then carded and transported in non-porous bags to the user industry.

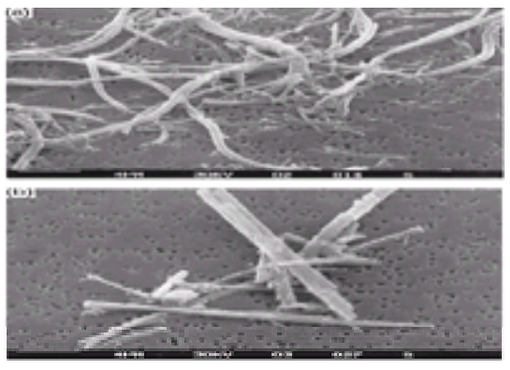

Fig. 10 Scanning electron micrographs of (a) chrysotile and (b) amosite on Millipore filters. The curly configuration and microfibrils of chrysotile should be noted. Scale bar, 4 µm.

Asbestos causes several separate pleuropulmonary lesions. The commonest are benign pleural plaques, but acute effusion and diffuse fibrosis also occur. Mesothelioma, discussed in Chapter 17.14.1), is the most important. It now occurs in over 1000 people in Britain annually and the incidence is predicted to rise further in relation to exposures some 30 years previously. It is most frequent in people who have worked in construction, ship repair, and such trades as electrician, plumber, and insulator, where regular direct or indirect exposure to asbestos has occurred. The pulmonary disease asbestosis occurs in about 100 people annually in the United Kingdom; all have worked regularly with asbestos for many years. Risk of lung carcinoma is also related to asbestos exposure, interacting multiplicatively with smoking. All these risks appear to have been greater with exposure to amphiboles than with exposure to chrysotile, but most workers (except in specific mining/production industries) have usually been exposed to a mixture of the different types.

Aetiology and pathology

The harmful asbestos fibres are those less than 3 µm in transverse diameter and greater than 10 µm in length, that is, sufficiently narrow to be inhaled to the acinus, yet too long to be removed by macrophages. Their toxicity depends on their dimensions and their persistence in lung tissue once inhaled. All types of asbestos of these dimensions can cause fibrosis and carcinoma when inhaled by rats. Moreover, injection of any asbestos type (and indeed many non-asbestos fibres) into the peritoneum of rats causes mesothelioma in a dose-related manner. The lower risk of mesothelioma in association with pure chrysotile exposure in humans is related to this fibre's curly configuration, which reduces the number penetrating the acinus, and its propensity to break up into minute short fibrils that can eventually be removed from the lung by the action of macrophages. As with coal and silica, the fibrogenicity of asbestos is probably related to damage to macrophages which are unable to cope with fibres much longer than themselves and the liberation of substances that activate fibroblasts to produce collagen. Among the substances shown to result from experimental challenge of rats with asbestos are tumour necrosis factor and macrophage- and platelet-derived growth factors.

The macroscopic appearance of an asbestotic lung is of grey fibrosis more marked peripherally and in the lower zones. In severe cases the fibrosis appears like a honeycomb. Yellow shiny parietal pleural plaques are also usually seen in the thoracic cavity, although these frequently also occur in the absence of pulmonary fibrosis. Microscopically there is diffuse alveolar wall fibrosis with minimal cellular infiltrate or desquamation of type 2 pneumocytes, initially around the centre of the acinus and later spreading to destroy the acinar structure, leading to the appearance of honeycombing. Larger asbestos fibres may be seen coated with a protein–ferritin complex (the asbestos or ferruginous bodies), while smaller fibres remain uncoated but may still just be visible with the light microscope (Fig. 11). However, for every fibre visible by light microscopy, several hundred uncoated fine fibres can always be found on electron microscopy. Pleural plaques have the appearance of basket-weave collagen, and fibres are almost never seen within them.

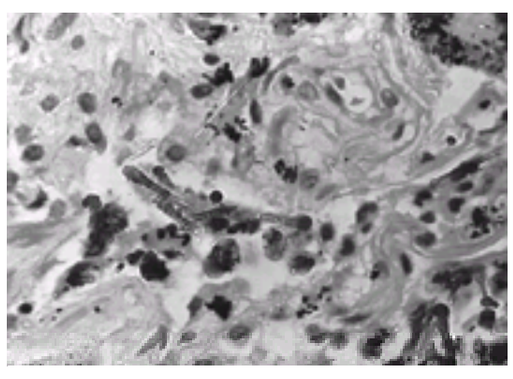

Fig. 11 Histological appearance of asbestosis, with interstitial fibrosis, asbestos bodies, and several uncoated fibres.

Clinical features

Asbestosis occurs in people exposed regularly over years to airborne asbestos as a result of the material being used or removed, and not as a result of occasional exposure. It is more likely to be seen in trades involving the application or removal of asbestos in lagging and insulation than in asbestos mining, preparation, or weaving, where control of fibre levels is more careful. The disease may first become apparent and progress after exposure has ceased.

The symptoms are shortness of breath, initially on exertion, and dry cough. Repetitive end-inspiratory basal crackles commonly precede symptoms, and finger clubbing may occur later. The disease is usually progressive, the speed of progression being related to the dose of asbestos to which the lungs have been subjected, and results in increasing disability and death from cardiorespiratory failure. Forty to fifty per cent of smokers with asbestosis die of bronchial carcinoma, but there is

no increased risk of tuberculosis.

The radiological appearance of asbestosis is identical to that of cryptogenic pulmonary fibrosis —predominantly basal and peripheral irregular linear shadowing progressing to honeycombing (Fig. 12). The presence of pleural plaques, which frequently calcify, is an indication of asbestos exposure and may help in the differential diagnosis (Fig. 13). In advanced asbestosis the fibrosis obscures the cardiac border, giving a shaggy appearance. The radiological appearances are best described by comparison with the International Labour Organization standard radiographs. CT scans are useful in differentiating asbestosis from diffuse pleural fibrosis, which may mimic it clinically and radiologically (Fig. 14).

Fig. 12 Radiograph of a lagger with asbestosis. The irregular basal and middle zone fibrosis should be noted.

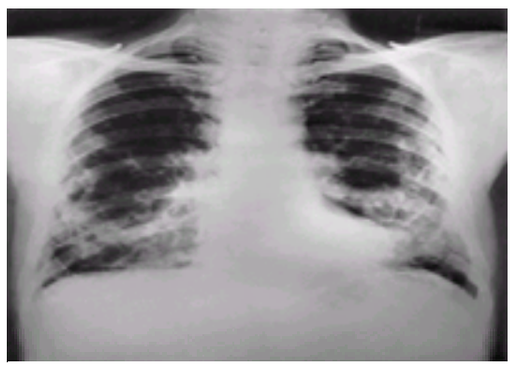

Fig. 13 Radiograph of a lagger, showing extensive calcified pleural plaques.

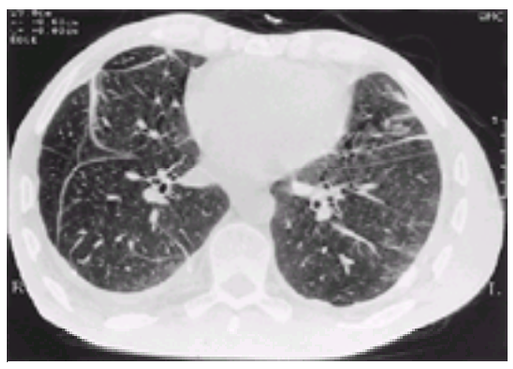

Fig. 14 CT scan of a thermal insulator, showing bilateral pleural fibrosis with areas of calcification and fibrous strands extending into peripheral lung. This does not imply the same functional effects or prognosis as asbestosis.

Asbestosis causes a restrictive pattern of lung function, with reduced volumes and transfer factor. These measurements are the most suitable for screening for the disease and following its progress. Pulmonary compliance is reduced in relation to the extent of the fibrosis, and arterial oxygen desaturation occurs in the later stages.

Pleural plaques cause no symptoms and are usually a coincidental finding on chest radiography. Diffuse bilateral pleural thickening, often calcified, which can cause breathlessness and restricted lung volumes, occurs infrequently. Inspiratory crackles may be heard over this in the absence of significant asbestosis. Very uncommonly, benign pleural effusion may occur. This develops within the first two decades after exposure as a transient haemorrhagic effusion and is diagnosed by the exclusion of infective and malignant causes. There is no evidence that any of these benign disorders predisposes to pleural mesothelioma, the risk of which relates to the prior extent of asbestos exposure.

Prevention and management

The prevention of asbestosis, as of other pneumoconioses, depends on reducing the exposure of individuals to fibre levels that have been shown to be insufficient to cause the disease in a lifetime of exposure. Unfortunately, the difficulties of making valid measurements of airborne fibres and the uncertainties attached to the early diagnosis of asbestosis have prevented the formulation of really reliable evidence on which to base a standard. The present British standard for chrysotile of 0.5 respirable fibres/ml has been based on work that suggests such levels would, when breathed over a working lifetime, result in asbestosis in fewer than 1 per cent of those exposed. The corresponding standard for amphiboles is 0.2 fibres/ml. Many industries have now introduced other fibrous or crystalline minerals in place of asbestos. The potential of such new materials to cause similar diseases depends on their fibre dimensions, solubility in tissue, and the concentrations achieved in the workplace air. It is important that they should be handled with appropriate care by industry.

Regular medical and radiological examination of asbestos workers is essential for the early detection of asbestosis, and there is some evidence that removal of the worker from exposure at this stage is associated with slower progression. Workers should also be advised not to smoke in view of the interaction between cigarettes and asbestos in causing lung cancer. Once asbestosis is suspected, the British worker should apply to the Benefits Agency for assessment for industrial injuries benefit. Diffuse pleural fibrosis also attracts benefits, as does lung cancer in the presence of asbestosis or pleural fibrosis, but pleural plaques do not.

Risks of asbestos-related disease in the non-occupationally exposed population

Much anxiety has been engendered amongst the general public by media interest in asbestos, and doctors may find themselves being asked about, for example, the risks to children of asbestos wall panelling in houses or asbestos inserts in ironing boards. In general it can be stated that asbestosis only occurs in people working regularly with asbestos for years. However, this has included, at least in the past, wives washing the dusty clothes of asbestos workers and people who have lived or worked near polluting asbestos factories. Occasional or incidental exposure to asbestos can be dismissed as a significant cause of asbestosis. Similarly, lung cancer risks seem to be significantly increased only with the doses of asbestos that lead to asbestosis, and individuals who do not smoke and who only have asbestos fittings in their houses can be reassured that their risks of this disease are negligible. Mesothelioma however, while also dose-related, occurs after smaller exposures and it

is well established that a sufficient dose of crocidolite or amosite can be inhaled in a period of intense exposure of a few months. Of the 1000 cases occurring in the United Kingdom each year, almost all individuals give a history of having worked in a trade known to have been associated with asbestos use and have large numbers of fibres in their lungs, suggesting that employment rather than incidental exposure has been responsible. Small and occasional exposures to asbestos are highly unlikely to entail an important risk, but if regular exposures are thought to be occurring in the domestic or general environment, steps should be taken to eliminate them.

Other silicate pneumoconioses

Several silicates apart from asbestos are of commercial importance, and some of these have been shown to cause pneumoconiosis. Talc (hydrated magnesium silicate) is mined as soapstone in the United States, China, and the Pyrenees. It is milled and has many uses including in cosmetics, the rubber industry, paints, ceramics, and pharmaceuticals. Kaolin (hydrated aluminium silicate) is quarried in south-west England, Georgia in the United States, Japan, Egypt, Germany, and former Czechoslovakia. It is used mainly in the manufacture of ceramics, paper and paint, and in pharmaceuticals. Fuller's earth (calcium montmorillonite) is an absorbent clay quarried in England, the United States, and Germany. It was originally used in fulling or removing grease from wool, and is now used in oil refining and bonding foundry moulds. Mica is a complex aluminium silicate occurring in two forms—muscovite and phlogopite. The former is mined in the United States and India and used in fire-resistant windows and the manufacture of paper and paint. Phlogopite, mined in Canada, is used in the electrical industry because of its resistance to heat and electricity.

Two widely used silicate materials—cement and vitreous fibres—are not established as causes of pulmonary disease. Although cement exposure has occasionally been reported to be associated with pneumoconiosis, the evidence for this is flimsy. It is often mixed with asbestos, and asbestosis may occur in its production. Artificial vitreous fibres (glass wool and rock wool) have not so far been shown to cause pulmonary fibrosis or neoplasia in humans exposed to them, although mesothelioma has been produced by intraperitoneal injection in rats.

Other pneumoconioses

Talc pneumoconiosis

Talc is commonly contaminated with tremolite, a non-commercially exploited amphibole asbestos, and with silica. It has been difficult to disentangle the effects of these components. The disease appears clinically to resemble asbestosis, with finger clubbing and basal crackles, although radiological descriptions emphasize lesions predominantly in the middle zones with nodular as well as reticular components. Progressive massive fibrosis has been described.

Talc has also been shown to be associated with pulmonary disease in a number of other circumstances. Bronchoconstriction may occur in children exposed to high concentrations and drug users may have granulomatous reactions in the lungs as a result of either intravenous injection or inhalation of ground-up tablets. Fortunately, the widespread use of talc for producing pleurodesis has not been shown to be associated with the later development of mesothelioma, probably because the grades of talc used have not been contaminated with tremolite.

Kaolin pneumoconiosis

Kaolin causes a pneumoconiosis similar to coal-worker's pneumoconiosis with small discrete nodular lesions initially and a tendency to produce massive fibrosis. It has been described in workers involved in the drying and milling processes in the production of china clay. Kaolin may also have been the component of the dust responsible for pneumoconiosis in the now defunct Scottish shale oil industry. There is no evidence linking kaolin pneumoconiosis with carcinoma or tuberculosis.

Fuller's earth pneumoconiosis

This condition has been described in workers extracting this clay mineral. It is a benign nodular pneumoconiosis similar in pathological and radiological appearance to simple coal-worker's pneumoconiosis; progressive massive fibrosis has not been described.

Mica pneumoconiosis

A few reports of radiological change in those exposed to ground mica have been recorded, but there is no recent publication describing pathological or clinical features.

Fibrous erionite

Exposure to this fibrous hydrated aluminium silicate occurs in certain areas of Turkey and probably elsewhere in the Middle East. The populations of several villages have been exposed for many generations as they use local erionite rock as stucco and whitewash in their homes. Pleural plaques, pulmonary fibrosis, and both lung cancer and mesothelioma are endemic in these villages. Fibrous erionite has no general commercial use, but this episode illustrates the potential dangers of inhaling fine fibrous material, whether asbestos or some other mineral.

Berylliosis

Beryllium is a metal that is used in alloys for the nuclear industry and in the production of X-ray tubes. It was used in ceramics, metallic alloys, and fluorescent lights until its toxicity was recognized and it was replaced by other materials. It is mined as an ore mostly in South America and extracted by chemical processes.

Beryllium is highly toxic when inhaled, and may also cause granulomatous ulcers on contact with the skin. Inhalation of high concentrations causes an acute pneumonitis and tracheobronchitis, which can be fatal. Chronic berylliosis, which may occur as a sequel to acute exposure, usually follows more prolonged exposure to lower levels. It is not common in the United Kingdom, where no more than about 50 cases have been diagnosed, but it has been recorded much more frequently in the United States. Reported cases have occurred in beryllium workers, in wives exposed to dust from their husbands' clothes, and in people living near the factories.

The patient with chronic berylliosis presents with cough and shortness of breath. The features mimic those of sarcoidosis: bilateral pulmonary mottling with upper lobe fibrosis is the usual radiographic feature initially, with bilateral hilar lymphadenopathy being less common. The disease typically progresses to diffuse fibrosis (Fig. 15), but the rate of progression is very variable. The functional lesion is a restrictive pattern with a low transfer factor. The progress of the disease can be controlled with corticosteroid therapy, but this needs to be continued indefinitely in most cases.

Fig. 15 Radiograph of a beryllium refiner worker, showing the diffuse fibrosis of berylliosis.

The pathological lesion is identical with that of sarcoidosis, with non-caseating granulomas and varying amounts of interstitial fibrosis. The diagnosis is made on the basis of a history of exposure, compatible clinical and histological features, and a negative Kveim test. A skin-patch test is inadvisable as it can cause sensitization.

Berylliosis is prevented by keeping exposures below the threshold limit value (2 ng/m ^{3}), although as it is a hypersensitivity disease even this will not prevent all cases. Efficient respiratory protection should also be provided.

Less common pneumoconioses

Many other pneumoconioses have been described, although most are of very limited prevalence and are relatively benign. Haematite lung, occurring in iron ore miners, used to be seen in Cumbria in the United Kingdom; it is a fibrotic reaction to a mixed dust containing silica and iron. Radiographically it resembles silicosis and pathologically only differs from it in that the lungs are coloured red. There was an increased risk of lung cancer, probably due to radiation in the mines. Closely related to haematite lung is siderosis, a benign iron oxide pneumoconiosis occurring in welders and other workers in iron foundries. The radiological lesions often regress after exposure ceases. Barium processing and tin refining may be associated with the development of dramatic radiological nodular shadowing—baritosis and stannosis, respectively. These are also benign conditions, the radiological appearances reflecting radio-opaque dust in macrophages. Pneumoconiosis associated with diffuse lung fibrosis has been described in work with aluminium oxide (Shaver's disease) and tungsten carbide (hard metal disease). This latter condition, which is probably a hypersensitivity reaction to cobalt in cooling liquids, may also present with features of asthma or allergic alveolitis. A pneumoconiosis resembling that in coal miners has been described in workers with graphite and other forms of carbon, and in shale miners. A benign pneumoconiosis, consisting of simple accumulations of dust and macrophages with minimal nodular radiological shadowing, has also been described in workers producing polyvinyl chloride.

17.11.8 Pulmonary haemorrhagic disorders

*D. J. Hendrick and G. P. Spicketi**

Bleeding within the lung and subsequent haemoptysis is common in clinical practice and may be the consequence of many unrelated disorders. What then is the value of the term 'pulmonary haemorrhagic disorder'? The answer lies with its use in special circumstances only—bleeding arising diffusely from pulmonary alveolar capillaries. A preferable and more explicit diagnostic term is therefore pulmonary capillary (or alveolar) haemorrhage. This is not a disease entity of itself, merely a feature of several diseases, but most notable in two conditions, Goodpasture's syndrome and idiopathic pulmonary haemosiderosis.

While the lung can accommodate only small quantities of blood in the major airways without threatening life from asphyxiation, it can sequester surprisingly large amounts (litres) at alveolar level. This leads to a curious characteristic, unique among diffuse parenchymal diseases of the lung and of considerable diagnostic value; the carbon monoxide gas transfer (*TL*CO) is raised significantly above normal. Not only are physiologically useful red cells within the alveolar capillaries able to absorb the inhaled carbon monoxide, but so too are those lost from the circulation into the alveolar spaces.

Pulmonary capillary haemorrhage is thus characterized by haemoptysis, breathlessness, diffuse air space shadowing on the chest radiograph (Fig. 1), anaemia (normochromic normocytic if acute, iron deficient with chronicity), and an elevated *TL*CO (see Chapter 17.3.2). The extravasated red cells are not readily expectorated, although enough generally escape to cause haemoptysis, and so haemosiderin accumulates within alveolar macrophages as the red cells and their debris are engulfed. When haemosiderin-laden macrophages are identified in sputum, the diagnosis of pulmonary capillary haemorrhage is largely confirmed, but if sputum is not expectorated or haemoptysis is absent, minimal, or otherwise explained, then bronchoalveolar lavage and/or lung biopsy are often necessary to establish the diagnosis. An alternative approach is CT and MRI, which may alone provide convincing evidence of blood sited diffusely within the alveoli.

Fig. 1 Radiograph showing gross alveolar shadowing following major pulmonary haemorrhage in a 60-year-old man with systemic vasculitis.

While diffuse alveolar capillary haemorrhage may characterize or complicate a wide variety of specific diseases or disease settings (each associated with its particular range of clinical, diagnostic, and mechanistic features, and management options), the direct effects of the haemorrhage itself are not influenced by the cause, nor are the means by which it can be recognized. There may, nevertheless, be substantial differences at presentation from case to case according to severity and chronicity.

Goodpasture's syndrome

Goodpasture described a man with renal failure, glomerulonephritis, and pulmonary haemorrhage. A number of conditions can cause such a 'pulmonary–renal syndrome', the best characterized of which (although almost certainly not the illness suffered by the patient in the original report) is now termed Goodpasture's disease, which consists of diffuse pulmonary haemorrhage and glomerulonephritis with linear deposition of antibody (90 per cent of which are directed against the a-3 chain of type IV collagen) along the glomerular basement membrane. Goodpasture's disease is described in Chapter 20.7.9 and other causes of pulmonary–renal syndrome in Chapter 20.10.3.

Clinical features

In practice, glomerulonephritis proves to be a much commoner threat to survival than lung haemorrhage, and the diagnosis of Goodpasture's disease is reached more conveniently by serological testing (for anti-GBM antibodies) and from kidney rather than lung biopsy. In some cases, however, lung disease dominates the clinical picture, when the majority of patients are male smokers and some have recent exposure to volatile hydrocarbons; case reports have additionally identified recent exposure to chlorine and smoked cocaine. This suggests that when there is susceptibility, inhaled toxic agents enhance pulmonary endothelial damage and thus allow the initiation of autoimmunity or the ready access of existing autoantibody to basement membrane. Respiratory presentation is with cough, breathlessness, and haemoptysis, which is intermittent and ranges from occasional streaks to massive fatal bleeding. Systemic symptoms of fever, joint pains, or weight loss are unusual. The chest radiograph shows patchy or diffuse shadowing due to intra-alveolar blood, usually resolving over the course of 2 weeks unless there is further bleeding. At the time of bleeding there may be arterial hypoxaemia and reduced lung volumes. Serial measurement of *TL*CO can be used to monitor progression, and prolonged bleeding may lead to iron-deficiency anaemia. Renal function may be normal initially and then deteriorate over days to weeks. Steroids, other immunosuppressant drugs (cyclophosphamide in particular), and plasmapheresis are all used (in some circumstances) to control renal disease, and are additionally helpful in treating pulmonary haemorrhage. Patients should not smoke and should avoid hydrocarbon exposure.

Idiopathic pulmonary haemosiderosis

This is a rare disorder of children and young adults in which there is recurrent alveolar bleeding in the absence of kidney disease. Anti-basement membrane antibody has not been detected, and nor have any other substantial immunological clues to the causal mechanism, although serum IgA is commonly elevated. The electron microscopic appearance of the basement membrane shows no consistent abnormality. The alveolar blood may provoke a fibrogenic stimulus and the development of diffuse pulmonary fibrosis, as may recurrent alveolar bleeding from mitral stenosis and chronic severe left ventricular failure.

Although termed idiopathic pulmonary haemosiderosis, the condition is associated with premature birth and an increasing number of environmental exposures. One such that has incited particular interest is to the mould, *Stachybotrys*, which may contaminate wet or damp accommodation, and which releases a particularly potent toxin with haemorrhagic properties. This is now thought to have aetiological significance in some childhood cases, perhaps in synergy with environmental tobacco smoke. Associations with cow's milk allergy, rheumatoid arthritis, and coeliac disease are also recognized, but the latter might be a consequence of cow's milk allergy also rather than gluten intolerance. A number of other environmental causes have been suggested; but the stronger the evidence for their causal roles, the less appropriate is the diagnostic rubric, idiopathic pulmonary haemosiderosis. They are consequently identified below under the heading 'other causes'.

Clinical features

Recurrent alveolar haemorrhage is generally manifested by cough with haemoptysis and breathlessness, but haemoptysis is not invariably present, and in children a failure to thrive may be prominent, together with the effects of severe chronic iron-deficiency anaemia. Acute bleeds are more common in childhood and may be life threatening. Physical examination is unhelpful. The chest radiograph and CT scan show the non-specific appearances of intra-alveolar blood, which usually clear spontaneously over 1 to 3 weeks. With chronicity, the appearances of diffuse pulmonary fibrosis with honeycombing may supervene. Lung function tests then show a progressive loss of volume and reduction of gas transfer; an obstructive pulmonary defect occurs occasionally, which is unexplained.

Treatment and prognosis

Supportive treatment is required during acute bleeding, and artificial ventilation is occasionally necessary. There are case reports recording responses to the avoidance of milk and gluten, and to the use of immunosuppressive agents including corticosteroids and cyclophosphamide. Some patients recover spontaneously with or without residual pulmonary damage.

Other causes of diffuse alveolar haemorrhage

Although diffuse alveolar haemorrhage is not a principal pulmonary feature of disorders other than Goodpasture's syndrome and idiopathic pulmonary haemosiderosis, it may occur with or complicate a wide variety of disorders with immunological, vasculitic, vascular, haemostatic, toxic, or unknown origins. In many of the cases that have been reported, several different disorders, their complications, and their various treatments could all have played a contributory role.

Vasculitic disorders can occasionally cause prominent diffuse alveolar haemorrhage, particularly Wegener's granulomatosis. This may simulate Goodpasture's disease, since it commonly causes acute necrotizing glomerulonephritis, but is distinguished from it clinically by the common involvement of upper respiratory tract structures (and because diffuse alveolar haemorrhage is an uncommon respiratory manifestation); histologically by the appearances of a granulomatous vasculitis; and immunologically by the presence of circulating anti-neutrophil cytoplasmic antibodies (**ANCA**), directed against proteinase-3, in about 90 per cent of cases. Other vasculitic disorders involving the lung are very rare causes of diffuse alveolar haemorrhage; they include Henoch–Schönlein purpura and Churg–Strauss syndrome. The latter may be associated with ANCA directed against myeloperoxidase and against eosinophil granule enzymes.

Diffuse alveolar haemorrhage may also arise as an unusual respiratory feature of several non-vasculitic immunological disorders. Most prominent is systemic lupus erythematosus (in which lupus anticoagulant, thrombcytopenia, and active nephritis may all play a role), but there are reports also of diffuse alveolar haemorrhage complicating antiphospholipid antibody syndrome, IgA nephropathy, idiopathic membranous nephropathy, scleroderma, renal and bone marrow transplantation, and chronic active hepatitis.

Other reports have implicated hymenopteran stings, moulds other than *Stachybotrys* and their mycotoxins, infections (group A streptococcal, leptospirosis, strongyloidiasis, *Stenotrophomonas*, dengue fever, cytomegalovirus, AIDS, varicella), occupational exposure to tri- and pyro-mellitic anhydride, lymphangiography contrast media, and several medications (valproate, nitrofurantoin, mitomycin C, azathioprine, D-penicillamine, surfactant therapy, anaesthetic agents). The list is completed by causes of chronic pulmonary venous congestion (mitral stenosis, chronic left ventricular failure, pulmonary veno-occlusive disease), malignant hypertension, and disorders that disrupt bleeding and coagulation mechanisms (thrombocytopenia, leukaemia, thrombinolytic therapy, platelet glycoprotein IIb/IIIa inhibitor, anticoagulant poisoning, factor V deficiency). Combinations of such factors are commonly found in individual cases, and it may be that important interactions occur, without which the probability of diffuse haemorrhage is remote. Although capillary stress from high pressure gradients is thought to be a major factor underlying diffuse pulmonary haemorrhage in exercizing horses (and camels), it appears a rare or unheard cause in most other species. Nevertheless, the use of negative pressure ventilation in humans has been reported to have a similar effect.

17.11.9 Eosinophilic pneumonia

*D. J. Hendrick and G. P. Spicketi**

When alveolar spaces are consolidated because of eosinophil inflammation/infiltration, there is said to be eosinophilic pneumonia. This is not meant to imply that there is microbial infection, and most commonly there is not. There is characteristically an accompanying eosinophilia of peripheral blood, hence the alternative terms, pulmonary eosinophilia and pulmonary infiltrates with eosinophilia (PIE syndrome). Eosinophilic pneumonia is the preferred term, however, since eosinophilia of peripheral blood may be present coincidently when eosinophils are not relevant to a pulmonary infiltrate, and conversely true eosinophilic pneumonia is occasionally not associated with blood eosinophilia. To avoid further confusion, it should be noted that eosinophilic granuloma is a distinct disease unrelated to eosinophilic pneumonia: it is a disorder of Langerhans (dendritic) cells and not characterized by eosinophil infiltration of the alveolar spaces.

The plethora of diagnostic terms is exceeded by the multitude of causes, and evenly matched by the systems of classification that have been suggested. In essence they reflect the following points concerning eosinophilic pneumonia.

1. It may arise acutely and resolve quickly (acute eosinophilic pneumonia, Löffler's syndrome, simple pulmonary eosinophilia).
2. It may arise gradually and persist for many months, leading sometimes to pulmonary fibrosis (chronic eosinophilic pneumonia, prolonged pulmonary eosinophilia).
3. It may be a consequence of allergy, particularly to bloodborne parasites (tropical eosinophilia), moulds (allergic bronchopulmonary mycosis), or other common environmental allergens.
4. It is often associated with asthma (asthmatic eosinophilia).
5. It is often due to drugs (whether through allergy, idiosyncrasy, or toxicity).
6. It may be associated with pulmonary vasculitis (Churg–Strauss syndrome, polyarteritis nodosa, Wegener's granulomatosis).
7. It may be a component of the hypereosinophilic syndrome.
8. It may be associated with a variety of other distinct disease entities (rheumatoid disease, sarcoidosis, T-cell lymphoma, Hodgkin's disease, shock, and the adult respiratory distress syndrome).
9. It may seem to be idiopathic.

Since there is often overlap—to give a recent example, the affected subject may have asthma, be taking a relevant drug (a leukotriene receptor antagonist), have prolonged manifestations, and have a pulmonary vasculitis (Churg–Strauss syndrome)—there is limited benefit from using any classification. The important issue is to identify any potentially remediable cause.

Diagnosis

In practice the finding of a blood eosinophilia in association with a radiographic pulmonary infiltrate provides a valuable clue that pneumonia of infectious origin may not be the explanation. Since such a disorder is not likely to respond to conventional antibiotic medication, the need to confirm or exclude the possibility of eosinophilic pneumonia will soon arise. Equally, if an apparent pneumonia fails to respond to antibiotics, a blood eosinophil count should be obtained. Once suspected, eosinophilic pneumonia is most conveniently confirmed by demonstrating an excess of eosinophils in bronchoalveolar lavage fluid in the absence of pathogenic micro-organisms. Sometimes sputum alone is sufficient, whether expectorated spontaneously or induced. Alternatively, an excess of alveolar eosinophils is revealed in lung biopsy tissue. The use of CT scanning has shown that episodes of recurrent pulmonary infiltration occur, not surprisingly, more frequently than can be detected from plain chest radiographs in subjects with confirmed eosinophilic pneumonia.

Once eosinophilic pneumonia is confirmed, a variety of possible causes should be considered before it is assumed to be idiopathic in origin and before empirical treatment with corticosteroids is administered.

1. Is there parasitic infestation?
2. Have any drugs been administered?
3. Is there asthma?
4. Is there evidence of allergy to parasites or drugs?
5. Is there evidence of allergic bronchopulmonary mycosis (particularly aspergillosis)?
6. Is there evidence of vasculitis?
7. Is there evidence of the hypereosinophilic syndrome?
8. Is there evidence of other disorders known to be associated with eosinophilic pneumonia?

Treatment

Eosinophilic pneumonia itself often responds well to corticosteroid medication, though treatment may need to be prolonged (6 months or more) in the chronic forms of the disorder. The importance of identifying whether it is associated with the causal factors listed above lies with the additional need to treat these also. Otherwise eosinophilic pneumonia may not respond adequately to steroid therapy and the associated diseases may produce other manifestations.

Particular varieties of eosinophilic pneumonia

Löffler's syndrome (acute eosinophilic pneumonia, simple pulmonary eosinophilia)

The essential features of the syndrome are transitory migratory pulmonary shadows with associated modest peripheral eosinophilia in patients with a mild self-limiting illness. Some cases are asymptomatic and discovered incidentally. Most patients present with cough, sometimes with oddly yellowish sputum containing an abundance of eosinophils, and a few have general malaise and a mild fever. The pulmonary shadows reflect fan-shaped areas of consolidation, often peripheral and sometimes rather nodular, which last a few days only and appear haphazardly in various lobes, seldom following a truly segmental pattern. In some cases they are single and in others they are multiple. The peripheral eosinophilia is obvious but rarely gross; a differential of more than 20 per cent in a modestly raised total white cell count is unusual and more often the absolute eosinophil count ranges between 1×10^{9} and 2×10^{9}/l (normal: $< 0.4 \times 10^{9}$/l).

Patients who develop Löffler's syndrome are often atopic and may have other manifestations of an atopic diathesis such as asthma, urticaria, and angio-oedema. Allergy has been shown since Löffler's original description to play an important role, and cases can be seen to fall into two broad aetiological groups with a third miscellaneous group of unexplained aetiology.

In the first group eosinophilic pneumonia represents an allergic reaction to bloodborne parasites migrating through the lung, particularly larvae of *Ascaris lumbricoides* and occasionally *A. suum. Ancylostoma*, *Trichuris*, *Trichinella*, *Taenia*, and *Strongyloides* species provide further examples.

Drugs form the second major aetiological group. Löffler's syndrome is well described after administration of *p*-amino salicylic acid, aspirin, sulphonamides (including

the antimalarial combination sulphadiazine and pyrimethamine or Fansidar), penicillin, and imipramine. It may also occur with nitrofurantoin (although this can also give a diffuse reticulonodular radiological picture and is a cause of the more chronic type of eosinophilic pneumonia), toxic smoke, and lymphangiography contrast medium.

Successful management requires the irradication of any parasites or the cessation of relevant medication, as well as the administration (if necessary) of oral corticosteroids.

Tropical eosinophilia

Eosinophilic pneumonia in tropical climates is often a consequence of migrating larvae of the filarial worms *Wucheria bancrofti* and *Brugia malayi*. The effects are fundamentally similar to those of Löffler's syndrome, but tend to be more persistent and more serious, are more often associated with asthma, and may be associated with systemic symptoms of weight loss, persistent fever, and lymphadenopathy. Also the peripheral eosinophil count tends to be greater than in Löffler's syndrome (> 3×10^9/l), and the total serum IgE level is markedly elevated. With chronicity, pulmonary fibrosis is characteristic. A cure is to be expected with antifilariasis medication (diethylcarbamazine).

Chronic eosinophilic pneumonia (prolonged pulmonary eosinophilia)

Eosinophilic pneumonia persisting for more than a month is distinguished from the more transitory Löffler's syndrome, although its clinical characteristics are fundamentally similar. As with eosinophilic pneumonia associated with tropical filariasis, it tends to be more persistent and more serious than Löffler's syndrome (it is sometimes life threatening), and to be associated with systemic symptoms (particularly fever), progressive pulmonary fibrosis, and fixed airway obstruction. It may last for several months and be associated additionally with eosinophilic pleural effusion, focal skin lesions, atopic manifestations such as rhinitis, sinusitis, and angio-oedema, hepatosplenomegaly, and even hepatic necrosis. The pulmonary disease is often extensive, causing dyspnoea and hypoxia, and is characterized radiologically by a curious peripheral distribution dubbed a 'negative photographic image of pulmonary oedema'. The radiological abnormalities tend to recur and last for weeks or months, and like the shadows of Löffler's syndrome may vary in site during the course of the illness.

Chronic eosinophilic pneumonia is more commonly idiopathic (cryptogenic) than Löffler's syndrome, but may also be a consequence of parasite infestation (e.g. tropical filariasis) or drug hypersensitivity. Case reports over recent years have identified aminoglutethimide, bicalutamide, chlorpropamide, clomipramine, dapsone, diflunisal, ethambutol, mesalazine, minocycline, nitrofurantoin, sertraline, sotalol, sulphonamides, and venlafaxine as possible causes. Peripheral blood eosinophilia is less consistent with chronic compared with acute forms of eosinophilic pneumonia, although is often of greater level (> 1×10^9/l). When a definitive cause is identified, appropriate specific management should follow, but often no cause is evident and oral corticosteroid therapy should be given. Responses are often dramatic, but recurrences are common if treatment is discontinued within 6 to 12 months. There may be a persistent mixed obstructive and restrictive loss of ventilatory function, and radiographic evidence of persistent pulmonary fibrosis.

Eosinophilic pneumonia with asthma

Eosinophilic pneumonia is commonly associated with asthma, even in the absence of parasite infestation or drug hypersensitivity. Two particular associations are noteworthy.

Allergic bronchopulmonary mycosis

When fungal hypersensitivity develops in atopic subjects with asthma, additional manifestations may occur in the lung: these include eosinophilic pneumonia, mucoid impaction, bronchiectasis, and pulmonary fibrosis. The ensuing syndrome of allergic bronchopulmonary mycosis occurs most commonly with *Aspergillus fumigatus*, though has been reported with other *Aspergillus*, *Candida*, *Curvularia*, and *Helminthosporium* species. It accounts for most cases of eosinophilic pneumonia with asthma in the United Kingdom and is best considered a complication of atopic asthma, appearing to result from airway colonization by the relevant mould. The mechanism, however, is clearly one of hypersensitivity, not infection/invasion, and both IgE and IgG antibodies are necessary to support its diagnosis.

In acute phases, there is patchy obstruction of bronchi with inspissated mucus that, if expectorated, appears as brown rubbery lumps in the sputum (plugs). Fungal hyphae may be recovered from them, indicating fungal growth has occurred within the airway. This impaction of mucus in one or more bronchi leads to patchy atelectasis within, or of, segments (even lobes) and is often associated with eosinophilic pneumonia. The radiographic appearances are of fleeting pulmonary infiltrates (Fig. 1). It usually responds well to corticosteroids, a useful diagnostic feature being the expectoration of plugs during this period of resolution. In the medium term the involved bronchi (generally proximal) may become bronchiectatic, leading in turn to the characteristic features of bronchiectasis (productive cough, intermittent haemoptysis). In the longer term, pulmonary fibrosis may ensue, particularly in the upper lobes and apices, so that the radiographic appearances resemble tuberculosis, and if mucoid impaction and/or eosinophilic pneumonia become superimposed, the radiographic appearances may simulate active tuberculosis very closely. Suspicion of tuberculosis in an individual with atopic asthma should always prompt consideration of allergic bronchopulmonary mycosis.

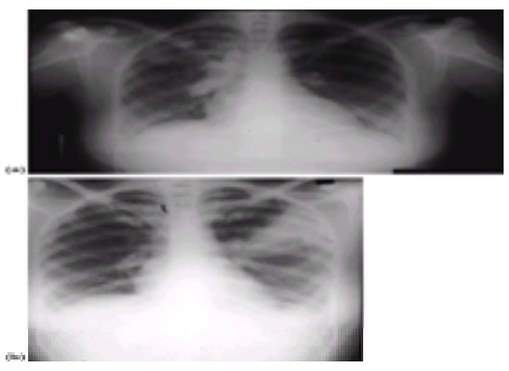

Fig. 1 Allergic bronchopulmonary aspergillosis: two radiographs taken 6 months apart from an East African woman with asthma, peripheral eosinophilia, and high titres of IgE and precipitating IgG antibodies to *Aspergillus fumigatus*.

Churg–Strauss syndrome

A much rarer association of eosinophilic pneumonia with asthma is that involving Churg–Strauss syndrome, a vasculitic and granulomatous disorder that commonly involves lungs, gut, peripheral nerves, skin, and kidneys. It is characterized typically by asthma, eosinophilic pneumonia, and very high numbers of circulating eosinophils (> 5×10^9/l), but the pulmonary manifestations may additionally include localized haemorrhage and haemoptysis. Serological investigation may also demonstrate raised serum levels of IgE and eosinophil cationic protein, P-ANCA (peripheral antineutrophil cytoplasmic antibodies) with myeloperoxidase activity (in 60 per cent of cases), and C-ANCA with proteinase-3 specificity (in 10 per cent). Other autoantibodies against eosinophil granule enzymes have also been described. Pathologically there is vasculitis of small arteries and veins with necrotizing extravascular granulomas. Biopsy tissue is needed to confirm the diagnosis.

The clinical syndrome and the histological features resemble those of polyarteritis nodosa, but the differences are sufficiently clear to establish Churg–Strauss syndrome as a separate entity. Although idiopathic in most cases, a minority appear to be a consequence of drug hypersensitivity, a recent example of particular interest being allergic granulomatosis and angiitis (the nomenclature of Churg and Strauss) complicating the use for asthma of newly introduced oral leukotriene receptor antagonists. It has been suggested, however, that the drugs themselves do not cause the disease, but merely lead to it being uncovered as the beneficial effect of leukotriene receptor antagonism allows a reduction (or withdrawal) of chronic steroid therapy. The disease may become life threatening if there is extensive vasculitic involvement of several organs, though generally responds satisfactorily to immunosuppressive therapy with corticosteroids. Other immunosuppressive or steroid sparing agents, such as azathioprine and cyclophosphamide, are usually required in addition.

Hypereosinophilic syndrome

The hypereosinophilic syndrome completes what might be described as a spectrum of overlapping disorders in which eosinophilic pneumonia is a prominent feature. The eosinophils appear mature, and infiltrate a number of organs by increasing degrees to cause progressive dysfunction, even death. The bone marrow is particularly densely infiltrated, raising the possibility that the disorder is primarily leukaemic in nature. Although the clinical picture does resemble that of eosinophilic leukaemia, the apparent maturity of the cells argues against this; current wisdom favours the hypereosinophilic syndrome as a distinct disorder, though one of unknown cause.

The clinical manifestations vary according to the organ(s) of principal involvement, and the extent of eosinophil infiltration. At the benign end of the spectrum the respiratory effects may be confined to an irritant cough, mild asthma, and minor episodes of eosinophilic pneumonia. When the disorder becomes life threatening, eosinophilic pneumonia may be extensive and associated with pleural effusion, but the chief threat to survival comes from myocardial and central nervous system infiltration. In most cases corticosteroids control progression, but when this fails, there may be progressive cardiac failure, or progressive functional impairment of central and peripheral nervous systems. This is often accompanied by weight loss, muscle weakness, enlargement of spleen and lymph nodes, gut and renal dysfunction, and venous thromboembolism. When corticosteroid therapy is ineffective, the use of antileukaemic agents may provide benefit.

17.11.10Lymphocytic infiltrations of the lung

D. J. Hendrick

Introduction

A number of disorders are characterized by lymphocytic infiltration of the lung. Several are rare and poorly understood, while others are relatively common and possess additional distinctive characteristics. For the latter group, classification poses few problems and individual diseases are readily distinguishable. These include, for example, Sjögren's syndrome, sarcoidosis, Wegener's granulomatosis, extrinsic allergic alveolitis, cryptogenic organizing pneumonia, bronchiolitis obliterans with organizing pneumonia, and cryptogenic fibrosing alveolitis, all of which are described separately in other chapters. However, for the first group, which constitutes the subject of this chapter, classification poses a continuing challenge: precise mechanisms and full natural histories are yet to be defined.

Disorders of lymphocytic infiltration are often considered as a spectrum of overlapping conditions, ranging from relatively benign infiltration of apparently normal lymphocytes without involvement of other cellular lines, through vasculitic and granulomatous inflammation, to frank malignancy. Apparent progression from disorder to disorder within the spectrum is not uncommon, but it is not always clear whether individuals affected in this way truly progress from one disease to another, or have a single disease whose early manifestations are similar to (and mistaken for) those of less serious neighbours in the disease spectrum. This has given rise to an alternative view that one end of the spectrum comprises a group of inflammatory disorders whose vasculitic and granulomatous features link more appropriately with diseases such as Wegener's granulomatosis and sarcoidosis; while the other end comprises the various malignant lymphomas.

Dominant lymphocytic infiltration is, nevertheless, a convenient definitive feature from which to consider the small group of uncommon pulmonary diseases that are described in this section. There is often paraprotein production, implying that a lymphocyte clone is involved. Depending on severity, these disorders are characterized clinically by cough (usually dry) and progressive undue exertional breathlessness; though systemic features of fever, malaise, and weight loss may also be prominent. Clubbing is not common, but there are frequently inspiratory crackles at the lung bases. The chest radiograph shows a diffuse interstitial pattern or patchy 'pneumonic' (i.e. air space) infiltrates with the more benign disorders, but nodular shadows at the more malignant end of the disease spectrum. Lung function tests show a non-specific pattern of ventilatory restriction with impaired parenchymal function.

Lymphocytic (and plasma cell) interstitial pneumonitis (pneumonia)

At the most benign end of the spectrum of lymphocytic infiltrations, lymphocytic (or lymphoid) interstitial pneumonitis is characterized by diffuse infiltration of the lung interstitium and alveolar walls with small mature lymphocytes, immunoblasts (activated lymphocytes), and plasma cells. Occasionally plasma cells dominate the lymphoid cell infiltrate, and in these circumstances the term plasma cell interstitial pneumonitis is preferred.

Lymphocytic pulmonary infiltration may occur in isolation without obvious cause; it may also be a non-specific feature of underlying pulmonary or systemic disease, such as HIV or Epstein–Barr virus (**EBV**) infection, drug hypersensitivity (sometimes toxicity), Castleman's disease (giant follicular lymph node hyperplasia), and (like Castleman's disease) a variety of autoimmune disorders, of which rheumatoid disease, Sjögren's syndrome, and systemic lupus erythematosus are most prominent. It may also be a consequence of a graft-versus-host reaction, and of common variable immunodeficiency—a primary antibody deficiency syndrome. When it occurs in children with AIDS it is thought to be largely a consequence of EBV infection. It may progress to (or be complicated by) the development of lymphoma, or be a feature of it. This too is particularly associated with Sjögren's syndrome.

The infiltrating lymphocytes show various levels of activation, and excess circulating immunoglobulins, whether monoclonal or polyclonal, are commonly observed. Occasionally there is hypo- rather than hypergammaglobulinaemia. When plasma cells rather than lymphocytes are dominant, the immunoglobulins are much less likely to be of the IgM class, though later complications may still include Waldenstrom's macroglobulinaemia or multiple myeloma. Bronchoalveolar lavage shows an excess of CD8+ T cells when lymphocytic interstitial pneumonitis is associated with HIV, whilst in Sjögren's syndrome the recovered lymphocytes are of the CD4+ phenotype.

The radiographic features, best seen with high resolution CT scans, are those of diffuse interstitial shadowing similar to cryptogenic fibrosing alveolitis, or (less commonly) air space filling. Cysts are often present, the mechanism being uncertain, and occasionally there are large nodules (> 10 mm in diameter). Effusion is not characteristic. The overall appearances are not specific, and since the disorder is rare, open biopsy is generally required for definitive diagnosis. It is seen in both sexes, usually in middle age, though children are not uncommonly represented. Slow progression is characteristic, though lymphocytic interstitial pneumonitis is rather more responsive to corticosteroid or other immunosuppressive therapy than is cryptogenic fibrosing alveolitis, and it sometimes remits spontaneously. There may, however, be complicating (even fatal) sepsis. The ultimate prognosis depends most on that of any underlying disease.

Benign lymphocytic angiitis

Lymphocytic infiltration in this condition is centred in small arteries and arterioles, necrosis is characteristically absent, and not infrequently there is granuloma formation. It therefore has both vasculitic and granulomatous features. It is rare, relatively benign, and usually affects the lungs or the skin. Most often there is no obvious provoking cause, but there have been reports of it emerging as a consequence of drug administration (streptokinase), HIV infection, or intrathoracic malignancy (thymoma).

Pulmonary lesions are usually single and most commonly present as asymptomatic nodules on a chance chest radiograph, the diagnosis being made following biopsy or resection. There may be systemic symptoms, however, and treatment with corticosteroids or cytotoxic agents may be necessary. The disease may progress to produce the more characteristic features of lymphomatoid granulomatosis, but more typically there is spontaneous remission. This suggests that benign lymphocytic angiitis is primarily a benign reactive vasculitis rather than a malignant lymphoma. It may be that similar histological features sometimes occur early in the course of lymphomatoid granulomatosis.

Immunoblastic (angio-immunoblastic) lymphadenopathy

This is a systemic and often febrile disorder characterized by widespread reactive lymphadenopathy and the infiltration of various organs by activated lymphoid cells, usually but not uniformly T lymphocytes. CD8+ cells, often clonal, are observed more commonly than CD4+ cells in affected organs, but in peripheral blood active disease is characterized by decreased numbers of T cells and an increase in B lymphocytes. The latter are possibly released from T-cell control and this might explain the frequency of paraprotein production. Infiltration of blood vessels may be prominent, hence the original term, angio-immunoblastic lymphadenopathy.

It occurs most commonly in the elderly and frequently in isolation, but it is often a consequence of infection (prominently HIV infection in recent years in younger subjects) or drug administration (often antibiotics), and it may be associated with autoimmunity.

Respiratory involvement is not common, usually comprising mediastinal or hilar lymphadenopathy, though diffuse interstitial infiltration and pleural effusion may occur. The involvement and enlargement of other lymphoid organs, particularly lymph nodes, liver, and spleen, usually offers a ready biopsy site for definitive diagnosis.

Management requires treatment of any provoking cause and, if necessary, the use of corticosteroids or other immunosuppressive agents. Occasionally there is spontaneous remission, but more commonly a T-cell lymphoma evolves. Indeed, the view is strengthening that most cases are due to peripheral (i.e. post-thymic)

T-cell lymphoma.

Lymphomatoid granulomatosis (angiocentric lymphoma)

Lymphomatoid granulomatosis is now widely considered to be a low-grade lymphoma, though the typical histological appearances of prominent infiltration of blood vessel walls and granuloma formation have, until recently, suggested a disease of more benign nature. The infiltrating cells comprise a mixture of lymphocytes, plasma cells, histiocytes, and atypical (usually malignant) lymphoid cells. The latter are derived from B lymphocytes, in some cases probably because of infection with EBV, but activated T cells are also prominent in focal lesions. Proliferation and vascular infiltration were initially assumed to cause luminal obstruction followed by ischaemic necrosis, but there are now doubts whether true vasculitis and true granuloma formation actually occur. As a consequence it has been proposed that angiocentric lymphoma is a more appropriate descriptive term.

The disease is uncommon in childhood but occurs throughout adult life with a slight predilection for males. It may arise on a background of an immunocompromised state. The lungs are almost invariably affected, but skin, central nervous system, and renal involvement is frequently seen, and there is often peripheral neuropathy. The disease is typically multifocal, affecting several organs, and may simulate disseminated carcinoma. Pulmonary lesions are usually discrete and nodular, whether single or multiple, but may vary in size from less than a centimetre in diameter to several centimetres across. Occasionally outlines are irregular and indistinct, suggesting patchy consolidation. Cavitation may occur, when an inflammatory cause may consequently be suspected, the radiographic appearances simulating those of Wegener's granulomatosis.

Symptoms are commonly dominated by systemic upset (fever, malaise, and weight loss), but respiratory involvement is likely to cause cough (sometimes with haemoptysis) or undue breathlessness. The involvement of other organs may provide valuable diagnostic insight, but biopsy is necessary for definitive diagnosis. Temporary improvement sometimes follows treatment with corticosteroids alone, but a realistic chance of cure requires cytotoxic therapy for lymphoma.

Lymphoma

Unquestionably at the malignant end of the disease spectrum lies lymphomatous infiltration of the lung. All lymphoma types may present with intrathoracic disease, and all may involve the thorax later if they present elsewhere. Lymph nodes, lymphatics, and lung parenchyma may all become infiltrated, but the pattern may vary between tumour types.

A comprehensive review of lymphomas is beyond the scope of this section, and the reader is referred to Section 22 for full details. To the chest physician the distinction of Hodgkin's disease and low-grade non-Hodgkin's disease from high-grade non-Hodgkin's disease is of particular value, since the former are now generally curable—or at least highly responsive to treatment.

Hodgkin's disease is generally a disease of adults and adolescents. When it involves the thorax it usually does so by infiltrating hilar or mediastinal lymph nodes, though patchy or even diffuse parenchymal infiltration does rarely occur, with or without lymphadenopathy. Asymmetrical nodal enlargement favours lymphoma over sarcoidosis, the other disorder (apart from tuberculosis in endemic areas) that commonly produces hilar and mediastinal adenopathy. Hodgkin's disease frequently involves other nodal sites at presentation, but may be confined to the thorax. Pleural effusion is not uncommon, and occasionally there is infiltration of the chest wall. Biopsy and staging are essential to diagnosis and management, though the advent of computed tomographic scanning has greatly simplified the latter by eliminating the need for laparotomy. Radiotherapy is normally curative for localized nodal disease and is invaluable as an adjunct in reducing local 'bulk' when the disease is disseminated. It carries much less risk than chemotherapy, which is required for parenchymal or disseminated disease, and for the small proportion of patients with localized nodal disease who show features of poor prognostic significance (e.g. high 'bulk', systemic symptoms, and anaemia).

Non-Hodgkin's lymphoma is more common than Hodgkin's disease and tends to affect a rather older population. Its thoracic manifestations are similar to those of Hodgkin's disease, but it is the more likely malignant 'complication' of the other lymphocytic pulmonary infiltrations discussed in this section. It also has a greater tendency to be disseminated at presentation, to have more 'high grade' features histologically and clinically, and (not surprisingly) to be less responsive to therapy. Nevertheless, localized and low-grade tumours are often curable, and useful palliation is generally achieved for all but the most high-grade tumours.

High resolution CT scanning shows that both types of lymphoma are most commonly characterized by an air space filling pattern rather than interstitial shadowing, and by large nodules and pleural effusions.

Chemotherapeutic regimens for the treatment of lymphoma continue to develop rapidly and have properly become the responsibility of specialist haemato-oncologists. Chemotherapy is, of course, attended by the familiar risks of bone marrow suppression and an immunocompromised state, but with regard to those with lung disease it is noteworthy that many of the chemotherapeutic agents can themselves cause interstitial lung disease—including lymphocytic infiltration. The supervising physician may consequently face a classic diagnostic dilemma when, following an initial satisfactory remission, the patient's radiographs show pulmonary shadows consistent with infection, drug hypersensitivity/toxicity, or recurrent lymphomatous infiltration. A prompt and accurate diagnosis is essential since each possibility requires fundamentally different management. Expectorated secretions may provide adequate evidence of infection to justify a trial of antibiotic therapy, but if immediate progress is unsatisfactory, fibreoptic bronchoscopy with lavage and/or transbronchial biopsy is generally needed. It may be that with increasing use of the polymerase chain reaction to amplify fragments of genetically specific microbial material, sputum or even oropharyngeal secretions will prove adequate to identify the infecting organisms. However, the cause of pulmonary shadows in this situation is often complex, and any combination of these three diagnostic groups may develop (perhaps with more than one infecting micro-organism). A multidisciplinary approach to management has consequently become essential, involving chest physicians, radiologists, microbiologists, and histopathologists under the expertise of supervising oncologists or haematologists.

17.11.11 Extrinsic allergic alveolitis

D. J. Hendrick and G. P. Spickett

Historical background

Farmer's lung is often regarded as the prototype of the alveolar and bronchiolar disorders that result from hypersensitivity to inhaled organic dusts. These occur worldwide and are known collectively by the term extrinsic allergic alveolitis, although it is recognized that the underlying inflammatory response occurs diffusely throughout the gas exchanging tissues and is not confined to the alveoli. For this reason many prefer the term hypersensitivity pneumonitis. These alveolar disorders were not clearly distinguished from asthma until 1932 when Campbell published his celebrated report describing three affected English farm workers, the appellation 'farmer's lung' being suggested in 1944. However, the disease had been recognized in Iceland in the nineteenth century, and probably contributed to the occupational ailments of grain workers so graphically described by Ramazzini in the eighteenth century.

Part of the eminence of farmer's lung itself stems from its industrial importance, and part from its historical role in the understanding of extrinsic allergic alveolitis. Its relation to the inhalation of dust from mouldy hay, straw, or grain had been recognized from the outset, but it was not until 1961 when Pepys and colleagues demonstrated the presence of precipitins to antigens of mouldy hay in patients suffering from the disease that the idea of an allergic aetiology gained general acceptance. These and other investigators showed that the main sources of antigen were contaminating thermophilic actinomycetes, particularly *Micropolyspora faeni* (now known as *Saccharopolyspora rectivirgula*) and *Thermoactinomyces vulgaris*. These thermophilic microbes (which are actually bacteria not fungi) colonize fermenting damp vegetable produce as it heats up. When it eventually dries, a respirable dust laden with antigenic microbial spores is left. Symptoms are consequently most common during winters following wet summer harvests, when hay or grain is used for feeding stock, and astonishing numbers of spores (thousands of millions per cubic metre) are released into the air.

For deposition of the dust to occur predominantly in the gas exchanging tissues, particle size must be largely confined to the range 0.5 to 5 µm. This encompasses the diameters of many antigenic bacterial and fungal spores, and a large number of microbial species are now recognized as causes of extrinsic allergic alveolitis. In addition, the disease has been described following respiratory exposure to a variety of antigens derived from animal, vegetable, and even chemical sources, both in the workplace and in the home. It may also occur because of allergy to ingested agents, chiefly medications, but only inhalant causes will be addressed in this chapter. Drug-induced examples of the disease are discussed in Chapter 17.11.19.

Causative agents

Table 1 lists the various agents, principally organic proteins, reported to cause extrinsic allergic alveolitis. Most are encountered in working environments and so the disease is usually occupational, but some are encountered in the home or in recreational environments. Most are micro-organisms that are found contaminating a variety of vegetable products, but some are derived directly from animal or vegetable sources, and a few are reactive chemicals. The latter are thought to act as haptens, combining with body proteins to produce a larger and now antigenic molecule. Although the micro-organisms associated with the more celebrated disorders—farmer's lung, mushroom worker's lung, and bagassosis—are usually thermophilic, the majority causing extrinsic allergic alveolitis are not. Even with mouldy hay and farmer's lung there is evidence that non-thermophilic organisms (e.g. *Aspergillus* spp.) may occasionally be involved.

Some microbial contamination may occur during growth of the vegetable host, but most of the antigenic load is usually acquired after harvest. Prolonged storage under damp conditions increases the risk of extrinsic allergic alveolitis substantially, whilst drying to reduce the water content below 30 per cent greatly lessens the risks. Farmer's lung and bagassosis are not therefore primary disorders of hay, grain, or sugar cane harvest. They usually arise months or even years later when the stored product is used or moved. In the interim, moulding is likely to have involved a series of different micro-organisms that colonize the forage material sequentially. As the exothermic process increases the ambient temperature, so thermophilic microbes come to dominate.

Inevitably there are situations where contamination arises with a number of different microbes, and affected subjects show antibodies to several of them. Unless time-consuming inhalation challenge tests are carried out with extracts of the individual microbial species, it is not possible to identify a single responsible agent in a given case or cases, and it is conceivable that several could be relevant in these circumstances. This is a characteristic feature of contaminated water reservoirs in humidifiers and air conditioners, and a great variety of agents have been suggested as possible causes of humidifier lung, including bacteria, mycobacteria, fungi, protozoa (amoebae), and metazoa (nematode debris). Some authors prefer to distinguish extrinsic allergic alveolitis attributable in such circumstances to micro-organisms growing in cool or cold water (humidifier lung) from that arising from heated water (ventilation pneumonitis). Additional sources of causal organisms include hot tubs and saunas, containing both thermophilic and non-thermophilic organisms (including non-tuberculous mycobacteria), and water-based metal working fluids. The latter, often contaminated with oil, are recycled during use to lubricate and cool rotating or cutting equipment in the metal working industry, and may therefore be dispersed as respirable aerosols. The chief microbial contaminants are generally environmental non-tuberculous mycobacteria or fungi, but a variety of other organisms may be involved. Since granulomatous responses might be expected from mycobacterial infection, the mechanism of diffuse pneumonitis when mycobacteria are involved may not be one of hypersensitivity.

Curiously, contamination with multiple microbial species does not seem to be a feature of Japanese summer-type pneumonitis, which arises seasonally in the hot and humid regions in the south and west of Japan and neighbouring countries. This is the result of the excessive growth of *Trichosporon* spp. in unsanitary and poorly ventilated homes.

Epidemiology

Extrinsic allergic alveolitis is an uncommon but not rare disease. Its comparative scarcity limits epidemiological knowledge, as does the use of different methods of investigation. For every case there may be 100 cases of 'extrinsic allergic' asthma, but there is even greater geographical variation than with asthma reflecting the

much larger dependence of extrinsic allergic alveolitis on occupational causes and climate. As a consequence, its incidence and its principal causes vary considerably from country to country, and from region to region.

Incidence

Experience over 3 years with the **SWORD** project (Surveillance of Work-related and Occupational Respiratory Disease) indicated that extrinsic allergic alveolitis of occupational origin accounted for 2 per cent of occupational lung diseases in the United Kingdom. Asthma, the most common, accounted for 26 per cent. This does, of course, ignore extrinsic allergic alveolitis of non-occupational origin, which is much less easily assessed. It also disguises the absolute risk since few workers encounter relevant occupational exposures. Almost 50 per cent of reported cases involved farmers or farm workers, followed by 15 per cent affecting workers in material, metal, or electrical processing trades. Among the farmers, the average incidence was 41 per million per year, though this approached 100 in some regions, and has been estimated at 3000 in Quebec, Canada. However, the estimated incidences are crude and must vary considerably according to the prevailing weather. They may be compared with 200 to 700 per million per year among working groups at greatest risk of developing occupational asthma in the United Kingdom. Contaminating micro-organisms underlie over 50 per cent of the cases of extrinsic allergic alveolitis reported to SWORD, followed in order of importance by animal antigens in 6 per cent and chemicals in 5 per cent. In 27 per cent of reports a suspected agent was not specified.

Prevalence

Figures for prevalence (the proportion affected among a given population at a given point of time) are more readily available than those for incidence, and demonstrate quite marked national differences. In developed countries, humidifier lung is being recognized with increasing frequency in both the workplace and the home, and remarkable prevalences of 15 to 70 per cent have been suggested in populations from contaminated offices in North America. Bird fancier's lung may be more prevalent at present over the whole of the United Kingdom, simply because of the great popularity of keeping budgerigars and pigeons. Budgerigars are kept in some 12 per cent of British homes, and it has been estimated that 0.5 to 7.5 per cent of the population involved are likely to have extrinsic allergic alveolitis as a consequence, albeit mildly in most cases. Pigeon keeping is 40 times less common, and the measured prevalence of pigeon fancier's lung among pigeon keepers has been a good deal more varied (0 to 21 per cent). This may reflect both true differences between groups of pigeon breeders as exposure levels vary, for instance, according to number of birds, duration of exposure, loft ventilation, and cleaning habits, and artefactual differences arising as a result of selection bias and the notorious lack of compliance shown by pigeon fanciers in epidemiological studies. The avian antigen responsible and its precise source have yet to be identified, but bloom from the feathers containing oil, saliva, and secretory IgA is currently favoured over dust emanating from dried droppings.

In areas of high rainfall where 'traditional' farming methods are used, the prevalence of farmer's lung may reach 10 per cent. This is likely to be the commonest cause of extrinsic allergic alveolitis in developing countries. In developed countries, where modern farming methods are used, prevalences rarely exceed 2 to 3 per cent and are usually a good deal less. Furthermore, the farming population at risk represents a mere 1 to 2 per cent of the population at large, although there are marked regional variations. Even smaller populations are employed making whisky from germinating barley (maltings), raising mushrooms on a variety of antigenic composts, or handling bagasse (the fibrous stem that remains when sugar is extracted from sugar cane), but within some of these populations extrinsic allergic alveolitis was a common problem until excessive exposure levels were controlled. Extrinsic allergic alveolitis associated with animals other than birds is extremely uncommon, as is the case with chemical-induced extrinsic allergic alveolitis.

In Japan, the seasonal summer growth of *T. cutaneum* in the home is by far the commonest cause of extrinsic allergic alveolitis where the remarkable 'summer-type hypersensitivity pneumonitis' accounts for about 75 per cent of all cases of extrinsic allergic alveolitis. It is approximately 10 times as common as farmer's lung and 20 times as common as bird fancier's lung. Occasionally other subspecies of *Tricosporon* are responsible.

Pathogenic mechanisms

Histology

There has been little opportunity to characterize the acute form of extrinsic allergic alveolitis histologically because biopsies are very rarely taken within 24 to 48 h of a provoking exposure, and because death leading to autopsy is even less common. Initially there is a non-specific diffuse pneumonitis with inflammatory cellular infiltration of the bronchioles, alveoli, and interstitium, accompanied by oedema and luminal exudation. With ongoing exposure, whether continuous or intermittent, the more familiar appearances of the subacute forms of extrinsic allergic alveolitis evolve. The most characteristic feature is the formation of epithelioid non-caseating granulomas. These are generally less well formed than in sarcoidosis, less profuse, and often evanescent. They can be recognized within 3 weeks of the initiating exposure, and generally resolve within 6 to 12 months. In parallel, fibrosis evolves alongside cellular infiltration of the interstitium with histiocytes, lymphocytes, and plasma cells. Macrophages with foamy cytoplasm may be prominent in the alveolar spaces, and organization of the inflammatory exudate may lead to intra-alveolar fibrosis. Obstruction or obliteration of bronchioles is common. Foreign body giant cells may reflect the dependence of extrinsic allergic alveolitis on antigens derived from inhaled foreign material, as does a peribronchial predominance of the inflammatory response. Vasculitis is notable by its absence. The typical histological appearance of subacute extrinsic allergic alveolitis is illustrated in Fig. 1.

Fig. 1 Histological appearance: subacute disease (by courtesy of Dr T. Ashcroft). Haematoxylin and eosin stain. Medium magnification. There is bronchocentric interstitial fibrosis and chronic inflammation, with poorly formed interstitial granulomas including giant cells.

With continued exposure, progressive, widespread, and irreversible fibrosis may occur, leading to disruption of the normal architecture of the lung. In advanced cases honeycombing may develop. Granulomas are no longer characteristic, and the overall appearances may differ little from other causes of progressive interstitial pulmonary fibrosis. With extrinsic allergic alveolitis, however, there may be disproportionate fibrosis of the upper lobes.

Immune mechanisms

An outline of the possible immunopathology of extrinsic allergic alveolitis through acute, subacute, and chronic phases is illustrated in Fig. 2 and Fig. 3. The presumption that complexes of antigen and complement-activating antibodies are primarily responsible for extrinsic allergic alveolitis is now largely discarded. The evidence for deposition of immune complexes is not convincing, and neither IgG nor IgM antibodies are uniformly demonstrated in the sera of affected subjects unless sensitive detection techniques such as the enzyme-linked immunosorbent assay or radioimmunoassays are used. More importantly, these antibodies are frequently found in subjects who are similarly exposed but clinically unaffected, irrespective of the method of detection. A closer association of disease with the IgG4 antibody subclass has been suggested, but the significance of this is not yet apparent. It is clear, however, that vasculitis—a cardinal feature of the experimental Arthus reaction—is not a characteristic; the inflammatory reaction is dominantly lymphocytic or mononuclear rather than polymorphonuclear. However, a transitory polymorphonuclear leucocyte response is typical immediately following exposure. Lung tissue is most commonly examined during subacute phases of the disease, at which time a non-caseating granulomatous response suggesting cell-mediated hypersensitivity is the usual finding.

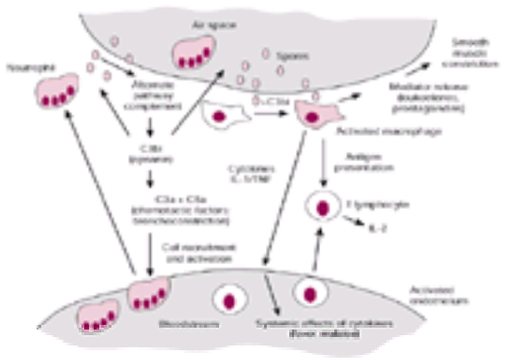

Fig. 2 Possible immunopathogenesis: acute phase.

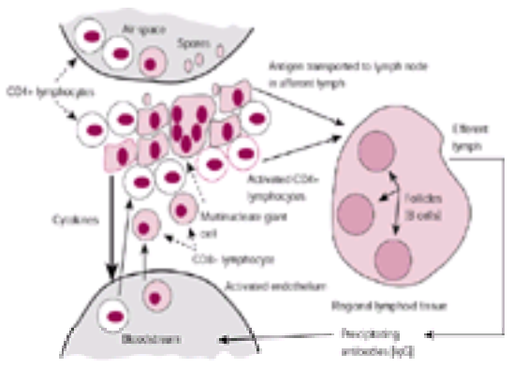

Fig. 3 Possible immunopathogenesis: subacute/chronic phase.

It could be argued that these histological appearances merely represent a healing reaction, but the consistent finding of an acute T-lymphocyte response in fluid obtained at bronchoalveolar lavage supports the current consensus that cell-mediated hypersensitivity plays the dominant pathogenic role in extrinsic allergic alveolitis. The results from animal models of the disease are consistent with this, disease being transferred from animal to animal only with sensitized T lymphocytes. This is not to say that other mechanisms play no role, nor that all inflammatory diseases of the gas exchanging tissues induced by organic dusts share a common mechanism. Indeed, the onset of symptoms within a few hours of exposure, coupled with polymorphonuclear leucocytosis in bronchoalveolar lavage fluid and peripheral blood, favours the participation of an additional (perhaps priming) immunological or toxic process, and B-lymphocyte aggregates have been noted in transbronchial biopsies obtained during the acute phase. Components of a number of organic dusts associated with extrinsic allergic alveolitis are known to activate complement by the alternative pathway and this, with or without humoral hypersensitivity, might also prove to be relevant.

In fact, bronchoalveolar lavage in similarly exposed subjects has shown excess numbers of T lymphocytes whether they were clinically affected or not, though the proportions of T-cell subpopulations has varied according to disease activity and the circumstances of exposure. Most investigators have detected a relative excess of CD8+ T cells in exposed but asymptomatic subjects, thereby 'inverting' the normal CD4+ to CD8+ ratio. The balance appears to be less disturbed in those with disease, and in one sequential study the ratio changed from 0.43 to 1.47 with disease progression. In an intriguing study of an animal model of extrinsic allergic alveolitis, monkeys that developed characteristic reactions to inhalation challenge showed a helper CD4+ cell lymphocytosis in bronchoalveolar fluid and a relative deficiency of suppressor CD8+ cells, compared with the monkeys giving no clinical reaction who showed responses with both CD4+ and CD8+ cells. When the non-reactors were challenged again after low doses of whole-body irradiation had impaired suppressor more than helper cell function, characteristic reactions were noted. These observations suggest that a relative impairment of suppressor cell function, or of its activation following antigenic exposure, is fundamental to the development of extrinsic allergic alveolitis—a situation that has interesting parallels with sarcoidosis. It is also interesting that lymphopenia in peripheral blood is a typical feature of acute exacerbations of the disease, the T lymphocytes migrating from blood to lungs within hours of the provoking exposure. It is small wonder that studies of systemic and local immune responses have given discordant results, and clear that continuing research should address both aspects of the immune response.

It is known that different antigenic determinants from a given inducing microbial source may lead to different immunological responses, and it seems likely that cytotoxic activity and released cytokines (e.g. interleukin 6 and tumour necrosis factor-a) play some role, possibly by activating the vascular endothelium and thereby recruiting and activating further macrophages and inflammatory cells. In experimental models interferon-g has been shown to play a major role (an excess of interferon-g-producing T cells is present in the lungs), and interleukin 10 ameliorates the disease. This indicates that extrinsic allergic alveolitis is a T_{H1}-type disease. Interleukin 8, a chemotactic factor for neutrophils, and monocyte chemotactic protein-1 are both elevated in some types of the disease, perhaps accounting for the increase in macrophage and neutrophil recruitment and activation. Serum levels of interleukin 6 and intercell adhesion molecule 1 (ICAM-1) are also raised. Bronchoalveolar lavage has shown that natural killer cells (CD57+) and mast cells may be prominent additional players in pathogenesis, and there is evidence that the capacity of macrophages to present antigen is enhanced by viral infection. It is diminished by cigarette smoking, which is known to decrease the severity of clinical symptoms as well as the immunological abnormalities.

Cytokines, possibly together with anaphylotoxins from the degradation of complement components (C4, C3, C5), are likely to be responsible for the systemic influenza-like symptoms that are so characteristic of the acute form of extrinsic allergic alveolitis. These symptoms are indistinguishable from those of grain fever in grain workers, 'Monday fever' in cotton workers, humidifier fever in subjects exposed to microbially contaminated humidifiers, and metal fume fever in welders. In these situations, the febrile disorder is not characteristically associated with clinical alveolitis, raising the possibility that its occurrence with the acute form of extrinsic allergic alveolitis is an independent phenomenon, not an integral part of extrinsic allergic alveolitis itself. In favour of this hypothesis has been the finding of high levels of endotoxin from Gram-negative bacteria (which are known to provoke these symptoms) in grain dust, cotton dust, contaminated humidifiers, and many of the 'mouldy' vegetable dusts that cause extrinsic allergic alveolitis. However, neither metal fume nor several other causative agents of extrinsic allergic alveolitis are likely to be contaminated with endotoxin, and so endotoxin-induced release of inflammatory mediators is not an entirely satisfactory explanation. For example, inhalation provocation tests with uncontaminated bird serum in subjects with bird fancier's lung reproduce both alveolar and influenza-like responses. Evidently the influenza-like response is an integral feature of the acute form of extrinsic allergic alveolitis, but it is relatively non-specific and can occur in many other situations.

Extrinsic allergic alveolitis occurs in families only sporadically, and few associations with HLA phenotypes have been demonstrated. However, a number of recent studies have suggested associations between HLA D alleles and pigeon fancier's lung and Japanese summer-type hypersensitivity pneumonitis. Such alleles may exert effects on immune suppression, and offer one mechanism by which a genetic predisposition could play a role in the development of extrinsic allergic alveolitis. It has also been suggested that an acute inflammatory episode (from viral infection or the inhalation of microbial toxins or chemicals) may be necessary to disrupt the normal defence equilibrium of surface membrane and local immune responses, and thereby permit antigen to be presented in a fashion that leads to hypersensitivity. Undue 'leakiness' of the alveolar membrane can be demonstrated by an increased clearance of inhaled $^{99}Tc^{m}$-DTPA, and this has been reported in both the early and continuing phases of extrinsic allergic alveolitis.

Relation to smoking

The disruptive effect of smoking on the alveolar membrane does not appear to augment the risk for extrinsic allergic alveolitis or to increase its severity. Rather, the reverse is true. Although smoking enhances acute-phase reactions and IgE production, it diminishes IgA, IgG, and IgM antibody responses, increases circulating CD8+ T-lymphocyte numbers, and probably reduces the incidence and severity of extrinsic allergic alveolitis. However, the smoker without IgG antibodies is particularly liable to find his respiratory symptoms attributed to other diseases, and so this negative association between extrinsic allergic alveolitis and smoking may have been exaggerated. That it is real is supported by evidence that smoking may also reduce the risk for other T-cell-mediated immunological disorders such as sarcoidosis, ulcerative colitis, and some types of occupational asthma (generally those associated with low molecular weight chemicals). The key cell in a complex series of interactions is probably the alveolar macrophage, which is critical in presenting antigen to CD4+ T lymphocytes and so to activating cellular immune

mechanisms. Although smoking increases macrophage numbers and their metabolic activity, the activated cells show impairment of both the expression of surface major histocompatibility class 2 antigens and the production or release of interleukin 1 and inflammatory mediators derived from arachidonic acid metabolism (leukotriene B4, prostaglandin E_2, thromboxane B_2). It is also argued that the increased macrophage numbers down-regulate pulmonary immune responses in a purely non-specific fashion by impairing antigen access to more effective blood monocytes.

Relation to coeliac disease

Reports that cryptogenic fibrosing alveolitis and extrinsic allergic alveolitis (and particularly bird fancier's lung) might be associated with coeliac disease led to the interesting hypothesis that in some cases absorbed food antigens from the disrupted bowel mucosa might play a role in the pathogenesis of the lung disorder; that is, the lung disorder might be a 'metastatic' complication of the bowel disease. Alternatively, systemic hypersensitivity to a common inhaled and ingested avian antigen might give rise to similar immune reactions and diseases in the relevant target organs. The avian IgG antibody response seen in coeliac disease is, however, distinct from that associated with bird fancier's lung and seems to be a response to dietary egg. It is not related to environmental exposure to birds but does correlate with the activity of the bowel disorder. Subsequent experience suggests a much less strong association between these bowel and lung disorders that, if real, is probably a consequence of their dependence on similar immunological mechanisms and host susceptibility to them.

Clinical features

Acute form

The acute form of extrinsic allergic alveolitis is the most easily recognized, because symptoms are often distressing and incapacitating, and have a high degree of specificity. Following a sensitizing period of exposure, which may vary from weeks to years, the affected subject experiences repeated episodes of an influenza-like illness accompanied by cough and undue breathlessness some hours (usually 3 to 9) after commencing exposure to the relevant organic dust. The systemic influenza-like symptoms generally dominate those that are respiratory, and the affected subject complains most of malaise, fever, chills, widespread aches and pains (particularly headache), anorexia, and tiredness. He is unlikely to feel like exercising and may well put himself to bed, therefore remaining unaware of undue shortness of breath, though he is likely to develop a dry cough without wheeze and to have some difficulty taking deep, satisfying breaths. Occasionally there is an asthmatic or bronchitic response and wheezing or productive cough becomes an additional feature.

Despite the delay in onset after exposure begins, affected subjects soon learn to associate symptoms with the causative environment, especially if they follow a period away from work or the causal exposure. Recognition is particularly easy for groups such as farmers and pigeon fanciers for whom these risks are well known. However, in some cases there may be a tendency to deny such a relationship for fear of compromising the ability to pursue livelihood or hobby, and the clinical history may appear much less convincing than it should.

The severity and duration of symptoms depend critically on exposure dose and individual susceptibility. With low levels of acute exposure, symptoms are mild and persist for a few hours only. When occupation is responsible, the affected worker may feel unwell only at home during the following evening or night, and be fully recovered by the next morning, hence obscuring the relevance of the workplace. When severe responses follow particularly heavy exposures the relation of the one to the other will be more obvious, and complete remission may require several days or even weeks.

In exceptionally severe cases, life-threatening respiratory failure may develop and emergency admission to hospital becomes necessary. Death is not unknown. Respiratory distress at rest with fever and gravity-dependent crackles comprise the major physical signs, with breathing being fast but shallow. Clubbing is very rarely seen. Hypoxaemia is typically accompanied by hypocapnia, and the chest radiograph shows a diffuse alveolar filling and interstitial pattern. Supplemental oxygen may be required, and in rare cases there may be a brief need for mechanical ventilatory support. Spontaneous recovery can be expected to begin within 12 to 24 h, and can be accelerated with corticosteroids.

Most subjects recover fully from each acute exacerbation, and if the cause is recognized and further exposure avoided, there is little risk of persisting pulmonary dysfunction. However, it is not always realistic to expect affected individuals to avoid further exposure, particularly among farming communities, and there is some risk that continuing exposure and repeated acute exacerbations will eventually lead to permanent impairment of lung function.

Chronic form

In some subjects extrinsic allergic alveolitis presents in a much less dramatic but potentially more serious way. Exercise tolerance is gradually lost due to shortness of breath, but without systemic upset aside from (in some cases only) prominent loss of weight. This is the result of diffuse pulmonary fibrosis, which has often been progressing for years before the affected subject seeks advice: the slower the progression, the longer the delay, and the greater the likely degree of permanent fibrotic damage. Eventually hypoxaemia and pulmonary hypertension may supervene, and the right heart fails. There are no acute exacerbations, and each day and each month are much like any other. The clinical features are similar to those of other varieties of pulmonary fibrosis, although clubbing is uncommon, and it may prove extremely difficult to distinguish this form of extrinsic allergic alveolitis from cryptogenic fibrosing alveolitis, sarcoidosis, or other slowly progressive forms of pulmonary fibrosis. There may also be asthmatic or bronchitic symptoms, but these are best regarded as independent airway manifestations of hypersensitivity to the causal agent.

The chronic form of extrinsic allergic alveolitis is typically seen in the subject who keeps a single budgerigar (known as a parakeet in North America) in the home. The level of antigenic exposure to avian dust is comparatively trivial (compared with the farm worker forking bales of heavily contaminated hay in a poorly ventilated barn), but it is encountered almost continuously, particularly if the affected subject is someone confined to the home. Differing exposure patterns are largely responsible for these distinct forms of extrinsic allergic alveolitis, although differences in host responsiveness must exert an important additional influence. There may consequently be considerable variability in clinical features among individuals affected by the same source of antigenic exposure.

Intermediate forms

The fact that the acute form of extrinsic allergic alveolitis can be produced by inhalation provocation tests in subjects with the chronic form of the disease emphasizes the major role that dose exerts in determining the clinical nature of the response that occurs. Depending on exposure dose and host responsiveness a variety of intermediate forms of extrinsic allergic alveolitis are recognized, and some subjects will experience different patterns of response at different times. Hence it is possible for acute exacerbations to occur in subjects manifesting predominantly the chronic form of the disease, and for a limited degree of recovery to follow cessation of exposure. In general, however, the individual affected by the chronic form of extrinsic allergic alveolitis should be satisfied if no further progression occurs following cessation of exposure, because in some cases fibrotic damage continues regardless.

Investigation

Establishing a diagnosis of extrinsic allergic alveolitis involves three areas of investigation: the lungs, the exposure, and the evidence for hypersensitivity.

Pulmonary

In many cases extrinsic allergic alveolitis is first suspected after the presence of diffuse alveolitis or progressive pulmonary fibrosis is established. With the acute form of the disease the chest radiograph commonly shows no abnormality unless symptoms are moderately severe. Normal radiographic appearances are particularly common with humidifier lung, possibly because antigen is largely presented in soluble rather than particulate form. When the radiograph is abnormal, there is a widespread ground-glass appearance or an alveolar filling pattern, particularly in the lower and mid-zones. This may resolve within a mere 24 to 48 h once exposure has ceased. In more subacute forms small reticular opacities, simulating asbestosis, are seen within the same distribution: these may persist for several weeks despite cessation of exposure and, if exposure continues, honeycombing may develop. Occasionally a more nodular pattern occurs. In contrast to the distribution of acute and subacute radiological abnormalities, the upper zones are predominantly affected by the irreversible fibrotic process that characterizes the chronic form of disease. This may simulate sarcoidosis or even tuberculosis, and may lead to considerable shrinkage and distortion. In practice, the radiographic appearances vary considerably from patient to patient, and correlate poorly with the clinical severity of the disease.

Computed tomographic (**CT**) scans provide a much clearer picture of the type of radiographic abnormality and of its extent, particularly when thin-section

high-resolution techniques are used, but they have shown that no single feature or pattern is pathognomonic (Fig. 4). Again, investigation within hours of exposure has been limited and experience is largely confined to patients with subacute and chronic disease. Increased ground-glass density of the lung parenchyma is the most prominent finding in the subacute form, followed almost equally by reticular or nodular infiltration. At end expiration a mosaic pattern is characteristic, reflecting patchy bronchiolar involvement and the different degrees by which residual gas can be expelled from distal lobules. The attenuated areas may then be normal, the translucent areas indicating gas retention. Neither lymph node enlargement nor pleural involvement are characteristic. The CT scan is appreciably more sensitive than the plain chest radiograph, and shows a more uniform involvement of the lung fields in subacute disease than is obvious from plain radiographs. With chronic forms, the CT scan shows a similar pattern of fibrosis and disruption to the plain radiograph, but again is considerably more sensitive.

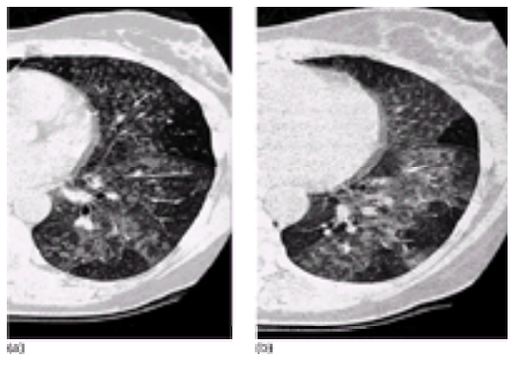

Fig. 4 (a) CT scan of a never-smoking woman aged 44 years whose lung biopsy showed the typical appearances of subacute EAA. She kept two budgerigars in her home and had serum precipitins to avian antigens. The scan shows marked groundglass attenuation of the lung parenchyma, which is nodular in some areas due to characteristic peribronchiolar (and centrilobular) foci. In other areas there is increased translucency because of bronchiolar obstruction and air trapping. Both the groundglass attenuation and the increases in translucency are exaggerated in the expiratory film (b), giving a 'mosaic' pattern. She recovered fully after the birds left her home..

Lung function studies vary according to severity and recent activity. As with asthma, they may be unremarkable in the acute form of the disease when there has been little recent exposure. When lung function is impaired, the pattern suggests parenchymal and interstitial disease but is otherwise non-specific. There is impaired carbon monoxide gas transfer (diminished TL_{CO} and K_{CO}) with restricted ventilation (i.e. forced vital capacity, FVC, is diminished as much as forced expiratory volume, FEV1, or more so, with respect to predicted values), decreased compliance, and (in more severe cases) arterial hypoxaemia and hypocapnia, particularly on exercise. Although total lung capacity is reduced, residual volume is often increased, suggesting air trapping as a result of bronchiolar involvement. Occasionally there is also obstruction of the large airways, but this implies a coincidental asthmatic or bronchitic effect. Serial measurements of lung function may be particularly useful in demonstrating that impairment is closely related to the relevant exposure.

Bronchoscopy and bronchoalveolar lavage are useful in demonstrating that there is no macroscopic abnormality, apart from the occasional presence of mucosal inflammation, and that no microbial growth occurs on culture. If lavage fluid is obtained within a matter of hours of exposure, a polymorphonuclear leucocyte response may dominate, simulating cryptogenic fibrosing alveolitis, but this is followed by an accumulation of lymphocytes over the following 24 to 48 h. In the subacute and chronic forms of the disease, T lymphocytes represent 10 to 20 per cent or more of recovered cells, though the absolute numbers of macrophages are generally increased also. This characteristic cellular picture is not specific for extrinsic allergic alveolitis, but it strongly supports the diagnosis if other suggestive features are present. Other granulomatous disorders, such as sarcoidosis and tuberculosis, hypersensitivity reactions to drugs, and a number of rare lymphoid infiltrative disorders are also associated with a lymphocytosis in lavage fluid, but in practice sarcoidosis is generally the most plausible alternative diagnosis.

In sarcoidosis, B-lymphocyte numbers are decreased and the excess T lymphocytes are typically CD4+ helper cells. The CD4+ to CD8+ ratio normally exceeds 1, and so is exaggerated. By contrast, the ratio is typically reversed in extrinsic allergic alveolitis, CD8+ cells outnumbering CD4+ cells, and B-lymphocyte numbers are not decreased. Lymphocyte markers may therefore help distinguish sarcoidosis from extrinsic allergic alveolitis. Unfortunately, the pattern favouring extrinsic allergic alveolitis does not distinguish so readily between subjects with exposure and symptoms and those with exposure but no symptoms. Both T-cell types show increased numbers if there is exposure, and the number of CD8+ cells tends to show a relatively greater, not lesser, increase in asymptomatic subjects, as described above. The absolute value of the CD4+ to CD8+ ratio therefore provides limited diagnostic benefit in identifying active disease, but this is rarely a relevant issue outside a research setting. A number of cytokines can also be recovered from the lavage fluid, but these are of research rather than diagnostic interest.

Transbronchial or open lung biopsy may occasionally be indicated when other diagnostic procedures do not distinguish extrinsic allergic alveolitis from cryptogenic fibrosing alveolitis or other diffuse infiltrative or fibrotic disorders of the lung. Biopsy is more likely to be needed in the subacute or chronic forms of the disease when hypersensitivity is less obvious, or acutely when there has been an unduly heavy exposure to microbial spores and there is suspicion of microbial invasion.

Environmental exposure

In many cases the history alone provides the evidence of relevant exposure, but this is not always reliable and an independent account of the exposures involved can be invaluable. Ideally, industrial hygiene measurements are made (particularly from personal samplers) so that respirable agents can be recognized and quantified, and microbiological techniques are used to identify specific microbial contaminants. These are sophisticated investigations and usually indicated only when extrinsic allergic alveolitis is first suspected in an environment not previously associated with the disease, particularly in industries where many individuals may be at risk and where modification of the plant and its respirable environment may be a costly matter.

Hypersensitivity

The demonstration of a serum IgG antibody response to the inducing organic dust is the most widely used method of 'confirming' hypersensitivity (saliva may be used more conveniently in children), but this has proved to be unsatisfactory. Although affected subjects tend to have higher antibody levels than those who are exposed but unaffected, the antibody response tends to correlate more closely with exposure than with disease. If the more sensitive enzyme-linked immunosorbent assay (ELISA) is used, rather than the traditional Ouchterlony double-gel diffusion test, even higher rates of false-positive results are obtained. However, this produces greater specificity and in practice the absence of an IgG precipitin response is extremely uncommon in subjects eventually proved to have extrinsic allergic alveolitis, providing they are non-smokers. This is of considerable value in that a negative test generally excludes the diagnosis. The limited value of a positive test is to be expected in view of the current belief that cellular, not humoral, immunity provides the principal mechanism underlying the disease. It is unfortunate that practicable tests for cellular hypersensitivity are not readily available.

When the diagnosis remains in doubt, some form of inhalation challenge test may be necessary. The simplest method involves comparison of experimental periods spent away from the suspected causative environment with similar periods of continuing exposure. The acute form of the disease is likely to be recognized in this way, though the procedure can be time consuming and there may be practical problems of compliance. When a definitive diagnosis is particularly important, laboratory-based inhalation challenge tests can be used. These employ a variety of techniques, ranging from nebulizing soluble extracts to recreating natural environmental exposures in an exposure chamber. The influenza-like component of positive reactions is often uncomfortable, and if excessive doses are administered these tests can be hazardous. What is more, objective evidence for positive reactions may be difficult to obtain from conventional lung function tests. Tests of this nature should therefore be restricted to centres with special expertise. Personal experience of evaluating objective changes in body temperature, circulating neutrophil and lymphocyte numbers, forced vital capacity, and exercise tests from 144 tests is summarized in Table 2. Together they provide high specificity and high sensitivity. Auscultation, chest radiography, measurements of gas transfer, and arterial blood gas analyses are often too insensitive to provide useful diagnostic information.

Differential diagnosis

Acute extrinsic allergic alveolitis is not the only disorder characterized by systemic influenza-like symptoms and respiratory distress to follow an unusually heavy exposure to microbially contaminated vegetable produce. In 1986 an international symposium considered a further disorder that occurs within hours of heavy respiratory exposure to dusts containing fungal toxins, especially those released on decapping silos. It is the result of direct toxicity rather than hypersensitivity and

the term organic dust toxic syndrome was recommended to describe it. Its effects are usually mild and self-limiting, but severe respiratory embarrassment can occur and there is a small risk of ongoing, and potentially fatal, fungal invasion of the lungs. This risk could be enhanced if corticosteroid treatment is given, and death has occurred in subjects who appear to have been fully immunocompetent. Not only does organic dust toxic syndrome occur in circumstances which favour the occurrence of extrinsic allergic alveolitis (particularly silos and swine/poultry confinement buildings), but its clinical features have much in common with extrinsic allergic alveolitis, and to a lesser extent with nitrogen dioxide toxicity, which may also affect silo workers. Indeed, there is so much overlap that it can be very difficult indeed to distinguish one disorder from the others (Table 3).

The acute form of extrinsic allergic alveolitis can only be the result of an acute and recent (a matter of hours) exposure to the relevant causal antigen. This limits the opportunity for diagnostic error, though the circumstances of an unusually heavy exposure may be subtle. For example, a pigeon fancier might spend rather less time than usual with his birds, but much more time than usual in the more hazardous dusty car he uses regularly to transport racing birds for training exercises.

Just as acute and heavy exposures to organic dusts may cause disorders other than extrinsic allergic alveolitis, they may also be quite irrelevant and purely coincidental to the acute respiratory disorder with which the patient presents. Consequently the differential diagnosis should include consideration of other acute disorders of the lung parenchyma and interstitium, such as infections, other immunological disorders, drug reactions, and even paraquat poisoning, which sometimes occurs accidentally in farm workers. In bird keepers the diagnosis of viral, mycoplasmal, and chlamydial infection may itself be confounded by false-positive microbial antibody tests. This is the result of pre-existing avian antibodies cross-reacting with egg protein in the microbial cultures used to provide the test agents.

When subacute or chronic forms of extrinsic allergic alveolitis are encountered, the differential diagnosis lies with other diffuse infiltrative and fibrotic disorders of the lung. Those most frequently resembling extrinsic allergic alveolitis include cryptogenic fibrosing alveolitis, sarcoidosis, pneumoconiosis, tuberculosis, and metastatic cancer, although a huge variety of less common disorders may also need to be considered.

Management

Management of the individual

Management centres on reducing any further exposure to a minimum, though first demands that the diagnosis is secure. There is no place for desensitization. Ideally, the affected individual changes the relevant working, domestic, or recreational environment completely, but this may mean a profound loss in income or great expense, and is often unrealistic. Nor is it fully justified on purely medical grounds since continued exposure does not lead inevitably to progressive disease.

The affected individual who continues to work in the occupation responsible for his disease can often reduce his exposure substantially by changing the pattern of his particular duties. An alternative is the use of industrial respirators, which filter out 98 to 99 per cent of respirable dust from the ambient air. They are especially valuable when exposures are intermittent and short, but may be uncomfortably hot when worn for long periods or when there is heavy work, and so compliance with their use may be poor.

Whatever course is followed, continuing exposure should be accompanied by regular medical surveillance. If there is no progression, it is reasonable for some exposure to continue. When there is progressive disease, exposure should cease. This may involve a loss of earnings, and may entitle the affected worker to compensation. Rarely, the individual with progressive disease will refuse to change his occupation or hobby, and the physician must weigh the possible advantages of long-term corticosteroid therapy against the risks.

Management of the environment

Once extrinsic allergic alveolitis is recognized in one individual, the environment concerned should be assessed for the risk it poses to others. In many circumstances this will be well known already, and exposure levels will be within the range considered acceptable. In others, neither the risk nor the precise causative agent (nor its level of exposure) will be known, and in such unfamiliar circumstances there may be a need to survey the exposed population at risk. Questionnaires and serological tests are most convenient for this, at least as a screening procedure. When large populations are involved, comprehensive investigation is sensible before major modifications are considered to the working environment.

Modifications can always be made to the environment to lessen the level of exposure, but their extent will be limited by expense and should be justified by need. Dry storage and adequate ventilation are the two most important factors when vegetable produce is involved, and in some farming areas there is benefit in drying produce artificially after harvest. An alternative is some form of 'pickling', so that the produce is preserved chemically. With silage, for example, newly cut grass is kept under impervious covering in relatively sealed conditions. Initial enzymic and moulding processes use up available oxygen, and produce aldehydes and other preservative chemicals. These create nearly anaerobic conditions which protect the produce until it is used. Similarly, hay may be sealed in plastic bags, or grain or bagasse may be treated with propionic acid.

When ventilation and humidification systems are themselves responsible for extrinsic allergic alveolitis, major mechanical alterations may be necessary and the methods of humidification and temperature control may need to be changed. The crucial need is to reduce the ease with which normal airborne microbial contaminants are able to proliferate in stagnant collections of water. For this there may be a role for 'biocide' sterilizing agents, but these are also likely to become airborne and respirable and so must have low intrinsic toxicity and sensitizing potency. For one such biocide (isothiazolinone) there have been reports of occupational dermatitis and asthma, though not of extrinsic allergic alveolitis.

The need for rapid air changes coupled with close control of humidity and temperature poses formidable problems. The use of recirculated filtered air is the most economical, but effective filters are expensive and can become contaminated themselves, increasing rather than decreasing the load of respirable microbial antigens. The use of heat exchangers minimizes the cost of temperature control if contaminated exhaust air is not recirculated but does not conserve water.

Outcome

No further exposure

As with occupational asthma, the risk of continuing symptoms following cessation of exposure increases with the duration of exposure. With the acute form of extrinsic allergic alveolitis the exposure period is generally short and the disorder usually resolves without sequelae once the diagnosis is made and exposure ceases. However, one study using bronchoalveolar lavage and DTPA clearance has indicated continuing inflammation and membrane leakiness after a follow up period of 2 to 15 years. The significance of this is unclear, since all subjects were asymptomatic and gave normal results on radiographic and lung function studies.

Continuing exposure

There is greater concern when exposure continues. This may lead not only to recurrent acute attacks but to progressive and permanent fibrotic damage—that is, to the chronic form of the disease. While concern for the risk of progressive fibrosis is undoubtedly justified, this happens in only a minority of affected subjects. A 2- to 40-year follow-up survey of 92 farm workers presenting with the acute form of farmer's lung showed that while most continued to live on farms, only some developed radiographic evidence of pulmonary fibrosis (39 per cent) or impairment of carbon monoxide gas transfer (30 per cent). As many as 28 per cent gave histories of chronic productive cough and 25 per cent had airway obstruction. A similar 10-year outcome has been reported in pigeon fanciers with acute extrinsic allergic alveolitis; again the majority elected to continue their antigenic exposures despite medical advice to the contrary.

Therefore, in some cases—perhaps the majority—important protective mechanisms emerge that lead to tolerance of the effects of further acute exposures, or at least prevent the development of damaging fibrosis. A history of similar increasing tolerance is occasionally noted with occupational asthma, and tolerance not progressive disease is the rule rather than the exception in most animal models of extrinsic allergic alveolitis. However, with both asthma and extrinsic allergic alveolitis some affected subjects give clear accounts of increased responsiveness to a given level of exposure months or years after initial antigen exclusion, which suggests that protective mechanisms may be down-graded more quickly than the causal mechanisms.

As with sarcoidosis, there is debate as to whether the use of corticosteroids for acute episodes confers any long-term benefit. The answer is not clear, but one recent investigation failed to demonstrate any long-term functional differences between groups treated randomly with corticosteroids or placebo for the initial acute episode

of farmer's lung. Whilst the corticosteroid group recovered more quickly from the acute episode, there was the suspicion, already voiced by other investigators, that early steroid therapy carries a greater risk of long-term recurrence. It is possible that the initial response to steroids encouraged less care over subsequent exposures. Alternatively steroid therapy may have induced a different equilibrium between immunological responses, perhaps interfering disproportionately with the development of protective mechanisms.

Compensation of industrial causes

In the United Kingdom, industrial injuries legislation provides compensation from central government for disability in employees (but not employers) from extrinsic allergic alveolitis of occupational origin. The level of disability, and hence compensation, is assessed following examination by a 'Medical Board'. If disability arose before 1991, the affected worker may also be entitled to a 'reduced earnings allowance' if ongoing employment (or lack of it) has resulted in a loss of earned income. Both benefits are limited to a joint maximum figure, which is adjusted from time to time according to inflation. Reduced earnings allowance for new cases was discontinued in 1991.

Acceptance of state compensation in the United Kingdom no longer debars the recipient from seeking redress additionally in the civil courts, which is the primary mechanism of compensation in many countries.

17.11.12Eosinophilic granuloma of the lung and pulmonary lymphangiomyomatosis

*D. J. Hendrick**

Pulmonary histiocytosis X

Eosinophilic granuloma is a disorder of dendritic (Langerhans) cells that arise from CD34+ progenitors and have special function in presenting antigen to T cells. In this context, however, an abnormal proliferation of these cells is associated with eosinophils (though not peripheral eosinophilia) and granulomatous damage of the lung. Lesions characteristically show cavitation and fibrotic healing, which results in foci of 'stellate' scars, alveolar wall deformation, honeycombing, and the formation of small cysts.

Langerhans cell granulomatosis is the currently favoured generic term rather than histiocytosis X, which was used previously to describe eosinophilic granuloma, Letterer–Siwe disease, and Hand–Schüller–Christian disease. The latter term is used to describe Langerhans granulomas in organs other than the lung (principally bone and the posterior pituitary), and so can be considered a multifocal form of Langerhans cell granulomatosis (eosinophilic granuloma). It is not clear whether Letterer–Siwe disease is truly related to the other two, or whether it is even primarily a disease of Langerhans cells. It is best considered separately. For further discussion, see Section 22.

Eosinophilic granuloma generally affects men and women between the ages of 20 and 40 who are almost exclusively smokers. The main clinical manifestations reflect its chief pathological features—diffuse interstitial fibrosis and cyst formation. The cysts may rupture causing spontaneous pneumothorax, and the fibrosis may progress causing exertional dyspnoea. Cough is common also, and cyst rupture may be associated with pleuritic pain. Because cysts occur bilaterally there is the potential for devastating and immediately life-threatening pneumothoraces to occur on both sides concurrently. One report indicates that occasionally a single pulmonary granuloma may occur, closely simulating carcinoma.

The chest radiograph typically shows diffuse micronodular and reticular changes in the early stages (Fig. 1), which progress with the development of honeycombing. Appearances on high-resolution CT scanning are characteristic (Fig. 1). Pulmonary physiological tests reveal a mixed obstructive and restrictive pattern (decreased vital capacity and total lung capacity, increased residual volume, and decreased carbon monoxide transfer). Bronchoalveolar lavage may reveal Langerhans cells or 'atypical histiocytes', which are most readily identified by immunohistochemical staining of the S100 protein. The major histological characteristics are not readily identified from transbronchial biopsy, and so open biopsy or video-assisted thoracoscopic biopsy is generally required. The major identifying feature of the Langerhans cell is an X body or Birbeck granule, which appears as a pentalaminar rod-like structure in the cytoplasm under the electron microscope.

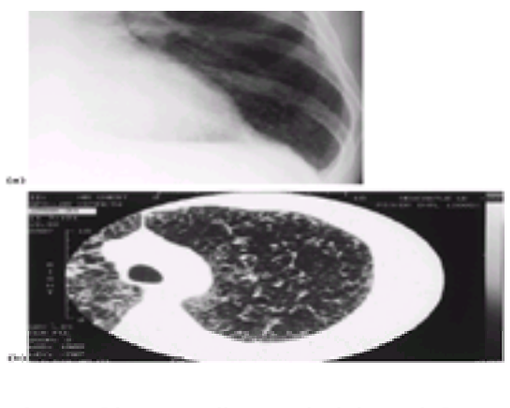

Fig. 1 Chest radiograph (a) and CT scan (b) of a 45-year-old smoking man with biopsy proven (S100 positive) eosinophilic granuloma. The plain film shows a mixed micronodular and reticular pattern which is due principally to multiple small cysts that make the surrounding interstitium more prominent. This is more readily evident from the CT image.

Eosinophilic granuloma of the lung usually occurs in isolation, but may be associated with wider manifestations of multifocal Langerhans cell granulomatosis, particularly skin rashes, bone pain, and diabetes insipidus from granulomas in skin, bone, and pituitary. The clinical course is variable, and treatment in general is supportive rather than specific. In many cases the disease ceases to progress at some point, leaving residual impairment of variable degree. In one case where lung transplantation became necessary, the disease recurred in the transplanted lung, though responded to cyclosphosphamide therapy.

Lymphangiomyomatosis

Lymphangio(leio)myomatosis of the lung is a rare disorder characterized clinically by progressive interstitial disease causing breathlessness and cough, and cyst formation causing spontaneous pneumothorax. Further features are chylous pleural effusion and haemoptysis. It occurs almost exclusively in women of reproductive age, and appears to be a 'forme fruste' of tuberous sclerosis. However, only a minority of patients with tuberous sclerosis show evidence of lymphangiomyomatosis in the lung, and most patients presenting with pulmonary lymphangiomyomatosis do not show other manifestations of tuberous sclerosis. Nor do they appear to pass on the disorder to the next generation. The pulmonary disorder is characterized pathologically by hamartomatous proliferation of smooth-muscle cells in pulmonary lymphatics, venules, and airways. It is often associated with angiomyolipomas of the kidney (and bleeding into the renal tract), and this has been linked with a shared cell surface marker, premelansosome glycoprotein (HMB-45), that can be recognized by immunohistochemical staining.

The typical clinical picture is of progressive loss of exercise capacity associated with a dominantly obstructive loss of ventilatory function and reduced gas transfer. This is interrupted by intermittent episodes of chylous pleural effusion, spontaneous pneumothorax, and haemoptysis. The early chest radiographic appearances are of reticular shadowing and Kerley B lines because of obstructed lymphatics, small nodules due to hamartomatous smooth-muscle aggregates, and pleural effusions. Honeycombing and cystic dilation occur later when pneumothorax becomes increasingly common. These abnormalities are most readily seen by CT scanning (Fig. 2). The diagnosis generally follows lung biopsy, but can been made from cytological examination of aspirated pleural fluid if this contains clusters of immature smooth muscle cells.

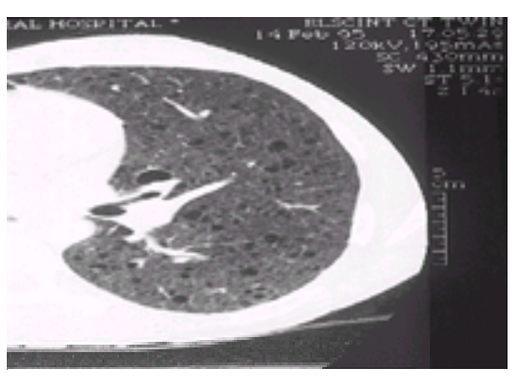

Fig. 2 CT scan of a 37-year-old woman with tuberous sclerosis and pulmonary lymphangiomyomatosis. She had experienced sequential spontaneous

pneumothoraces affecting each side. The scan shows multiple thin-walled cysts throughout the lung. (By courtesy of Dr S. J. Bourke.)

Progesterone therapy or bilateral oophorectomy is sometimes effective in limiting disease progression, and may also help to control pleural effusions. If untreated, most patients die within 10 years, and so lung transplantation becomes the principal option if anti-oestrogen therapy is ineffective. In one case this was associated with recurrent disease in the allograft.

17.11.13 Pulmonary alveolar proteinosis

D. J. Hendrick

First described in 1958, pulmonary alveolar proteinosis is a rare but interesting disorder that exerts its primary effects in the alveolar spaces. Over a period ranging from months to years, these become filled with an amorphous, largely cell-free, lipoproteinaceous material that is not readily expectorated. Inflammation and fibrosis are conspicuously absent and there are two major consequences. First, depending on the number of alveoli involved, the lungs become stiff, ventilatory function becomes restricted, and shunting occurs at the alveolar capillary level, causing hypoxaemia. The outcome is breathlessness, reduced exercise tolerance, and in some cases death from respiratory failure. Second, and a not uncommon cause of death, is secondary infection. The responsible organisms are generally those that are associated with intracellular infection and impaired T-lymphocyte function, nocardia being particularly prominent. In many cases, however, extensive involvement does not occur, there being little or no progression, or even spontaneous remission. Epidemiological data are scarce but one estimate suggests an annual incidence of the order 2 to 5 per million worldwide.

Pathogenesis

Men appear to be affected more commonly than women: all age groups may be involved, and smoking may enhance the risk. The cause in most cases is unknown, but an apparently identical (though relentlessly progressive) disorder can arise within months of massive exposure to respirable mineral dust, especially silica—both in the unfortunate worker exposed negligently without adequate respiratory protection and in experimental animal models. This has been called acute silicoproteinosis or silicolipoproteinosis. Less commonly aluminium dust may be responsible, and there have been reports implicating titanium and insecticides. A few reports describe affected siblings, implying a possible hereditary factor, and some associate pulmonary alveolar proteinosis with haematological disorders (usually malignant and often after the use of cytotoxic agents) or immunodeficiency disorders.

The secreted material is rich in protein and phospholipid, and stains strongly with periodic acid–Schiff (**PAS**) and eosin. It also contains structures resembling tubular myelin, which are derived from lamellar bodies of surfactant-producing type II pneumocytes. The secretions themselves are chiefly the product of these cells, and the chief phospholipid is dipalmitoyl phosphatidylcholine—the dominant phospholipid of normal surfactant. It is unclear, however, whether the accumulation of these secretions results from an abnormality of the type II pneumocytes (excessive or abnormal production), or from impaired resorption by alveolar macrophages. Recent research suggests that both mechanisms may be relevant, also that the pulmonary alveolar proteinosis phenotype can arise through a number of different processes. In most cases the PAS stain is taken up uniformly, as is peroxidase-labelled immunoglobulin raised against the apolipoproteins of surfactant. In others, particularly those associated with haematological or immunological disorders, uptake is heterogeneous, and it has been suggested that fundamentally different processes underlie this 'secondary' form of pulmonary alveolar proteinosis.

Mice deficient in granulocyte-macrophage colony-stimulating factor (**GM-CSF**), or with a disrupted GM-CSF receptor, develop alveolar accumulations of surfactant material, simulating pulmonary alveolar proteinosis. Benefit occurs when GM-CSF is administered locally, when normal bone marrow is transplanted, or when the faulty gene is replaced by some other method. This suggests that pulmonary alveolar proteinosis could arise because of impaired macrophage differentiation and function as a consequence of an inherited genetic defect, or an acquired defective bone marrow clone. The vulnerability to infection with opportunistic organisms and the *in vitro* demonstration of a number of abnormalities of macrophage function additionally incriminate the macrophage more than the pneumocyte. This is also consistent with pulmonary alveolar proteinosis arising after macrophage function has been disrupted by massive exposure to silica, and with pulmonary alveolar proteinosis being associated with impaired T-cell immunity (and hence diminished macrophage activation).

It has been shown, however, that ingestion of material produced in pulmonary alveolar proteinosis may itself cause impairment of phagocytic function in macrophages harvested from normal controls, and so in some cases the primary abnormality could still lie with the type II pneumocyte and its alveolar secretions. This would be consistent with the belief that chemotherapeutic agents associated with the development of pulmonary alveolar proteinosis (e.g. bleomycin) are more likely to damage pneumocytes than macrophages. Strong support for this view comes from the recent demonstration of a GM-CSF inhibitory factor within the bronchoalveolar secretions of pulmonary alveolar proteinosis, to which GM-CSF binds more avidly than it does to the cells it should stimulate. Its source of origin, however, has not yet been shown to be the type II pneumocyte.

Clinical features

The patient usually presents with progressive shortness of breath due to the disease itself or with a pneumonic illness due to superimposed infection. Occasionally, the disease is without symptoms and is first recognized from the appearances of an incidental chest radiograph, when it may be mistaken for sarcoidosis. Cough is common and may be productive, particularly if there is infection. Low-grade fever, haemoptysis, and pleuritic pain occur infrequently, though some authors report an initial febrile incident. There may be crackles and clubbing in advanced stages, and fever becomes typical when infection supervenes. When nocardia is not responsible for this, aspergillus, candida, cryptococcus, cytomegalovirus, histoplasma, HIV, mucor, mycobacteria, pneumocystis, and viruses are the most common culprits.

Diagnosis

The chest radiograph characteristically shows an alveolar filling pattern, which radiates from the hila and simulates pulmonary oedema. There is no associated evidence of heart failure, however, and the appearances may be somewhat patchy and asymmetrical. Diffuse pulmonary fibrosis is very rare, unless provoked by complicating infection. A micronodular infiltration is occasionally seen, particularly in children, but lymphadenopathy is usually absent. CT scanning, particularly with high resolution, shows the non-specific features of air space filling (ground-glass attenuation), and commonly a patchiness which distinguishes affected from unaffected lobules. There may also be septal thickening and hence the 'crazy paving' appearance typical of combined alveolar and interstitial disease.

Pneumonia or aspiration is often suspected initially, but the cough produces little or no sputum and no organisms are isolated if the disease remains uncomplicated. Occasionally, white gelatinous material is expectorated, and bronchoalveolar lavage fluid is typically milky in colour. Gallium scanning may be useful in showing negligible pulmonary uptake in contrast to the findings in pneumonia. In established pulmonary alveolar proteinosis, a positive gallium scan (or a CT scan) may be invaluable in suggesting the development of superimposed infection.

The key to the diagnosis of uncomplicated pulmonary alveolar proteinosis rests with the demonstration that the alveolar secretions are strongly PAS-positive but contain no organisms and no excessive cellular response. Indeed, the macrophages appear to be deficient in numbers as well as function. Biochemical and immunochemical tests may be used to show that phospholipids and specific surfactant proteins are present in excess. Occasionally the sputum provides diagnostic material, identification of lamellar bodies or their debris by electron microscopy being particularly useful. These may be found within macrophages or pneumocytes, or may lie free within the secretions. More commonly, bronchoalveolar lavage or transbronchial lung biopsy is required, though the former should suffice since PAS-positive amorphous globules demonstrated by cytological smears have high diagnostic specificity. Ultrastructural examination shows that these also generally contain multilaminated structures derived from lamellar bodies. The characteristic histological features are shown in Fig. 1.

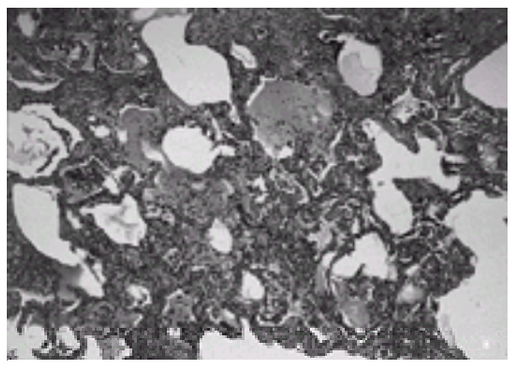

Fig. 1 Pulmonary alveolar proteinosis arising acutely following massive exposure to silica (by courtesy of Dr D.E. Banks). Some alveoli are filled with a non-inflammatory proteinaceous exudate, characteristic of pulmonary alveolar proteinosis. The lung interstitium shows fibrosis and inflammation which can be attributed to acute silicosis (haematoxylin and eosin, medium magnification).

Raised serum levels of surfactant proteins and lactic dehydrogenase are to be expected, but these occur in a number of other diffuse disorders of the lung and so are of no value in diagnosis. Serum levels of the mucin-like glycoprotein KL-6, which is released from type II pneumocytes, are also raised in pulmonary alveolar proteinosis. Although not specific, it has been suggested that these provide a good biochemical correlate for disease activity, and may therefore be a useful marker in assessing when treatment becomes necessary.

Management

In a third to a half of cases, no appreciable disability develops and the disease remits spontaneously or fails to progress. The choice of treatment, when necessary, is strictly limited. Corticosteroids are of no value and may increase the risk of infection. Prolonged periods of inhalation therapy with expectorants (potassium iodide) or proteolytic enzymes (trypsin) have been claimed to offer benefit, but frequently cause irritative responses in the airways. Furthermore, trypsin does not digest *in vitro* the material produced in pulmonary alveolar proteinosis. Neither form of treatment is currently recommended, although the addition of trypsin to therapeutic bronchalveolar lavage fluid has been reported to be both effective and well tolerated.

The most effective measure is physical removal of secretions by bronchoalveolar lavage, usually performed under general anaesthesia using a double-lumen endotracheal tube. The treatment is repeatedly carried out on one lung with a total of 20 to 50 litres of warm sterile buffered saline while the other is mechanically ventilated. The procedure is then reversed so that the other lung is treated. The practice of adding heparin and acetyl cysteine to the lavage fluid has not been shown to be beneficial, but chest percussion during the procedure does seem to enhance the yield. When severe respiratory failure has already supervened despite ventilatory support, cardiopulmonary bypass has been used successfully to maintain gas exchange during the lavage procedure. An alternative is sequential lobar lavage using a fibreoptic bronchoscope and a cuffed catheter. Further lavage is usually necessary every few weeks or months, but the activity of the disease may lessen and the need for frequent treatment may diminish.

Sometimes there is fatal progression with marked loss of weight despite repeated lavage. It may be that current experimental use of GM-CSF might lead to an improved outlook for such patients in the future. In one prominent case treatment involved bilateral lung transplantation, but this was followed by recurrent pulmonary alveolar proteinosis, raising the question of whether bone marrow transplantation might be more appropriate.

The risk of premature death in most series has been low (mostly less than 10 per cent), but a considerable threat to life is associated with complicating infection. This should be recognized and treated promptly. An accelerated clinical course together with the development of fever, increased (and productive) cough, malaise, evidence of systemic illness, and the radiographic demonstration of cavitation or pleural effusion all provide pointers to its development. Blood cultures together with smear and culture studies of sputum may identify the organism or organisms responsible, but often bronchoscopy with brushings and diagnostic lavage is needed. Sometimes a biopsy procedure is considered necessary, particularly when the underlying presence of alveolar proteinosis is not clearly established. When opportunistic organisms are involved, the eradication of infection may prove to be unduly difficult, perhaps reflecting an underlying impairment of macrophage (or GM-CSF) function. It has therefore been argued that regular bronchoalveolar lavage, even in the absence of impaired exercise tolerance, may limit the degree of immunosuppression and provide valuable prophylaxis against such life-theatening infections. A recent study did indeed demonstrate improved macrophage function following lavage, which slowly diminished over 18 months as clinical relapse occurred. If the argument is followed fully, lavage may also play a role in eradicating the acute infection.

17.11.14 Pulmonary amyloidosis

D. J. Hendrick

Clinically important involvement of the lungs in amyloidosis is extremely uncommon, only a few dozen cases having been reported over recent decades, but lung infiltration is said to occur in the majority of cases of primary (**AL**) amyloid, less commonly in secondary (**AA**) amyloid. The proteinaceous material which is responsible for amyloid infiltration is composed of a fibrillar polypeptide and a non-fibrillar glycoprotein. They produce a unique b-pleated structure which may be deposited progressively and widely, eventually interfering with organ function. The glycoprotein (amyloid P or AP protein) comprises a mere 10 per cent of amyloid tissue. It is derived from a parent serum protein (SAP) made in the liver and is common to all types of amyloid tissue. The fibrillar polypeptide on the other hand is of two distinct types (Fig. 1).

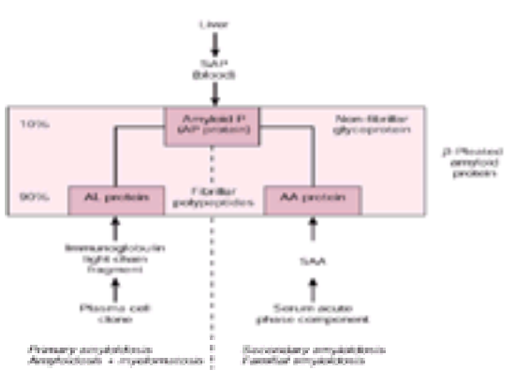

Fig. 1 Pathogenic pathways underlying primary and secondary amyloidosis.

The type seen with 'primary' amyloidosis and amyloidosis associated with myeloma is derived from the variable region of immunoglobulin light chains and is known as AL protein. It is the product of a plasma cell clone, whether benign or malignant. Monoclonal immunoglobulin (M-compo-nent) may sometimes be detected in the serum by electrophoresis, and free light chains (Bence Jones protein) may be detected in the urine. The type of fibrillar polypeptide (AA protein) seen with 'secondary' amyloidosis and most of the familial forms of amyloidosis (such as Mediterranean fever) is derived from an acute phase serum component (SAA). The chronic inflammatory diseases associated with persistently raised levels of SAA (and C reactive protein and interleukin-6) are those that are most commonly associated with secondary amyloidosis, but only a small minority of subjects affected by these chronic inflammatory disorders show evidence of complicating amyloidosis.

Clinical features

Those affected are usually middle aged or elderly, and the sexes are equally represented. Hilar or mediastinal lymphadenopathy is rarely demonstrated on plain chest radiographs, but mild nodal enlargement is commonly seen on CT scanning. The pleura are rarely involved, but recurrent pleural effusion may occur.

Symptomatic pulmonary involvement is generally a consequence of localized disease affecting the upper and central airways, or systemic disease at alveolar–interstitial level. Localized disease is usually due to deposition of amyloid containing the light chain derived AL protein, and is essentially benign in nature. Its effects depend on the site of deposition. Diffuse alveolar–interstitial disease is usually associated with systemic disease and may be the consequence of either AL or AA protein deposition. It carries a poor prognosis, though death is usually due to the involvement of organs other than the lung.

The following varieties of pulmonary amyloidosis, in descending order of epidemiological importance, are the most clearly recognized.

1. Localized laryngotracheobronchial: discrete, and often multiple, masses of amyloid protein enlarge in the walls of the airways or the peribronchial tissues causing cough, obstruction, and sometimes bleeding. Obstruction of airways may lead to wheeze, stridor, breathlessness, atelectasis, and infection, and may eventually give rise to bronchiectasis. When a single lesion is involved it may simulate the effects of a bronchial adenoma, appearing as a polypoid mass on endoscopic inspection.
2. Localized parenchymal nodule(s): discrete nodules or masses, which may be single or multiple and may occasionally reach the size of a tennis ball, are seen within the lung parenchyma on the chest radiograph. They rarely cause symptoms or disrupt lung function and may eventually calcify, cavitate, or even ossify. They are likely to simulate bronchial neoplasms if single and so be resected; if multiple they often lead to biopsy. Biopsy in one unusual case (that of an HIV-positive intravenous drug abuser) showed no evidence of AL protein, but there was focal birefringency and a foreign body giant cell reaction reflecting deposition of the carrier material of the illicit drug. This implies that focal inflammation within the lung may occasionally lead to localized 'secondary' amyloid (i.e. AA protein) deposition. In the future it may be that CT and MRI will offer a useful means of distinguishing amyloid tissue from tumour, so obviating the need for biopsy.
3. Diffuse alveolar–interstitial: amyloid tissue is deposited diffusely throughout the alveolar walls and interstitium of the lung, and is usually a feature of systemic amyloidosis (Fig. 2 and Fig. 3). There is progressive breathlessness and dry cough. Scattered crackles are characteristic and there may be pleural effusions. Eventually respiratory failure may supervene as ventilation becomes increasingly restricted and gas transfer impaired, though death more commonly results from cardiac or renal involvement.

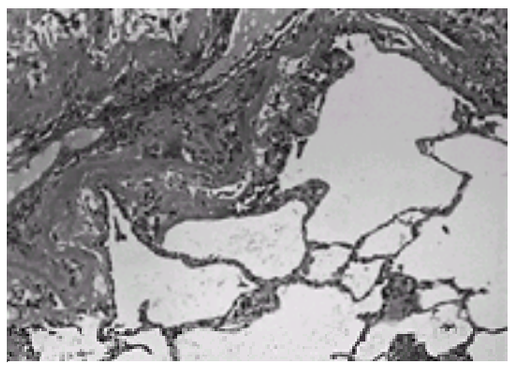

Fig. 2 Amyloidosis of the lung: alveolar-interstitial type [i] (by courtesy of Dr T. Ashcroft). There are interstital deposits of hyaline eosinophilic material with a foreign body type giant cell response in adjacent tissue. This is an almost unique feature of amyloidosis affecting the lung (haematoxylin and eosin, medium magnification).

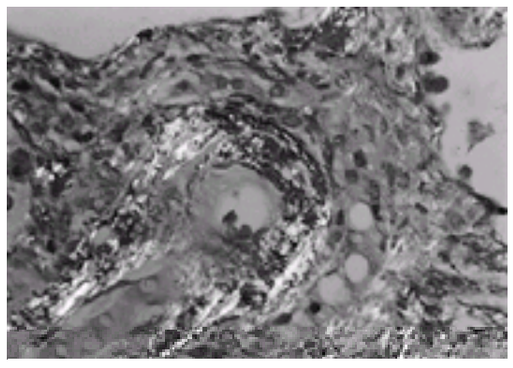

Fig. 3 Amyloidosis of the lung: alveolar-interstitial type [ii] (by courtesy of Dr T. Ashcroft).Amyloid gives a characteristic dichroic birefringence (Congo red stain under polarized light. High magnification).

Histological examination may also show evidence of amyloid infiltration of the pulmonary vasculature. This is usually of no clinical consequence, but has been reported to cause pulmonary hypertension and undue bleeding after biopsy, although other reports suggest that biopsy, particularly transbronchial biopsy, is generally both safe and effective. Another rare effect of amyloidosis on respiratory function is enlargement of the tongue, which can cause or exacerbate obstructive sleep apnoea.

Diagnosis

The diagnosis rests on the demonstration of amyloid tissue in an affected organ. When the protein is derived from plasma cells or lymphocytes, it may be possible to demonstrate light chains in the urine or M-component in the serum, and a plasma cell or lymphocyte dyscrasia may be clinically evident. When systemic reactive amyloidosis is the diagnosis, a provoking chronic inflammatory disease should be obvious, and high levels of SAA will be present in the serum. Measurement of SAA is rarely routinely available, but C-reactive protein is a useful surrogate. Immunohistochemical studies should, in any event, identify the specific biochemical nature of the protein sampled at biopsy, as should the ultrastructural appearances at electron microscopy.

Management

For discussion of the treatment of systemic amyloidosis, which is often unrewarding, see Section 11.12. Ultimately, organ transplantation may become the only hope of survival, and when renal failure or cardiac failure is the only immediate threat to life, this is often carried out. A need for lung transplantation has not yet been reported.

With the local forms of the disease of whatever aetiology, the outlook is a good deal brighter. Progression may be slow, and the disease may become quiescent. The laryngotracheobronchial deposits can sometimes be resected or depleted piecemeal endoscopically, perhaps using laser therapy, but there is some risk of serious bleeding from this. Corticosteroids have been reported to have a beneficial effect when there is critical airway stenosis. Parenchymal nodules in the lung rarely need to be removed, providing their histological nature is not in doubt.

17.11.15 Lipoid (lipid) pneumonia

D. J. Hendrick

Exogenous

When mineral or vegetable lipids are deposited in the lung, they usually prove to be relatively inert but difficult to remove. Lung lipases have little effect, and the macrophages are slow to transport the free or emulsified material into the lymphatics. The result is often a chronic low-grade inflammatory response that may lead to secondary infection and/or local fibrosis. It is known as lipoid, or lipid, pneumonia. It should be suspected whenever a 'pneumonic' illness is slow to resolve or is recurrent, especially if there is the possibility of impaired swallowing and recurrent aspiration. Some animal lipids are more readily degraded by lung lipases, thus releasing irritating fatty acids. In these circumstances a brisk pneumonitis may occur.

Pathogenesis

Aspiration of vegetable or mineral oil is not common in the population at large, but is seen not infrequently within certain subgroups—particularly those with impaired swallowing mechanisms. Most affected are the very young and the elderly, and the regular nasal instillation of vegetable oils (e.g. olive oil) or paraffin to relieve congestion, or their ingestion to relieve constipation, are often responsible. A portion of any nasal dose is likely to enter the trachea, as may part of an ingested dose if the subject then reclines in bed or has any disturbance of swallowing. The critical point is that paraffin and many vegetable oils are not irritating to the tracheal mucosa, and so coughing is rarely excited and aspiration occurs without immediate sequelae.

The reluctant child forced to swallow cod liver oil is said to have encountered similar risks during the 1940s and 1950s, though infants are likely to face much greater hazard by virtue of less well developed deglutition. Patients fed by nasogastric tube are particularly vulnerable, as are those fed regularly with high lipid diets (for example with milk fat, ghee). A recent case report indicates a rather less obvious risk in an infant—that of lipid embolism from repeated mineral oil enemas. Lipoid pneumonia from embolism may also occur because of intravenous infusion, whether accidental or wilful.

Adults with unimpaired swallowing are affected only sporadically. Shipwrecked sailors have occasionally aspirated floating oil, and lipoid pneumonia has been recognized in workers exposed to oil mists and burning fats. In an exceptional case associated with recurrent tuberculosis, the spontaneous rupture of a longstanding oleothorax (oil plombage) led to a widespread iatrogenic lipoid pneumonia. Aspirated petroleum products such as kerosene may be absorbed from the lung and give rise to toxic responses in other organs (particularly the heart), and this may prove to be life threatening. The potential risk from oil aerosols has been highlighted recently in a diver breathing unfiltered air from an oil-contaminated surface compressor. Less unwilling inhalers of mineral oil and vaseline have been the blackfat tobacco smokers of Guyana, who obtain more satisfaction when these additives are mixed to native tobacco leaf. A distinctive geographical picture of progressive and often fatal pulmonary fibrosis complicates this habit in some 20 per cent of blackfat users, but has not been observed among non-smoking residents.

Clinical features

If there is little or no pulmonary response, there may be no symptoms, and the affected subject presents by chance with an abnormal chest radiograph. In about 50 per cent of cases there is a chronic 'pneumonic' illness with productive cough, low-grade fever, and (occasionally) haemoptysis. Often there is a cyclical course with intermittent symptoms. Repeated aspiration may lead to fibrotic shrinkage of the affected segment or segments (usually in the lower lobes or the middle lobe), bronchiectasis, or persistent consolidation. The radiographic appearances may closely simulate bronchial carcinoma, and many resections have been carried for this reason, sometimes revealing a characteristic granulomatous mass (paraffinoma). When more substantial quantities are aspirated the radiographic abnormalities are necessarily more diffuse, and when the lipid material is more reactive an acute 'pneumonic' illness occurs.

Diagnosis

The key to diagnosis is the demonstration of lipid material within pulmonary secretions or alveolar macrophages, whether obtained from sputum or bronchoalveolar lavage. If lung tissue is resected or a biopsy is taken, there may be fibrosis, evidence of chronic inflammation, and foreign body granulomas/giant cells in addition to lipid material retained within alveoli and macrophages (Fig. 1). An innovative use of computed tomography has recently identified excess deposits of lipid from its X-ray absorption characteristics, a technique that could offer a valuable alternative to biopsy or bronchoalveolar lavage in the diagnosis of atypical pneumonias. More generally, computed tomography shows patchy areas of ground-glass attenuation and interstitial thickening, thereby producing a 'crazy paving' pattern. This may be seen more readily with high resolution scans, which may additionally show interspersed poorly defined small nodules. Nuclear magnetic resonance scanning appears less effective, though a loss of signal intensity has been reported to have diagnostic specificity.

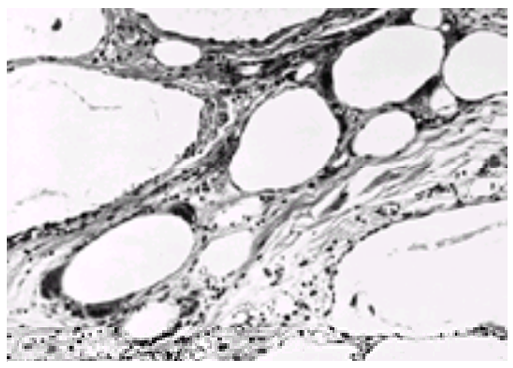

Fig. 1 Lipoid pneumonia (by courtesy of Dr T. Ashcroft). Exogenous lipoid pneumonia due to aspirated paraffin. There is interstitial fibrosis containing oil vacuoles which are enclosed within multinucleated giant cells (haematoxylin and eosin stain, medium magnification).

Management

Prophylactic management centres on minimizing any tendency to aspiration associated with impaired swallowing, and in persuading the misuser (or abuser) of vegetable and mineral oils to adopt alternative habits. Once aspiration has occurred there may be a role for therapeutic bronchoalveolar lavage, since this may remove substantial quantities of lipid from the alveoli. During episodes of secondary bacterial infection, there is an obvious role for antibiotics, and when there is acute inflammation corticosteroids are sometimes used.

Endogenous

The body may itself produce and retain lipid (mainly cholesterol) within the lungs, though this is not a common phenomenon. It occurs chiefly at sites of chronic inflammation, obstruction, or tissue necrosis, and is derived from the necrotic cells. This lipid will also be ingested by macrophages and may be recovered in the sputum. Sputum macrophages laden with lipid are not therefore pathognomonic of aspiration from an exogenous source, though chemical tests can distinguish the two varieties and histological examination of affected lung does not show a granulomatous response to endogenous lipid. Endogenous lipid is most commonly deposited when chronic inflammation accompanies bronchiectasis, bronchial carcinoma, or some other cause of persisting localized bronchial obstruction, and appears to depend on cigarette smoking. The radiological appearances are of a persisting pneumonia, which may also stimulate resection for fear a carcinoma is present. Very recently endogenous lipoid pneumonia in a more diffuse form has been associated with the use of amiodarone in patients dying with adult respiratory distress syndrome.

17.11.16 Pulmonary alveolar microlithiasis

D. J. Hendrick

This is a very rare disorder, with only 200 to 300 cases reported since its initial description in 1918. It is remarkable for a number of unusual if not unique features. Tiny 0.2- to 5-mm calcified concretions, which may be concentrically laminated, form progressively in the alveolar spaces, usually with some degree of interstitial fibrosis. As their profusion slowly increases in the lung, they produce a striking 'white-out' appearance on the chest radiograph as the border of one intensely radio-opaque microlith overlaps that of another, even if the two are not immediately adjacent. There are few clues to the cause of this curious disorder and, apart from transplantation, there is no effective means of therapy.

Pathogenesis

No abnormality of calcium metabolism has been demonstrated, but a disproportionate number of cases (almost half) occurs in siblings and in countries bordering the eastern Mediterranean. This points to a genetic rather than environmental basis, perhaps autosomal recessive inheritance. One hypothesis suggests that the calcific response is directed to an alveolar exudate (whether induced by inhaled particles or microbes) that cannot be reabsorbed adequately. The primary explanation could thus lie with an unusual inhalant stimulus, a deranged alveolar exudative response, or a failure of the usual mechanisms of reabsorption.

That similar concretions are not generally noted in other sites of membrane reabsorption possibly diminishes the probability of the last of these, though microliths have been noted in seminal vesicles in some cases, and azoospermia in others. Analytical studies, including X-ray energy spectroscopy and microscopic infrared spectroscopy, have showed no evidence of mineral dust deposition, and no microbial cause has been confirmed. The possibility of a deranged alveolar response has consequently attracted particular interest, perhaps an abnormality of surfactant function following oxidant stress. The calcified microliths (salts of calcium and phosphorus, and calcium carboxyapatite) are formed in the alveolar spaces, and some can be flushed out by bronchoalveolar lavage or even expectorated in sputum.

Clinical features

The disease usually presents in middle age, but the whole age spectrum may be involved and both sexes are equally represented. Almost invariably the patient is symptom free when an initial film is taken for incidental reasons, and there may be wonder that this can be possible when the radiograph is grossly abnormal. This is a consequence of there being no associated cellular, exudative, fibrotic, or vascular disruption of normal physiological processes in the early stages of the disease. Physical signs are conspicuous by their absence for most of its long course, though crackles, clubbing (even hypertrophic pulmonary osteoarthropathy), and signs of respiratory failure may be observed ultimately as the alveolar spaces are progressively filled with microliths and fibrosis of the interstitium advances. Shunting occurs at alveolar-capillary level causing hypoxaemia, and the bronchial circulation contributes increasingly to pulmonary venous return. In some cases subpleural cysts give rise to spontaneous pneumothoraces, and pleural adhesions may become prominent.

Although death supervened rapidly in the reported cases of two newborn infants, survival of 10 to 20 years is characteristic, and may be much longer. In most cases there is slowly progressive undue breathlessness with dry cough. Haemoptysis occurs occasionally. The lungs stiffen, ventilation becomes restricted, and gas transfer is impaired. Eventually respiratory failure and cor pulmonale supervene. At death, extensive areas of the chest radiograph show a dense 'white-out' appearance due to the considerable accumulation of calcium, the lungs are difficult to cut, and they sink in water.

Diagnosis

The radiographic appearances of profuse small calcified nodules are almost specific, particularly in moderately advanced cases when the dense 'white-out' picture is seen but symptoms are still absent or unimpressive. One case of sarcoidosis has been reported with similar appearances. With less advanced disease, biopsy, bronchoalveolar lavage, or expectorated sputum should provide diagnostic material, but with transbronchial biopsy it may prove difficult to close the forceps and extract them through the fibreoptic bronchoscope. Initially the chest radiograph shows a mere haziness of the lower zones, and computed tomography may be invaluable in demonstrating the nodular shadows and their calcific nature. It may also confirm an early predominance for the basal and posterior segments. High resolution images may also demonstrate the presence of interstitial fibrosis. As profusion and size of the calcified concretions increase, the lung fields become diffusely and densely opaque. Measurement of lung function during the asymptomatic stage reveals little or no abnormality, the affected subject remaining well for many years, but eventually ventilatory restriction, impairment of gas transfer, and arterial hypoxaemia are to be expected.

Management

Corticosteroids, calcium chelating agents, bisphosphonates, and bronchoalveolar lavage have not proved to be effective therapies, and in the absence of lung transplantation, treatment is merely supportive. A detailed description of a 37-year-old man presenting in respiratory failure, recorded severe hypoxia and pulmonary hypertension. Considerable intrapulmonary shunting was demonstrated, which was greatly improved by nasal continuous positive airway pressure, but not by conventional supplemental oxygen therapy. This presumably reflects the dominant effect of the disease in restricting alveolar ventilation over impairing gas diffusion. Although lung transplantation experience is necessarily limited in such a rare disorder, it clearly provides the most optimistic outlook for advanced disease. The dilemma is that the natural history is characteristically one of very slow progression, implying that duration of survival may not be greatly improved unless transplantation is left until the terminal phase. At such a time the probability of success is much reduced.

17.11.17Toxic gases and fumes

*D. J. Hendrick**

Noxious substances may be delivered airborne to the respiratory tract in molecular (gases and vapours) or particulate form. A vapour is the gaseous form of a substance that is liquid (occasionally solid) at ambient temperature and pressure. The effects of noxious gases and vapours are determined mainly by their solubility in water; those with high solubility are largely dissolved in the secretions lining the upper respiratory tract, those with low solubilities penetrate to the gas-exchanging tissues and exert their dominant effects there. However, with overwhelming exposures adverse effects will occur at all levels of the respiratory tract, and dose becomes a more important determinant of outcome than solubility.

Particulates that are dispersed in air (aerosols) may be solid (dusts) or liquid (mists), and may carry toxic chemicals through surface adsorption or solution, even if the carrier agent itself is harmless. If the particles are large (diameter > 10 μm), they become trapped in the nose, throat, or major airways. If they are small (diameter < 5 μm), they are deemed 'respirable' and may readily penetrate deeply to become retained in the gas-exchanging tissue and (through macrophage transport) the lung interstitium. Fume is a dispersion of fine (readily respirable) particles that form as vaporized metal condenses at ambient temperature and oxidizes to produce the metal oxide.

Many adverse effects may follow the inhalation of irritant or toxic gases and aerosols. Most are manifested in the lung itself, but some are manifested in other organs after the lung provides a route for absorption (e.g. poisoning from carbon monoxide or hydrogen cyanide). Not only do the respiratory effects occur at different levels, but they may appear at different times. It is useful, therefore, to consider acute and chronic (and sometimes subacute) effects separately, and to recognize that some are dominantly airway effects while others are dominantly parenchymal effects. The chronic effects, such as chronic bronchitis, emphysema, pneumoconiosis, pleural thickening, and lung cancer, generally require months or years of exposure, and arise only after a latency of 10 to 20 years or more. Although 'toxic' or 'irritant' in nature, rather than a consequence of allergy or infection, they are usually considered separately from the disorders attributable to 'toxic gases and fumes', and are described in other chapters.

In general, the acute effects of toxic gases and aerosols are the result of industrial or farming accidents, since the potential for toxic exposure is rare outside occupational environments. However, train or tanker crashes have occasionally caused the rupture of chemical containers and the release of toxic gases into non-occupational environments, and the tragic events at Bhopal illustrate the alarming potential for an industrial accident to have profound effects well beyond the work place.

Site of respiratory injury

Acute upper airway toxicity

If gases or vapours of high solubility (e.g. ammonia, hydrogen chloride, or sulphur dioxide) are involved, or aerosols comprising particles of large average diameter, the adverse effects will dominate in the upper respiratory tract and large airways. Laryngeal oedema, severe enough to cause airflow obstruction and require intubation, is the most important effect, but oedema is to be expected also in the conjunctivae, nose, mouth, and throat, together with inflammatory secretions, even bleeding. One breath is usually sufficient to provoke an immediate withdrawal from further exposure, if this is possible, and so protects against further damage.

Acute tracheobronchitis

If withdrawal from exposure is not possible, or less soluble gases are involved at less pungent levels of exposure (e.g. chlorine), there will be greater penetration beyond the larynx and an acute tracheobronchitis results. This too may become life threatening, and may predispose to secondary infection. If there is survival, full recovery is the rule, but a minority of patients are left with asthma that persists for weeks, months, or even indefinitely. Such an outcome has been called the reactive airways dysfunction syndrome.

Acute pneumonitis

Gases of low solubility (e.g. oxides of nitrogen, ozone, or phosgene) penetrate readily to the gas-exchanging tissues. In the absence of immediate toxicity to the upper respiratory tract they may be encountered in an increasing cumulative and hence dangerous dose. The outcome is an acute pneumonitis and pulmonary oedema some hours later, and is exemplified by nitrogen dioxide toxicity. This gas may be encountered in hazardous concentrations in unventilated silos, particularly when they are decapped (silo filler's disease), when welding is carried out in poorly ventilated sites, and with the combustion of nitrogen-containing substances, such as nitrocellulose. One notorious episode involved a fire of stored radiographs. When grain is stored in silos (or silage is preserved under impervious coverings) microbial contamination leads to the release of nitrogen dioxide along with other toxic gases (principally aldehydes) and asphyxiants (carbon dioxide, methane) and the removal of oxygen. Such processes have the beneficial effect of 'pickling' and preserving the vegetable produce, but they create a dangerous environment for the unwary farm worker. Moulding vegetable produce can similarly provoke a toxic pneumonitis through releasing microbial toxins, and it may be difficult to distinguish this (pulmonary mycotoxicosis or organic dust toxic syndrome, see Chapter 17.11.11) from nitrogen dioxide toxicity.

A curious observation with nitrogen dioxide toxicity has been a recurrent episode of pulmonary oedema 1 to 3 weeks after the initial exposure. The explanation is not clear, though possibly represents the well recognized complication of adult respiratory distress syndrome (**ARDS**) that may follow any cause of toxic pneumonitis. The prophylactic use of oral steroid is said to reduce this risk. Once ARDS occurs, additional risks of pneumothorax and secondary infection arise, sometimes with fatal result. Otherwise recovery is usually full, though rarely bronchiolitis obliterans (or bronchiolitis obliterans with organizing pneumonia) complicates the picture (Chapter 17.11.3).

Illustrative causal agents

Fire smoke

Smoke from fires is a complex mixture of gases and particulates released during combustion and pyrolysis. Its nature can vary greatly with the severity of the fire, the availability of oxygen, and the nature of the burning materials. It may contain toxic concentrations of carbon monoxide, hydrogen cyanide, ammonia, sulphur dioxide, chlorine, phosgene, nitrogen dioxide, aldehydes, and other gases, together with particulates derived from the burning material and surface absorbed gases. Thus, its effects may be diverse, and include suffocation or metabolic poisoning as well as direct toxic injury throughout the respiratory tract.

Metal fume fever

Metal fume fever is an acute and self-limiting febrile illness that characteristically occurs after unusually heavy exposures to metal fume, and recurs on re-exposure after a brief absence from work. It closely simulates other occupational fevers, such as Monday fever in cotton workers (see byssinosis, Chapter 17.4.1.5), polymer fever in chemical workers, and the fevers associated with humidifier lung and allergic alveolitis (see Chapter 17.11.11). It can occur on the first day of exposure. It

results from alveolar deposition of very fine particulate metal oxides (fumes) produced in processes such as welding, burning (oxyacetylene cutting), and smelting of metal. It particularly, but not exclusively, involves zinc, copper, and magnesium. Within some 6 h of exposure, there is thirst, a metallic taste in the mouth, cough, tightness in the chest, and chills, with fever, headache, myalgia, and leucocytosis. Resolution follows within 24 h without permanent sequelae. This benign course is dramatically distinguished from that associated with heavy exposure to fume released from heating cadmium. Cadmium is an anticorrosive metal used in electroplating and the production of alloys. Cadmium fumes may be encountered during extraction, soldering, burning, and welding in poorly ventilated conditions, and may lead to an acute toxic reaction in both lungs and kidneys. It is associated with high mortality.

Simple asphyxiants

Some inhaled gases have no toxic effects, but may severely threaten life through asphyxiation by displacing oxygen from inhaled air. Most common are carbon dioxide and methane, which replace oxygen when vegetable produce decomposes through microbial contamination. A less common source is the slow combustion of coal in disused mines or cellars. Oxygen-deficient air in working mines (blackdamp) has been long recognized as a cause of asphyxiation in miners, but careful monitoring and high levels of ventilation provide effective prevention. Occasionally, however, disused mines accumulate blackdamp during periods of high barometric pressure, only to release the asphyxiant gas when the barometric pressure falls. Most escapes harmlessly to the atmosphere from mine shafts but some may be trapped in the ground under impervious layers of rock or clay. This may find an escape route through faults in the strata and so be emitted at high flow rates into surface buildings. Cellars that breach a layer of clay in coal mining areas may provide a particularly dangerous environment for the unsuspecting. Decaying vegetable matter in the soil may also provide the mechanism for carbon dioxide to replace oxygen, and entry of this oxygen-deficient air into wells during periods of low barometric pressure has also led to asphyxiation.

Management

The management of toxic and asphyxiant insults is essentially supportive. Prompt removal from the source of exposure is followed by attention to the airway, and the administration of specific antidotes when, rarely, this is indicated (for example with cyanide poisoning or methaemoglobinaemia). Because of the risk of laryngeal obstruction or pulmonary oedema following toxic insults, a minimum period of 24 h of hospital care is needed for subjects presenting with hoarseness, stridor, wheeze, or hypoxaemia, and those with a history indicative of heavy exposure to a poorly soluble toxic gas. Humidified air, oxygen supplementation, and bronchodilators may be required. Bronchoscopy may be needed to remove excessive secretions and clear the airway. Laryngeal obstruction demands intubation, and tracheostomy may be necessary if there is extensive upper airway inflammation. Severe pulmonary oedema should be managed as for the adult respiratory distress syndrome (see section 16.04.02). The role of corticosteroids in limiting inflammation is unclear; these drugs add to the risk of secondary infection but have been claimed to prevent the development of late pulmonary oedema after nitrogen dioxide exposure.

17.11.18 Radiation pneumonitis

*D. J. Hendrick**

Local therapeutic irradiation of malignancies of the breast, oesophagus, mediastinum (including lymphoma), and lung may damage normal pulmonary tissue. Normal lung is also damaged by the total body irradiation used in preparation for bone marrow transplantation, and by any pulmonary shunting of therapeutic radioactive agents administered via the arterial route to other organs (e.g. yttrium-90 microspheres to the liver). Effects are compounded by the use of chemotherapeutic agents such as methotrexate. However, the risks appear to differ between the various chemotherapeutic agents, for instance that for adriamycin exceeds that for cisplatin. Furthermore, segments of irradiated lung may prove to be unduly susceptible to drug toxicity if chemotherapeutic agents are administered subsequently. Knowledge of the radiation port is therefore important in distinguishing localized toxic pneumonitis from infection.

The scale of pulmonary damage is strongly dependent on the volume of lung exposed, and the dose and fractionation of irradiation. Clinical manifestations range from asymptomatic radiographic opacification to fatal respiratory failure. The latter is fortunately vanishingly rare as radiotherapy techniques are better refined. The dose administered by each fraction is possibly the most important determinant, with values exceeding 2.67 Gy reported to carry most risk. If the same total dose is administered by two fractions during the same day, the risk appears to diminish. Pre-existing fibrotic damage and coincident infection additionally augment the risk.

Radiation releases toxic and mutagenic free radicals within tissue. The resultant DNA damage causes mitotic cell death as tissue cells pass through the first two or three cell divisions after irradiation. The principal cells injured in the lung (the capillary endothelium and type 2 alveolar pneumocyte) have turnover times ranging from 2 to 6 weeks under different circumstances, which explains why the maximum pulmonary effect occurs at about 2 months after injury. The capillary endothelium leaks protein and fluid, and the interalveolar septae become thickened, thereby leading to air space filling (consolidation) and interstitial fibrosis.

The pathogenic pathways appear to involve T lymphocytes. If thymectomy is performed before whole-body irradiation for bone marrow transplantation, the risk of radiation pneumonitis is reduced. When unilateral pneumonitis complicates the irradiation of only one lung in the treatment of breast cancer, a marked but equal increase in lymphocyte numbers from bronchoalveolar lavage in both lungs 4 to 6 weeks later is correlated with a decrease in vital capacity. Animal models suggest that the release of nitric oxide from alveolar macrophages and alveolar epithelial cells also plays a role, as does the recruitment of neutrophils.

The pathological changes can be categorized as (i) acute (up to 3 months), when there is vascular damage with thrombosis and packing of alveoli with surfactant (released from type 2 pneumocytes) and protein-rich fluid; (ii) subacute (2 to 6 months), when there is type 2 pneumocyte renewal and proliferation with macrophage and fibroblast infiltration into the alveoli and interstitium; and (iii) chronic (up to 24 months), when there is alveolar and interstitial fibrosis with capillary sclerosis.

Clinical features

Symptoms begin within a few weeks and may persist for weeks or months. They occur in 10 to 30 per cent of patients following radiotherapy for lung cancer. A rise of the plasma concentrations of transforming growth factor-b_1 and soluble intercellular adhesion molecule-1 have been shown to be markers for those at higher than average risk, thereby providing insights to possible mechanisms, and pointers to identifying subjects who are most suited to escalating radiotherapy treatment.

The severity of symptoms is dependent upon the extent of lung damage, and minor degrees may only be detected incidentally from routine chest radiographs. Cough, which can be severe and may produce thick sputum, and breathlessness are the principal symptoms, but may be accompanied by fever of variable degree. On examination there may be tachypnoea, cyanosis in severe disease, and local crepitations. Telangiectases, the result of cutaneous radiation damage, are often observed in the overlying skin.

The most characteristic radiographic feature is an area of hazy consolidation demarcated by a sharp margin (crossing anatomical pulmonary planes) that corresponds to the limits of the irradiation field, though additional effects are usually detectable beyond these boundaries. Radioisotope scanning shows marked perfusion impairment within the affected portion of lung. In extensive disease, the clinical and radiographic features may be typical of adult respiratory distress syndrome (Chapter 16.04.02). Computed tomography provides the best means of early identification, ground-glass attenuation and interalveolar septal thickening being the early characteristic features.

Up to a year or two after the radiation insult, dense local fibrosis may develop, and magnetic resonance imaging may be required to allow differentiation from tumour recurrence. This can also arise in the apparent absence of earlier pneumonitis, and it may be complicated by pleural effusion, pneumothorax, or fungal colonization (e.g. *Aspergillus* sp.). Fractures resulting from irradiation-induced bone necrosis may occur in nearby ribs.

Treatment

In cases where symptoms are slight, no specific treatment is needed. In more severe disease, corticosteroids produce relief during the acute phase in most patients. Any response to corticosteroids occurs within 3 to 4 days, with clinical and radiographic improvement, and treatment should be continued for 3 to 4 weeks before tapering and stopping. Corticosteroids do not, however, influence the extent of subsequent pulmonary fibrosis. Symptomatic relief of cough and hypoxaemia by an opioid antitussive and oxygen supplementation may also be needed. Prevention offers the best means of control, and further development of methods to detect undue susceptibility and early disease may prove to be valuable in developing safer fractioning protocols.

In laboratory animals, interferon-g has reduced neutrophil recruitment and protein leakage in the early phase of radiation pneumonitis, angiotensin-converting enzyme (**ACE**) inhibitors have prevented or limited increases in central venous and pulmonary artery pressure (and diminished exudation and oedema), and nitric oxide synthase inhibitors have reduced disease progression. Such observations may provide direction for additional measures of prevention and control in humans, though one study has already noted no significant benefit in those who by chance had used ACE inhibitor medication. A further experimental approach has involved the prophylactic use of selenium-enriched spiruline, which appeared to reduce the development of fibrosis by impairing the synthesis of hydroxyproline and type III collagen.

17.11.19 Drug-induced lung disease

*D. J. Hendrick and G. P. Spicketi**

Adverse effects of drugs on the lungs frequently present diagnostic problems. This chapter is centred on direct effects of drugs in usual therapeutic doses on the airways, alveoli and interstitium, pulmonary vasculature, pleura, and mediastinal structures. Respiratory disorders arising through occupational exposure (manufacture, transport, dispensing, administration) are considered only briefly. Excluded are indirect effects, such as the predisposition to opportunistic lung infection resulting from cytotoxic agents, the worsening of respiratory failure after sedatives, and the consequences of overdosage or inadequate control of dosage (e.g. pulmonary haemorrhage with anticoagulants).

Asthma

The underlying pathophysiological basis of asthma is an unusually high level of airway responsiveness—the tendency of the airways to constrict following a variety of stimuli, whether specific (e.g. allergens) or non-specific (e.g cold dry air). Airway responsiveness is distributed unimodally in the population at large, individuals with asthma being those in the tail with the highest levels. In theory, drugs (like other environmental agents) may produce asthmatic symptoms either by elevating the pre-existing level of airway responsiveness into the asthma range, or by acting as a specific or non-specific stimulus when airway responsiveness lies already within the asthmatic range. By the first mechanism, the drug acts as a cause of asthma (an asthma inducer), by the second it acts as a cause of asthmatic reactions (an asthma trigger). Some drugs doubtless act through both mechanisms. The mechanism is of limited consequence in the drug setting (though not in the occupational setting), since treatment cessation and future avoidance is the way forward in both circumstances. If, nevertheless, a given drug is known to be a potential trigger but not an inducer, concern over its use need arise only for individuals who are already asthmatic.

In practice, airway obstruction provoked by drugs usually presents as an exacerbation of pre-existing asthma, and the drug acts as a trigger not inducer. In some cases asthma has not previously been recognized until it is exacerbated by the adverse effect of a drug and thus 'uncovered'. In such instances clues to pre-existing asthma are usually elicited when the appropriate history is taken. Drugs that exacerbate symptoms in subjects with pre-existing asthma may conveniently be classified as those that produce a more or less predictable effect, related to their pharmacological properties, and those which produce bronchoconstriction due to an idiosyncratic effect (Table 1). Less commonly, asthma develops *de novo*, probably because immunological hypersensitivity has developed.

Asthmatic symptoms can also be a consequence of the particular formulation of a drug or its method of delivery. For example, nebulized solutions of low osmolality can trigger asthmatic reactions if there is a high level of airway responsiveness. This appears to have been the main mechanism of bronchoconstriction induced paradoxically by nebulized ipratropium bromide. Since the drug was reformulated in isotonic solution the problem has largely disappeared. A further cause of bronchconstriction from nebulized drugs has been the presence of certain preservatives or stabilizers (e.g. benzalkonium chloride, edetate disodium) in the excipient solution. If the administered drug is used for asthma, the effect is particularly unexpected. A further paradox is associated with the evolving use of hydrofluoroalkane propellants (rather than ozone-depleting chlorofluorocarbons) in pressurized aerosol inhalers used to treat asthma. These may have a minor non-specific irritant effect on hyperresponsive airways, which is masked if they are used as the vehicle to administer short-acting b-agonist bronchodilators. However, with the long-acting b-agonist salmeterol (though not eformoterol), the bronchodilator effect is less speedy and hydrofluoroalkane may trigger brief symptoms. The epidemiological importance of this adverse effect is at present unclear.

Pharmacological effects

Cholinergic drugs, such as carbachol, given systemically occasionally produce bronchoconstriction, and in very sensitive asthmatic patients exacerbations have occurred after use of pilocarpine as eye drops. An inhaled anticholinergic agent would seem a logical approach to this problem and has been shown to be effective in reversing occasional untoward effects of cholinesterase inhibitors in asthmatic patients with myasthenia gravis.

The bronchoconstrictor prostaglandin F_{2a}, if used to induce abortion, may be hazardous in asthmatic patients. The occurrence of bronchoconstriction after thiopentone, opiates, and muscle relaxants (tubocurarine, suxamethonium, and pancuronium) is probably due to their capacity to release histamine.

A more common problem is worsening of airway obstruction by b-adrenergic antagonist agents. Although these have been increasingly refined to select agents with the least b_2-antagonism, thus minimizing effects on the airways, none is completely specific for b_1-receptors. The degree of selectivity varies, with propranolol the least and practolol probably the most selective agents used so far. Unfortunately, practolol causes its own distinctive side-effects (see below) and is no longer available. Of the b-blockers currently available, atenolol and metoprolol seem to have the least adverse effects on airway function, but many patients with asthma will show a reduction in forced expiratory volume in 1 s (FEV_1) or peak flow on therapeutic doses of these agents and considerable caution is necessary. The problem of b-blockers in patients with clear-cut asthma is relatively straightforward, but the situation with chronic airway obstruction is less clear. Adverse reactions in such patients are less common and usually less severe, which possibly reflects the coincidental presence of mild asthma rather than a true adverse effect on chronic obstructive pulmonary disease attributable to emphysema or obstructive bronchiolitis. Many patients who develop symptoms and worsening airway obstruction after use of b-blockers are subsequently thought to have had 'latent' asthma.

Although the adverse effects of oral or systemic b-blockers are well recognized, those of ophthalmic preparations are easily overlooked. Timolol, which is used commonly in eye drops for the treatment of glaucoma, is a potent non-selective b-blocker. Its use has frequently been associated with worsening asthma. The ophthalmic formulation of the newer b-blocker betaxolol appears to be less dangerous, but should be avoided in patients with asthma unless no suitable alternative is available.

Effects from sensitization and idiosyncrasy

The mechanism by which drugs lead to asthmatic symptoms when there is no obvious pharmacological effect is often unclear, though immunological sensitization and idiosyncrasy are likely to provide the major pathways.

The most dramatic presentation of drug-related asthma is as part of an acute anaphylactic reaction, and penicillin and intravenously administered iron–dextran are particularly noteworthy among the causal agents. Other drug hypersensitivity reactions that include asthma among the manifestations are often associated with blood eosinophilia and/or eosinophilic pneumonia, and are discussed more fully in Chapter 17.11.9.

Immunological hypersensitivity is presumed to underlie most causes of occupational asthma, some of which involve pharmaceutical agents. Most prominent are certain antibiotics (e.g. cephalosporins, isoniazid, penicillins, piperazine, spiramycin, tetracycline,), the H_2-receptor antagonist cimetidine, the laxative psyllium (ispaghula), pancreatic enzymes, and certain hormones (adrenocorticotrophic hormone, gonadotrophin, pituitary snuff). If a sensitized worker subsequently uses the relevant drug therapeutically, the potential arises for an asthmatic reaction (Fig. 1). The history, when symptoms suggest asthma, should always include details of occupation and medication, and if the patient has ever worked in the pharmaceutical industry the possibility of occupationally induced hypersensitivity to a current medication should be considered.

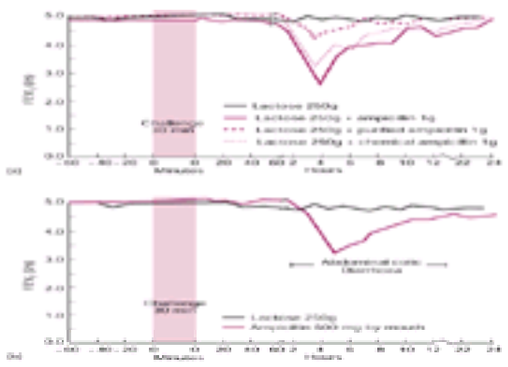

Fig. 1 Results of inhalation and ingestion challenge tests with ampicillin. The inhalation test confirmed that the patient had become sensitized to ampicillin as a consequence of respiratory exposure at work, and the ingestion test showed that asthmatic reactions would be provoked also by oral ingestion at therapeutic dose levels. (Data taken from Davies *et al*.(1974).)

Idiosyncrasy probably underlies many asthmatic symptoms related to medication, and is the likely explanation for exacerbations following use of intravenous *N*-acetylcysteine in severe paracetamol poisoning. Its use in asthmatic patients requires caution. Idiosyncrasy more obviously underlies asthmatic reactions to aspirin and other non-steroidal anti-inflammatory drugs (**NSAIDs**). Exacerbation of asthma after ingestion of aspirin was described as long ago as 1910, but its precise mechanism remains elusive. Most patients who are sensitive to aspirin also react to other NSAIDs, their widely differing chemical structures making an immunological hypersensitivity reaction unlikely. As with cholinergic drugs and b-blockers, asthmatic reactions to NSAIDs may rarely follow ocular administration, and so eye drops deserve careful attention when asthma worsens unexpectedly.

NSAIDs are inhibitors of prostaglandin synthesis via the cyclo-oxygenase pathway, and it is presumed that their adverse effects are mediated in this way. It is possible that metabolism of arachidonic acid is diverted to the production of bronchoconstrictor leukotrienes, but why only a proportion of patients with asthma should be affected is not clear (hence the idiosyncrasy). Deaths have been reported with both aspirin and indomethacin. Of the commonly used analgesic agents, paracetamol is the least likely to provoke a significant response, although occasional adverse reactions are well documented. A further interesting feature is that aspirin-sensitive individuals can be made tolerant to further aspirin by ingesting graded doses over a couple of days. This state of tolerance can then be maintained by daily treatment with aspirin, but sensitivity returns within a few days of discontinuing regular treatment. Any attempt at inducing tolerance in this way requires very careful supervision.

Many patients with analgesic-induced asthma are also sensitive to the azo dye tartrazine (and often to alcoholic beverages). Tartrazine has hitherto been a commonly used colouring agent in medications (particularly those coloured orange or red) and foodstuffs, and since it is an approved food and drug additive, its presence is not always declared and the extent of the problems it may cause is not clear. In the past tartrazine was present, ironically, in some medications used to treat asthma, but most pharmaceutical companies no longer use it in their formulations. Other dyes may, however, have similar adverse effects and some of these still occur in drug formulations. Patients with aspirin and tartrazine sensitivity may also develop troublesome nasal polyposis, as well as asthma. Such patients may benefit from a low salicylate and azo-dye free diet, in addition to strict avoidance of NSAIDs.

The potential exacerbation of asthma by drugs used to treat it presents an acute dilemma, as a drug effect may be difficult to dissociate from spontaneous deterioration. There are well documented reports of worsening asthma after both intravenous aminophylline and hydrocortisone. Sensitivity to hydrocortisone is a particular problem in asthmatic patients who also show adverse reactions to aspirin and NSAIDs. The sensitivity to hydrocortisone of these individuals does not extend to other steroids; it appears to be related to the succinate moiety of the hydrocortisone sodium succinate molecule as it is not seen with the alternative phosphate salt.

The frequent use of nebulized pentamidine for treatment or prophylaxis of pneumocystis infection in patients with HIV infection has been associated with bronchoconstriction in many individuals. The mechanism is unclear. Although patients with asthma show larger responses, others with no previous evidence of asthma may also be affected. The adverse effect is inhibited by prior use of a nebulized bronchodilator, an approach that has become standard in many centres.

Cough

Cough in the absence of asthma is a well-recognized side-effect of treatment with inhibitors of angiotensin-converting enzyme. It develops in 10 to 20 per cent of individuals so treated and is an effect of the class of drug rather than of specific agents. The cough is non-productive. There appears to be a weak relation to dose such that dose reduction may result in some improvement, but in many individuals the symptom is sufficiently troublesome to necessitate drug withdrawal. Deterioration of pre-existing asthma has also been reported occasionally, but in most individuals with cough related to angiotensin-converting enzyme inhibition, features of asthma are not present. The mechanism is unclear; angiotensin-converting enzyme catalyses not only the conversion of angiotensin I to angiotension II, but also the breakdown of bradykinin and substance P. Since these agents are cough stimulants, their accumulation offers a possible mechanism for this unusual adverse effect. The cough disappears on withdrawal of the drug.

Alveolar reactions

There is no generally accepted classification of alveolar reactions to drugs. They range from acute non-cardiogenic pulmonary oedema (e.g. from cremaphor, the agent used to provide soluble cyclosporin A for intravenous use) or the adult respiratory distress syndrome at one extreme to insidiously developing pulmonary fibrosis at the other. The reactions are conveniently considered under three main headings: alveolar capillary leakage, alveolar and interstitial inflammation/fibrosis, and eosinophilia (Table 2). Some overlap is inevitable: inflammatory reactions (whether toxic or allergic) may cause capillary leakage and hence radiographic air space filling; allergic reactions may or may not be characterized by inflammation and eosinophil infiltration.

Of the drugs that may produce the picture of adult respiratory distress syndrome, hydrochlorothiazide and salicylates are the commonest. The reaction to hydrochlorothiazide is idiosyncratic and is not shared by other thiazide drugs. In the case of salicylates there is a clearer relation to dose, with reactions usually occurring with frank overdose (as also occurs with opiates) or, occasionally, with chronic high-level ingestion. Infused b_2-adrenergic agonists are sometimes used as uterine relaxants (tocolytics) to inhibit premature labour. Several, in particular isoxsuprine, ritodrine, and terbutaline, have been associated with florid pulmonary oedema. This reaction is occasionally life threatening and caution is required over the rate of infusion.

Several drugs produce widespread alveolar damage ('pneumonitis' or 'alveolitis'), which may or may not be followed by fibrosis (Table 2). Patients can present acutely with cough, fever, shortness of breath, and occasionally systemic upset. Alternatively, there is slowly progressive fibrosis with gradually worsening dyspnoea and widespread shadowing on the chest radiograph. The mechanism(s) of such reactions are uncertain, but may include toxicity, hypersensitivity, and possibly idiosyncrasy. In some cases, including bleomycin, carmustine, amiodarone, and nitrofurantoin, there is evidence of a relation to dose or duration of treatment. Recent evidence in the cases of nitrofurantoin and bleomycin suggests a role for the production of toxic oxygen radicals in the lungs, perhaps providing a link with the known pulmonary toxicity of oxygen itself and with the synergistic adverse effects of high oxygen concentrations and some cytotoxic agents.

Much recent interest has centred on the cardiac antiarrhythmic drug, amiodarone. It has been estimated that approximately 6 per cent of patients taking 400 mg or more per day for 2 months or more will develop overt pulmonary toxicity. There have also been several well-documented cases involving smaller doses. The mechanism may include both immunologically mediated and direct toxic effects. Histologically the lung shows features of chronic inflammation together with interstitial and intra-alveolar fibrosis (Fig. 2). Characteristic 'foamy' macrophages are seen, but they are not specific for serious toxic reactions as they are also demonstrable in the majority of patients taking the drug without adverse clinical effects. Occasionally, the histological picture is of bronchiolitis obliterans organizing pneumonia (**BOOP**), which is also known as cryptogenic organizing pneumonia. Symptoms include progressive dyspnoea, a troublesome cough, and (occasionally) pleuritic chest pain. Radiographic appearances are varied: most frequently there is a diffuse nodular or alveolar filling pattern, sometimes with upper lobe predominance (Fig. 3); occasionally a pleural effusion is present.

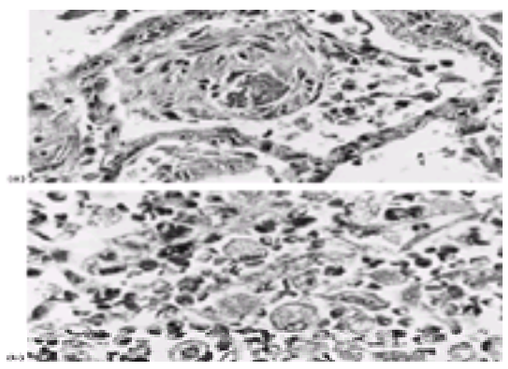

Fig. 2 Histological specimen of the lung of a patient who died from amiodarone pulmonary toxicity: (a) alveolar wall thickening and organizing intra-alveolar exudates; (b) higher power view of alveolar exudate showing characteristic 'foamy' macrophages. (Reproduced from Adams *et al.* (1986). *Quarterly Journal of Medicine* **59**, 449–71, with permission.)

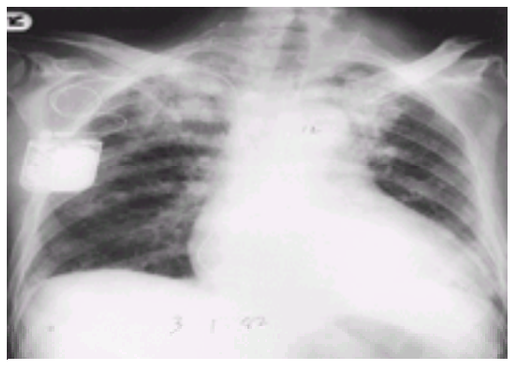

Fig. 3 Chest radiograph of a second patient with amiodarone pulmonary toxicity showing confluent alveolar shadowing in both upper lobes. (Reproduced from Adams *et al.* (1986). *Quarterly Journal of Medicine* **59**, 449–71, with permission.)

Differential diagnoses in the population of patients likely to be taking this drug include left ventricular failure and pneumonia. Further investigation, including measurement of pulmonary wedge pressure and lung biopsy, is often necessary. Bronchoalveolar lavage in some (but not all) patients shows a lymphocytic pattern. This investigation is also of value for the exclusion of infection, but the finding of 'foamy' macrophages in lavage fluid is, for the reasons discussed above, insufficient to confirm the diagnosis. If amiodarone lung toxicity is suspected, cessation of treatment is desirable, but the very long half-life of drug metabolites (many weeks) means that elimination will be very slow. Corticosteroids probably suppress the reaction and sometimes allow treatment to be continued or recommenced in cases of 'malignant' dysrhythmias unresponsive to other agents.

BOOP is a rare manifestation of drug-induced lung disease, but is increasingly recognized in complex settings where drug therapy may have played a dominant or contributory role. In addition to amiodarone, associations have been reported with carbamazepine, nitrofurantoin, phenytoin, sotalol, tacrolimus, ticlopidine, and a number of herbal medications. One of particular interest is a presumed (but unproven) anorectic agent derived from the leaf of an Asian shrub of the *Euphoriaceae* family, *Sauropus androgynus*. In a remarkable period of a few months, more than 60 people who had ingested juice containing uncooked leaf extract of *S. androgynus* presented to hospital in Taiwan with progressive undue breathlessness. In 23 of these patients whose breathlessness was severe, responses to corticosteroid therapy were poor. Plain radiographs were essentially normal, but CT scanning and biopsies demonstrated BOOP with (in a few cases) bronchiectasis in the segmental and subsegmental bronchi.

Cytotoxic and immunosuppressive drugs pose an increasing problem for the lung parenchyma, with the majority reported to cause pulmonary complications. Bleomycin causes problems most frequently, followed by busulphan and methotrexate. Cyclophosphamide and azathioprine are the most widely used drugs in this group, because of their roles in non-malignant disease, but produce adverse pulmonary reactions only occasionally. In most cases it is not clear whether the effects are due to direct toxicity or to hypersensitivity. With bleomycin, however, there is evidence of a dose–response relationship: cumulative doses of less than 150 mg are less likely to cause serious reactions, whereas death due to respiratory failure consequent upon severe fibrosis has occurred in about 10 per cent of patients receiving more than 500 mg.

The recorded frequency of adverse reactions varies with the means by which they are detected; for example, on clinical and functional criteria, fibrosis occurs in 5 to 10 per cent of patients treated with busulphan, but pathological and cytological evidence suggest lung toxicity in much higher proportions. Similarly, the increasing use of CT scanning shows an appreciably higher prevalence than found in surveys that employ plain chest radiography. The frequency of overt lung involvement may also be related to length of survival, as determined by the primary disease. With busulphan, the average interval between starting treatment and the appearance of toxic effects can be as long as 4 years, and in some cases the lung changes appear to progress after the drug has been discontinued. With carmustine (BCNU) it has been shown that pulmonary fibrosis may first be recognized several years after treatment has finished. Other factors that may increase the toxicity of a given drug include advanced patient age and synergism with other drugs, lung radiation, or the subsequent inhalation of high concentrations of oxygen.

Histologically, most cytotoxic drugs produce evidence of diffuse alveolar damage with destruction of lining cells, formation of hyaline membranes, and variable degrees of inflammatory infiltration and fibrosis. Fibrosis is particularly common with busulphan and bleomycin, but rare with methotrexate. With methotrexate and procarbazine (and very occasionally with bleomycin) there may be blood and tissue eosinophilia and correspondingly a good therapeutic response to steroids.

Eosinophilic reactions in the lung include conditions that would be classified as Löffler's syndrome, simple or prolonged pulmonary eosinophilia, and eosinophilic pneumonia (see Chapter 17.11.9). Tissue eosinophilia is a more consistent feature than peripheral blood eosinophilia. Historically, sulphonamides have been the drugs most frequently reported as causes of pulmonary eosinophilia; such reactions have even occurred to a vaginal cream containing sulphonamide. Sulphonamide sensitivity may also explain some of the reactions to sulphasalazine and to chlorpropamide, which is chemically related. The pulmonary eosinophilia recorded with aspirin appears to be distinct from aspirin-induced asthma. Nitrofurantoin may produce an acute eosinophilic reaction in addition to more insidious fibrosis.

The roles of gold salts and penicillamine in eosinophilic reactions have been a matter of some debate, but the evidence suggests that both are involved. It seems unlikely, however, that drugs are responsible for many of the cases of fibrosing alveolitis associated with rheumatoid arthritis. Penicillamine has been incriminated in two other types of adverse pulmonary reaction: first, Goodpasture's syndrome with pulmonary haemorrhage when used in high doses in treatment of Wilson's disease, and second, obliterative bronchiolitis, an unusual form of airway obstruction which is seen occasionally in patients with rheumatoid arthritis. The evidence against penicillamine in the latter is not conclusive.

The clinical severity of eosinophilic reactions is very variable, ranging from a transient and asymptomatic radiographic opacity to a severe illness with dyspnoea, cough, fever, and hypoxaemia due to widespread eosinophilic pneumonia. Concomitant asthma is not uncommon. The chest radiograph shows fluffy opacities, frequently with peripheral or predominantly upper-lobe distribution. The prognosis is usually good: the changes often subside spontaneously on withdrawal of the drug, and in more severely ill patients there is usually a dramatic improvement on instituting treatment with corticosteroids. Although repeated exposure to the offending agents continues to produce reactions, the severity of these may progressively decrease.

Pulmonary vascular reactions

Pulmonary thromboembolism related to use of the contraceptive pill is well established; its frequency correlates with the oestrogen content and has been reduced

since the introduction of low oestrogen preparations. (See Chapter 13.19 and Chapter 13.20 for further discussion.)

The statistical association between pulmonary hypertension and the use of the anorectic agent aminorex in Switzerland, Germany, and Austria in the 1960s was of great theoretical interest. When the drug was withdrawn, the epidemic of pulmonary hypertension subsided and no similar rise was seen in countries that did not introduce this agent. Occasional cases of pulmonary hypertension have been reported also in patients taking various amphetamine-like drugs, but the evidence is not conclusive. (See Section 15.15.2 for further discussion.)

Analgesics given during labour have been implicated in the development of pulmonary hypertension in the newborn; drugs such as aspirin, indomethacin, and naproxen delay premature labour but, by their inhibitory effects on prostaglandin synthesis, may also cause constriction of the ductus arteriosus leading to pulmonary hypertension *in utero* that persists into the postpartum period and causes respiratory distress.

Pleura and mediastinum

Hilar and mediastinal adenopathy are occasionally seen as part of the generalized lymphadenopathy produced by the anticonvulsant phenytoin, and mediastinal lipomatosis has been reported in patients receiving large doses of corticosteroids.

Drugs that have been associated with pleural reactions (effusion or thickening) are shown in Table 3. Several have been reported to produce a syndrome like systemic lupus: the anti-arrhythmic procainamide is most often implicated, but other agents include gold, hydralazine, isoniazid, penicillamine, and sulphonamides. The main respiratory target of this syndrome is the pleura, but (as with pleural disease induced by methysergide and bromocriptine) there is often some fibrosis of underlying lung.

The now obsolete selective b-sympathetic antagonist, practolol, produced a characteristic 'oculomucocutaneous' syndrome. This syndrome differed from systemic lupus erythematosus in that autoantibodies to histones were not usually present, and ocular symptoms are not usually a feature of drug-induced systemic lupus erythematosus. Pleural effusions and subsequent pleural thickening occurred in association with characteristic corneal ulceration, discoid rash, and fibrinous peritonitis. Affected patients sometimes developed effusions months or years after discontinuing the drug. In some the chronic changes led to significant respiratory disability. Minor degrees of pulmonary involvement were reported in some patients, but the predominant abnormality was related to the pleural surface. Other b-sympathetic antagonists, in particular acebutolol, have been reported occasionally to cause an alveolar or pleural reaction, but it seems unlikely that other b-blockers are associated with the full-blown and severe 'oculomucocutaneous' syndrome.

Methysergide, which is used in treatment of the carcinoid syndrome and occasionally for migraine, may induce mediastinal or pleural fibrosis with or without retroperitoneal fibrosis. Improvement follows early withdrawal of the drug. Bromocriptine has some structural similarities to methysergide and can also produce chronic pleural effusions and thickening. The pleural fluid characteristically contains a high proportion of lymphocytes. The frequency of this reaction is uncertain, but it may be relatively common. Methotrexate has been associated with pleurisy, independent of its alveolar effects. The smooth-muscle relaxant, dantrolene, which is used for relief of spasticity, has been reported to produce an unusual type of pleurisy with effusion in which fluid and blood eosinophilia are prominent. There is no evidence of any parenchymal abnormality, and although the changes gradually resolve on withdrawing the drug, some residual pleural fibrosis may remain.

Complications of radiographic and other procedures

Lipoid pneumonia may follow bronchography with oily media. There is an oleogranulomatous reaction that can progress to fibrosis and may sometimes produce a localized mass simulating a neoplasm. Similar reactions can follow aspiration of oily medicines (e.g. laxatives) into the lungs. (See Chapter 17.11.15 for further discussion.)

Lymphangiographic media that drain through the thoracic duct, and so into the venous circulation, enter and can impact in the pulmonary circulation. This is often symptomless, but may cause dyspnoea and cough with the expectoration of fat globules or haemoptysis. Occasional deaths have been recorded. The chest radiograph characteristically shows a fine stippling.

Pleural effusion and, less commonly, mediastinitis occur following endoscopic sclerotherapy of oesophageal varices. The symptoms usually subside within a few days.

17.12 Pleural disease

M. K. Benson

Introduction

The pleural surfaces form the interface between the lung parenchyma and chest wall. The parietal pleura is applied to the chest wall and the surfaces of the ribs, with a thin layer of connective tissue separating it from the periosteum. At the hilum, the pleura form a sleeve-like structure encompassing the major vessels and bronchi. The visceral pleura covers the surface of the lungs and extends into the major fissures which separate the lobes of the lung. The pleura is a membranous structure, the surface of which is covered with a single layer of mesothelial cells. These cells have microvilli over their surface that facilitate the absorption of pleural fluid.

The pleura is not essential for adequate functioning of the lungs, although the smooth surfaces do permit movement of the lungs within the thorax with minimal energy loss. Obliteration of the pleural space following surgery or as a result of inflammatory disease does not result in significant respiratory impairment. Between the two layers of pleura there is a potential space, the surfaces of which are lubricated by a thin layer of fluid. The pressures within the pleural cavity are generated by the difference between the elastic forces of the lungs and the chest wall. At functional residual capacity the outward recoil of the chest wall is equal to the inward recoil of the lung parenchyma (see Chapter 17.1.2).

A number of pathological processes can affect the pleura. Inflammation results in characteristic pleuritic pain, aggravated by deep inspiration, coughing or sneezing, and often accompanied by a pleural rub. The accumulation of fluid in the pleural space results in a pleural effusion. Air can also enter the pleural space resulting in a pneumothorax. Primary tumours of the pleura are relatively uncommon. Involvement by metastatic malignant disease or by lymphoma is much more frequent.

Pleural fluid formation

Normal lubrication of the pleura is provided by a thin layer of fluid, an ultrafiltrate of plasma, although surfactant may also be present and plays a role. Although the turnover of pleural fluid is probably in the order of 1 litre per day, the volume of fluid present at any one time is only 20 to 30 ml. Under normal circumstances two factors operate to prevent the accumulation of fluid in the pleural space: the pleura itself acts as a semipermeable membrane, and the flux of fluid across the pleural space is accounted for by the forces involved in Starling's law of transcapillary exchange. The hydrostatic gradient from the capillaries of the parietal pleura favours fluid efflux into the pleural space. Pressure in the capillaries in the visceral pleura is close to that of the pulmonary capillaries, and this lower pressure favours reabsorption of fluid. The lymphatic system provides a second important method of preventing excess fluid accumulation. In addition, it enables proteins to be recovered from the pleural space and return to the circulating plasma. Factors likely to result in excess fluid accumulation in the pleural space can be identified, including the following:

1. imbalance between the hydrostatic and oncotic forces as defined in Starling's equation, such fluid is usually a transudate;
2. alteration in the permeability of pleural capillaries;
3. impaired lymphatic drainage;
4. abnormal sites of entry (e.g. transdiaphragmatic passage of fluid in patients with ascites).

Pleural effusion

A pleural effusion is an abnormal accumulation of fluid in the pleural space. It is traditional to divide effusions into transudates and exudates, although blood, pus, or chyle can also form collections in the pleural space. The main causes are listed in Table .

Clinical features

The clinical history and examination play an important part in diagnosing the presence of pleural fluid and may yield significant clues as to the pathogenesis. Symptoms related to pleural disease are pain and breathlessness. The extent to which these occur is likely to vary and clinical presentation will, at least in part, be determined by the underlying pathogenesis. Pleuritic pain is relatively easy to recognize and causes severe discomfort on deep inspiration or coughing and is most often associated with an inflamed pleural surface or the presence of a pneumothorax. There can, however, be significant collections of pleural fluid without pain. The other major symptom is breathlessness, which only becomes apparent if there is a large effusion or in patients who already have impaired respiratory reserve.

There may be no abnormal physical signs if the effusion is relatively small, but these are often diagnostic if the effusion is large. Chest wall movement may be normal, although it will tend to be limited, particularly if there is pain, and there can also be a lag of chest wall motion on the affected side. The percussion note is very dull and breath sounds are diminished or absent, as are vocal resonance and tactile vocal fremitus. Compression of the lung above the effusion can result in signs of consolidation with bronchial breathing and increased vocal resonance. The position of the mediastinum, as judged by the trachea and apex beat, will help in distinguishing between a large effusion and a collapsed lung. In the former, the mediastinum is central or displaced away from the side of the effusion, whereas in the latter deviation is towards the affected side.

Given the diversity of pathologies that may result in pleural fluid, systemic symptoms and signs often yield important diagnostic information.

Investigation of pleural effusion

The presence of a pleural effusion should be suspected on clinical examination and can be confirmed by using radiographic imaging or ultrasound. Whilst clinical features play an important part in identifying the pathogenesis, examination of the pleural fluid or pleural biopsy material is most likely to lead to a definitive diagnosis.

Radiographic techniques

Radiographic techniques are helpful in identifying the presence of an effusion but are of limited value in determining the pathogenesis. A conventional posteroanterior chest radiograph is usually adequate to confirm the presence of a clinically significant effusion. Fluid tends to accumulate in dependent parts of the thorax and small effusions in the order of 200 ml will result in blunting of the costophrenic angle. Larger effusions produced increased opacification and mediastinal shift (Fig. 1).

Variations from the normal appearance will result if the fluid is loculated, a situation more likely to occur with an empyema or if there are pleural adhesions (Fig. 2).

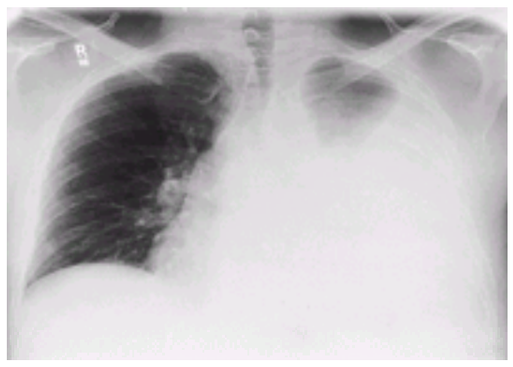

Fig. 1 Chest radiograph showing opacification of the left hemithorax and mediastinal shift indicating a large pleural effusion.

Fig. 2 CT scan demonstrating a loculated effusion due to an empyema.

Ultrasound can be helpful in confirming the presence and site of an effusion. Pleural fluid is identified as an echo-free space between chest wall and lung. The presence of echoes within the fluid may indicate an empyema or haemothorax, and ultrasound can also demonstrate the presence of septation and loculi (Fig. 3).

Fig. 3 Chest ultrasound showing pleural effusion with septation.

CT scan can complement ultrasound examination in demonstrating the site of a pleural collection and has the additional advantage of imaging the underlying lung. The appearance of the pleural surface can be useful in helping to differentiate between benign and malignant pleural disease. In addition, CT-guided percutaneous biopsy techniques can increase the diagnostic yield if taken from areas of gross pleural thickening, visualized on the CT scan.

Examination of pleural fluid

Thoracentesis, whereby pleural fluid is aspirated percutaneously, is a relatively simple procedure that can be undertaken for diagnostic purposes and, in the case of larger effusions, can relieve breathlessness. It is usually performed with the patient upright in a comfortable position with the arms and head supported on a pillow. Unless the fluid is loculated, a conventional site for aspiration is posteriorly about 10 cm lateral to the spine and one intercostal space below the upper level of the fluid as detected by percussion. A common error is to attempt aspiration as low as possible, but this often yields a dry tap since it is impossible on clinical grounds to determine the level of the diaphragm. The procedure is performed with strict aseptic technique. The skin and underlying tissues are infiltrated with local anaesthetic, taking care to avoid the intercostal nerves and vessels that run immediately beneath the rib. For diagnostic purposes it is usually adequate to remove 50 to 100 ml of fluid. If therapeutic aspiration of large amounts of fluid is being undertaken, it is best to introduce a small plastic cannula into the pleural space to minimize the risk of damage to the underlying lung.

Failure to obtain fluid can arise for a number of reasons, including misdiagnosis of the presence of fluid, incorrect site of aspiration, and the presence of viscid fluid. Ultrasound examination can help to identify the reason for a failed tap and guide further attempts if fluid is present. Biochemical, cytological, and microbiological examination of pleural fluid can help to establish a diagnosis if this is not apparent on clinical grounds (Table 2).

Macroscopic appearance

The appearance of the pleural fluid and its odour may provide diagnostic information. Transudates are clear, straw-coloured fluids that do not clot on standing. Many exudates have a similar appearance but they can be turbid due to the presence of cells. Blood-tinged fluid is of little diagnostic significance, but a uniformly bloody effusion is likely to be associated with malignancy. Pus can be very viscid and difficult to aspirate. It is turbid in appearance, yellow in colour, and often foul smelling. Chyle is odourless and milky in appearance.

Biochemistry

Exudates will generally have a higher protein content than transudates, but although a level of 30 g/l has traditionally been used to differentiate between the two, there is significant overlap and values should be interpreted with caution. Better differentiation may be obtained by comparing concentrations of protein and lactic dehydrogenase (LDH) in the pleural fluid with those in blood. The criteria that can prove helpful in identifying an exudate are as follows:

1. fluid to serum ratio of total protein above 0.5;
2. fluid to serum ratio of LDH above 0.6;
3. fluid LDH concentration above 200 international units.

The concentration of glucose in pleural fluid is normally equal to that in serum, but in effusions associated with rheumatoid arthritis the glucose concentration in the pleural fluid is rarely above 1.6 mmol/l. Reduced concentrations are also found in association with tuberculosis, empyema, malignancy, and lupus. Measurement of pleural fluid amylase may be diagnostically useful if the pleural effusion is associated with acute pancreatitis, a pancreatic pseudocyst, or oesophageal rupture. Pleural fluid with a pH less than 7.3 in the presence of a normal blood pH occurs in a number of conditions including empyema and parapneumonic effusions, malignancy, tuberculosis, and collagen vascular diseases. Thus as a diagnostic investigation its use is limited. It may have some prognostic significance in patients with malignant disease in that a low pH is associated with more extensive disease. When associated with infection, a pH of less than 7.2 is one of the criteria indicating the need for tube drainage.

Microscopic and cytological examination

Most transudates have cell counts of less than 1000/mm^3, with the cells being a mixture of lymphocytes, polymorphs, and mesothelial cells. Exudates tend to have higher white counts, although this in itself is of little diagnostic value. A polymorphonuclear leucocytosis is indicative of a bacterial infection but can also be seen in association with a pulmonary infarct or pancreatitis. A predominance of lymphocytes raises the possibility of tuberculosis but can also occur in association with malignancies, including lymphoma, and also is seen after coronary artery by-pass surgery. The presence of excess eosinophils is not in itself diagnostic but tends to be associated with benign inflammation.

Cytological examination of pleural fluid for suspected malignancy is a rapid and efficient diagnostic procedure. Fifty ml of fluid should be sent for immediate examination. The finding of malignant cells is likely to be diagnostic, although actively dividing mesothelial cells can mimic an adenocarcinoma. A positive diagnosis is made in approximately 60 per cent of malignant effusions. The diagnosis of a malignant mesothelioma presents particular difficulties but the use of monoclonal antibodies CEA, B72.3, and Leu-M1 can help distinguish an adenocarcinoma from mesothelioma.

Microbiology

Gram stain and culture of the pleural fluid are of diagnostic value if an infective aetiology is suspected. Identification of an organism confirms the diagnosis and sensitivity testing will assist in the appropriate choice of antibiotics. Tuberculous pleurisy is difficult to diagnose and acid fast smears are positive in only about 10 per cent of cases. Cultures are more likely to be positive if a reasonable volume of fluid is concentrated and then examined.

Pleural biopsy

Pleural biopsy may be indicated if initial analysis of pleural fluid fails to establish a diagnosis. It is most likely to give diagnostic information if there is an underlying malignancy or tuberculosis. The diagnostic yield is likely to be greatest when used in conjunction with CT scanning to identify areas of particular thickening or nodularity. Blind percutaneous biopsies are usually performed using an Abraham's or Cope's needle. Both of these are large blunt-tipped needles with a hook to catch a sample of parietal pleura. The technique is similar to that used for pleural aspiration except that a small incision is made in the skin and subcutaneous tissue to enable ease of insertion of the needle. The Abraham's needle consists of an outer trocar with a side hole and an inner cannula with a cutting edge. Once in the pleural space, confirmed by aspiration of fluid, the side hole is opened by rotating and slightly withdrawing the inner cannula. The needle is then withdrawn at an angle to the chest wall such that the side hole gently catches on to the parietal pleura, and at this point the inner cannula is advanced to obtain a biopsy. Several samples can be taken using this technique, but care is needed to avoid damage to the intercostal nerves and vessels. Samples for histological examination should be placed in 10 per cent formaldehyde and those for culture for mycobacteria should be put into saline.

Thoracoscopy

Direct visualization of the pleura is possible using a thoracoscope, and this should be considered as a diagnostic procedure when less invasive procedures have failed to yield a definitive diagnosis. It is particularly useful in suspected malignancy or tuberculosis. For further details regarding this technique, see Chapter 17.3.4.

The relative diagnostic yields of thoracocentesis, pleural biopsy, and thoracoscopy with respect to tuberculosis and malignancy are given in Table 3. Pleural aspiration is easy to perform, requires limited expertise, and has only minor risks. Pleural biopsy requires more expertise and complications include pain, pneumothorax, haemothorax, and vasovagal reactions. Thoracoscopy is only available in specialist centres and, in addition to the risks associated with pleural biopsy, may result in subcutaneous emphysema. The diagnostic yield and choice of technique will depend on the medical indications and local expertise.

Chest drain insertion

Chest drainage is used therapeutically in a number of clinical situations, including the management of malignant pleural effusions, empyemas, pneumothoraces, postoperatively, and when there has been bleeding into the pleural cavity. Doctors working in a variety of specialties should therefore be capable of inserting an intercostal drain. It is potentially a painful procedure and the patient needs reassurance, comfortable positioning, and adequate analgesia and local anaesthesia. Ideally, narcotic medication should be given prior to the procedure unless medically contraindicated. The position of the patient will depend on the site of insertion. For the axilla, the patient is usually lying at 45° with the arm behind their head such that the axillary area is exposed.

The site of insertion will depend on the clinical and radiological findings. In patients with a large pleural effusion or a pneumothorax, the most usual site is in the axilla, in a triangle bounded by the anterior axillary line, the lateral margin of the pectoralis major, and a horizontal line at the level of the nipple. An alternative site for an apical pneumothorax is in the second intercostal space in the mid clavicular line. Where there are loculated collections of air or fluid, real-time ultrasonography can ensure optimum placement of the catheter.

The appropriate drain size remains a subject of debate. Large bore tubes (28–30 French) are used postoperatively and in the management of haemothorax. Whilst some authorities advocate their use in other clinical situations, such as management of pneumothoraces and empyemas, small bore catheters (10–14 French) are as effective, easier to insert, and better tolerated by patients.

Insertion of a chest drain with aseptic technique is important to minimize the risk of infection. The site for tube insertion is infiltrated with local anaesthetic (1 per cent lignocaine—maximum dose 3 mg/kg) to achieve satisfactory anaesthesia of skin, subcutaneous tissues, and pleura, care being taken to avoid intercostal vessels that run beneath each rib. The infiltrating needle should also be used to aspirate air or fluid from the pleural space once the pleura has been punctured, and a chest tube should not be inserted until this has been achieved. An incision is made in the skin parallel to the ribs and slightly larger than the catheter to be inserted. Blunt dissection of subcutaneous tissue and muscle is achieved by opening and closing a curved clamp: this separates the muscle fibres and can also be used to penetrate the pleura. If a large tube is to be inserted, the track can be explored with a gloved finger to ensure that there are no organs that might be penetrated. However for smaller catheters, an inappropriately large track can result in leakage around the catheter. The central trocar can be used to support the catheter, but forcible insertion should be avoided because of potential for damage to lung and mediastinal structures. Alternative techniques include the use of pigtail catheters after insertion of a guide-wire and dilatation of the track.

Although traditionally the catheter is inserted towards the apex for pneumothoraces and towards the base for pleural effusions, precise positioning is relatively unimportant. There should, however, be sufficient catheter within the thorax to minimize the risk of displacement. A strong non-absorbable suture, such as 1–0 silk, should be used to secure the drain, which should also be supported with a small square of gauze and a bioclusive dressing over the insertion site. Tape can be wrapped around the drain at the point of ligature to help prevent the suture from slipping on the tube. Once the tube has been inserted and anchored, it is attached to an underwater-seal bottle, allowing one-way flow of air or fluid. This has the disadvantage of restricting mobility, but enables observations to be made about tube patency—judged by inspiratory pressure swings—and allows the continued drainage of air or fluid to be monitored. Good nursing care with regular 4-hourly observations are necessary to ensure that the tube has not become kinked or blocked and that it has not become displaced. Uni-jet directional flutter valves permit greater mobility and can be used in ambulant patients for the management of pneumothoraces, but they are inappropriate for use when there are fluid collections.

Specific pleural fluid collections

Transudates

A transudate is characterized by low concentration of protein and other large molecules. Excess fluid forms when there is an increase in capillary hydrostatic pressure or reduction in colloid osmotic pressure. The former occurs predominantly in congestive cardiac failure, and the latter when there is hypoalbuminaemia associated with nephrotic syndrome or hepatic disease.

Cardiac failure

Small effusions are common in congestive cardiac failure or constrictive pericarditis. Right-sided failure results in increased pressures in the systemic capillaries and thus an increased efflux of fluid from the parietal pleura. Elevated left heart pressures will be reflected in the pulmonary circulation with a consequent diminution in fluid reabsorption from the visceral pleura. The clinical features of cardiac failure are usually sufficient to make a diagnosis. Thus cardiomegaly, elevated jugular venous pressure, and third or fourth heart sounds may all be present. The effusions are frequently bilateral. Unilateral effusions are more common on the right side and may cause diagnostic uncertainty. Pleural aspiration can help to confirm the diagnosis by demonstrating the presence of a transudate. Resolution with treatment of heart failure offers further confirmation of the diagnosis.

Hepatic cirrhosis

Hypoalbuminaemia, which may occur in patients with chronic liver disease, is a major contributory factor to the development of generalized oedema. Ascites and pleural effusions are both common, with effusions more often seen on the right than on the left. In some patients, ascitic fluid seems to pass directly into the pleural space, either through a defect in the diaphragm or via lymphatics.

Exudates

Neoplastic pleural effusions

Malignant involvement of the pleura is the commonest cause of a large pleural effusion. Lung cancer may spread directly or via lymphatics and is the commonest metastatic cancer (40 per cent). Breast cancer also spreads via the lymphatic system and is the commonest cause of a malignant effusion in women. Metastatic spread from gastrointestinal or genitourinary tumours is less common. Lymphomas can occur at any age and account for approximately 10 per cent of malignant effusions. Extensive investigation for an asymptomatic primary is of limited value, although it may be appropriate to exclude disease originating in breast or ovary because of the potential response to hormonal treatment or chemotherapy.

Symptoms directly attributable to the effusion are most commonly breathlessness or chest discomfort. The degree of breathlessness depends on the size of the effusion and the presence of pre-existing lung disease. Specific symptoms attributable to the primary tumour are often absent. Non-specific symptoms include malaise, anorexia, weight loss, and sweats.

Appropriate investigations have already been outlined above. They include imaging with a posteroanterior chest radiograph and chest CT scan. Aspirated fluid is usually an exudate and is blood stained in approximately 50 per cent of cases. Malignant cells can be identified in approximately 60 per cent of cases. CT-guided pleural biopsy may be justified where aspiration has proved diagnostically unhelpful. If the diagnosis remains in doubt, the options are either to await events, since the diagnosis may become obvious with the passage of time, or to obtain further biopsy material at thoracoscopy.

Once cancer has metastasized to the pleura, treatment is essentially palliative, although chemotherapy or hormonal treatment may be appropriate depending on the primary, the cell type, and the functional status of the patients. Removal of the pleural fluid and measures to prevent reoccurrence are only necessary if the size of the effusion results in significant breathlessness. If the patient is comfortable, no action may be necessary. Percutaneous needle aspiration of 1 to 2 l of fluid is a simple outpatient procedure and often results in considerable symptomatic benefit. The fluid is likely to recur, but repeated aspiration may be an appropriate therapeutic option. Intercostal tube drainage can be used to remove the bulk of the fluid, but this is also likely to be of temporary benefit unless combined with pleurodesis. If the effusion is large, it should be drained gradually over 24 h to reduce the risk of re-expansion pulmonary oedema. A number of sclerosing agents have been used with varying degrees of success. Unfortunately there is a marked paucity of comparative data. Sclerosing agents include antibiotics (tetracycline, doxycycline, minocycline), antineoplastic agents (bleomycin), and non-specific irritants (sterile talc, *Corynebacterium parvum*, mepacrine). Until recently, tetracycline (1 g/50 ml saline) has been the most widely used sclerosant, but production of the intravenous preparation has been discontinued. Of the remaining sclerosants, talc slurry (2–5 g in 100 ml) achieves success rates of about 90 per cent and is likely to be the most effective. The pleural space is drained to dryness and after adequate local and systemic analgesia, the sclerosant is injected and the tube clamped for 2 to 4 h. Any residual fluid is then drained and the tube removed after 24 h. An alternative approach is to insufflate iodized talc into the pleural space at thoracoscopy. Surgical pleurectomy or pleural abrasion is also very effective at preventing recurrence, although rarely regarded as an appropriate option because of its invasive nature and unacceptably high morbidity and mortality.

Meigs' syndrome

This rare syndrome describes an association between pleural effusions, ascites, and a benign ovarian tumour. Surgical removal of the tumour results in disappearance of the pleural and peritoneal fluid. The mechanism of pleural effusion is uncertain, but it is generally assumed that ascitic fluid reaches the pleura through diaphragmatic channels or lymphatics. There is no evidence of spread of the tumour, and the syndrome should not be confused with effusions that can result from metastatic spread of ovarian cancer.

Endometriosis of the pleura

This rare condition is one in which endometrial tissue is implanted on visceral or parietal pleura. Catamenial pleural chest pain or a pneumothorax can be presenting features. More commonly, there is an associated effusion that on aspiration reveals blood or chocolate brown fluid. Thoracotomy will reveal multiple cystic structures, but surgical ablation is unsuccessful because of the nature of the disease. Treatment is directed at suppressing ovulation using progesterones or androgens.

Infection

Inflammation of the pleura associated with infection is usually due to pneumonia or lung abscess. Other possible sources of pleural infection include subdiaphragmatic pathology, mediastinitis, oesophageal perforation, or direct contamination following penetrating trauma or surgery. Inflammation can result in pleurisy without significant fluid production, a non-infective exudate (a parapneumonic effusion), or infected fluid (an empyema). Distinction between a parapneumonic effusion and an empyema is somewhat arbitrary since there can be a transition from one to the other. A parapneumonic effusion may be slightly turbid, contains an excess of polymorphs, but has no organisms: by contrast, an empyema contains increased numbers of polymorphs and is frankly turbid. pH measurement of the pleural fluid can assist in management: a pH below 7.2 is generally regarded as an indication for pleural drainage. Organisms are likely to be present when there is frank pus, although isolation and identification may be difficult if antibiotics have already been administered. The spectrum of organisms most frequently encountered in the United Kingdom is listed in Table 4.

The presentation will vary depending on the pathogenesis. In a patient with pneumonia, an empyema should be suspected if there is persisting fever and elevated white count despite appropriate use of antibiotics. Pleuritic chest pain may be present but is not invariable. Classical signs of effusion can be difficult to detect, particularly if the pleural collection is loculated. Anaerobic organisms are commonly encountered; these may be secondary to aspiration from the oropharynx or upper respiratory tract.

A chest radiograph that shows apparent loculation of pleural fluid should alert the clinician to the possibility of an empyema. Gas may be present, revealed by a fluid level. Ultrasound examination or CT scan can be useful for identifying the most appropriate approach for attempted aspiration, and also demonstrate the presence of loculi.

Treatment is discussed elsewhere.

Tuberculous pleurisy

Pleural involvement with tuberculosis is a common manifestation of primary infection with direct extension from a subpleural focus. Gross parenchymal disease is rare and the primary site often cannot be identified clinically or radiologically. It is more common in younger patients and in those of Asian origin.

The presenting features are usually acute or subacute with fever, pleuritic pain, and breathlessness, but some patients may give a longer history of malaise, sweats, and weight loss. The effusion is often large (in excess of 2 l) and tends to recur after initial aspiration. The fluid is a serous exudates, often with an excess of lymphocytes whose presence should alert the clinician to the possibility of tuberculosis. Bacilli are rarely identified on pleural aspirate. Culture is more likely to be positive, but even so the diagnostic yield is low, and pleural biopsy is more likely to give a diagnostic result, showing granulomatous inflammation in approximately two-thirds of patients. Thoracoscopic biopsy is most likely to give a definitive diagnosis, but this is not universally available and often it may be appropriate to commence treatment on clinical grounds alone.

A tuberculous empyema with pus in the pleural space is rare, but occasionally complicates cavitating parenchymal disease. A bronchopleural fistula can result, and in advanced disease the empyema can present with a draining sinus through the chest wall. Other bacterial pathogens may be present in the pleural fluid.

Treatment involves the use of standard antituberculous chemotherapy together with adequate drainage if there is frank pus. Steroids have been shown to promote rapid resolution of the effusion and improve symptoms in the short term, but may have no long-term benefits. Rarely, surgical closure of a bronchopleural fistula or decortication is required.

Subdiaphragmatic infection

Inflammation or infection below the diaphragm should always been considered if there is an unexplained effusion with features suggesting infection. A subphrenic abscess is frequently associated with an effusion, usually on the right side. This may follow abdominal surgery, but can also be caused by perforated peptic ulcer, appendicitis, diverticular disease, or cholecystitis. Hepatic abscesses can also cause a right-sided effusion. Even without infection, upper abdominal surgery can result in pleural effusion, but such effusions are usually small and transient.

If there is evidence of sepsis, the source needs to be identified, and if pus is present it must be drained. Ultrasound examination or CT scanning are both effective ways of diagnosing a subphrenic abscess and guiding percutaneous aspiration. The pleural fluid is usually an exudate and although turbid with a polymorphonuclear leucocytosis, it rarely becomes infected.

Pancreatitis is associated with a pleural effusion in approximately 20 per cent of patients. In the majority, the effusion is on the left side and results from inflammation caused by enzyme-rich pancreatic fluid. Whilst the classical symptoms of abdominal pain, nausea, and vomiting usually predominate, pleurisy and breathlessness can occasionally be presenting features. The pleural fluid is often blood stained and contains abnormally high levels of amylase.

Pulmonary emboli

Pleurisy, often associated with a pleural effusion, is a common presenting feature of pulmonary emboli, particularly if there is associated pulmonary infarction. The effusion is usually small and in itself does not require specific treatment. The fluid is often blood stained but the cellular content is variable and there are no specific diagnostic features. The diagnosis of pulmonary emboli is based on clinical features supplemented by appropriate radiographic or isotopic imaging techniques.

Rheumatoid arthritis

Pleural effusions are the commonest pulmonary manifestation of rheumatoid arthritis. They occur in approximately 3 per cent of patients with active rheumatoid disease and are more common in men than in women. The development of an effusion can antedate the onset of joint symptoms in a small proportion of patients. There is no relationship to the severity of the arthritis, but effusions are more likely to occur in patients with subcutaneous nodules and those who have high titres of rheumatoid factor.

The effusions are usually small but can enlarge to a size that results in breathlessness. Although usually unilateral they may be bilateral in about 20 per cent of patients. The fluid is an exudate and may appear turbid due to cholesterol crystals. The cellular content is not diagnostic, but polymorphonuclear cells usually predominate. Although not specific to rheumatoid effusions, a diagnostic clue is the presence of a low glucose concentration (usually below 1.5 mmol/l). The pH is also low and the lactic dehydrogenase concentration elevated. Whilst these findings may also be present in infective and malignant effusions, the associated clinical features rarely lead to diagnostic uncertainty. Pleural biopsy is non-specific although it can reveal the epithelioid cells and multinucleate giant cells found in rheumatoid nodules.

Symptomatic treatment with anti-inflammatory analgesics is indicated if pleuritic pain is a feature. Systemic steroids can speed resolution of the pleural fluid although they are rarely necessary. The majority of effusions resolve spontaneously within a few months but there may be some residual fibrosis.

Systemic lupus erythematosus

Pleural involvement is common in patients with this condition. Approximately 50 per cent of patients will have pleurisy at some stage and the majority of these will have an associated effusion, usually small. Aspiration of the fluid is rarely necessary for either diagnostic or therapeutic purposes. The fluid is an exudate and has high concentrations of antinuclear antibodies. Lupus erythematosus cells can also be identified. There is a good therapeutic response to oral corticosteroids.

Haemothorax

A haemothorax is the result of bleeding into the pleural space and is arbitrarily diagnosed on the basis of having a haematocrit more than half that of peripheral blood. This distinguishes it from a blood stained effusion, which can be associated with a number of different pathological processes. The vast majority of haemothoraces are associated with penetrating or non-penetrating trauma, including iatrogenic procedures such as central venous catheterization. Bleeding usually results from parenchymal laceration or damage to intercostal vessels. A pneumothorax is present in a high proportion of patients.

The treatment of choice is to insert a large intercostal drain (28–32 French), allowing evacuation of blood and reducing the incidence of subsequent fibrothorax. If this reveals continued bleeding, thoracotomy may be required. Surgery is not indicated simply to remove any residual blood clots since in a majority of patients there is spontaneous lysis with no residual damage.

Spontaneous bleeding into the pleural space can occur in association with a pneumothorax (a haemopneumothorax) and presumably results from the tearing of pleural adhesions. Other rare causes of a haemothorax include bleeding disorders, or excess anticoagulants and rupture of the thoracic aorta.

Chylothorax

A chylothorax results from leakage of chylous fluid from the thoracic duct. Absorbed fat is transported as chylomicrons in the intestinal lymphatics and, together with lymph originating in the lower limbs and abdomen, reaches the blood stream via the thoracic duct. The flow of lymph in the thoracic duct is approximately 100 ml/h under basal conditions but can increase five-fold after a fatty meal.

Congenital absence of the thoracic duct is a rare cause of a chylothorax, but the majority of cases are acquired either as a result of trauma or neoplastic invasion. Surgery is the commonest cause of traumatic damage, particularly those operations that involve mobilization of the aortic arch or oesophageal resection. Penetrating trauma occasionally results in damage to the thoracic duct but rupture can also occur from non-penetrating injuries. The commonest single cause of rupture of the thoracic duct is damage caused by neoplastic infiltration, including lymphomas and carcinomas. Other rare associations include pulmonary lymphangioliomyomatosis, the yellow nail syndrome, and filiariasis.

There are no specific clinical features and the diagnosis of a chylothorax is usually made after pleural aspiration. The fat is typically milky and opalescent due to the presence of fat globules, and needs to be distinguished from an empyema or from pseudochyle. In empyema, any discoloration is due to a cellular deposit and after

centrifugation the supernatant is clear. Pseudochyle is due to high lipid levels, usually cholesterol crystals, which occur in chronic effusions, particularly following tuberculosis. Cholesterol crystals can be recognized on smears of the sediment, and the addition of ethyl alcohol to the fluid results in clearing if high concentrations of cholesterol are responsible for the opalescence.

Spontaneous resolution can occur if the chyle is removed by thoracocentesis and the subsequent flow of chyle reduced by the use of medium chain triglyceride diets or parenteral nutrition. If there is known malignancy, mediastinal irradiation may also assist resolution. Malnutrition and lymphopenia are likely to occur if large volumes of chyle continue to be drained, and under such circumstances surgical ligation of the thoracic duct above the diaphragm can be combined with pleurodesis.

Pneumothorax

A pneumothorax results from gas entering the potential space between visceral and parietal pleura. A spontaneous pneumothorax is a consequence of rupture of a bulla or cyst on the surface of the lung, allowing air to escape from the alveoli into the pleural space. Following penetrating trauma, atmospheric air may enter the pleural space through the wound or the visceral pleura may be punctured allowing entry of alveolar gas. An iatrogenic pneumothorax can occur as a result of damage inflicted during catheterization of a subclavian vein or following percutaneous or transbronchial lung biopsy.

Pathophysiology

At functional residual capacity the inward elastic recoil of the lung and the outward recoil of the chest wall results in a negative pressure in the potential space between visceral and parietal pleura. Pressures with respect to atmosphere become more negative during inspiration and only become positive during forced expiration. Because of the elastic recoil of the lung, pleural pressure is always less than alveolar pressure. Thus, if there is a breach of the visceral pleura due to rupture of a surface bulla, gas moves from lung to pleural space. As the lung collapses down, the pressures equilibrate and net flow of gas ceases.

The functional effect of a pneumothorax is to reduce the vital capacity and the total lung capacity as the lung collapses. Ventilation of the affected side is reduced, although perfusion may also fall such that the anticipated alveolar–arterial oxygen gradient and consequent hypoxia are less than might be anticipated. Ventilatory failure with a rise in arterial PCO_2 is rare, except in patients with pre-existing lung disease.

Once the original leak has sealed, reabsorption of pleural gas occurs and re-expansion of the lung takes place at approximately 1.25 per cent of the volume of the hemithorax per day. Pleural gas is absorbed because the total gas pressure, which is similar to that of arterial gas, is greater than that of venous blood.

Tension pneumothorax

Occasionally, and with devastating consequences, the site of air leak acts as a valve, allowing air to enter the pleural space during inspiration but preventing return flow during expiration. If this happens, then pleural pressure rises and a tension pneumothorax results, with compromise of the circulation, mediastinal shift, and impaired function of the opposite lung.

Clinical syndromes

A spontaneous pneumothorax usually occurs without any warning or obvious precipitating factor. A primary pneumothorax occurs in individuals with apparently normal lungs. A secondary pneumothorax is a consequence of pre-existing lung disease.

Primary pneumothorax

A primary pneumothorax is a relatively common condition with an annual incidence of about 9/100 000. It is particularly common in young men, with a male to female ratio of approximately 4 to 1. It is commoner in smokers. Patients are often tall with a marfanoid appearance. The cause of the pneumothorax is assumed to be rupture of a surface bulla or cyst, often near the lung apex. Only rarely can these be visualized radiologically. Approximately 50 per cent of patients suffer from a recurrence within 4 years. Whilst this is usually on the same side as the initial event, there is also an increased chance of contralateral pneumothorax.

Secondary pneumothorax

Older patients presenting with a spontaneous pneumothorax are likely to have underlying lung disease as a predisposing factor, most commonly chronic obstructive pulmonary disease. Rarely, acute exacerbations of asthma may be complicated by a spontaneous pneumothorax, presumably due to high alveolar pressures associated with gas trapping. Some pulmonary infections can result in rupture of necrotic lung with subsequent air leak into the pleura. Staphylococcal pneumonia, anaerobic lung abscesses, and tuberculosis are among the most likely infecting organisms. A secondary pneumothorax can also be caused by lung malignancy. There are also a number of parenchymal and connective tissue disorders in which pneumothorax is a recognized complication; these include cystic fibrosis, lymphangiomyomatosis, pulmonary neurofibromatosis, Langerhan's cell histiocytosis, Marfan's syndrome, and Ehlers–Danlos syndrome.

Iatrogenic pneumothorax

A number of diagnostic and therapeutic procedures can cause pneumothorax. Percutaneous needle aspiration or biopsy of the lung carries the greatest risk, with estimates ranging from 5 to 50 per cent. The risk is related to the presence of underlying lung disease, the size of the needle, and the depth of penetration. Bronchoscopy rarely causes problems, but a transbronchial biopsy carries a small risk, particularly if undertaken in the absence of screening. Intermittent positive pressure ventilation, especially when used with positive end-expiratory pressures, can result in pneumothorax, which can present under tension. Attempted catheterization of subclavian veins can result in puncture of the lung, particularly when carried out by inexperienced personnel.

Clinical features

Symptomatically, a spontaneous pneumothorax will present with chest pain and breathlessness. The pain is usually of sudden onset and typically pleuritic, being localized to the affected side. Inspiration is often painful and breathing is shallow to minimize discomfort. Dyspnoea is partly engendered by the difficulty in taking a deep breath, but is also dependent on the size of the pneumothorax and the presence of underlying lung disease. The initial sensation of breathlessness can improve rapidly before the resolution of the pneumothorax and may be due to reflex changes from receptors in the lung and airways. A significant proportion of patients do not tend to seek medical advice for several days.

Abnormal physical signs may be difficult to detect if the pneumothorax is small or the underlying lung is emphysematous. The most consistent finding is a reduction in breath sounds on the affected side. Movement of the chest wall may be reduced, particularly if there is pain. The percussion note will be resonant, and although hyper-resonance is a recorded feature, it may be difficult to detect any difference from the non-affected side. Vocal fremitus and tactile vocal resonance are diminished. A left sided pneumothorax is occasionally associated with a clicking noise synchronous with the heart beat (Hamman's sign), probably due to contact and separation of the pleural surfaces in time with the heart beat.

Tension pneumothorax

Pneumothorax rarely causes severe respiratory distress and hypoxia unless associated with pre-existing lung disease, or the pneumothorax is under tension. Tension pneumothorax is rare, but a medical emergency. The patient looks as though they are about to die, with severe breathlessness, cyanosis, tachycardia, hypotension, grossly elevated jugular venous pulse, and evidence of mediastinal shift (trachea and apex displaced away from the side of the chest under tension, which may appear unduly prominent).

Associated conditions

Pneumomediastinum

A pneumomediastinum can present in isolation or together with a pneumothorax. Air tracks along the bronchovascular sheath to the hilum and mediastinum. It can be

associated with sudden rises in alveolar pressure during sneezing or straining, and be found in patients undergoing intermittent positive pressure ventilation. Precordial chest discomfort may be a presenting symptom and subcutaneous emphysema can usually be detected in the neck and supraclavicular fossae. No specific treatment is indicated since the condition is benign and self-limiting.

Haemothorax

The presence of blood and air in the pleural space is most commonly the result of trauma. A spontaneous pneumothorax can occasionally have associated bleeding into the pleural space, presumably due to tearing of pleural adhesions.

Pyopneumothorax

A pyopneumothorax usually results from rupture of necrotic lung, but can also be due to oesophageal perforation. The clinical picture is one of a combined empyema and pneumothorax.

Investigations

Confirmation of a pneumothorax is best made by chest radiograph. An erect posteroanterior film is adequate. Although a film during expiration increases the radiodensity of the lung and enhances the contrast between lung and pleural gas, it is rarely necessary. The cardinal radiological features are illustrated in Fig. 4. The outer margin of the lung can be seen as a thin line with the space between it and the chest wall devoid of any lung markings. Pleural adhesions can result in part of the lung being tethered to the chest wall with some distortion of the normal radiographic appearance. A large emphysematous bulla can sometimes be mistaken for a pneumothorax on both clinical and radiological grounds, although the inner margins are usually concave. A CT scan may help to resolve the diagnostic uncertainty.

Fig. 4 Chest radiograph demonstrating a tension pneumothorax.

Lung function tests are inappropriate in the presence of a suspected pneumothorax, although oximetry or arterial blood gases may provide information that will influence decisions regarding treatment.

Management

The diversity of therapeutic options listed in Table 5 is a manifestation of uncertainty as to what is best. Two principal therapeutic objectives are to achieve rapid resolution of the pneumothorax, particularly if there is evidence of respiratory distress, and to reduce the likelihood of recurrence.

Natural resolution

A small pneumothorax with a radiological rim of air of less than 2 cm in an otherwise healthy patient may require no treatment other than reassurance and relief of pain. Non-steroidal anti-inflammatory drugs are usually effective in this respect. Admission to hospital is unnecessary provided the patient has ready access to medical care and is advised to return if symptoms worsen.

Simple aspiration

Simple aspiration is the treatment of choice for a patient with a large primary pneumothorax and is also the initial emergency treatment in patients with a tension pneumothorax. If successful, it will not only speed resolution but also relieve associated breathlessness or chest discomfort. It is simple to perform and has negligible morbidity, even in relatively inexperienced hands. The site for aspiration is usually the second intercostal space in the mid clavicular line. After infiltrating with local anaesthetic, a 16 to 18 gauge intravenous cannula attached to a syringe containing a small amount of sterile water is inserted through the chest wall gently aspirating until bubbling seen in the syringe confirms that the pleural space has been entered. The internal needle is then removed (in tension pneumothorax allowing immediate release of pleural pressure) and a 50-ml syringe with three-way tap is connected to the cannula to allow aspiration of air, which should stop if resistance is encountered or if the patient experiences undue discomfort or coughing. If more than 2 to 3 l of air has been evacuated, it is likely that there is a persisting air leak, and aspiration should be abandoned and a decision made as to whether an intercostal drain should be inserted. This is likely to be necessary if the patient is breathless, but conservative management with repeated aspiration after an interval of a day or two may be more appropriate for those who are relatively asymptomatic. Simple aspiration has been shown to be less painful and require a shorter duration of hospital stay than treatment with an intercostal drain. There are no significant differences in recurrence rate.

Intercostal tube drain

This approach may be indicated if simple aspiration has failed. It is more likely to be needed in patients with underlying lung disease, when even a small pneumothorax can result in severe respiratory failure. The technique for insertion has already been described. Bubbling will cease once the air leak has ceased and the lung fully expanded. A check radiograph should be undertaken before the catheter is removed since drainage of air will also cease if the tube is blocked or has become dislodged. Clamping of the tube prior to removal is unnecessary. The value of additional suction is unproven and may serve to maintain the patency of the original air leak. It can be tried if the lung fails to re-expand, with the aim of evacuating the pleural air and allowing apposition of the pleural surfaces.

Medical pleurodesis

This is undertaken in an attempt to obliterate the pleural space and reduce the likelihood of recurrent pneumothorax. There is a marked paucity of information as to who might benefit and as to the best approach (see previous discussion). It should be considered in those with recurrent pneumothoraces whose underlying condition makes a surgical operation unduly hazardous.

Surgical intervention

Referral rates for surgery vary considerably. The main indications include persisting air leak after prolonged intubation (usually 1–2 weeks) and recurrent pneumothoraces. In the latter group, referral is most commonly made after the second or third ipsilateral recurrence, or if there have been bilateral pneumothoraces. The preferred surgical options include over-sewing or excision of any large bullae, combined with apicolateral pleurectomy or pleural abrasion. Surgical morbidity in otherwise healthy patients is very low. Risks are greater in those with underlying lung disease, but this must be balanced against the life-threatening potential of further pneumothorax.

Video-assisted thoracoscopic surgery (VATS) offers a less invasive approach to the surgical management of pneumothoraces, but experience is limited. The morbidity

does not seem to be significantly different from that of thoracotomy, and there is a significant chance of recurrence (5–10 per cent). Its role may be limited to those who would be regarded as otherwise unfit for an open procedure.

17.13 Disorders of the thoracic cage and diaphragm

J. M. Shneerson

Introduction

Skeletal disorders of the thorax are an important group of conditions that frequently impair ventilation. They are often associated with respiratory muscle weakness due to neuromuscular disorders, which are described elsewhere. Most of these conditions restrict the development and/or the expansion of the lungs so that alveolar ventilation rather than intrapulmonary gas exchange is primarily impaired.

Disorders of the spine

Scoliosis

Scoliosis is defined as a lateral curvature of the spine, but it is invariably also associated with rotation of the vertebral bodies. This results in an unstable lordosis rather than a kyphosis, and hence the frequently used term kyphoscoliosis is inaccurate. A mild degree of scoliosis is very common. Angles of curvature of 5° or 10° have been used to define when it becomes pathological, but these are arbitrary figures. Postural scoliosis can be distinguished from a structural scoliosis by its temporary nature and because it disappears on bending forward.

The age of onset and natural history of scoliosis vary according to its cause (Table 1). When it is due to a neuromuscular disorder ('paralytic' scoliosis) it usually arises during childhood or adolescence, or in poliomyelitis within about 2 years of the acute infection. Typically, the curve has a long C shape and may be severe. The scoliosis is due to asymmetrical weakness of the axial muscles so that the spine rotates and moves to one side. Weakness of chest wall muscles is almost invariable, occurs in a pattern which is characteristic of each disorder, and may have a profound influence on the clinical features.

When the scoliosis is due to a congenital abnormality, such as a hemivertebra or a segmentation defect, it usually becomes apparent early in childhood. The scoliosis of neurofibromatosis and Marfan's syndrome is probably due to an abnormality of connective tissue. Scoliosis due to pleural or pulmonary disease is less common than in the past, now that chronic infections are less frequent and more successfully treated.

The commonest type is adolescent idiopathic scoliosis, where the spinal deformity develops at the time of the pubertal growth spurt. It is around four times as common in girls as in boys, and the convexity of the deformity is on the right in 80 per cent of cases. The scoliosis may continue to worsen slightly even after growth of the spine stops. An infantile form of idiopathic scoliosis is less common, and, although it often resolves spontaneously, it can progress to a severe deformity.

Pathophysiology

The most important organic consequence of scoliosis is the respiratory abnormality. A direct result is that the compliance of the chest wall is reduced. This is more marked in older subjects, possibly owing to degenerative changes in the costovertebral joints. The compliance of the lungs is also reduced, largely because of their small volume. In addition, the distortion of the rib cage puts the inspiratory muscles at a mechanical disadvantage; those on the side of the convexity of the scoliosis are shortened and those on the side of the concavity lengthened. The vital capacity falls when changing from the sitting to the supine position, implying that diaphragmatic function is impaired. A restrictive defect and reduction of the maximum inspiratory and expiratory pressures develops even in the absence of any muscle weakness, but is more marked if this is present.

In adults with severe scoliosis, exercise capacity is linked to the degree of reduction of the vital capacity and the forced expiratory volume in 1 s (FEV_1). The tidal volume increases initially and then remains constant, whilst respiratory rate rises as exercise becomes more intense. Ventilation at any given oxygen uptake is greater than normal, and maximal exercise ventilation, which limits exercise capability, is often severely curtailed. The cardiac output may increase normally during exercise, but pulmonary artery pressure rises rapidly, and its rate of increase is linearly related to oxygen uptake and inversely related to the vital capacity.

In mild scoliosis, the arterial blood gases are often normal, but the first abnormality is a fall in the partial pressure of oxygen (PO_2). This is due to suboptimal ventilation and perfusion matching, particularly at the bases of the lungs. Even when the anatomical distortion of the two lungs is gross, there is usually rather less difference in function between the two lungs than might be expected. Acute ventilatory failure may be precipitated by, for instance, a chest infection or asthma, but chronic hypoventilation initially occurs during sleep. Sleep is associated with loss of the voluntary respiratory drive and a reduction in the reflex drive in response to hypoxia, hypercapnia, and other stimuli. Muscle activity is reduced, and whereas in non-rapid eye movement sleep (NREM) this affects all the respiratory muscles to an equal extent, in rapid eye movement sleep (REM) diaphragmatic activity is selectively retained. Relaxation of the other respiratory muscles is more intense than during NREM and loss of activity in the upper airway dilator muscles increases the upper airway resistance and the work of the chest wall muscles.

These changes during sleep are particularly important in scoliosis, where the diaphragm is attached to an asymmetrical rib cage and where the respiratory pump often has little reserve. The effects of sleep are accentuated when the scoliosis is the result of neuromuscular disorders, because the presence of muscle weakness in addition to the skeletal deformity reduces tidal volume and increases respiratory frequency, leading to alveolar hypoventilation. Arousals from sleep initially occur in REM, which becomes fragmented, and at a later stage in NREM, with loss particularly of stages 3 and 4. Sleep fragmentation itself reduces the respiratory drive and impairs the strength and probably the endurance of the respiratory muscles, promoting a vicious circle in which there are progressively more respiratory-induced arousals and a deterioration in respiratory drive and muscle function. Central apnoeas and hypopnoeas develop; hypercapnia then appears during wakefulness as well as in sleep.

Chronic hypercapnia during the day is uncommon in childhood and is determined by the following:

1. Age of onset: if the scoliosis appears before the age of about 8 years it may prevent normal alveolar multiplication so that the lungs fail to develop fully. The capillary surface area is reduced and there is an increased risk of developing respiratory and right heart failure later in life. The later onset of adolescent idiopathic scoliosis is probably the major reason why these complications only rarely occur in this condition.
2. Level of the scoliosis: in general, the higher the curve in the thoracic spine, the more marked are the cardiac and respiratory problems. Thoracolumbar or lumbar scoliosis has virtually no effect on respiration.
3. Severity of scoliosis: the angle of scoliosis is closely related to the reduction in lung volume. This association is seen with the residual volume, total lung capacity, and functional residual capacity, as well as with vital capacity, except in patients with neuromuscular disorders, where the changes in lung volumes are

due to the weakness of the respiratory muscles as well as the degree of deformity. The changes in lung volumes become significant when the angle of scoliosis is greater than about 100°.

4. Presence of muscle weakness: the functioning of the respiratory muscles is impaired in scoliosis, and any further loss of strength or endurance due to neuromuscular disorders may precipitate respiratory failure. Conversely, respiratory function often worsens in neuromuscular disorders when scoliosis develops as the strength of the axial muscle becomes asymmetrical.
5. Small lung volumes: respiratory failure usually occurs when lung volumes have been reduced to a degree such that vital capacity is less than 1.0 to 1.5 1.

Hypoxia causes pulmonary vasoconstriction which increases the pulmonary vascular resistance and leads to pulmonary hypertension. If this is prolonged, right ventricular and atrial hypertrophy develop. Significant pulmonary hypertension is rarely seen unless the arterial PO_2 is less than around 8 kPa. Pulmonary hypertension by itself rarely causes right heart failure, and the exact mechanisms underlying this are uncertain. The increase in sympathetic activity and circulating catecholamines associated with hypoxia cause renal vasoconstriction and a reduction in renal blood flow. This activates the renin–angiotensin–aldosterone system leading to sodium and water retention. Hypercapnia is associated with an increase in renal tubular hydrogen ion excretion with sodium reabsorption in exchange for hydrogen. This leads to fluid retention, which is accentuated by an increase in antidiuretic hormone secretion. Hypercapnia probably also increases capillary permeability, which contributes to the appearance of oedema.

Polycythaemia occasionally occurs as a result of erythropoietin release from the kidneys in response to hypoxia. This adaptive mechanism increases the oxygen content of the blood, but also increases blood viscosity, which increases the work of the right and left ventricles and predisposes to arterial and venous thrombosis.

Symptoms and physical signs

The earliest symptom of scoliosis is usually a change in the appearance of the patient, such as asymmetry of the shoulders or prominence of the posterior rib hump. Backache is a late and uncommon symptom. With mild curvatures there may be no respiratory symptoms, but mild shortness of breath on exertion is common. A change in this often signifies the development of complications such as respiratory failure. Orthopnoea suggests that diaphragmatic function is impaired. When respiratory failure develops, fatigue, ankle swelling, and even syncope may indicate that pulmonary hypertension and right heart failure are present. Frequent awakenings during sleep, associated with excessive daytime somnolence, indicate sleep fragmentation due to apnoeas and hypopnoeas, and are important symptoms that warn of impending respiratory failure.

Physical examination may reveal the cause of the scoliosis, such as Marfan's syndrome or neurofibromatosis, and other congenital abnormalities. Any associated muscle weakness or congenital heart disease may be apparent. Rib cage expansion may be predominantly lateral or anterior, or achieved by extension of the spine. In some subjects, chest expansion is mainly oblique because of the rotation of the spine, and some areas of the chest wall may move paradoxically. Accessory muscle action is usually prominent. The presence of central cyanosis indicates that the arterial oxygen saturation is below around 80 per cent. Signs of hypercapnia may also be present. These include tachycardia, large volume pulse, peripheral venous dilatation, papilloedema, a flapping tremor, reduction in tendon reflexes, small pupils and, if severe, confusion and coma (CO_2 'narcosis').

Investigations

The severity of scoliosis can be demonstrated radiologically, but chest radiography is often unhelpful in thoracic scoliosis because rotation of the spine obscures much of the lung fields. This can be overcome by obtaining an oblique view of the chest which, by aligning the spine behind the heart, simulates a posteroanterior view. Lung function testing reveals a restrictive defect with reduction in all lung volumes, although the change in residual volume is least marked and, therefore, the ratio of residual volume to total lung capacity is increased. KCO is raised, as in other chest wall disorders that cause a restrictive defect and in which the lung tissue is normal. Maximum inspiratory and expiratory pressures and trans-diaphragmatic pressure are reduced. Chest wall and lung compliance are less than normal, and exercise tolerance is impaired. Arterial blood gas analysis reveals a slightly low PCO_2 in mildly affected subjects, but later in the course of disease a rise in PCO_2 and a proportional fall in PO_2 develop. Sleep studies show a variable degree of hypoxia and hypercapnia which are usually most marked in REM sleep. Electrocardiography and echocardiography may be required to establish whether congenital heart disease is present and, if so, to identify the abnormality.

Prognosis

The prognosis in adolescent idiopathic scoliosis is virtually normal, but life expectancy is reduced in many of the other forms of scoliosis. This is particularly so in scoliosis of early onset, when it is both severe and high in the thorax and associated with respiratory muscle weakness, low vital capacity, and abnormal blood gases.

In most subjects the cause of death is either cardiac or respiratory. Pneumonia and respiratory failure are particularly common in neuromuscular disorders, but hypoxic dysrhythmias during sleep are probably responsible for some deaths. Congenital heart defects, which have an increased prevalence in subjects with scoliosis, particularly when this is due to a congenital abnormality or of the idiopathic type, also contribute to mortality.

Treatment

Mild scoliosis does not need any specific treatment. The prognosis is normal and there is minimal respiratory deficit. However, as the scoliosis becomes more severe, spinal fusion or a costectomy, in which the parts of the ribs comprising the posterior hump are removed, may be of cosmetic value. Spinal fusion may also be required to prevent progression of the scoliosis, to stabilize the spine, particularly in neuromuscular disorders, and in selected cases to try to improve cardiac or respiratory function or to prevent its deterioration.

The value of spinal fusion to prevent cardiorespiratory deterioration in adolescent idiopathic scoliosis is still under debate. A large number of studies of respiratory function before and after surgery have shown remarkably little change in lung volumes, blood gases, or exercise ability. However, in some patients with muscle weakness, particularly Duchenne's muscular dystrophy, the rate of fall of the vital capacity can be slowed considerably, and it can even be improved in patients who have had poliomyelitis. Despite these short-term improvements, there have been no studies which indicate whether or not spinal fusion performed in childhood or adolescence prevents respiratory failure from appearing later in life. If respiratory failure does develop, any acute illness which may have precipitated it should be actively treated. This is most commonly an infection or bronchial asthma. Non-invasive ventilation or endotracheal intubation and ventilation may be required during the acute illness. If the latter is needed, the patient is then weaned from this either completely or onto a non-invasive method of long-term respiratory support.

Chronic ventilatory failure usually responds to long-term mechanical respiratory support. Administration of oxygen at night and/or during the day may be dangerous because of the risk of hypercapnia. Nasal or face mask positive pressure ventilation is the treatment of choice, but a negative pressure system, such as a cuirass or jacket, is an alternative. Non-invasive ventilation is usually only required during sleep, but some patients benefit from 1 or 2 h treatment during the day as well. A tracheostomy is rarely required to provide ventilatory support, but in complex neuromuscular disorders it may be indicated to bypass upper airway obstruction, for instance due to vocal cord adduction, or to gain access to the tracheobronchial tree to aspirate secretions, or to protect the airway from aspiration of material from the pharynx.

Non-invasive ventilatory support can considerably improve the quality of life, arterial blood gases, maximum inspiratory and expiratory pressures, and the quality of sleep, as well as reducing the number of visits required by general practitioners and the quantity of drugs prescribed. Survival once treatment has been instituted is around 75 per cent at 5 years and 60 per cent at 10 years (Fig. 1).

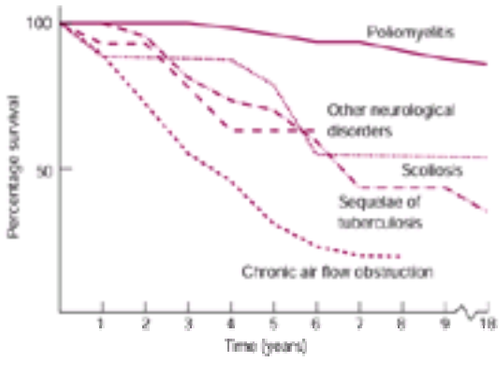

Fig. 1 Actuarial survival during treatment with ventilatory assistance for respiratory failure. (Reproduced with permission from Shneerson JM (1988). *Disorders of ventilation*, Blackwell, Oxford.)

Kyphosis

Exaggeration of the normal thoracic kyphosis is most commonly due to osteoporosis and is not usually associated with any significant changes in respiratory function. The exception to this is when a very sharp kyphosis (gibbus) develops. This is usually caused by tuberculous osteomyelitis of the spine (Pott's disease), although other conditions such as radiotherapy can cause a similar picture.

The spine becomes rigid in the region of the gibbus, and when tuberculosis is the cause the costovertebral joints also become ankylosed and limit the expansion of the rib cage. A restrictive defect in which the total lung capacity is reduced more than the residual volume is characteristic, but respiratory problems are uncommon unless the gibbus is high in the thoracic spine and develops in early childhood. This is probably because the thoracic deformity prevents the normal development of the lungs in a similar way to early-onset scoliosis. Hypoxia and hypercapnia appear during sleep before they become apparent during wakefulness, but may be severe. Pulmonary hypertension and right heart failure frequently develop once chronic hypercapnia has become established.

Slight breathlessness on exertion is common in the presence of a gibbus, but is rare in other types of kyphosis. Physical examination reveals the spinal deformity and limitation of rib cage expansion.

The posteroanterior chest radiograph shows superimposition of the spinal deformity on the lung fields and heart, which makes it difficult to interpret. The extent and severity of the kyphosis is usually well seen on a lateral projection. The typical changes in lung volumes have been described above. The arterial P_{O_2} and P_{CO_2} are usually normal, and, as in scoliosis, the earliest abnormalities are revealed by sleep studies.

Treatment of the acute tuberculous infection with chemotherapy often prevents a gibbus from developing. Once it has been established and respiratory failure has developed, the only effective treatment is long-term respiratory support. This is best provided non-invasively by a nasal positive pressure ventilator, rather than a negative pressure system, since the sharp kyphosis makes it difficult to lie in the supine position required for negative pressure ventilation.

Straight-back syndrome

In this disorder the normal thoracic kyphosis is absent or greatly reduced. This may result in a mild restrictive ventilatory defect, but cardiac problems are more prominent. The heart and great vessels may be compressed between the anterior rib cage and the spine with results similar to those seen in pectus excavatum. The right ventricular outflow tract or pulmonary artery may be narrowed, causing a systolic murmur, and occasionally right ventricular filling is impaired.

Ankylosing spondylitis

The initial manifestation of ankylosing spondylitis is usually painful inflammation of the sacroiliac joints, but this may spread to affect almost any joint including the intervertebral, costovertebral, manubriosternal, costochondral, and chondrosternal joints. When the inflammatory phase of the disease subsides, the joints become ankylosed and the spinal ligaments calcify.

The effect of ankylosing spondylitis on the thorax is that the rib cage becomes rigid. There is little spinal mobility, and a pronounced kyphosis often develops. The changes in lung volumes are characteristic in that, unlike all other skeletal disorders affecting the thorax, functional residual capacity increases. This is because the rib cage becomes fixed at its own relaxation volume. This is greater than the normal functional residual capacity which is influenced by the inward pull of the elastic recoil of the lungs. Total lung capacity and vital capacity are slightly reduced, and residual volume often increases.

The immobility of the rib cage leads to atrophy of the intercostal muscles and both maximal inspiratory and expiratory pressures are reduced. However, there is no impairment of diaphragmatic function and this largely compensates for the restriction of rib cage expansion. The ventilatory responses to exercise are virtually normal and exercise is usually limited by circulatory rather than respiratory factors. Respiratory failure is extremely uncommon in ankylosing spondylitis, probably as a result of the normal diaphragmatic function, unless another complication develops, which may be one of the following:

1. Air flow obstruction: cricoarytenoid arthritis is a feature of ankylosing spondylitis and may present with stridor, hoarseness of the voice, breathlessness, obstructive sleep apnoeas, or respiratory failure.
2. Pleural thickening and effusion: these rare complications of ankylosing spondylitis may precipitate respiratory failure.
3. Aspiration pneumonia: oesophageal motility is often impaired in ankylosing spondylitis and aspiration pneumonia may develop.
4. Bullae: apical fibrobullous lung disease is a feature of ankylosing spondylitis and may be complicated by opportunist infections such as *Aspergillus fumigatus* or saprophytic Mycobacteria, and occasionally pulmonary tuberculosis.
5. Abdominal surgery: this restricts diaphragmatic function on which adequate respiration depends. Conversely, thoracic surgery has relatively little effect on respiration because of the small contribution that rib cage expansion plays.

Chest pain during sudden movements such as coughing and laughing is common if the active phase of inflammation affects the thorax. These symptoms, which originate in either the joints or the muscles, become less prominent as the disease advances. Breathlessness and other respiratory symptoms are uncommon. Occasionally, cricoarytenoid arthritis may present with hoarseness, stridor, or breathlessness, and extensive fibrobullous disease may also cause breathlessness.

The most obvious physical sign is restriction of rib cage movement associated with prominent accessory muscle activity and abdominal respiratory movements.

Chest radiography may show calcification of the paraspinal ligaments (bamboo spine) and reveal evidence of complications of ankylosing spondylitis such as pleural thickening, aspiration pneumonia, and apical fibrobullous disease. The changes in lung volumes have been described above. Chest wall compliance is reduced but lung compliance is normal. The K_{CO} is increased and arterial blood gases are normal during both rest and exertion.

Physiotherapy and non-steroidal anti-inflammatory drugs may improve vital capacity and chest expansion, particularly in the early phase of the disease or during acute exacerbations.

Disorders of the sternum and ribs

Congenital abnormalities

Congenital abnormalities of the ribs and sternum rarely cause any important respiratory problems. Occasionally, multiple congenital rib abnormalities may lead to paradoxical movement of the chest wall or impair diaphragmatic function if they occur in the region of the insertion of this muscle. Severe congenital defects of the sternum, such as agenesis or a bifid sternum, are rare, but may require surgery in the neonatal period in order to stabilize the anterior chest wall.

Pectus excavatum

Pectus excavatum is a depression deformity of the sternum which is often present at birth but may worsen during the adolescent growth spurt. It is occasionally familial and may be associated with other abnormalities such as the straight-back syndrome or scoliosis. It appears to result either from an increased inward pull on the sternum by the sternal diaphragmatic fibres or from an abnormally compliant chest wall.

Transient paradoxical movement of the sternum during respiration is seen in eonates, particularly in the presence of upper airway obstruction or pneumonia. The

sternal depression may become permanent even if the cause, such as enlarged tonsils, resolves completely.

In adults pectus excavatum rarely causes any symptoms. Lung volumes are normal or only slightly diminished, and chest wall mobility appears to be normal. Arterial blood gases are normal both at rest and during exercise. Right ventricular filling can be impaired if the heart is compressed between the depressed sternum and the spine, and compression of the pulmonary outflow tract may cause a systolic murmur. These problems are most marked in the erect position and during exercise. Occasionally atrial arrhythmias develop. Surgery is sometimes indicated for cosmetic reasons, although the result can be disappointing. It has little or no effect on the mild restrictive defect or exercise ability, except in the rare situation when right ventricular filling is impaired or atrial arrhythmias have developed.

Pectus carinatum

Pectus carinatum is a protrusion deformity of the sternum in which the chest is often narrowed transversely as well. It becomes most marked during the pubertal growth spurt, although it may be present from birth and is occasionally associated with severe childhood asthma or ventricular septal defects. It is probably the result of excessive growth of the ribs or costal cartilages, and if this is asymmetrical the sternum becomes oblique.

The respiratory consequences of pectus carinatum have hardly been investigated. Chest pain may arise at the insertions of the intercostal muscles anteriorly, or in the costal cartilages and anterior ribs. Lung volumes appear to be normal, and surgery is indicated only for cosmetic reasons and not in order to improve respiratory function or exercise ability.

Asphyxiating thoracic dystrophy (Jeune's disease)

Asphyxiating thoracic dystrophy is a generalized disorder of cartilage in which the radiological changes are most prominent in the pelvis, phalanges, and other limb bones. Like the other long bones, the ribs are shortened so that the rib cage becomes narrowed. Lung development may be impaired as a result, and respiratory failure often appears during infancy or childhood. Surgical reconstruction of the rib cage with splitting of the sternum to enable lung growth to occur has been largely unsuccessful.

Acquired abnormalities

Flail chest

A flail chest is one in which multiple rib fractures cause paradoxical movement of the chest wall during respiration. It may be associated with other injuries, such as rupture of the aortic arch or spleen, and with fractures of the skull and long bones. It is frequently associated with pulmonary contusion, pneumothorax, or haemothorax.

Surgical stabilization of the chest wall is rarely required. In milder cases, sufficient analgesia to enable the patient to cough adequately may be all that is required, as long as the paradoxical movement does not impair alveolar ventilation. If it is more severe, positive pressure ventilation achieves 'pneumatic splinting' of the flail segment. The effectiveness of this has not been definitely established, but it appears that positive end expiratory pressure or continuous positive airway pressure is beneficial by preventing any negative pressure swings within the pleura.

Thoracoplasty

The operation of thoracoplasty was developed for the treatment of pulmonary tuberculosis. Varying lengths of up to 11 ribs were removed in order to collapse the chest on the affected side. It has been superseded by antituberculous chemotherapy, but is still occasionally required to treat chronic infections, particularly when there is a problem in obliterating the pleural space after pulmonary resection. It is estimated that as many as 30 000 operations were carried out in the United Kingdom between 1951 and 1960, and many of these patients still survive. Increasing numbers of this important cohort are being seen by chest physicians because of the late complications of the surgical procedure.

The consequences of thoracoplasty on respiratory function have been hard to elucidate because they are often combined with the effects of the underlying lung disease for which the surgery was carried out, and those of other treatments such as lung resection. However, the removal of the ribs has the direct result of flattening the chest and reducing the volume of the thorax. The normal movements of the rib cage may be impaired and paradoxical movement at the site of the thoracoplasty is common. The compliance of the chest wall is reduced, and it may fall further because the small range of movements of the costovertebral joints after surgery probably induces soft tissue changes which further limit the mobility of these joints. Chest wall compliance is also reduced by the almost invariable development of a thoracic scoliosis. This is convex to the side of the thoracoplasty and may progress for several years after the surgery. The severity of the scoliosis correlates with the number of ribs removed, but also depends on the details of the surgical technique.

Respiratory muscle function is impaired by a thoracoplasty. The intercostal and shoulder girdle muscles are directly damaged by the surgery, and distortion of the rib cage and the development of a scoliosis put the inspiratory muscles at an additional mechanical disadvantage. Diaphragmatic excursion is reduced, particularly on the side of the thoracoplasty, but also occasionally contralaterally.

The combination of reduced chest wall compliance and impaired respiratory muscle function accounts for the restrictive defect. All lung volumes are reduced, and in general the severity of the restrictive defect is proportional to the number of ribs that have been resected. A rapid respiratory rate with a small tidal volume is the characteristic respiratory pattern, particularly during exertion. Exercise is limited by ventilatory factors rather than by the cardiovascular system. In some patients, chronic air flow obstruction, which may be due to either tuberculous endobronchitis or the effects of tobacco smoking, may be significant, resulting in a progressive fall in exercise ability and contributing to the development of respiratory failure.

Ventilation and perfusion of the lung on the side of the thoracoplasty are usually reduced equally, so that the arterial $P\mathrm{O}_2$ often remains virtually normal. The function of the contralateral lung is much more important in determining the blood gases. Hypoxaemia usually first appears during sleep, as in scoliosis, and may be associated with hypercapnia. The presence of daytime hypercapnia correlates with the reduction in maximal inspiratory and transdiaphragmatic pressures.

The symptoms of patients with a thoracoplasty are similar to those with a scoliosis, but if a productive cough develops, recurrence of pulmonary tuberculosis should be suspected and investigated. Right heart failure often develops insidiously, either when respiratory failure appears or subsequently. It may be manifested by progressively worsening ankle swelling and fatigue. Physical examination reveals a thoracotomy scar and a flattened area of chest in the region of the thoracoplasty which may move paradoxically. Accessory muscle activity, particularly on the side of the thoracoplasty, is often marked.

The chest radiograph shows the extent of the thoracoplasty, other features which indicate the site and extent of previous tuberculous infection, and the sequelae of treatment such as a previous phrenic nerve crush or an artificial pneumothorax. This often causes extensive, calcified pleural thickening. The characteristic physiological defect is restrictive, but airflow obstruction may also be significant. Maximum inspiratory and expiratory pressures and transdiaphragmatic pressures are reduced. Most patients are mildly hypoxic, but later in the clinical course the arterial $P\mathrm{CO}_2$ may rise, particularly during sleep.

Life expectancy is reduced after a thoracoplasty for pulmonary tuberculosis: death occurs particularly from respiratory but also from cardiac causes. These complications are related to the extent of the tuberculosis and to whether or not an artificial pneumothorax was induced on the contralateral side to the thoracoplasty, since this often leads to pleural thickening and may indicate extensive tuberculous damage of the underlying lung. Respiratory failure can develop quite suddenly after a long period of stability, even when an acute illness such as a chest infection is not responsible.

Conventional treatment of airflow obstruction with, for instance, bronchodilators may be effective and right heart failure may respond to diuretics and angiotensin-converting enzyme inhibitors

Chronic ventilatory failure usually responds well to nocturnal, non-invasive respiratory support. Some patients can be managed adequately with oxygen during the day and/or at night as long as the $P\mathrm{CO}_2$remains normal or only slightly raised. When respiratory support is required, a nasal positive pressure ventilation or a negative pressure system such as a cuirass or jacket used at night is usually adequate initially. Some patients gradually require more intensive support, so that treatment is needed during the day as well as at night. This deterioration may be due to progressive worsening of small airway obstruction or respiratory muscle function, or to a

fall in oxygen delivery to the tissues caused by a deteriorating cardiac output associated with advancing pulmonary hypertension.

Disorders of the diaphragm

Aetiology

Diaphragmatic paralysis or paresis may be due to lesions affecting either the diaphragm itself or the phrenic nerve, its nucleus, or higher control centres or pathways. The most common causes of diaphragmatic weakness are shown in Table 2. Often no cause is found in unilateral weakness, and it is presumed to be due to a cryptogenic phrenic neuropathy, either as part of a widespread peripheral neuropathy or isolated to the phrenic nerves.

Pathophysiology

Unilateral weakness of the diaphragm causes it to move upwards (paradoxically) into the thorax during inspiration, instead of descending. This decreases the tidal volume and the mechanical efficiency of breathing. It is worse in the supine position when the weight of the abdominal contents pushes the paralysed diaphragm further into the thorax and decreases the functional residual capacity. The diaphragm is splinted in an expiratory position so that it moves relatively little even though it is paralysed. When the subject lies on one side, the lower half of the diaphragm behaves in this way if it is paralysed, but if the upper half is paralysed it moves paradoxically.

The loss of inspiratory muscle strength is partially compensated by recruitment of intercostal and accessory muscles, but the maximum inspiratory and transdiaphragmatic pressures are reduced. The vital capacity in the upright position is approximately 20 to 25 per cent less than normal and a further fall of about 15 per cent occurs when lying supine. Similar changes in the total lung capacity and functional residual capacity occur. The residual volume is unchanged and expiratory muscle strength is largely preserved.

The distribution of ventilation and perfusion is affected by unilateral diaphragm weakness. Ventilation is slightly diminished, particularly at the base on the side of the diaphragmatic paralysis in the sitting position, but this is more marked when supine. Similar changes occur with perfusion on a regional basis, but ventilation–perfusion matching is impaired and hypoxia results. Hypercapnia does not occur during wakefulness or sleep.

The physiological abnormalities seen with bilateral diaphragmatic weakness in adults are much more marked than in unilateral diaphragmatic disorders. The diaphragm moves paradoxically during inspiration and expiration, and intrapleural pressure changes are transmitted across it so that abdominal pressure falls during inspiration and the anterior abdominal wall moves paradoxically. The maximum transdiaphragmatic pressure falls in proportion to the degree of diaphragm weakness, and since the diaphragm is the main inspiratory muscle, the maximum inspiratory pressure is correspondingly reduced. The vital capacity in the sitting position is about 50 per cent of that predicted and may fall by a further 50 per cent when supine. The influence of the supine position is greater than with unilateral diaphragmatic weakness because the weight of the abdominal contents pushes both halves of the diaphragm into the thorax. Ventilation is particularly reduced at the bases in the supine position, with less change in perfusion so that the arterial P_{O_2}falls. This postural change is partly responsible for the hypoxia that has been observed during sleep, but the rapid respiratory rate, small tidal volume, and short inspiratory time contribute to this and to hypercapnia.

Symptoms and physical signs

Unilateral diaphragmatic paralysis in adults rarely causes symptoms unless there is coexisting pulmonary disease or weakness of other respiratory muscles. In contrast, bilateral weakness can cause severe breathlessness. This may occur during exertion, but a specific feature is orthopnoea. This occurs within a few seconds of lying flat and is relieved promptly by sitting up, in contrast to left ventricular failure and nocturnal asthma with which it is frequently confused. Breathlessness may also occur when standing in water since the passive inspiratory descent of the diaphragm due to gravity is prevented by the raised extra abdominal pressure.

The physical signs of unilateral diaphragm weakness can be subtle. Dullness to percussion over the lower part of the thorax may be present and the level of dullness may rise paradoxically on the paralysed side during inspiration. The normal inspiratory outward movement of the abdomen may be reduced or absent on the side of diaphragmatic paralysis, and expansion of the lower chest may lag behind the normal expansion of the other side.

The physical signs of bilateral diaphragmatic paralysis are much more clear cut. Orthopnoea is usually readily apparent and the abdomen moves paradoxically inwards as the diaphragm ascends during inspiration. A maximum transdiaphragmatic pressure of less than 30 cmH_20 is necessary for this sign to be detected. The accessory muscles are active, particularly in the supine position. The quality of sleep is often poor and as a result excessive daytime somnolence may be a problem. Bilateral, basal dullness due to the high diaphragms is characteristic, but can be mimicked by bilateral pleural effusions.

Investigations

The chest radiograph in unilateral diaphragmatic paralysis shows whether the affected diaphragm is elevated and usually reveals any adjacent mass that may be responsible. If there is bilateral paralysis, both the diaphragms are raised. There is often some basal linear shadowing due to subsegmental lung collapse. Diaphragmatic screening or ultrasound examination reveals that the diaphragm moves paradoxically, particularly during sniffing. This test should be carried out in the supine position with a weight on the abdomen. These precautions prevent abdominal muscle contraction during expiration from mimicking diaphragmatic activity by reducing the end expiratory volume below functional residual capacity, so that inspiration then occurs through the elastic recoil of the lungs and chest wall. In the upright position, the effect of gravity on the abdominal contents can lead to inspiration without any diaphragmatic activity.

A low vital capacity, which falls further in the supine position, is the hallmark of diaphragmatic weakness, particularly when this is severe and bilateral. All lung volumes are reduced except for the residual volume since expiratory muscle strength is largely preserved. Maximum inspiratory pressure is also reduced, but diaphragmatic weakness can be more specifically diagnosed by estimating the transdiaphragmatic pressure. This can be carried out by asking the patient to sniff or to take a maximum inspiratory effort, or by magnetic or percutaneous electrical stimulation of the phrenic nerve in the neck. Care is required to carry out these investigations using a standardized method in order to obtain repeatable results. The function of the phrenic nerve can be estimated by measuring its conduction time. This is normally less than about 9.5 ms, but is prolonged if the nerves are diseased.

The arterial $P_{O_2}$is characteristically slightly reduced, with a normal P_{CO_2}during the daytime and in sleep as long as pulmonary function is normal and there is no other muscle weakness. If either of these are present, however, bilateral diaphragmatic weakness can cause hypercapnia with profound hypoxia during sleep.

Treatment

Plication for hemidiaphragmatic paralysis is rarely required in adults unless coexistent pulmonary disease is severe enough to cause breathlessness. Bilateral plication is not effective and mechanical respiratory support is often required if there is bilateral weakness. Treatment with nasal positive pressure ventilation or a negative pressure ventilator, such as a cuirass or jacket is usually required, although rocking beds have also been found to be effective in the past. Ventilatory support is usually needed only at night and until the function of the diaphragm or phrenic nerve improves. Phrenic nerve pacemakers are only indicated when diaphragmatic weakness is due to lesions above the phrenic nerve nucleus in C3 to 5 or 6. The commonest cause of this is a high cervical spinal cord injury. Breathlessness on exertion often remains a problem, but may lessen as other inspiratory muscles partially compensate for diaphragmatic weakness.

17.14.1 Lung cancer

S. G. Spiro

General epidemiology

Lung cancer is the most common malignant disease in the Western world. It has shown the greatest relative and absolute rise in mortality of any tumour this century in England and Wales, and particularly in Scotland. It causes 38 000 deaths per year in England and Wales, with 80 per cent of these occurring in men. In the European Community, there were 1.35 million deaths per annum in men (the highest death rate from any tumour) and 229 000 deaths per annum in women during the period 1978 to 1982. In the United States, it has been increasing in incidence by up to 10 per cent per year since the 1930s, but over the last decade this trend has levelled off, particularly in men. Nevertheless, approximately 120 000 American men die of lung cancer each year; the figure for women being 34 000, similar to that for breast cancer.

Age-standardized mortality rates for cancer for 1985 to 1989 show that in the European Community lung cancer in men was by far the commonest cause of death. Belgium has the highest mortality (77.16 deaths per 100 000 population) with Scotland (75.9) second, and England and Wales (60.9) fifth. The figures for Central and Eastern Europe are worse in that the death rates for lung cancer are rising exponentially, particularly in men—75.8/100 000 in the Czeck Republic, 74.0 in Hungary, 69.4 in Poland, and 68.7 in Slovakia. For females, Scotland has the highest incidence (27.2, equal to the rate of breast cancer in Scottish women), with England and Wales (20.4) third. Age-adjusted lung cancer death rates in Eastern Europe are still considerably less than in the Western countries, ranging from 14.4 in Hungary to 6.8 in Slovakia. Perhaps the worst epidemic is in China where 0.8 million men will die in the year 2000 from smoking-related diseases. The relative risk of dying from lung cancer is about 3.0 in male smokers compared to non-smokers, and 2.0 for female smokers. Of all deaths attributed to tobacco in China, 15 per cent were due to lung cancer.

Aetiological factors

Tobacco

In every country, the increase in mortality from lung cancer has appeared to coincide with an increase in tobacco usage, particularly cigarette smoking, after what seemed to be an appropriate latent interval. Early retrospective studies showed that, amongst patients with carcinoma of the bronchus, there were many fewer non-smokers and many more heavy smokers than among the controls, and that there was an association between the amount smoked and the risk of lung cancer. Prospective studies, amongst which the long-term study of British doctors was particularly informative, confirmed the increased risk of death from lung cancer from any tobacco use, but most specifically that of cigarettes. There was a strong dose–response relationship with the number of cigarettes smoked, illustrated in Table 1. The most important variable in smoking intensity is the number of cigarettes smoked, but other variables include the depth of inhalation, number of puffs, butt length, use of a filter, and the type of tobacco smoked. Further evidence that the relationship was causal came from a study which documented reduction in mortality after stopping smoking: 15 years after cessation the risk of death fell from 15.8 times to twice that in non-smokers, equivalent to 11 per cent of that pertaining in those who continued to smoke.

Globally, there has been a huge change in cigarette consumption. While there has been a drop of 25 per cent and 9 per cent in consumption in the United Kingdom and the United States, respectively, between 1970 and 1985, the overall world consumption has risen by 7 per cent. This is due to huge increases in Asia (22 per cent), Latin America (24 per cent), and Africa (42 per cent). The current epidemic of smoking in China lags behind Western society by 20 years. Thus in China in 1996, the average number of cigarettes smoked per adult male was 11 per day, a figure that that peaked in the West at 10 a day in 1980.

Wide differences in smoking habits in the United Kingdom are seen between social classes, with 57 per cent of unskilled manual workers smoking compared with only 21 per cent of professional workers. During the last 5 years the number of adult men smoking in England and Wales has fallen from 64 to 36 per cent, but has remained at 35 per cent for adult women. The effect of the lower-tar cigarettes has not yet had time to become established.

Passive smoking

Evidence that passive smoking predisposes to lung cancer is far from certain. Approximately 15 per cent of lung cancers occur in non-smokers, and 5 per cent of these have been attributed to passive smoking.

Occupation

A number of different factors have now been identified as associated with lung cancer; subjects who develop this disease as a result of their occupation represent a small but important group. The association of asbestos with lung cancer is now firmly established; various studies have identified that those exposed are at 4.9 to 7.3 times greater risk than those who are not. This risk is much enhanced if the asbestos industry worker smokes cigarettes; one study estimating this at 93 times that for non-smokers not exposed to asbestos. In Norway, it is illegal to employ a smoker in an asbestos-related job. Exposure to radioactive isotopes, mainly radon

daughters, is associated with a higher risk of lung cancer and occurs among various groups of miners, particularly those involved in extraction of pitchblende and uranium. Polycyclic aromatic hydrocarbons are believed to be responsible for the increased risk in workers in gas and coke ovens and in foundry workers. Nickel refining, chromate manufacture, and arsenical industrial workers are also exposed to a higher risk of lung cancer. The amount of lung cancer caused by occupational exposure may well have been underestimated in the past, and a summary of the importance industrial products and processes involved appears in Table 2.

Air pollution

The decline in male mortality is occurring earlier than would be expected from changes in smoking habits. The high mortality figures in the United Kingdom and Germany compared with France and Italy, for example, seem likely to be due in part to heavy industry and coal burning. Analysis by county in the United States shows an association between lung cancer deaths and counties with chemical, petroleum, ship-building, and paper industries. Legislation for cleaner air has caused both environmental and occupational pollution to fall dramatically in the past 30 years, and this has preceded changes in smoking habits.

Pathology

A detailed understanding of the natural history, pathology, and pathogenesis of bronchial carcinoma is becoming increasingly important as the assessment, management, and prognosis of the disease depends largely upon the cell type and the presence or absence of metastases at the time of presentation. It has been estimated that about seven-eighths of a tumour's life will have passed when it is diagnosed and that the vast majority will be disseminated at the time of diagnosis.

Bronchogenic carcinomas seem to arise most commonly in segmental and subsegmental bronchi in response to repetitive carcinogenic stimuli or inflammation and irritation. The mucosal lining is most susceptible to injury at the bifurcation of bronchial structures. Dysplasia is followed by carcinoma *in situ* when the entire thickness of the mucosa may be replaced by proliferating neoplastic cells. These changes may be strictly localized or multicentric. Tumour infiltration follows loss of the basal membrane. The precise origins of small-cell carcinomas remain an enigma, and those of adenocarcinomas are not precisely defined. The latter may arise from the mucosal lining or from the submucosal bronchial mucous glands. A significant number of lung tumours arise in the periphery of the lung, perhaps three-quarters of adenocarcinomas and large-cell anaplastic malignancies, one-third of squamous (or epidermoid) carcinomas, and one-fifth of small-cell carcinomas.

The WHO classification of lung cancer according to cell type and the approximate distribution of each type as a percentage of all lung cancers is shown in Table 3. The squamous-cell tumour has a relatively slow growth rate (volume doubling time, 90 days) and the lowest incidence of distant haematogenous metastasis. Small-cell tumours grow rapidly (volume doubling time, 30 days) and there is very early dissemination by both the haematogenous and the lymphatic routes, with metastasis being present in more than 90 per cent of patients at the time of diagnosis. Adenocarcinomas and anaplastic large-cell tumours occupy an intermediate position. It is now recognized that significant heterogeneity of cell morphology can be visualized within individual tumours. Squamous-cell tumours, adenocarcinomas, and large-cell tumours are often collectively called non-small-cell lung cancers, and the approach to their management differs from that for small-cell lung cancer.

Squamous (epidermoid) carcinoma

These tumours are composed predominantly of flattened to polygonal neoplastic cells that tend to stratify, form intercellular bridges, and elaborate keratin. About 60 per cent present as obstructive lesions in lobar and main-stem bronchi. The tumours tend to be bulky and to produce intraluminar granular or polypoid masses. As a result, distal pneumonia and abscess formation is common, and cavitation is seen in about 10 per cent. The cells are usually well differentiated, but in some cases differentiation is poor and the appearances are those of predominantly anaplastic cells, frequently arranged in the classical pattern of stratifying sheets.

Small-cell (oat-cell) anaplastic carcinoma

This is now recognized as a pathologically and clinically distinct form of lung cancer. Small-cell lung cancer may originate from the amine precursor uptake and decarboxylation (APUD) series of cells. The tumour is composed of neoplastic cells with dark oval to round spindled nuclei and scanty, indistinct cytoplasm arranged in ribbons, nests, and sheets. The cells tend to crush easily on biopsy, and extensive areas may be necrotic. This type of tumour presents as a proximal lesion in 75 per cent of cases and may arise anywhere in the tracheobronchial tree and rapidly invade vessels and lymph nodes, disseminating widely even before symptoms arise from the primary tumour. Extensive, advanced disease exists in more than half the patients at presentation. The cells secrete peptides which cause clinical syndromes in 10 per cent of cases.

Adenocarcinoma

This tumour forms acinar or granular structures, having prominent papillary processes, and may be mucin-provoking. About 70 per cent appear to originate peripherally in the lung and are frequently fairly circumscribed; in about 10 per cent, the initial presentation is a pleural effusion. If related to bronchi, they tend to cuff and stenose the lumen. They occasionally arise in old tuberculous scars.

Large-cell carcinoma

These tumours, which have been described as an unclassified category, include all tumours that show no evidence of maturation or differentiation. They are composed of pleomorphic cells with variable enlarged nuclei, prominent nucleoli, and nuclear inclusions, and abundant cytoplasm; they are mucin-producing in many instances. The tumours tend to be bulky and are often necrotic; they are frequently peripheral, they invade locally, and disseminate widely, with about half the patients having disseminated disease on presentation. Although they are highly malignant and undifferentiated, the cure rate after surgery is surprisingly high, but radiotherapy is ineffective in controlling the disease. Large-cell carcinoma is a smoking-related disease in over 90 per cent of patients.

Bronchioloalveolar carcinoma

There has been considerable controversy as to whether this tumour, which has the least association with tobacco smoking, arises from alveolar or bronchial epithelium, but derivation from the alveolar type II cell has been suggested. The tumour tends to spread as cuboidal or columnar 'epithelium' along the lining of the alveoli, with single or multiple rows of cells and often papillary formation (Fig. 1). There is production of a large amount of mucus in 20 per cent of cases and it is believed that malignant cells shed into the mucus may carry over into the contralateral lung. The tumour can spread within a lobe and occupy it fully. Sometimes, however, the tumour is multicentric in origin, and diffuse nodular lesions are to be found on radiographic examination. Invasion of neighbouring tissue and lymph nodes is common, but extrathoracic spread is unusual. There is some resemblance to metastases from adenocarcinomas emanating from other organs, and this sometimes leads to confusion. The tumour tends to grow along alveolar septae as a framework, and it may be difficult to distinguish from metastatic tumours from colon, breast, or pancreas.

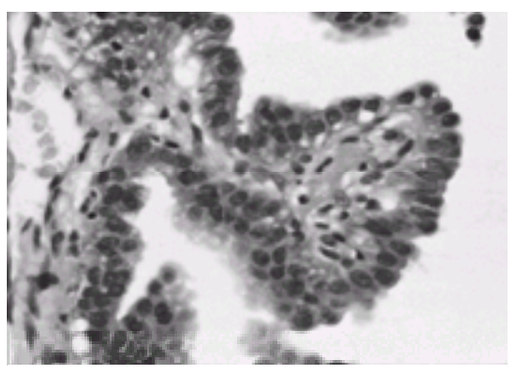

Fig. 1 Bronchoalveolar cell carcinoma: malignant cuboidal epithelium spreads along alveolar walls.

Carcinoid tumours

Carcinoid tumours are described in Chapter 14.8.

Carcinoma *in situ*

Many investigators have suggested that cells undergoing malignant change do not necessarily invade the lungs at the onset of this biological mutation, but continue to exist at a particular location (cancer *in situ*). Exfoliated cancer cells sloughed from such a location may be seen fortuitously by the cytologist; even more rarely, such a site may be biopsied at bronchoscopy.

Genetics and biology

Genetic influences may play a role in the development of lung cancers, particularly in patients under 50. In one study, lung cancers were attributable to a mendelian dominant inheritance pattern in 27 per cent of patients under 50, but only 9 per cent of those over 70.

Both small-cell and non-small-cell lung cancer can be cultured as cell lines which can be transplanted into nude mice. The resultant tumours are morphologically and histologically similar to the original human tumour. Two major categories of cell lines are established for small-cell lung cancer—classic and variant. Classic cell lines account for 70 per cent of the total and are characterized by high expression of neuroendocrine markers such as L-dopa decarboxylase and bombesin/gastrin-releasing peptide, neurone-specific enolase, and creatine kinase-BB. The variant cell lines have selective loss of some of these neuroendocrine markers, and many have substituted amplification of the c-*myc* oncogene. These neuroendocrine and proto-oncogenic properties are thought to be of prognostic significance, playing an important role in regulation of tumourigenesis. In non-small cell lung cancer, approximately 8 per cent of tumours and 20 per cent of tumour cell lines have myc family amplification, and overexpression of these proteins is associated with poorer prognosis.

The ras family of oncogenes (H, K, and N) was the first to be described in association with lung cancer. Ras gene mutations occur in 20 to 40 per cent of non-small cell lung cancer, especially adenocarcinomas, and the presence of K- *ras* mutations is linked with significantly shortened survival.

Lung cancer cells not only show mutations that activate dominant cellular proto-oncogenes, but also genetic mechanisms that inactivate recessive tumour suppressors. The commonest abnormality is a deletion in the short arm of chromosome 3, which is found in over 90 per cent of small-cell lung cancer and 50 per cent of non-small-cell lung cancer patients. Other sites of loss of heterozygosity include 11p, 13q, and 17p. Tumour suppressor genes have been identified in inherited cancers, mainly in studies of familial retinoblastoma. Mutations in P53 occur in 75 per cent of small cell lung cancer and 50 per cent of non-small cell lung cancer. The gene is located on the short arm of chromosome 13q14, and it is thought that it may normally protect cells against accumulation of mutations. Depletions and mutations of P53 are linked with metastatic disease. Alterations of P53 protein have been found in early bronchial neoplasia, and may be a useful marker for the early detection of lung cancer. Other markers, including heterogenous nuclear ribonuclear protein A2/B1 overexpression in sputum, may allow earlier detection of tumours.

Several monoclonal antibodies have been generated against lung-cancer-associated antigens. Thirty-six monoclonal antibodies raised against small-cell lung cancer have been grouped into eight clusters. No antigen is specific for small-cell lung cancer. Antibodies belonging to the major cluster (cluster 1) are directed against the neural-cell adhesion molecule (NCAM), whilst the nature of the other antigens remains unclear. Studies of both small-cell and non-small-cell lung cancer cell lines show that NCAM expression is associated with a neuroendocrine phenotype irrespective of the histological type of lung cancer. Monoclonal antibodies may have a therapeutic value when coupled with a radionuclide or a toxin. Radiolabelled antibodies can be used to detect minimal disease in bone marrow aspirates or biopsy specimens.

The growth factors bombesin/gastrin-releasing peptide, insulin-like growth factor 1, and transferrin stimulate can all stimulate tumour growth. There is much interest in attempts to retard or disrupt these processes.

Clinical features

The clinical features of lung cancer are very variable. In about 5 per cent of patients the presentation is a radiographic abnormality found on routine examination and unassociated with symptoms, but patients may present with extremely advanced disease and die rapidly.

Clinical manifestations may be due to: local presence of the tumour in the lung, including bronchial obstruction or invasion of contiguous structures in the thorax and mediastinum; metastasis through blood or lymph vessels; and endocrine, metabolic, and neurological syndromes.

Cough is the most common initial presenting symptom (Table 4), but because it is a symptom of so many respiratory disorders, the possibility of tumour may be overlooked and cough may be attributed to some other cause, particularly in smokers who have had chronic bronchitis for many years. Patients who have a persistent cough should have a chest radiograph, particularly if they are smokers over 40 years of age. A change in the cough habit is significant and also requires investigation. If the trachea or main bronchi are involved, the cough may be brassy in character and may be accompanied by wheezing or stridor. If cough is manifestly ineffective, involvement of the recurrent laryngeal nerve should be suspected.

Expectoration of sputum may be due to spread of the tumour itself or to infection occurring distal to partial bronchial obstruction. In the early stages of the disease the sputum is often grey and viscid; it is usually purulent in the presence of infection distal to a tumour and in cavitated tumours. The value of sputum cytology in diagnosis is described below.

Haemoptysis, which occurs as a sole presenting symptom in about 5 per cent of cases and at some stage in the disease in 50 per cent of patients, is a symptom not easily ignored by patient or physician. The degree varies from streaking of the sputum with blood to larger amounts, but massive haemoptysis (>200 ml) is rare, except as a terminal event. The most significant description given by patients is that of coughing up blood every morning for several days in succession.

Wheeze may be observed in a few patients. Localized persistent wheeze even after coughing is a significant observation indicating obstruction of a larger or central airway.

Stridor is a feature which is poorly recognized and is often confused with wheeze. It is due to narrowing of the glottis, trachea, or major bronchi, and is best heard after the patient coughs and then breathes in deeply with the mouth open.

Dyspnoea is a presenting symptom in only a small number of patients. As the disease progresses dyspnoea is inevitable, being proportional to the amount of lung involved, either directly by tumour replacement or indirectly by endobronchial disease causing airway narrowing or obstruction. Progressive breathlessness is also a salient feature of malignant pleural and, rarely, pericardial effusion, superior vena caval obstruction, and lymphangitis carcinomatosis.

Chest discomfort is a common symptom, occurring in up to 40 per cent of patients at diagnosis. The discomfort is often of an ill-defined nature and may be described in terms of intermittent aching somewhere in the chest. Definite pleural pain may occur in the presence of infection, but invasion of the pleura by tumour is often painless. However, invasion of the ribs or vertebrae causes continuous, gnawing, localized pain. A tumour in the superior pulmonary sulcus (Pancoast tumour) can cause progressive constant pain in the shoulder, upper anterior chest, or interscapular region, soon spreading to the arm once the brachial plexus is invaded. Other symptoms of this type of tumour include weakness and atrophy of the muscles of the hand, Horner's syndrome, hoarseness, and spinal cord compression at levels D1 and D2.

Lack of energy and, more particularly, loss of interest in normal pursuits are symptoms of great importance; a sensation of vague ill health commonly occurs.

Fever, chills, and night sweats may occur due to chest infection, but fever may very rarely be present in rapidly progressive tumours without evidence of infection, particularly if there are hepatic metastases.

Invasion of adjacent intrathoracic structures gives rise to certain specific clinical features. Involvement of the last cervical and first thoracic segment of the sympathetic

trunk by cancer produces Horner's syndrome. Malignant infiltration of the recurrent laryngeal nerve—almost always the left branch because of its course adjacent to the left hilum—gives rise to vocal chord paralysis. The right recurrent laryngeal nerve is occasionally affected in the base of the neck. Recurrent aspiration pneumonias may follow vocal chord paralysis. Extension of the tumour with invasion or compression of the superior vena cava or by paratracheal lymphadenopathy results in the characteristic features of superior vena caval obstruction—awareness of tightness of the collar, fullness of the head, and suffusion of the face, particularly after bending down, blackouts, breathlessness, and engorgement of veins with a downward venous flow in the neck, the upper half of the thorax, and arms, often accompanied by oedema of the face.

Dysphagia is due to compression of the oesophagus from without by tumour masses and only rarely to direct invasion. Cardiac metastases usually occur late in the disease and are manifested clinically by tachycardia, arrhythmias, pericardial effusion, breathlessness, and cardiac failure. Invasion of the phrenic nerve results in elevation and paralysis of the hemidiaphragm.

The clinical features associated with involvement of the ribs, spine, and pleura are described elsewhere. Very rarely bronchogenic carcinoma causes spontaneous pneumothorax. It must not be forgotten that spread of tumour to the other lung may occur or that synchronous primaries may coexist.

Metastatic lesions from lung cancer may occur in any organ of the body and produce symptoms which form the presenting complaint. Metastases to nodes are frequent and should be sought with great care, particularly those in the scalene area, which are usually the first to be involved and can be palpated. The best position for examination is from behind with the patient seated relaxed in a chair. The side affected usually corresponds to the side of the lung lesion, the exception being that tumours from the left lower lobe may metastasize to the nodes in the right scalene area. Involvement of the nodes in the floor of the supraclavicular fossa is equally common.

Bony metastases are common, particularly in small-cell tumours, and occur predominantly in the ribs, vertebrae, humeri, and femora. Early involvement may be detected by a rise in alkaline phosphatase of bony origin, isotope scanning, or biopsy. Conventional skeletal surveys are often unhelpful and misleading. Liver secondaries are common and may be silent, although a rise in liver enzymes, particularly alkaline phosphatase of liver origin, may be an early sign. Isotope liver scans and ultrasound may detect involvement in a liver which is not clinically enlarged, but as the metastases develop the liver becomes grossly enlarged with an irregular outline. Friction rubs may sometimes be heard over a grossly involved liver. Metastases to brain may account for the presenting symptom in lung cancer in 4 per cent of patients and may be encountered at some time in the illness in 30 per cent. The symptoms simulate those of any expanding brain tumour. The adrenal glands are involved in 15 to 20 per cent of patients, rarely producing symptoms. The skin should be examined for the presence of the typical, slightly bluish, umbilicated lesions of tumour spread. Subcutaneous metastases may be found at almost any site.

Endocrine and metabolic manifestations

It is becoming more apparent that many of the hitherto unexplained and often unusual manifestations of malignant disease are the result of endocrine and metabolic manifestations of the cancer itself. Cancer cells appear to be able to synthesize polypeptides that mimic virtually all the hormones produced by conventional endocrine organs—hence the term 'ectopic hormones'. From time to time the clinical features resulting from ectopic hormone secretion precede those of the pulmonary tumour, emphasizing the importance of a high index of suspicion in such circumstances. Ectopic hormone measurement cannot, however, be used for screening purposes.

Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)

The continued secretion of vasopressin (ADH) in an amount in excess of the body's needs leads to overhydration in both the intracellular and extracellular compartments. The cerebral oedema resulting from water intoxication causes drowsiness, lethargy, irritability, mental confusion, and disorientation, with fits and coma being the most profound features. Peripheral oedema is remarkably rare. The patient is usually asymptomatic until the sodium falls below 120 mmol/l and the hyponatraemia is dilutional in type with a low serum osmolality. Urine osmolality usually exceeds 300 mosmol/kg. The commonest cancer causing this syndrome is small-cell cancer, where it is clinically obvious in 10 per cent of cases, with subclinical involvement detectable by a water-loading test in more than 50 per cent. Restriction of fluid to a daily intake of 700 to 1000 ml may redress the hyponatraemia, but demethylchlortetracycline (demeclocycline) 600 to 1200 mg daily is often highly effective, making water restriction unnecessary. Azotaemia may occur as a result of increased urea production and a mild drug-induced nephrotoxicity so that adjustment of dosage may be necessary. Infusion of hypertonic saline is hazardous, often precipitating cardiac failure or cerebral oedema.

Ectopic ACTH syndrome

Secretion of an adrenocorticotrophic substance by a small-cell carcinoma or bronchial carcinoid leads to bilateral adrenal hyperplasia and to secretion of large amounts of cortisol. The onset of symptoms may be so acute that death may occur within a few weeks, and the typical features of Cushing's syndrome do not have time to develop. Chief clinical features are thirst and polyuria, oedema, pigmentation, and hypokalaemia. Hypertension and profound myopathy may also be present. Serum cortisol is often grossly elevated, with loss of the normal diurnal rhythm; the level is not suppressed by dexamethasone; and hypokalaemic alkalosis can be severe, with plasma potassium frequently below 3.0 mmol/l and HCO_3 above 30 mmol/l. Drugs which block adrenocortical steroid biosynthesis may produce partial and reversible medical adrenalectomy, and metyrapone in doses from 250 mg thrice daily to 1 g four times daily may cause temporary relief of symptoms. Removal of the tumour, if practicable, will cause remission.

Hypercalcaemia (see also Chapter 12.6)

Hypercalcaemia may be associated with ectopic secretion of parathormone by squamous-cell cancers but is more commonly due directly to the presence of multiple bone metastases. The primary tumour may also produce a cyclic-AMP-stimulating factor or a prostaglandin causing hypercalcaemia. Hypercalcaemia is unlikely to cause symptoms unless the serum calcium exceeds 2.8 mmol/l, and levels much higher than this are sometimes encountered. The main clinical features are nausea, vomiting, abdominal pain and constipation, polyuria, thirst and dehydration, muscular weakness, psychosis, drowsiness, and eventually coma. Immediate treatment is to relieve fluid depletion, and large volumes of intravenous saline (up to 5 litres in 24 h) may be required. Corticosteroids (400 mg hydrocortisone or 40 mg prednisolone in 24 h initially) are effective in about half of the cases. However, intravenous diphosphonates followed by oral maintenance therapy is now the treatment of choice. Other treatments which are sometimes effective are calcitonin 200 to 400 units every 8 h, mithramycin 10 to 15 µg/kg by infusion over 4 h every 21 days, aspirin 2 to 4 g/day, and indomethacin 50 to 100 mg/day. The calcium level drops dramatically within 48 h if the tumour is removed.

Gynaecomastia

Swelling of the breasts, which may be painful, occurs mainly in the subareolar area, and there may be atrophy of the testes. The association is chiefly with large-cell carcinomas. Increased gonadatrophin production is the cause.

Other endocrine manifestations

Hyperthyroidism occurs rarely, but neither goitre nor eye signs are prominent features. Spontaneous hypoglycaemia, the masculinizing syndrome in young women, and hyperglycaemia are very rarely encountered. Pigmentation associated with a- and b-melanocyte-stimulating hormone may occur. The carcinoid syndromes are described elsewhere.

Neuromyopathies

The term carcinomatous neuropathy is used to describe those abnormalities of the central nervous system, the peripheral nerves, the muscles, and the autonomic nervous system that occur in association with malignancy. These disorders can be subdivided as follows: myopathies (polymyositis, myasthenia, and dermatomyositis), neuropathies (sensory and mixed sensorimotor, encephalopathy, and myelopathy). Toxic, infective, nutritional, and autoimmune causes have been suggested, but none has been fully substantiated. Neuromyopathies respond variably following treatment of the primary tumour by surgery, radiotherapy, or chemotherapy.

Most neuromyopathies are not tumour-cell-type specific, except for the Lambert–Eaton syndrome seen occasionally in small-cell lung cancer patients. This often precedes the appearance of the tumour by up to 15 months, and is characterized by proximal muscle weakness, depressed tendon reflexes (which often return following repetitive exercise), autonomic features, and difficulty with swallowing. There appears to be an association with HLA-B8 and the IgG heavy-chain allotype

GM2. Prednisolone and 3–4 amidopyridine 10 to 20 mg four times daily are used for treatment.

Finger clubbing and hypertrophic pulmonary osteoarthropathy

Finger clubbing accompanies a variety of intrathoracic disorders. Gross clubbing is readily recognizable; its early presence may best be demonstrated by the ability to rock the nail on its abnormally spongy bed. Clubbing of the toes is usually present also. Its incidence in lung cancer has variously been reported as being between 10 and 30 per cent. Clubbing may disappear after resection of tumour.

Hypertrophic pulmonary osteoarthropathy, which may be preceded by finger clubbing alone, consists of periostitis, arthropathy, and usually gross finger clubbing. It is most commonly associated with lung tumours but is also very common in pleural tumours, preceding the diagnosis of tumour in about one-third of patients. It is much commoner in peripheral lesions and squamous tumours.

The long bones of the extremities are affected by a periosteal reaction resembling elm bark; the changes are symmetrical and affect mainly the distal ends of the bones of the forearms and shins, with the knees and elbows being involved less commonly. Synovial thickening and joint effusions are rare. The typical radiographic appearances are shown in Fig. 2. The affected areas are hot and painful and sometimes oedematous, making walking difficult. Removal of the tumour is followed by immediate regression, but symptoms recur if the tumour recurs. Vagotomy alone is sometimes effective, supporting the theory of a vagal mediation of increased blood flow as an aetiological factor in hypertrophic pulmonary osteoarthropathy.

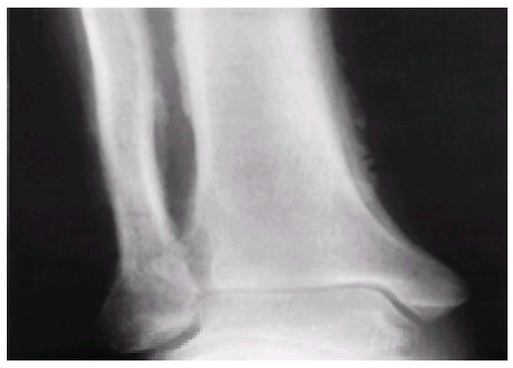

Fig. 2 Hypertrophic pulmonary osteoarthropathy showing persistent new bone formation.

Miscellaneous

The haematological effects of lung cancer are normally non-specific. Normocytic normochromic anaemia is the most common finding. Leucoerythroblastic anaemia denotes bone marrow infiltration and is particularly likely in small-cell lung cancer. Venous thrombosis and thrombophlebitis due to hypercoagulability are common complications of malignancy and may precede the detection of the underlying cancer; recurrent migratory phlebitis resistant to anticoagulation is an ominous feature. Marantic endocarditis is extremely rare, as are skin lesions such as acanthosis nigricans, dermatomyositis, hypertrichosis languinosa, and erythema gyratum repens. Rarely, the nephrotic syndrome due to membranous glomerulonephritis is encountered.

Staging and investigations

The investigations used to make the diagnosis and assess the stage of lung cancer will vary according to the presentation, the cell type, and the age and general condition of the patient.

The very rapid doubling time of small-cell lung cancer causes it to disseminate rapidly and widely, and at diagnosis is very rarely considered operable. However, the slower doubling times for squamous-cell cancers and adenocarcinomas, together with the relatively lesser tendency for the former to disseminate, makes surgery the best option whenever possible for the non-small-cell lung cancers. A precise anatomical staging classification was only applied to lung cancer in 1973 and immediately demonstrated that the prognosis of non-small-cell lung cancer depended strongly on the extent (or stage) of the disease. The introduction of the TNM staging system (T describing the primary tumour, N the extent of regional lymph node involvement, and M the absence or presence of metastases) encouraged an ordered assessment of investigations and selection of cases for surgery. On the basis of this experience, the system was modified in 1997 (Table 5).

Investigations

The following investigations form the basis for the diagnosis and staging of patients with lung cancer.

Radiological assessment

The value of the chest radiograph in the diagnosis and management of pulmonary neoplasm needs no emphasis. No initial examination is complete without a lateral film. Coned views of the ribs may help where rib invasion is suspected clinically.

The finding of a normal radiograph of the chest does not exclude bronchial carcinoma as patients presenting with haemoptysis and a normal chest radiograph are sometimes found to have a central tumour on bronchoscopy. The rounded or ovoid shadow of a peripheral tumour is described in greater detail below; these are sometimes cavitated (Fig. 3). The common appearance of a tumour arising from the main central airways (70 per cent of all cases) is enlargement of one or other hilum (Fig. 4). Even experienced observers sometimes have difficulty in deciding whether or not a hilar shadow is enlarged, and if there is any suspicion, investigation by bronchoscopy and/or CT should be pursued. Consolidation and collapse distal to the tumour may have occurred by the time that the patient presents, with the tumour itself often being obscured in the process. Collapse of the left lower lobe is often hard to identify (Fig. 5), as is a tumour situated behind the heart (Fig. 6). Apically located masses or superior sulcus tumours (Pancoast tumours) may be misdiagnosed as pleural caps, and often have a long history of pain in the distribution of the brachial nerve roots. Loss of the head of the first, second, or third rib is not unusual (Fig. 7).

Fig. 4 Enlarged right hilum. Bronchoscopy revealed a tumour in the right intermediate bronchus.

Fig. 5 Collapsed left lower lobe showing loss of the medial third of the left diaphragm.

Fig. 6 Squamous-cell carcinoma lying behind the heart in the left lower lobe.

Fig. 7 Huge apical tumour with destruction of posterior parts of the second and third ribs.

The mediastinum may be widened by enlarged nodes. Involvement of the phrenic nerve may lead to paralysis and elevation of the hemidiaphragm, which then moves paradoxically on sniffing. Tumour spreading to the pleura causes effusion, but such an abnormality may be secondary to infection beyond obstruction caused by a central tumour. The ribs and spine should be carefully examined for the presence of metastasis. Spread of tumour from mediastinal nodes peripherally along the lymphatics gives the appearance characteristic of lymphangitis carcinomatosa—bilateral hilar enlargement with streaky shadows fanning out into the lung fields on either side. Rarely, localized obstructive emphysema may be observed.

Sputum cytology

Cytological examination of sputum is a very useful, non-invasive test for the diagnosis of malignant pulmonary disease. The yield increases according to the number of specimens examined, and three consecutive morning specimens should be submitted in the first instance. The yield increases with the number of specimens examined, rising to 85 per cent after four samples in a study of those in whom a diagnosis of lung cancer was made. The positive incidence is lower with tumours less than 2 cm in diameter (40 per cent) and higher with larger masses (60 per cent). Central tumour yields a higher proportion of positive results (60 per cent) than peripheral lesions (48 per cent).

Bronchoscopy

Bronchoscopy, which is described in detail in Chapter xxx, is frequently the definitive diagnostic method in lung cancer. About 70 per cent of all lung cancers arise in a main bronchus, lobar, first, or second generation subsequent division, and will be visible and within biopsy or cytology brush range. Bronchoscopy also yields valuable information regarding suitability for surgical resection. Attempts to resect are ill-advised if the main carina is obviously involved, or unequivocally broad with splaying of the main bronchi and immobility on respiration, or where there is involvement of the trachea, unless confined to the right lateral wall. Histological confirmation is now obtainable in 85 to 90 per cent of bronchoscopically visible lesions.

Transbronchial biopsy

Transbronchial biopsy via the fibreoptic bronchoscope is rarely used for peripheral tumours. It remains useful for more diffuse lesions such as may be seen in adenocarcinoma, bronchoalveolar-cell carcinoma, and lymphangitis carcinomatosis. However, transthoracic needle biopsy under imaging guidance has largely

replaced this technique.

Percutaneous needle biopsy

Percutaneous needle biopsy may be carried out using a variety of cutting needles to obtain a core of tissue for both histology and cytology. The procedure should be performed under fluoroscopic, CT, or ultrasound control, and is best avoided in patients with poor respiratory function or with bleeding diatheses. Positive yields as high as 90 per cent have been reported. Cytological samples remain the least satisfactory for cell type specificity. It is a useful diagnostic method in patients for whom exploratory thoracotomy may be hazardous, or in attempts to determine whether a solid mass is a primary, secondary, or benign tumour. Pneumothorax occurs following about 25 per cent of procedures, with some 5 per cent requiring a chest drain. Small haemoptyses are a common complication.

Thoracoscopy

Visualization of the parietal and visceral pleura plays an important part in the diagnosis of effusions and pleural tumours. Biopsy of lesions can be carried out under direct vision, and absence of pleural tumour is important in decisions about resectability of a lung tumour. Thoracoscopy is inadvisable in the absence of effusion or pneumothorax, and is unsatisfactory in the presence of empyema or gross haemothorax. However, in otherwise operable tumours with a pleural effusion that is not bloodstained and without positive cytology or pleural biopsy, thoracoscopy may be a useful next step in determining operability. Video-assisted thoracoscopy (VATS) has extended this technique and will also permit inspection and sampling of suspicious mediastinal lymph nodes.

Computed axial tomography (CT)

Thoracic CT scanning is important in the staging of lung cancer. It can identify the site, size, and extension of the primary tumour far more clearly than conventional radiology. It also frequently identifies mediastinal lymphadenopathy when posteroanterior and lateral chest radiographs fail to show any abnormality. Mediastinal lymphadenopathy on CT is arbitrarily taken to be pathological by most centres if the glands are greater than 1.0 cm in transverse diameter. However, previous infective conditions such as tuberculosis or an associated distal pneumonia can cause appearances identical with that of malignant enlargement. Thus positive CT scans of the mediastinum must be confirmed preoperatively by mediastinal lymph node biopsy (mediastinoscopy) to confirm tumour involvement.

Another potential advantage of CT is its ability to detect tumour invasion of the surrounding pleura and chest wall, in addition to the mediastinum itself. However, not all tumours with CT evidence of invasion prove unresectable, and if possible invasion of the mediastinum or chest wall appears the only contraindication to resection, then thoracotomy should be performed.

The predictive value of a negative CT is of the order of 90 to 95 per cent, and in such cases a mediastinoscopy can be omitted before thoracotomy. However, microscopic invasion of normal-sized mediastinal nodes is increasingly reported in patients with adenocarcinoma of the lung. Perhaps patients with this cell type should undergo mediastinoscopy routinely, irrespective of whether the mediastinal lymph nodes appear normal in size on a staging CT scan.

Positron emission tomography (PET) scanning

PET scanning shows promise, particularly in identifying the nature of a solitary pulmonary nodule, showing uptake in mediastinal nodes involved by tumour, and in assessing extrathoracic spread. When used in addition to CT, unsuspected metastases have been identified in up to 30 per cent of cases, changing management in up to 40 per cent of cases. The procedure is expensive and has limited availability but might become the final staging test where CT scans fail to show evidence of metastatic disease.

Lung function testing

The ability to climb one flight of stairs without breathlessness has been claimed to be a very good indication of fitness for resection, but formal evaluation of lung function is essential in all patients for whom surgery is being considered. Simple spirometry is usually adequate, but it may be necessary to evaluate exercise capability in a more sophisticated manner. Pneumonectomy should probably not be undertaken if the patient cannot sustain a forced expiratory volume in 1 s (FEV1) of more than 1.2 litres, bearing in mind that patients who have coexistent chronic obstructive airflow disease may not sustain their usual value during exacerbations. In borderline cases, the risk of resection is a matter requiring careful judgement based on estimation of maximum tolerable resection and assessment of the functional integrity of the non-tumour-bearing lung. A combination of pulmonary function tests, including the 6-min walking test and regional function studies using xenon-133, may be used in patients with borderline function. However, as lung cancer is such a serious disease, consideration may sometimes have to be given to carrying out resection in patients whose physical performance defies the results of pulmonary function tests.

Other investigations

In general, the ability to identify small metastatic deposits is as unsatisfactory for lung carcinomas as for other solid tumours. The available techniques are relatively crude, and this partially explains the high extrathoracic relapse rate following so-called 'curative' resections for non-small-cell lung cancer. In patients with no symptoms other than those caused by their primary tumour, imaging scans of brain, liver, and bones are unhelpful if there is no clinical evidence of neurological, hepatic, or bony disease and normal biochemistry. CT brain scans have a high accuracy in detailing cerebral metastases in patients with neurological symptoms. In patients with a palpable liver and/or abnormal liver function tests, a liver CT scan or ultrasound should be performed. CT scan of the upper abdomen identifies abnormalities of one or both adrenal glands in up to 10 per cent of patients considered for surgery. Fine-needle aspiration of the adrenal gland should be performed if this remains the only contraindication to pulmonary resection. Bone scans have a high false-positive rate due to Paget's disease, active arthritis, healing fractures, renal disease, and hyperparathyroidism. However, a bone scan should be ordered in patients with bone pain, local tenderness, or non-specific symptoms of weight loss or malaise.

Biopsy or cytology aspiration of enlarged lymph nodes and skin metastases should be carried out whenever indicated. If an isolated hepatic or bony lesion identified with isotope or CT scanning appears to be the only contraindication to surgery, this should be biopsied under radiological control.

The staging investigations for non-small-cell lung cancer are summarized in Fig. 8. The final procedure before thoracotomy is assessment of the mediastinum, since this may be involved in up to 50 per cent of patients with a peripheral, poorly differentiated tumour and in a much greater percentage of centrally occurring lesions. If CT scanning is normal, the surgeon can proceed directly to thoracotomy. If the CT scan is abnormal or is not available, mediastinal exploration should be performed first. Cervical mediastinoscopy in patients who appear radiologically operable on conventional films will demonstrate mediastinal lymph node involvement in 10 to 15 per cent of cases considered for surgery. Left anterior mediastinotomy can provide further information. This involves an approach through the bed of the second left costal cartilage to palpate glands draining tumours from the left upper lobe.

Treatment and prognosis of non-small cell lung cancer

Surgery

Surgery remains the single modality most likely to be curative in non-small-cell lung cancer. Prior to surgery the patient should have been carefully staged (Fig. 8), and the chances of long-term survival will be greatly influenced by this. All patients with stage IIIB disease (Table 5) should be rejected for thoracotomy, but those with stage I, II, and some with IIIA disease can be resected. In general, patients with squamous-cell carcinomas have higher 5 and 10-year survival rates than those with adenocarcinoma and large-cell carcinomas, and the more differentiated the tumour the better is the prognosis. Table 6 summarizes survival data at 5 years for preoperatively staged non-small-cell lung cancer. Clearly, small peripheral lesions with no nodal disease fare best (up to 70 per cent survival at 5 years), but the survival rate decreases with both size of tumour and increasing involvement of hilar nodes.

In all, approximately 20 per cent of patients who present with non-small-cell lung cancer eventually come to thoracotomy. Most of the others are excluded almost immediately because of clinically evident metastatic disease, radiological or bronchoscopic evidence of inoperability, too advanced an age to withstand surgery, significant associated other illnesses, or inadequate lung function. Of those having a 'curative' resection, the overall survival rate at 5 years is approximately 25 per cent and at 10 years is 16 to 18 per cent. Death from local or distant recurrence of the tumour is equally probable, highlighting the inadequacies of current staging techniques. However, the careful application of the TNM system and the advent of more sophisticated scanning equipment may lead to improvement.

Only very rarely is there an indication for palliative surgery, and resection should not be considered in the presence of intrathoracic or distant metastasis. There are diametrically opposed views as to whether surgery should be undertaken in Pancoast tumours.

Advanced age is not a contraindication to surgery. Patients over 70 years of age appear to tolerate lobectomy as well as younger patients, although the mortality for pneumonectomy (8–10 per cent) is double that of those under 70. There is no evidence that tumours grow more slowly in the elderly, and therefore the disease is as likely to be the terminal event in the aged as in younger patients. Hence resection should be encouraged in fit patients. Smokers should be persuaded to stop smoking before thoracotomy; continued smoking increases perioperative complications.

Thoracoscopic resection of peripheral masses is currently reserved for those with inadequate lung function for lobectomy, as hilar and mediastinal node evaluation and dissection is not always possible. The cure rates for segmentectomy by video-assisted thoracic surgery is less good than by open thoracotomy and lobectomy with lymph node dissection.

Radiotherapy

Patients who are excluded from surgery because of adverse prognostic factors, advanced stage of tumour, or other coincidental disease constitute the largest group treated with radiotherapy. Although the usual aim of radiotherapy will be palliative, there will be a small group of patients in whom more aggressive therapy will be used in the hope of cure, or at least long-term survival, particularly in those who have refused surgery. Radiotherapy for lung cancer is limited by the comparative radiosensitivity of three critical normal tissues likely to be included in the radiation beam: normal lung, spinal cord, and heart, each of which has a critical tolerance dose. Increased radiation dose leads to greater killing of tumour cells but may produce unwanted damage to normal cells. Radiation dose must be expressed not only in terms of total dose but also numbers of fractions and overall time. There is no clear evidence for an optimum radiation dose, but doses of 5000 to 6000 rad (50–60 Gy) in 5 to 6 weeks are appropriate; higher doses will be associated with unacceptable morbidity.

The role of radiotherapy

Alternative to surgery

In some patients with a technically resectable tumour, there may be medical contraindications for resection or the patient may refuse surgery. In general, the results of radical radiotherapy in these patients are inferior to the 5-year survival following surgery. The best result for radiotherapy was a 5-year survival rate of 22 per cent for peripheral squamous-cell cancers, but other series post a 5-year survival rate of 6 per cent.

Preoperative radiotherapy

Preoperative radiotherapy has been attempted in a few uncontrolled studies, but there is no evidence that this approach improves survival.

Postoperative radiotherapy

A recent meta-analysis has shown no benefit from postoperative radiotherapy for stage I and II disease. Any value in stage IIIA disease with nodal involvement is not as clear, but benefit is likely to be small.

Radical radiotherapy for locally inoperable disease

In otherwise fit patients with small-volume intrathoracic disease which is not resectable, usually because of mediastinal involvement, it is common practice to attempt to cure with radiotherapy. Results with daily single fractions are disappointing, even with doses of up to 60 Gy, with 5-year survival rates ranging from 5 to 17 per cent.

Recently, continuous hyperfractionated accelerated radiotherapy (CHART), with three fractions a day for 12 consecutive days to a total of 54 Gy have been compared to conventional radiotherapy in non-small cell lung cancer. CHART gave an absolute improvement in 2-year survival from 20 per cent to 29 per cent, with the greatest benefit (14 per cent absolute improvement) in squamous cell cancers. This appears a real advance in the provision of radiotherapy for locally advanced, inoperable tumours.

Palliation

The value of radiotherapy in palliating certain symptoms is beyond dispute. Haemoptysis and cough, two of the most distressing symptoms, can be controlled by radiotherapy in up to 80 per cent of cases. Administration of single fractions (each of 8.5 Gy, 1 week apart) appears adequate. Dyspnoea from bronchial obstruction and dysphagia are relieved in the majority of cases. The syndrome of superior vena caval obstruction is relieved in about 80 per cent of sufferers, but usually requires a more conventional course of five to ten fractions of radiotherapy. Pain from bone secondaries can be relieved in more than 50 per cent of sufferers by a single fraction of 8 Gy, often given at the same time as a clinic visit. Brain metastases generally respond poorly to radiotherapy. A 48-h trial of dexamethasone, 4 mg orally four times daily, is recommended as initial management. If a worthwhile response follows the resolution of the oedema surrounding the metastases, then radiotherapy will consolidate this gain. The steroids should then be rapidly withdrawn on completion of radiotherapy. Spinal cord compression is a relatively common occurrence associated with vertebral body metastatic disease. Pain and bony tenderness often precede it and may be helpful in localizing the lesion. Responses to radiotherapy are usually incomplete and disappointing, often because of interruption of the vascular supply to the spinal cord by the tumour.

Chemotherapy

Several cytotoxic agents show activity against non-small cell lung cancer, but much less frequently than with small-cell tumours (Table 7). However, combination chemotherapy can achieve impressive response rates; partial responses in 50 per cent of patients with locally advanced disease and in 35 per cent of those with advanced extrathoracic disease have been reported. The most active regimens include: cisplatin, ifosfamide, and mitomycin; or cisplatin, mitomycin, and vindesine. A meta-analysis of all controlled studies randomizing patients to receive or not receive chemotherapy in addition to surgery, radiotherapy, or to best supportive care was published in 1995. This suggested a 5 per cent advantage for the addition of chemotherapy to surgery (confidence intervals –1 to 7 per cent), a smaller non-significant advantage for the addition of chemotherapy to radiotherapy, and a 10 per cent improvement in survival at 1 year for the addition of chemotherapy to best supportive care. Many institutions are attempting to confirm these encouraging data. In advanced disease, chemotherapy only confers a survival advantage of 6 to 8 weeks compared to best supportive care alone, making evaluation of effects on quality of life important. Thus chemotherapy in non-small cell lung cancer is still recommended to be given within clinical trials. The place of the newer agents such as carboplatin, vinorelbine, gemcitabine, the taxols, and campotethecins are being

evaluated.

Treatment and prognosis of small-cell lung cancer

Small cell lung cancer is separated from the other types of lung cancer because of its very different biological and clinical features. It has an explosive growth pattern so that the TNM staging classification makes no impact on prognosis or survival, almost certainly because careful staging puts most patients into the inoperable category and because small metastases remain undetected for a few months. However, simple staging has some prognostic impact and those with limited disease (tumour confined to one hemithorax and the ipsilateral supraclavicular fossa) fare better than those with extensive disease (involvement of any site outside the hemithorax). The life expectancy of those with untreated small-cell lung cancer is about 3.5 months for limited disease and 6 weeks for extensive disease.

Prognostic factors

Multivariate analyses of large patient populations show that routine biochemical values such as serum sodium, albumin, and alkaline phosphatase allow separation of prognostic subgroups. In addition, performance status and extent of disease are important influences. For instance a good performance status and normal biochemical values (i.e. a good prognostic category) has a 2-year survival rate of 20 per cent, yet a correspondingly low performance status with one or more abnormal biochemical parameters (poor prognosis) has virtually no 2 year survivors (Fig. 9). Women tend to do better than men and those under 60 better than those over 60 years of age. These factors are helpful both for stratification within clinical studies and for identifying those patients likely to do well with chemotherapy and those for whom intensive toxic chemotherapy would appear inappropriate. Survival beyond 5 years (cure) is achieved in 4 to 12 per cent of patients with limited disease and in hardly anyone with extensive disease at diagnosis. Most studies of long-term survival report late deaths due to other cancers, including non-small-cell lung cancers in up to 30 per cent of these long-term survivors.

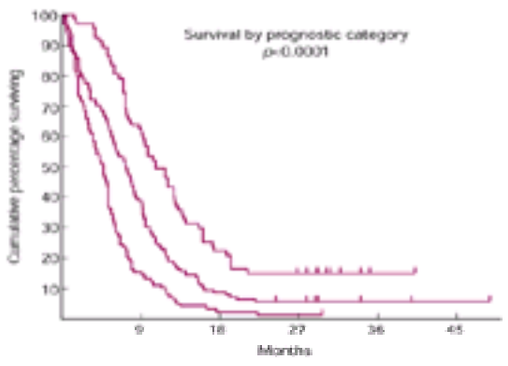

Fig. 9 The effect of prognostic grouping in survival in small-cell lung cancer. The upper curve represents good prognosis patients; the lower two curves are intermediate and poor prognosis groups respectively.

Surgery

In small-cell lung cancer the very occasional patient can be surgically cured, usually those presenting with a peripheral tumour and no evidence of local spread or metastasis despite extensive staging investigations. These patients are rare, but nevertheless have a 5-year survival rate in the region of 30 to 40 per cent.

Radiotherapy

Radiotherapy has an important role in palliation of symptoms that may develop after relapse following chemotherapy. However, in approximately 15 per cent of patients with limited disease, there is a small but definite benefit when thoracic irradiation is added to combination chemotherapy. Chest irradiation also significantly decreases the rate of recurrence at the primary tumour site and in the mediastinum. A total dose of 40 to 50 Gy is usually given. The optimal timing of radiotherapy in relation to chemotherapy is not clear, but the trend is in favour of early radiotherapy given concurrently with chemotherapy. However, acute and late toxicity are both increased when radiotherapy and chemotherapy are given in combination.

Cranial irradiation

Cranial metastases are common. Ten per cent of patients in remission develop brain metastases as their first site of relapse. Prophylactic cranial irradiation given at the end of chemotherapy will delay the presentation of cerebral metastases and also reduce their overall incidence. However, there is no evidence of prolonged survival, and those who receive prophylactic cranial irradiation are at greater risk of late neurological complications—particularly psychometric and psychological impairment. However, the morbidity of cerebral metastases is so great that it seems helpful to attempt to prevent this socially disastrous form of relapse.

Chemotherapy

Small-cell lung cancer is much more sensitive to cytotoxic chemotherapy than the non-small-cell lung cancer tumours, with a much higher response rate for several cytotoxic drugs (Table 7). In the late 1970s, there was a very rapid improvement in median survival using combinations of three and four drugs, but responses have subsequently reached a plateau. Nevertheless, with modern combination cytotoxic treatment, which is usually given on an outpatient basis every 3 weeks, the median survival has been extended to 14 to 18 months for limited disease and to 9 to 12 months for extensive disease. Most combinations include etoposide, cisplatin, cyclophosphamide, doxorubicin, and vincristine. Modern regimens would be expected to achieve a complete response rate (i.e. disappearance of all measurable disease) in 40 to 50 per cent of cases and a partial response rate (greater than 50 per cent reduction in tumour bulk) in a further 40 per cent, giving a total response rate of 80 to 85 per cent. All these regimens have side-effects. Most patients will experience some nausea and vomiting, and alopecia is practically universal. Life-threatening septicaemia occurs in 1 to 4 per cent, but treatment-related deaths are uncommon.

Much effort has been applied during the last 5 years to improve the median and long-term survival of patients with small-cell lung cancer. In general, those patients in whom further progress is to be made are those who present with limited disease and a good performance status. Patients with extensive disease tend to have a universally bad prognosis and very few survive beyond 2 years. However, it seems that some metastatic sites (bone and bone marrow) are not as sinister as others (brain or liver) and the occasional patient with extensive disease does well with chemotherapy, but in general treatment is offered in this circumstance for palliation and not in the hope of cure. Studies assessing the quality of life in patients presenting with small-cell lung cancer have shown that over 70 per cent have important symptoms such as weight loss, malaise, bone pain, dyspnoea, and haemoptysis. The majority of these patients have extensive disease, but after 3 months of chemotherapy symptoms can be relieved in 60 to 70 per cent of sufferers, making chemotherapy worthwhile, with symptomatic benefits far outweighing the potential side-effects. Ten per cent of small-cell lung cancer patients present with superior vena caval obstruction: this responds as well as any presentation to chemotherapy.

Intensity of treatment

Intensifying the dosage or the frequency of administration of cytotoxic agents has been thoroughly explored without real benefit on median survival. Small advantages are occasionally seen, but these have to be balanced by the increased toxicity resulting from a more aggressive approach. Attempts to overcome or delay the emergence of cell resistance to chemotherapy have involved alternating combinations of drugs, but these more complicated regimens have not been rewarding either.

Duration of treatment

Toxicity of chemotherapy increases with the number of courses given. It is now apparent that most of the tumour response to chemotherapy occurs within the first two or three cycles. Studies attempting to minimize the duration of chemotherapy without adversely affecting survival have shown that six courses of combination

chemotherapy, that is a course every 3 weeks, is optimal, with no benefit from maintenance regimens.

General management of patients with lung cancer

There are certain complications which require specific measures to alleviate symptoms.

Patients who seem likely to survive for 6 months or more and who have vocal chord paralysis find considerable help from an injection of Teflon into the affected chord which restores voice production in a high percentage of cases and reduces the risk of aspiration. Occurrence of upper airway obstruction causing stridor, or obstruction of the lower major airways, in non-small-cell lung cancer patients is usually initially treated with radiotherapy. Should this complication recur or be unsuitable for radiotherapy, it can sometimes be treated by laser photocoagulation administered either via a fibreoptic bronchoscope or under general anaesthetic via a rigid instrument. Laser therapy for carcinoma of the bronchus is most suitable as a palliative treatment in central tumours occluding large airways. There are technical limitations to its application via the flexible bronchoscope, but removal of considerable quantities of tumour can be achieved in a single treatment session with the rigid instrument. Laser therapy is used predominantly for recurrence of tumour in the central airways, usually after radiotherapy has failed. Trials are in progress assessing the additional benefits of endobronchial radiotherapy (brachytherapy) using iridium or caesium wires delivered via the fibre optic bronchoscope. This procedure irradiates endobronchial tumour to a circumferential depth of about 1 cm, and will often produce a further remission. It is used where further external beam radiotherapy cannot be given because of the risk of exceeding normal tissue tolerance.

Infection distal to tumour requires antibiotic therapy and, where appropriate, oxygen therapy and bronchodilators. Severe, recurrent haemoptysis may be controlled by radiotherapy or laser.

Malignant pleural effusion recurs after aspiration unless the pleural space is obliterated. Chemical pleurodesis can be induced by intrapleural instillation of a number of agents or by the more invasive procedure of talc pleurodesis. Intrapleural tetracycline is most commonly used, giving successful pleurodesis in 50 to 70 per cent of patients. However, the increasing availability of thoracoscopy makes a talc pleurodesis preferable in all reasonably fit patients who can undergo a general anaesthetic.

Dexamethasone, 4 to 16 mg orally daily, may control the symptoms of brain metastasis and, if so, this should be consolidated with radiotherapy to prevent severe steroid-induced myopathy. Prednisolone, 20 mg orally daily, is often used to improve the sense of well-being, as are blood transfusion or hyperalimentation.

Terminal care is described in Section 30, but the importance of the combined support to the patient and the family given by the family doctor, palliative care medical and nursing staff, and hospice organizations, and the hospital team cannot be overemphasized.

Prevention

Lung cancer is an almost totally preventable disease and is very largely due to smoking, particularly of cigarettes. The strategy of any preventive measures must be based on the following observations. Firstly, that lung cancer is extremely rare in non-smokers. Secondly, that there is no threshold limit below which no effect is produced, although the risk increases proportionately to the amount smoked. Thirdly, that the benefit from stopping smoking is evident within 5 years. Fourthly, that the risk for an exsmoker at any given time after stopping is determined by the length of time he or she had smoked before stopping. Thus strenuous efforts must be made to persuade people not to start smoking, to establish more effective methods of enabling people to stop smoking, and to promote further research into effective methods of health education. The promotion of cigarettes with low tar, nicotine, and carbon monoxide contents may have made a small contribution to prevention, but low-tar cigarettes are not a substitute for giving up smoking. Penal taxation by governments may also help.

The identification of occupational hazards and implementation of appropriate measures to safeguard the health of employees are clearly important preventive measures, even although the number at risk is very small.

Prospective lung cancer screening programmes in males aged 45 years and above who smoke at least 20 cigarettes per day have been carried out using both chest radiography and pooled 3-day sputum analysis every 4 months. They are unlikely to form the basis of standard practice as there is no evidence that early detection is translated into increased cure rate.

Carcinoid tumours

The slow-growing intrabronchial lesions previously grouped under the heading of bronchial adenoma have now been reclassified into bronchial carcinoids, adenoid cystic tumours, and mucoepidermoid tumours. They are not related to cigarette smoking, and tend to be diagnosed at a younger age than carcinoma of the bronchus. True bronchial adenomas derived from bronchial glands are rare. These tumours were once thought to be benign, but they are potentially and often frankly malignant, being capable not only of destructive local growth but also of metastasis to regional lymph nodes in about one-third of patients and to distant organs, particularly liver and brain, in about 10 per cent. They are occasionally located in the trachea.

The most common symptoms are cough, haemoptysis, and recurrent pneumonia, although not infrequently the lesion is discovered on routine radiographic examination before symptoms develop. In the few cases that have extensive liver secondaries, there may be the classical symptom pattern of intermittent cyanotic flushings, intestinal cramps and diarrhoea, bronchoconstriction, and cardiovascular lesions. The radiographic appearances are those of a solitary nodule, pulmonary collapse, or obstructive hyperinflation. As the majority of the tumours occur in main stem or proximal portions of lobar bronchi, bronchoscopy is usually the definitive diagnostic measure. The tumour appears as a white or pink polypoid or lobulated mass, with the bronchial mucosa appearing to be intact. Biopsy may be followed by brisk haemoptysis.

Surgical resection is the treatment of choice. In the absence of regional spread or distant metastases 5-year survival prospects are excellent, but if there is involvement of regional nodes, survival rates fall to 70 per cent. Some aggressive carcinoid tumours carry a much worse prognosis. The mechanism and management of the general symptoms of the carcinoid syndrome are described in Chapter 14.8.

17.14.2 Pulmonary metastases

S. G. Spiro

Further reading

Malignant metastasis to the lung may present as a solitary enlarging nodule, as multiple nodules, or with diffuse lymphatic involvement.

Solitary metastasis represents some 10 per cent of round lesions in general, but some 70 per cent of round lesions in patients with a known malignancy. Colorectal cancer is reported to be the commonest tumour of origin. Diagnosis can usually be secured by percutaneous CT-guided biopsy. In rare cases, surgical excision may prolong survival or result in cure, depending on the state of the primary tumour and the likelihood of other occult metastases. In general, the longer the interval between resection of the primary tumour and the appearance of the metastases the better the prognosis.

Multiple metastases range enormously in size and number from 'cannon balls' to miliary shadowing, and may be accompanied by hilar lymphadenopathy or pleural effusion. Breast, colon, renal, and lung primaries are probably the commonest underlying tumours, but other tumours amenable to chemotherapy, such as testicular cancer and choriocarcinoma, and also sarcomas, occur. Diagnosis may be achieved by cytology or histology on various samples from the pleura or lung and can occasionally be made from cytology on expectoration or induced sputum. Tumours that are suitable for chemotherapy (e.g. choriocarcinoma) or endocrine manipulation (e.g. breast) need to be recognized. Solitary or multiple Kaposi's sarcoma is a feature of AIDS, and can involve the bronchi and pleura as well as lung tissue.

Lymphangitis carcinomatosa is most commonly due to breast and primary lung tumours (usually adenocarcinomas). Patients can be asymptomatic when the disease is first suspected on the basis of a radiograph showing diffusely increased interstitial markings accompanied by Kerley B lines, hilar lymphadenopathy, or pleural effusion. Diagnosis may be established by cytology from sputum or pleural fluid, but often requires bronchoscopic or transbronchial lung biopsy. Later, progressive and severe breathlessness with hypoxaemia often develops, and requires vigorous palliative relief with opiate and oxygen administration.

Occasionally metastasis, presenting as haemoptysis, may be confined to a bronchus and not visible on a plain chest radiograph. Renal carcinoma and malignant melanoma are recorded causes. Diagnosis requires bronchoscopy, and radiotherapy is usually effective in controlling the haemoptysis.

17.14.3Pleural tumours

M. K. Benson

Primary pleural tumours are relatively rare, although malignant mesothelioma has received much attention because of its increasing incidence and association with asbestos exposure. Pleural plaques are also associated with asbestos exposure but should not be regarded as tumours since they simply represent local areas of fibrocollagenous thickening. The classical benign tumour of the pleura is a fibrous mesothelioma (pleural fibroma).

By contrast, pleural involvement by metastatic disease is very common. It can occur with most carcinomas, but is particularly associated with primary tumours arising in the lung, breast, colon, and ovary. Malignant lymphomas can also present with pleural involvement. Tumours arising in adjacent structures, such as diaphragm and chest wall, may also involve the pleura, and both benign and malignant tumours can originate from muscle, adipose tissue, nerves, blood vessels, and bony thorax. All are rare, and the diversity of sites and types of tumour results in a variety of clinical presentations. Radiographic techniques can help to demonstrate the site and nature of the tumour, but diagnosis is usually established on biopsy.

Benign tumours

Benign fibrous mesothelioma

These tumours are rare but can occur in virtually any age group. They bear no relationship to the development of malignant mesothelioma and are not associated with exposure to asbestos or other industrial pollutant. They originate from a pedicle, usually from the visceral pleura. Macroscopically they are firm, lobulated, and well encapsulated. The cut surface is white or grey and can have a whorled appearance. They vary in size, but can on occasions be very large, weighing up to 2 or 3 kg.

The tumours are often discovered on routine chest radiology in otherwise asymptomatic individuals (Fig. 1). Large tumours can cause chest discomfort and breathlessness, presumably due to compression of adjacent lung. Spontaneous hypoglycaemia is an associated feature in a small proportion of patients.

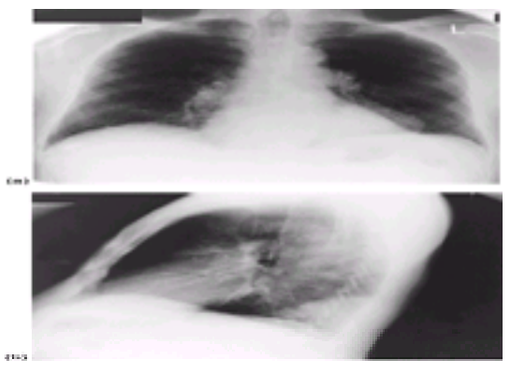

Fig. 1 Chest radiographs, posteroanterior (a) and lateral (b), showing a pleural-based nodule at the left base. The patient had no respiratory symptoms and resection confirmed this to be a benign fibrous mesothelioma.

Radiologically, it can be difficult to decide whether a nodule arises from the pleura or within adjacent lung. The differential diagnosis includes a localized area of pleural thickening, a whorled nodule, although this generally has a less clearly defined outline. The diagnosis is usually established only after surgical excision. Although a fibrous mesothelioma is benign, with no potential for metastatic spread, there is a possibility of local recurrence if the pedicle has not been completely excised.

Pleural plaques

These are areas of fibrocollagenous thickening. They produce no clinical symptoms and are usually detected on routine chest radiographs. They can be single or multiple and are best seen in oblique projection or using tomography. Although associated with asbestos exposure, they are entirely benign and should not be regarded as precursors to the development of a malignant mesothelioma.

Malignant tumours

Malignant mesothelioma

Malignant mesothelioma derives from mesothelial cells, most commonly in the pleura, but also in the peritoneum or (rarely) pericardium. Malignant mesothelioma arising from the pleura was first recognized in the 1950s, and during the 1960s much evidence accumulated indicating a strong link between the condition and exposure to asbestos. Asbestos is a collective term given to a group of silicate minerals, commercially useful because of their heat resistant properties, and widely used in industry for the past 100 years. In addition to asbestos exposure, there has been recent interest in the possible role of Simian virus 40 (SV40) in the aetiology of mesothelioma. This oncogenic virus was a contaminant of polio vaccines used in the 1950s, and SV40-like DNA sequences have been found in pleural mesotheliomas, although it is not clear what this means.

Epidemiology

There is overwhelming evidence that mesotheliomas are caused by asbestos, and the higher incidence in men indicates that most exposure is occupational rather than environmental. The risk is a function of the concentration of fibres and duration of exposure. Fibre type is also of relevance, since although most asbestos workers have been exposed to a mixture of fibres, there is good evidence that crocidolite (blue asbestos) is more hazardous than chrysotile (white asbestos). Exposure is greatest in those involved in mining or quarrying the material and those who handle the raw fibres. Significant exposure has also occurred in individuals employed in the manufacture and use of asbestos-containing products. Many workers engaged in the ship-building industry in the 1940s and 50s were exposed to asbestos, and more recently there has been widespread use in the building industry.

The increasing incidence of mesothelioma is a reflection of the long latent interval between exposure and the development of disease. It is rare for mesotheliomas to develop within 20 years of exposure and most patients were initially exposed 30 or more years before clinical presentation. In the United Kingdom, although the risk was first recognized in the 1960s, it was not until the mid-1970s that there was a significant reduction in exposure to asbestos. Current mesothelioma rates are a quantitive indication of previous population exposure. The increasing rates in the United Kingdom are predicted to continue for the next 20 years, with annual deaths increasing from the current levels of approximately 1100 to 2000 per annum. Men born between 1945 and 50 are those at greatest risk. Similar trends are also being

seen in much of Western Europe, although in North America mortality rates may have already peaked because of earlier measures to limit asbestos exposure.

Low levels of environmental contamination have been shown to result in a slightly increased risk of mesothelioma, although it has been estimated that the annual incidence in subjects with no clear history of asbestos exposure is about 1 per million. Endemic pleural mesothelioma has been reported from certain areas of central Turkey, Cyprus, and Greece. Locally mined zeolite and other environmental asbestos minerals are regarded as responsible.

Pathology

A mesothelioma can arise from either the visceral or parietal pleura, initially as a local mass, often associated with pleural effusion. As it progresses, there is gradual encasement of the lung and extension into adjacent structures including the chest wall, mediastinum, and pericardium. Macroscopically, the tumour is usually white and fibrous in texture, sometimes with areas of necrosis. Metastatic disease is relatively uncommon, but involvement of the contralateral lung and pleura, liver, and bone are recognized sites for secondary spread.

The histological diagnosis can be difficult as there are a variety of appearances, ranging from well-differentiated epithelial or sarcomatous patterns to undifferentiated forms. Even after biopsy there can be difficulty in distinguishing between a malignant mesothelioma and benign pleural disease on purely morphological grounds. A second problem is differentiation between mesothelioma and secondary adenocarcinoma. Histochemistry, immunohistochemistry, and electron microscopy can also provide useful information when there is diagnostic uncertainty.

Clinical presentation

The age of presentation is usually between 50 and 70, although incidence is increasing in older patients. There is a male predominance, reflecting the greater likelihood of previous occupational exposure, which should be sought with a careful lifetime occupational history. Symptoms due to local disease are mainly those of pain and breathlessness. Pain may be pleuritic in nature, but is often a dull ache due to direct involvement of the chest wall. Shortness of breath is usually associated with a pleural effusion, although as the tumour progresses is gradually encases the lung. Systemic symptoms include tiredness, anorexia, weight loss, fever, and occasionally drenching sweats. Finger clubbing has been recorded but is rare. Physical findings in the chest are those of a pleural effusion, but with advanced disease there is progressive reduction in chest wall movement. Direct extension through the chest wall can result in a palpable mass, and this may develop at the site of previous biopsy.

Investigations

A chest radiograph often demonstrates a pleural effusion, with tumour suspected if there is pleural thickening with a lobulated outline (Fig. 2). This can be more easily identified on CT scanning, which can also be used as a staging procedure. Magnetic resonance imaging gives similar information. The presence of benign pleural plaques offers evidence of previous asbestos exposure, although they are not in themselves precursors of malignant change.

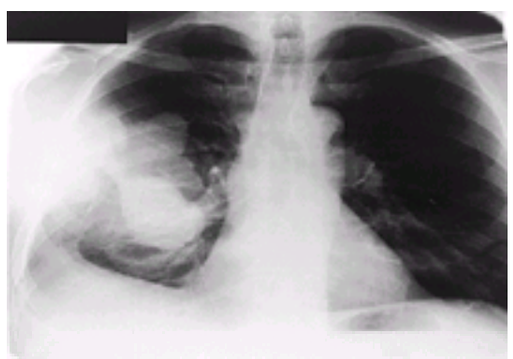

Fig. 2 Chest radiograph showing lobulated pleural thickening due to mesothelioma.

Pleural aspiration with cytological examination of pleural fluid yields a definitive diagnosis in up to a third of patients. There is further modest diagnostic yield from percutaneous needle biopsy. Samples obtained under direct vision, either at thoracoscopy or thoracotomy, have the highest diagnostic yield, with thoracoscopy being the investigation of choice. In some instances, it may be appropriate to make a diagnosis solely on the basis of clinical and radiological features, since even with histological confirmation there is unlikely to be any alteration in management. However, it is important to note that malignant mesothelioma is an industrially notifiable disease for which the patient and family can receive financial compensation.

Treatment and prognosis

A variety of treatments have been used for patients with mesothelioma, but rates of cure are uniformly disappointing. Surgical resection employing extrapleural pneumonectomy has its advocates, but reports are of highly selected patients with no satisfactory control group. There is significant perioperative morbidity and mortality, with median survival figures in the range of 10 to 20 months. Response to radiotherapy is also disappointing, although occasionally palliative relief of pain can be achieved when there has been direct extension into the chest wall. It may also prevent seeding along a biopsy tract. A variety of cytotoxic agents have been tried, either as single agents or in combination, but so far without any convincing success.

Relief of pain usually requires regular opiates, although nerve blocks may also be helpful for localized pain. Pleural aspiration and pleurodesis is of benefit for the relief of breathlessness due to recurrent pleural effusions.

The prognosis is poor with the median survival of approximately 12 months. A few patients seem to have fairly indolent disease and may survive for periods of up to 5 years.

17.14.4 Mediastinal tumours and cysts

M. K. Benson

The mediastinum encompasses those structures within the thorax, excluding the lungs. The superior boundary is the thoracic inlet represented by a plane at the level of the first rib. The inferior boundary is the diaphragm. Traditionally, the mediastinum is subdivided into a number of compartments: superior and inferior, with the latter being subdivided into anterior, middle, and posterior divisions. However, there are no true anatomical boundaries, and structures in the superior mediastinum are in general contiguous with those inferiorly. Thus a more logical subdivision is simply into anterior, middle, and posterior compartments (Fig. 1 and Fig. 2). Such a division can help to compartmentalize complex anatomical arrangements and give some guide as to the most likely pathology occurring in any particular area.

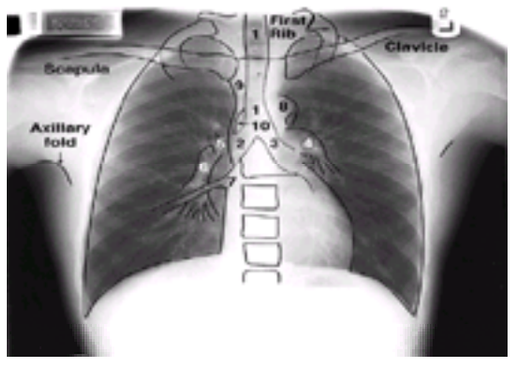

Fig. 1 Posteroanterior chest radiograph with diagrammatic overlay to illustrate normal mediastinal structures: (1) trachea, (2) right main bronchus, (3) left main bronchus, (4) left main pulmonary artery, (5) right upper lobe pulmonary vein, (6) right interlobar artery, (7) right lower and middle lobe vein, (8) aortic knuckle, (9) superior vena cava, (10) azygos vein.

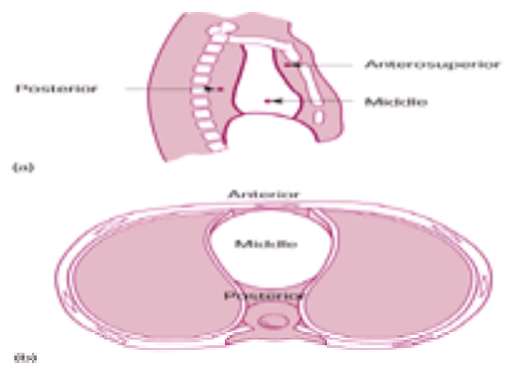

Fig. 2 A schematic representation of the mediastinal compartments: (a) lateral projection showing division into anterior (or anterosuperior), middle, and posterior compartments, (b) cross-sectional depiction.

The anterior mediastinum is bounded anteriorly by the sternum and posteriorly by the pericardium, aorta, and brachiocephalic vessels. It contains the remnant of the thymus gland, branches of the internal mammary artery, veins, and associated lymph nodes. The middle mediastinum contains the pericardium, ascending aorta and aortic arch, the vena cavae, the brachiocephalic vessels, and the pulmonary arteries and veins. It also encompasses the trachea and major bronchi with their associated lymph nodes, the phrenic nerves, and the vagus nerve. The posterior mediastinum is bounded anteriorly by the pericardium, laterally by the mediastinal pleura, and posteriorly by the vertebral bodies, including structures in the paravertebral gutter. It contains the descending thoracic aorta, oesophagus, azygos veins, thoracic duct, lymph nodes, and autonomic nerves.

Lymph nodes are common to all three compartments and knowledge of their anatomical relationships, together with sites of drainage, is helpful in interpreting an abnormal chest radiograph with mediastinal enlargement. The most important group of visceral nodes lie in the middle mediastinum and are predominantly subcarinal and paratracheal. Bronchopulmonary or hilar nodes are numerous but are not visible radiographically unless pathologically enlarged.

Diagnostic approach

The finding of a mediastinal abnormality on chest radiograph, whether or not accompanied by specific clinical features, is usually an indication for further investigation. Computed tomography (CT) provides accurate localization of mediastinal masses. It can define their relationship to and displacement of normal structures, and may be able to define lines of demarcation, particularly if there is adjacent fatty tissue. It is not ideal for determining the composition of any particular mass, although it can demonstrate heterogeneity or the presence of calcification. Contrast enhancement can be used to identify vascularity. Magnetic resonance imaging has relatively little to offer over and above CT scanning, the one exception being in the assessment of spinal tumours.

Fine-needle aspiration biopsy is valuable in the investigation of pulmonary masses, but is of more limited use in assessing those in the mediastinum. The presence of a cyst can be confirmed by aspiration of clear fluid. Anterior mediastinal masses can easily be approached percutaneously, although cytological examination alone may be insufficient for diagnosis. Anterior mediastinotomy allows open biopsy of such lesions. This is performed through an incision in the neck and allows inspection of structures surrounding the superior vena cava and trachea as far as the carina. It is particularly useful for obtaining lymph node biopsies when surgery for lung cancer is contemplated. Bronchoscopy is of limited value in the evaluation of mediastinal masses, except when there is a suspicion of a bronchial neoplasm or possible lymphadenopathy due to sarcoidosis. Neural tumours arising in the posterior mediastinum usually require surgical resection and there is little to be gained by preceding this with fine-needle aspiration.

Clinical features

General considerations

It is not surprising that the diversity of anatomical structures in the mediastinum is reflected in an equally diverse range of neoplastic, developmental, and inflammatory masses (Table 1). Whilst clinical symptoms and signs may give diagnostic clues, a significant proportion of mediastinal masses, particularly those which

are benign, tend to be asymptomatic and are usually detected on routine chest radiography.

Mediastinal masses in children are more likely to be malignant than those in adults. There have been a large number of studies documenting the relative frequency of different causes of primary mediastinal tumours and cysts: neurogenic and thymic tumours are the commonest (approximately 20 per cent each), followed by lymphoma, reduplication cysts, germ cell tumours, and thyroid masses.

Non-specific, constitutional symptoms such as fever or weight loss are more likely to occur with malignant tumours such as lymphomas or thymomas. The commonest symptoms are cough and chest pain, arising as a consequence of distortion of normal mediastinal anatomy. Compression of vital structures can also result in specific symptoms. Thus, tracheal or bronchial compression leads to breathlessness with stridor or wheeze; oesophageal narrowing results in dysphagia; and superior vena caval compression produces the characteristic features of facial and periorbital oedema, chemosis, and distended veins. Involvement of the recurrent laryngeal nerve results in hoarseness and a bovine cough; whilst this usually results from a malignant tumour, it can also occur with benign lesions such as aneurysm of the aortic arch. Involvement of the sympathetic chain as it emerges in the upper mediastinum is also likely to be due to malignant infiltration and results in Horner's syndrome with enophthalmos, miosis, ptosis, and unilateral facial anhidrosis. Compression of intercostal nerves can produce neuralgia, and intraspinal extension of tumours lead to long tract signs.

Anterior mediastinal masses

Thymus

The normal thymus is located in the superior portion of the anterior mediastinum. Its main function is the production of T lymphocytes. Radiographically, the normal thymus can only be seen in infancy and regression occurs during adolescence. Enlargement of the thymus is the commonest single cause of an anterior mediastinal mass. It can be due to the development of a thymoma, thymic hyperplasia, or a thymic cyst. In addition, the thymus can be a site of involvement by lymphoma, particularly Hodgkin's disease.

Thymomas are neoplastic proliferations of the thymus gland, with peak incidence in middle age. They are often benign, but can behave in a malignant fashion, with invasion of adjacent structures and distant metastases, in which case localized symptoms of chest pain and cough are more common. Systemic symptoms that can occur in association with thymic tumours are of particular interest. Myasthenia gravis is the commonest, occurring in some 30 per cent of patients. Other rare associations include red cell aplasia, hypogamma–globulinaemia, systemic lupus erythematosus, and polymyositis.

The majority of thymomas are slowly growing, lobulated masses that are well encapsulated. In these patients surgical resection can be expected to be curative. Local invasion is not common, but often precludes complete resection and recurrence is the rule. Adjuvant radiotherapy or chemotherapy has been used in such patients with debatable benefit.

Thymic cysts are uncommon. They can be unilocular or multilocular and usually contain straw-coloured fluid. The majority of patients are asymptomatic, but since cystic change can occur in some thymomas and in Hodgkin's disease, thorough cytological examination of the cyst's contents and wall must be carried out to exclude malignant disease.

Thymic lymphoma is fairly frequent, particularly in patients with Hodgkin's disease. The histological picture is usually of the nodular sclerosing variety, and the presence of mediastinal or hilar nodes should alert the clinician to the possibility of a lymphoma.

Germ cell tumours

This group of neoplasms includes tumours that are identical to certain testicular and ovarian neoplasms, and thought to be derived from primitive germ cells which have migrated to the mediastinum during oncogenesis.

Benign teratomas (dermoid cysts) consist of a disorganized mixture of ectodermal, mesodermal, and endodermal tissues, which can include skin, hair, cartilage, bone, epithelium, and neural tissue. They often contain cystic areas and CT appearances give a strong clue to the diagnosis. Unless there is a substantial contraindication to surgery, they should be excised to prevent further expansion and to exclude malignant change.

Malignant germ cell tumours are classically divided into seminomas and teratomas, although biopsy often reveals a spectrum of malignant tissue. Non-seminomatous germ cell tumours (malignant teratoma) can range from well-differentiated to trophoblastic. They are associated with elevated serum levels of b-human chorionic gonadotropin and a-fetoprotein, which can be used both diagnostically and to monitor response to treatment. Seminomas tend to be non-secretory. Both types of tumour are very malignant and invade adjacent mediastinal structures. They are not curable by surgery, but both are responsive to chemotherapy using cisplatin-based regimes, although results are disappointing when compared with their testicular counterparts, with response rates ranging from 30 to 70 per cent.

Thyroid masses

Retrosternal extension of an enlarged thyroid represents one the commoner causes of a mass in the superior mediastinum. The majority are multinodular benign goitres, arising in the neck and extending into the mediastinum through the thoracic inlet. They may contain cystic areas, sometimes with haemorrhage and areas of calcification. Radiographically, they have a sharply defined and often lobulated outline. Whilst they rarely cause symptoms, compression of the trachea at the thoracic inlet can result in respiratory distress and is an indication for surgical resection. Thyroid cancer can also involve the mediastinum, either by direct extension or by metastases to intrathoracic nodes.

Middle mediastinal masses

Lymphadenopathy

Enlarged nodes are not confined the middle mediastinum although this represents the commonest site of intrathoracic lymphadenopathy. Reactive changes occur in association with many pulmonary infections, although nodes are not grossly enlarged and are often undetected on plain chest radiograph. Gross lymphadenopathy is a feature of tuberculosis and also occurs in histoplasmosis. Other common causes of significant lymph node enlargement include metastatic carcinoma, lymphomas, and sarcoidosis.

Giant follicular lymph node hyperplasia (Castleman's disease) is rare but merits specific mention (Fig. 3). Its aetiology is unknown and it is not clear whether it represents a focus of lymphoid hyperplasia or has an infectious origin. The lesion consists of a vascular tumour with satellite lymphadenopathy. Two histological subgroups are described, (1) a more common hyaline vascular picture with lymphoid follicles and penetrating capillaries, and (2) a plasma cell type characterized by sheets of plasma cells between germinal centres. Both types can result in symptoms from local pressure, but the plasma cell type also causes systemic symptoms with fever, anaemia, and weight loss. There are no diagnostic radiographic features. The picture is simply one of a solitary mass and the diagnosis is usually made after surgical resection or biopsy. The condition is regarded as benign, but a small group of patients with multicentric disease have progressive hyperplasia, recurrent infections, and subsequently develop a frank lymphoma.

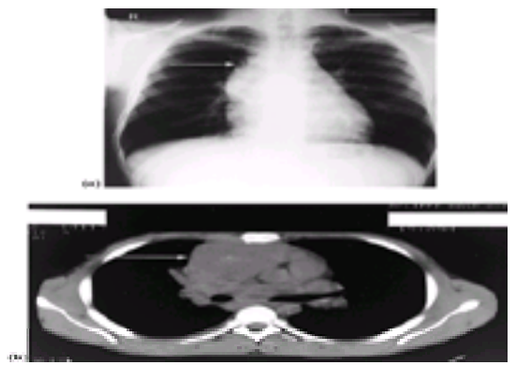

Fig. 3 Chest radiograph and CT scan showing large anterior mediastinal mass which on histology showed features of Castleman's disease.

Mediastinal cysts

Cysts within the mediastinum are a relatively common cause of a mediastinal mass. They can arise in association with the pericardium, bronchi, gut, or thoracic duct. The majority of patients are asymptomatic.

Pericardial cysts develop embryologically in relationship to the pericardium, although direct communication with the pericardial sac is rare. Radiographically they appear as smooth, clear, demarcated densities that can be mistaken for a pericardial fat pad or a hernia through the foramen of Morgagni. Aspiration reveals clear fluid. Surgical excision is not recommended.

Bronchogenic cysts arise in association with the major airways and are lined by respiratory epithelium. They may contain inspissated mucus. Local pressure on the trachea or bronchi can result in cough or wheezing. Occasionally the cysts communicate with the trachea, and when this is the case there is an increased tendency to recurrent infections. Surgical excision is recommended, particularly if there are associated symptoms (Fig. 4).

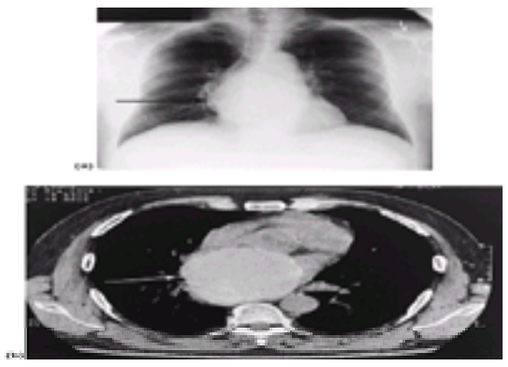

Fig. 4 Chest radiograph and CT scan showing a large mass in the mediastinum. This is a large bronchogenic cyst, present for 20 years, and finally removed when compression of the oesophagus resulted in dysphagia.

Reduplication cysts may also be associated with the oesophagus and can be lined by gastric or oesophageal mucosa.

Posterior mediastinal masses

Oesophageal lesions and aneurysms of the descending thoracic aorta can both result in abnormal shadows in the posterior mediastinum. Tumours, particularly those found in the paravertebral gutters, are likely to be neural in origin. Benign tumours tend to be asymptomatic, whilst malignant tumours cause pressure effects. Occasionally, spinal cord compression results from direct extension into the intravertebral foramen. Tumours arising from peripheral nerve cell sheaths include neurilemmoma (Schwannoma) and neurofibroma together with their malignant counterparts. Tumours of the autonomic chain include ganglioneuroma and neuroblastoma.

A neurilemmoma is the commonest neural tumour arising in the mediastinum. These are more common in middle age and can extend into the intravertebral foramen producing a dumb-bell appearance. Radiographically they can erode adjacent bone and CT scanning or MRI should be undertaken prior to surgical excision. Neurofibromata are also common. They may be solitary and the clinical and radiological features are very similar to those of a neurilemmoma. A significant proportion of patients will have neurofibromatosis. Surgical resection is recommended, in part because of the small risk of developing a malignant neurosarcoma **.** These tumours have a poor prognosis.

Ganglioneuroma arise from the autonomic plexus and are usually found close to the spine. Associated endocrine symptoms include hypertension, flushing, sweating, and diarrhoea. These tumours are often very large before they become clinically apparent. Prognosis is good after surgical resection. Ganglioneuroblastoma and neuroblastoma represent the malignant end of the spectrum and are predominantly tumours of infants and children. Neuroblastoma in particular is very invasive, with metastatic spread often established by the time of presentation.

17.15 The genetics of lung diseases

J. M. Hopkin

Genetic factors are important in lung biology and disease, ranging from monogenic disorders, for example cystic fibrosis, to multifactorial effects, for example those underlying the syndrome of asthma, in which there are crucial interactions between heterogeneous genetic effects and environmental factors. Subtle genetic factors are being steadily uncovered, for example those that modulate the risk of respiratory infection such as tuberculosis.

The bronchial tree

Cystic fibrosis

Cystic fibrosis is the most common fatal, autosomal recessive disease in Caucasians, with an incidence of 1/1500 and carrier frequency of 1/22. This condition is discussed in detail in Chapter 17.10.

Immotile ciliary syndrome

The immotile ciliary syndrome, or primary ciliary dyskinesia, is a rare (incidence 1/30 000), genetically heterogeneous disorder in which inheritance is usually autosomal recessive. The ciliary abnormality, especially lack of dynein arms, can normally be observed on electron microscopy of a ciliated mucosal biopsy or in spermatozoa. Impaired ciliary function results in impaired mucus clearance and leads to bronchiectasis, sinusitis (often with absence of the frontal sinuses and ear disease), and infertility in males. Kartegener's syndrome is one clinical subgroup of the immotile cilia syndrome where there is also dextracardia or situs inversus as the result of impaired organ rotation in development. Multiple linkages have been found. Loss of function mutations in dyneia chain is one cause

Atopy and asthma

Atopy is an immune disorder in which there is allergy or hypersensitivity to common antigens, such as the house dust mite and pollens, and which results in muocsal inflammation. It is one leading cause of the asthma syndrome and is characterized by exuberant Th-2 immune mechanisms and excessive production of IgE to such common antigens (see Chapter 17.4.1).

Twin studies demonstrate the shared input of genetic and environmental factors. For example the concordance in monozygotic twins for allergy to any common inhaled antigen is 71 per cent, compared with 36 per cent in dizygotic twins. Genetic searches for linkage to either high IgE levels or clinical asthma have identified a whole set of linkages on many chromosomes, thus confirming the heterogeneous genetic input. The first genetic variant shown to have both epidemiological and functional links to atopy and asthma is within the cellular receptor for the Th-2 cytokine IL-4 (IL4Ra). Substitution of isoleucine for valine in the extracellular domain of the receptor (position 50, Ile50Val) associates strongly with atopic asthma in Japanese children. In transfection experiments, Ile50Val up-regulated cellular response to IL-4 challenge and increased secretion of IgE. An amino acid charge-changing variant of another key Th-2 signalling cytokine, IL-13, also predicts asthma and atopy in different populations. One possible benefit of unravelling the heterogeneous genetics of atopy and asthma is the tailoring of novel therapies to patients with genetic variants of specific proteins or pathways.

The pulmonary parenchyma

a_1-Antitrypsin deficiency

Emphysema is mainly the consequence of cigarette smoking, but a_1-antitrypsin deficiency is a substantial risk factor for the development of accelerated emphysema in cigarette smokers. This leads to the proteolysis hypothesis for emphysema in smokers, which proposes that proteases such as elastase are released from pulmonary neutrophils and macrophages 'excited' by cigarette smoke. The actions of elastase on supportive tissue in the lung are opposed by the serine protease inhibitor (serpin) a_1-antitrypsin. When a_1-antitrypsin is deficient, or when smoking is very heavy, then the balance falls in favour of tissue destruction and the development of emphysema. This condition is discussed elsewhere.

In deficient individuals, the most important practical point in management is absolute avoidance of cigarette smoking. Replacement of a_1-antitrypsin protein, now available as a molecular engineered product, can increase lung levels when administered by infusion or by aerosol inhalation—but trials showing major clinical impact are still awaited. In a family with an affected individual, the risk of a_1-antitrypsin deficiency in a further sibling is one-quarter: molecular prenatal diagnosis is possible. The risk to the children of carrier siblings is very small since the incidence of severe a_1-antitrypsin deficiency alleles in the population is low.

Miscellaneous rare disorders

Pulmonary alveolar proteinosis is a rare heterogeneous disorder, characterized by the accumulation of PAS positive proteinaceous material in the alveoli. It can be secondary to malignancy or infection, for example histoplasmosis. The infant form is usually fatal and in some cases is probably a genetic disease. In one family with two affected siblings there was absence of surfactant protein B and its mRNA in the alveoli but markedly increased amounts of surfactant protein C.

Rare, but striking, reports of familial aggregation of early-onset diffuse alveolitis and pulmonary fibrosis are recorded, but their molecular genetic origins are obscure. In pulmonary alveolar microlithiasis, there are multiple, minute calcifications in the alveoli producing a typical radiographic appearance. Affected sib-pairs are well described and the observation of consanguinity suggests a very rare autosomal recessive disorder of obscure molecular genetic origin.

General genetic syndromes with parenchymal lung involvement

A number of well-described genetic syndromes may display a pulmonary component.

Diffuse interstitial pulmonary infiltrates on chest radiograph are recorded in a number of 'in-born errors of metabolism'—such as Farber's lipogranulomatosis, Niemann–Pick's disease type A and Gaucher's disease types I and III. Lethal pulmonary involvement may occur in lysinuric protein intolerance. Niemann–Pick's disease is caused by mutations in the gene for acid sphingomyelinase and results in the development of abnormal 'Niemann–Pick cells' that are histocytes whose

cytoplasm is filled with lipid droplets or particles. Particularly severe pulmonary involvement in Niemann–Pick type B is accompanied by infiltration of these abnormal cells into the substance of the lung and also its lymphatics and vessels. In Gaucher's disease, a lysosomal glycolipid storage disorder characterized by the accumulation of glucosyl ceramide (glucocerebroside), there are mutations in the gene on chromosome 1 encoding the enzyme b-glucosidase. Although pulmonary involvement is rare, it is severe and progressive when present; pathology shows infiltration by Gaucher monocytes/macrophage cells with their characteristic tubular cytoplasmic inclusions.

In the phakomatoses, for example neurofibromatosis or tuberose sclerosis, pulmonary involvement may be observed with pulmonary fibrosis, bulla formation, or lyomyomatosis.

In Marfan's syndrome there is an increased risk of spontaneous pneumothorax. In some subjects, apical bullae are present; more rarely, congenital cystic lung disease may be found. There is also a clear clinical impression that many young individuals presenting with spontaneous pneumothorax are rather tall and thin, whilst not having Marfan's syndrome. They may ultimately prove to have some genetically determined, mild connective tissue disorder.

The immune system

The lung is constantly exposed to the risk of infection and there are well-recognized genetic syndromes that predispose to chest infection. Many genetic variants with subtle effects on the risk of infection, for example tuberculosis, are being discovered.

Antibody deficiency may be secondary (for example to protein loss in renal or bowel disorder) or primary. X-linked and autosomal recessive forms of the latter are described and make infection with encapsulated bacteria and mycoplasmas common and severe. Variable combinations of IgA and IgG subclass and IgM deficiency are recognized. The clinical picture may be of repeated pneumonias, with typical systemic upset, or of bronchiectasis with chronic sepsis.

Severe combined immunodeficiency is a genetically heterogeneous syndrome with profound functional deficiency of both cellular (T cell) and humeral (B cell) immunity. In the X-linked form of disease, most of the mutations are in the gamma chain of the cellular receptor for the cytokine interleukin-2. Recessive disease in most cases is due to mutations in the purine catabolic enzyme, adenosine deaminase, and genotherapy may become possible in this condition. In severe combined immunodeficiency, symptoms start in infancy with failure to thrive, diarrhoea due to parasitic and viral infections, and pneumonia due to *Pneumocystis carinii*, an organism that typically requires effective T-lymphocyte function for its control.

Loss of function mutations in the receptors for Il-12 and IFN-g signalling leads to impaired Th-1 immunity and predispose to disseminated BCG infection, and disease due to environmental mycobacteria of low pathogenicity.

Ataxia telangiectasia is a complex autosomal recessive disorder that includes variable immune deficiency, cerebellar ataxia, and a propensity to develop leukaemias; it results from mutations in ATM kinase. The Wiskcott–Aldrich syndrome includes combined immune deficiency, haemorrhage due to thrombocytopenia, autoimmune disorder, and a tendency to malignancy. The locus X-chromosome encodes for a protein (WASP) that is important in the actin-based cytosketon.

Chronic granulomatous disease is associated with recurrent pyogenic infection of the respiratory tract, skin, and lymphoid tissue by catalase-positive bacteria and fungi. It is genetically heterogeneous. Oxygen-dependent microbial killing is crucial in phagocytes and the process is mediated by a multicomponent NADPH oxidase; the four major oxidase components being encoded at different chromosome locations—1q, 7q, 16p, and Xp. The most frequent form is X-linked and due to mutation in the gene for the large subunit of cytochrome b. Another important property of the phagocyte is accumulation at the site of infection, which is dependent upon the cell's adhesive properties and mobility. In leucocyte adhesion deficiency, an autosomal recessive condition, there are mutations in the CD18 gene, which codes for the b2 integrin subunit.

The complement system plays an essential role in the propagation of inflammation and host defence. Deficiencies have been described for many of its components. Deficiency of C3, an autosomal recessive, increases susceptibility to encapsulated bacteria because of the deficiency of C3b-dependent opsonization.

The vascular system

Pulmonary embolism

Pulmonary embolism, from venous thrombosis, is a common and important pulmonary syndrome. Genetic deficiencies, causing thrombophilia underlie the disorder in some individuals, particularly those with early-onset of disease, unusual sites of venous thrombosis, and recurrent disease.

Miscellaneous rare syndromes

Pulmonary arterial venous fistulas can be single or multiple and may be sporadic or genetic disorders. They can occur as part of the Osler–Rendu–Weber (hereditary haemorrhagic telangiectasia) syndrome. This is a genetically heterogeneous autosomal dominant in which the pulmonary lesions are usually multiple and asymptomatic but can bleed and cause haemoptysis, breathlessness, and chest pain. There are a number of reports of primary pulmonary hypertension clustering in families. This is rare and its mechanism, if distinct from a thrombotic tendency, is unknown.

Neuromuscular disorders affecting pulmonary function

Many genetic syndromes of the neuromuscular system can cause secondary respiratory insufficiency or failure, with a tendency to recurring chest infection because of impaired coughing. The most notable are the muscular dystrophies (for example the X-linked recessive Duchenne muscular dystrophy), dominantly inherited myotonic dystrophy, and autosomal recessive acid maltase deficiency (type II glycogenosis). In acid maltase deficiency, diaphragmatic involvement is common and patients sometimes present with respiratory failure.

Pharmacogenetics

Idiosyncratic reactions to various therapeutic drugs are well recognized and cause a great range of pulmonary disorders. The response of patients to therapeutic agents administered for lung disease also varies in terms of both therapeutic benefit and toxicity. A number of factors underlie such behaviour—including age, state of nutrition, hepatic function, and renal function. In a significant proportion, there may be discrete underlying genetic causes, but relatively few have been well characterized.

The cytochromes P450 are a large family of haemoproteins that metabolize foreign chemicals, including therapeutic drugs and some carcinogens, as well as some endogenous compounds such as steroids. Genetic polymorphisms influence their function and hence the response to drugs; debrisoquine and phenytoin are well described. Genetic polymorphism is also recognized at the locus for NAT2 encoding *N*-acetyltransferase. These polymorphisms or variants of NAT2 influence the rate of acetylation and therefore detoxification of isoniazid; slow acetylators are at risk of drug-related neuropathy (due to accumulated isoniazid) or hepatitis (thought to be due to production of a toxic isoniazid metabolite through an alternative biochemical pathway). Slow acetylators therefore need lower doses of medication to achieve a therapeutic effect and to avoid toxicity. The genetic variants of NAT2 can now be recognized by direct and simple PCR based assays; they are most commonly found in Asian populations.

Tumour genetics

Many potent carcinogens are also potent mutagens, suggesting that malignant transformation is based on heritable mutations in somatic cells. Cigarette smoke is a particularly powerful mutagen, containing a great range of chemical mutagens including aromatic hydrocarbons, nitrosamines, and pyrrholized amino acids.

There are varying sites and types of somatic mutation underlying malignancy, including visible chromosomal rearrangements and discrete mutations at 'oncogene' loci encoding cellular growth factors and their receptors, and growth regulators. For example in both small-cell and non small-cell carcinomas of the bronchus somatic

mutations in the gene for P53, an important growth regulator, are well described. Mutations in the cellular oncogene K *-ras* are found in adenocarcinomas of the lung.

Germline mutations are also important in influencing risk of tumour development in a number of ways—for example through pre-existent mutations in an oncogene or through variant metabolism of carcinogens. Thus polymorphisms of P4501A1 (which metabolizes polycyclic aromatic hydrocarbons) and of P4502E1 (which metabolizes nitrosamines) are associated with increased risk of lung cancer in smokers.

Microbial genetics

Respiratory infection is of massive, world-wide importance. The molecular genetics of the diverse organisms are being defined and the essential genetic foundations for pathogenicity and response to antimicrobial drugs are being clarified.

In antibiotic resistance, a number of genetic mechanisms have been identified. Antibiotic inactivating enzymes are an important mechanism and involve b-lactams, macrolides, and chloramphenicol, for example b-lactamase production by *Haemophilus influenzae*. This kind of resistance can be transferred between bacteria by gene transfer on plasmids.

Change of target is another mechanism, for example mutation in bacterial cell wall peptidoglycans inhibits penicillin binding in *Streptococcus pneumoniae*. In one form of resistance of *M. tuberculosis* to isoniazid, there are mutations in the *InhA* gene (whose protein mediates mycolic acid metabolism and hence cell wall structure), resulting in impaired binding of isoniazid to the target enzyme.

A third mechanism involves bacterial mutations that limit antibiotic penetration through the cell wall; this is thought to occur in the lipoproteins of the cell wall of pseudomonas species and causes reduced permeability and hence resistance to b-lactams and aminoglycosides.

Detailing the molecular genetics of respiratory pathogens offers important practical gains. For example organism-specific DNA sequences can be used as powerful diagnostic tools whose specificity and sensitivity are impressive when linked to *in vitro* DNA amplification. Successful PCR diagnostic assays have been developed for a number of pulmonary pathogens, including *Pneumocystis carinii*. Rapid DNA diagnostics can be used also to identify specific mutations that predict antibiotic resistance. DNA vaccines may become very effective immunizers for intracellular pathogens such as the influenza virus or *M. tuberculosis*, since the microbial DNA is taken up by cells and, following incorporation and expression, presented 'more naturally' to the immune system.

17.16 Lung and heart–lung transplantation

K. McNeil

Introduction

The first successful heart–lung transplant in 1981 heralded lung transplantation as a viable therapeutic option for endstage cardiopulmonary and pulmonary lung disease. The successful introduction of single and bilateral lung transplantation in the late 1980s led to greater availability of donor organs, with a consequent expansion in the number of potential recipients. Over 12 000 lung and heart–lung procedures have been performed over the past 18 years, with steadily improving results. Patients can now realistically expect a survival of 5 or more years and there is every prospect that these results will continue to improve.

The lung allograft is unique in that it remains in contact with the external environment, exposing it directly to numerous potential infections and allergens, which predispose to many of the problems encountered immediately post-transplant and in the longer term.

The major obstacles faced by lung transplant programmes are the shortage of suitable donor organs, the need to find more selective (less toxic) methods of immunosuppression, and the means to either prevent or reduce the impact of chronic allograft dysfunction.

The transplant process

The five factors which constitute the transplant process are recipient selection, donor selection, donor/recipient matching and the surgical procedure, immediate post-operative care, and long term follow-up.

Recipient selection

From the 'pulmonary' point of view, recipient suitability is determined by two factors—the underlying disease indication and the severity of that disease. Virtually any endstage pulmonary disease is amenable to transplantation. Most suitable diseases are confined to the thorax, although there are a number of systemic diseases with pulmonary manifestations where carefully selected patients can be transplanted successfully.

The diseases fall into four main categories: septic lung diseases (cystic fibrosis, bronchiectasis), obstructive lung diseases (emphysema/chronic obstructive pulmonary disease, asthma, obliterative bronchiolitis), fibrotic lung diseases (cryptogenic fibrosing alveolitis, sarcoidosis, fibrosis related to drug reactions, occupational exposures, acute lung injury, etc.), and pulmonary vascular diseases (primary pulmonary hypertension, Eisenmenger's syndrome). In addition, a number of other conditions such as lymphangioleiomyomatosis, histiocytosis, and even bronchoalveolar cell carcinoma have been treated successfully with transplantation.

Patients are usually listed for transplantation when their survival is estimated to be less than 2 years and there are no further medical or alternative therapies available. For patients with cystic fibrosis, primary pulmonary hypertension, and cryptogenic fibrosing alveolitis, prognostic indices are available to guide appropriate timing for referral and listing for transplantation. By contrast, it has become apparent that the survival of patients with Eisenmenger's syndrome and emphysema is the same on the waiting list as following transplantation. In this setting, transplantation is performed primarily for quality of life issues. Table 1 summarizes referral recommendations based on the guidelines used at Papworth Hospital, United Kingdom.

Contraindications are well defined. Most are relative, and considered in the context of the patient's overall status. Older patients have a poorer outcome, particularly with the more extensive surgical procedures. Thus, for heart–lung transplantation the upper age limit is usually 55 years, whereas for single and bilateral transplants the limit is usually set at 60 years. Recipients well above these limits have, however, been transplanted successfully.

Well-controlled diabetes and low-dose steroid therapy are no longer considered exclusion criteria. Significant coexisting kidney or liver disease precludes isolated thoracic organ transplantation, but selected patients can be considered for combined thoracic and abdominal organ transplants. Pleural disease (previous pleurectomy, infection, etc.) must be considered carefully because of the increased risk of bleeding. Patients with antibiotic-resistant organisms such as *Burkholderia cepacia* are at increased risk of perioperative sepsis and death, and different units will have individual policies on their suitability for transplantation.

Active malignancy (excluding localized squamous and basal cell carcinomas of the skin), major psychosis, extrapulmonary infection, severe malnutrition, and significant extrathoracic organ dysfunction are considered absolute exclusion criteria. Mechanical ventilation is an absolute contraindication in some units, but this does not generally include non-invasive or ambulatory support.

Donor selection

As the shortage of donor organs increases, criteria for acceptance of donor organs has liberalized. All donors are brainstem dead and should be free of systemic infection or disease. Lung allograft donors are generally less than 55 years of age, although there is an increasing trend to accept organs from older donors with acceptable results. Lung allograft suitability is based on function (gas exchange and compliance) and appearance (macroscopic, bronchoscopic, and radiographic). Haemodynamic performance and the macroscopic appearance of the coronary arteries determine the cardiac status of the heart–lung donor. Echocardiography and angiography are sometimes used but are not routinely available at every donor hospital.

Following acceptance of the allograft, matching of the donor organ with a suitable recipient is based on ABO blood group and size. Size matching is determined by comparing predicted donor total lung capacity (based on height, age, and sex) with measured and/or predicted recipient total lung capacity. Perfect size matching is rarely achieved but significant (more than 10 per cent) oversizing should be avoided because of the resultant lung compression and atelectasis. Conversely, undersizing of 10 to 20 per cent is easily accommodated by the natural compliance of the lung(s).

Surgery

There are three basic options when replacing diseased lung tissue—single-lung transplantation, bilateral sequential single (double) lung transplantation, and heart–lung transplantation. The choice of procedure is determined by the recipient's underlying disease. Diseases involving both the heart and lungs such as Eisenmenger's syndrome and endstage primary pulmonary hypertension are usually treated with heart–lung transplantation. Septic lung diseases such as cystic fibrosis and bronchiectasis require replacement of both lungs (bilateral lung transplantation or heart–lung transplantation). Most other diseases can be treated with

single-lung transplantation.

Single-lung transplantation involves a pneumonectomy followed by implantation of the allograft with anastomoses of the main bronchus, pulmonary vein, and pulmonary artery. Bilateral lung transplantation is performed as two sequential single-lung transplants. These are performed via either a sternotomy or bilateral thoracotomy, with or without cardiopulmonary bypass. Heart–lung transplantation mandates cardiopulmonary bypass and is performed via a sternotomy. Implantation is performed with tracheal, aortic, and atrial anastomoses.

The surgery must be performed meticulously. Careful dissection avoids damage to important structures such as the phrenic and recurrent laryngeal nerves and minimizes the chance of bleeding. Careful implantation reduces the risks of anastomotic complications. Ideally, implantation and reperfusion should be completed within 6 h.

Postoperative care

The first 24 to 48 h are critical to the long-term outcome of the transplant as well as for the survival of the recipient, and a principal aim of immediate postoperative care is to reduce allograft injury during this critical period.

The allograft inevitably sustains endothelial injury because of ischaemia and preservation, causing a breakdown of the capillary–endothelial barrier, resulting in leakage of fluid into alveoli. Increasing damage leads to a progressive impairment in gas exchange. This may necessitate prolonged mechanical ventilatory support, with an increased risk of infection and barotrauma often resulting in irreversible damage to the allograft.

The main principles of postoperative care of the lung transplant recipient are detailed below.

Early extubation

In the majority of patients, extubation is possible within 12 h of the procedure (in many cases much earlier than this). Extubation permits active coughing and clearance of secretions, institution of enteral nutrition, and early commencement of rehabilitation.

Fluid (crystalloid) restriction and diuresis

During the first 24 to 48 h, restriction of crystalloid intake and promotion of diuresis minimize the development of the pulmonary oedema characteristic of ischaemia-reperfusion injury. Crystalloid intake is limited to 1500 ml/day during this time. Colloid solutions are used for haemodynamic requirements.

Early mobilization

Patients with endstage lung disease are usually debilitated and in poor condition. It is therefore vitally important they are mobilized as early as possible. This improves appetite and sleep, and prevents complications such as basal atelectasis and deep venous thrombosis. Most patients are able to sit out of bed within 24 h and can participate in a gymnasium program by day 3. Adequate analgaesia is imperative for effective rehabilitation at this early stage.

Nutrition

The early institution of adequate calorie intake is necessary to overcome the severe catabolism stimulated by surgery. This is particularly important in patients with a poor pretransplant nutritional state. In most cases, enteral feeding can be started within 24 h (orally or via a nasogastric or percutaneous gastrostomy tube). If the gut is not functioning, parenteral nutrition should be used.

Prevention of infection

Bacterial infection remains the most significant early problem and is responsible for most deaths during the perioperative period. In most cases the organism is recipient derived. Antibiotic prophylaxis is administered until the patient is mobile, all drains have been removed, and respiratory secretions are clear. The underlying disease and/or pretransplant microbiology results dictate the choice of antibiotic. In cystic fibrosis and other septic lung diseases the antibiotics used cover *Pseudomonas aeruginosa* and *Staphylococcus aureus*. In other patients, community acquired respiratory pathogens (pneumococcus, haemophilus, etc.) and *Staphylococcus aureus* are targeted.

Fungal infection in the form of oropharyngeal candidiasis is common post-transplant and prophylaxis with topical nystatin or amphotericin is effective. Systemic prophylaxis against candida is not generally necessary. Aspergillus is the commonest cause of invasive fungal disease, and in single and bilateral lung transplantation, nebulized amphotericin (5 mg three times a day) given for the first month post-transplant is effective in reducing aspergillus-related problems. Routine use of itraconazole prophylaxis is dependent on local policy and experience. It is very uncommon for heart–lung transplantation recipients to have problems with aspergillus in this period as the tracheal anastomosis is not ischaemic, and all diseased lung tissue is removed. Routine prophylactic strategies are therefore not required.

Viral infections (specifically herpesviruses) tend to occur later in the recovery period but prophylaxis must be administered from the early stages to be effective. Ganciclovir is very effective in reducing both the incidence and severity of cytomegalovirus and other herpesvirus related illness, but there is no consensus on the optimal prophylaxis regimen. Most units opt for a combination of intravenous and oral therapy for 1 to 3 months, given to any recipient who is serologically cytomegalovirus-positive or who receives an allograft from a cytomegalovirus-positive donor. Herpes simplex virus commonly causes mucocutaneous infection. In the occasional cytomegalovirus-negative donor/recipient match (where ganciclovir is unnecessary) aciclovir is used for herpes simplex prophylaxis.

Cotrimoxazole prophylaxis is used to prevent both pneumocystis infection and toxoplasma reactivation. Standard therapy is 480 mg daily or 960 mg three times a week. Therapy is given for a minimum of 12 months or until corticosteroid therapy has been reduced to physiological replacement doses. If cotrimoxazole is not tolerated, nebulized pentamidine (300 mg per month) is an effective alternative.

Prevention of rejection

In lung transplantation, there are three basic phases of immuno-suppression—induction, consolidation, and maintenance. The details of the exact combinations and doses of agents used vary from unit to unit. Table 2 shows a typical regimen.

Induction phase

Typically, antithymocyte globulin, azathioprine, and corticosteroids are used. Therapy commences immediately pretransplant. The use and length of induction with antithymocyte globulin is not standardized and varies with local unit policy.

Consolidation phase

This phase covers the period when stabilization of the immunosuppressive regimen is achieved. The aim is to achieve optimal immunosuppression (prevention of acute rejection) with tolerable side-effects. It is important to remember that the primary goal is to minimize acute rejection. Inevitably side-effects do occur, but these should not determine immunosuppression levels at the expense of acute rejection. Cyclosporin is introduced and dosing modified to achieve whole blood trough levels above 350 ng/litre. This is usually achieved with doses around 10 mg/kg/day (given in two divided doses). Drug absorption in the perioperative period can be very variable, especially in cystic fibrosis patients where dosing three times a day is usually necessary to achieve satisfactory levels. Azathioprine is continued at a dose of 1 to 2 mg/kg/day, aiming for a white blood cell count of 4×10^9 to 6×10^9/litre. Prednisolone doses are gradually reduced to a maintenance level of 0.2 mg/kg/day.

Maintenance phase

This phase continues for the life of the recipient and is discussed below.

Follow–up

The thrust of management in the longer term is to maintain allograft function, and to minimize the side-effects of immunosuppression. Best lung function is usually established by 6 to 9 months post-transplant. The incidences of acute rejection and infection are highest in the first 3 months. Immunosuppression can be slowly reduced, aiming to stop prednisolone after 12 months and achieving target cyclosporin levels at this time of 150 to 250 ng/litre. Immunosuppression must, however, be tailored to individual requirements and prevention of acute rejection remains the primary goal.

Monitoring of symptoms, chest radiography, and spirometry are the basis of allograft surveillance. Small handheld spirometers enable daily home monitoring of lung function. A 10 per cent or greater fall in the forced expiratory volume in 1 s (FEV_1) prompts review and investigation of the cause.

When allograft dysfunction occurs, transbronchial biopsies are performed to diagnose the cause. Acute rejection and infection cannot be distinguished clinically, and may occur simultaneously. Histopathological diagnosis of the cause of dysfunction is therefore mandatory. Some units perform regular surveillance transbronchial biopsies, but there is no evidence that there is any advantage to this approach in terms of outcomes.

Specific complications

Lung transplantation is rarely an uncomplicated endeavour. All recipients will suffer at some stage either a complication of the process or a side-effect of medication. Surprisingly, however, most patients do not experience life-threatening or major complications until the inevitable onset of chronic allograft dysfunction.

Many of the complications experienced by lung transplant recipients are common to all forms of solid organ transplantation and relate to drug side-effects (hypertension, renal dysfunction, osteoporosis, hypercholesterolaemia, etc.). The following problems relate specifically to lung transplantation.

Rejection

Rejection occurs in three distinct forms, defined by the underlying immunological events and the histological changes. Acute and chronic rejection are not defined by the timing of occurrence after transplant. Acute rejection can occur at any time, and 'chronic rejection' can occur after only 3 months. The two processes can coexist and probably have distinct immunological aetiologies.

Hyperacute rejection

This occurs within 24 to 48 h of transplantation and is caused by the presence of preformed antibodies in the recipient directed against donor HLA. Complement activation and widespread endothelial damage with vascular thrombosis result in rapid and severe allograft dysfunction, which is usually fatal. Removal of the antibodies with plasma exchange, and institution of an anti-B-cell therapy such as cyclophosphamide is the usual treatment.

Acute rejection

Almost all patients will experience at least one episode of acute rejection defined by the strict histological criteria listed in Table 3. The essential findings are a perivascular lymphocytic (predominantly T cell) infiltrate. Clinically, the patient often complains of 'flu-like' symptoms with dyspnoea and low-grade fever. In the early stages the chest radiograph may be normal or show pleural effusion and/or subtle alveolar shadowing. Left untreated, widespread alveolar shadowing and hypoxaemia occur. The diagnosis should be confirmed histologically (via transbronchial biopsy), as it is common for infection to occur simultaneously. These problems cannot be distinguished clinically.

Acute rejection is treated with intravenous methylprednisolone (0.5–1 g daily for 3 days). This is effective in the majority of cases. Steroid-resistant rejection is usually treated with either a polyclonal (ATG) or monoclonal (OKT3) antilymphocytic agent. In addition, it is also now usual to change the background immunosuppression by substituting either tacrolimus for cyclosporin or mycophenolate for azathioprine (or both).

Chronic rejection (obliterative bronchiolitis)

In lung transplantation, the term 'chronic rejection' denotes the presence of obliterative bronchiolitis. It is defined histologically (airway fibrosis and/or vascular sclerosis), not by the time of occurrence after transplant. The term 'chronic rejection' is something of a misnomer in this setting, as there are many processes (both alloimmune and non-alloimmune) that result in fibrotic obliteration of the airway lumen. The term 'chronic allograft dysfunction' is preferred: this implies the presence of obliterative bronchiolitis but does not imply an exclusively alloimmune aetiolgy.

Pathology

Obliterative bronchiolitis is a fibroproliferative scarring process, resulting in either total or subtotal obliteration of the airway lumen. In some cases, there is accompanying vascular sclerosis. Rarely, vascular sclerosis exists without airway changes

Physiology

The airway pathology translates into fixed airflow obstruction. This has enabled a non-invasive marker of the presence and severity of obliterative bronchiolitis to be developed, namely the bronchiolitis obliterans syndrome. Bronchiolitis obliterans syndrome is functionally defined by a fall in the FEV_1, as measured from a baseline average of the two best FEV_1 measurements achieved post-transplant taken at least 1 month apart. No reversible cause of the fall in lung function should be present. Table 4 summarizes the bronchiolitis obliterans syndrome grading system. It has been confirmed in a number of large series that bronchiolitis obliterans syndrome accurately reflects the presence and severity of obliterative bronchiolitis, and is widely used in clinical practice for this purpose.

Aetiology

Obliterative bronchiolitis is undoubtedly multifactorial in aetiology. Any discrete insult resulting in significant damage (e.g. aspiration, viral pneumonitis) will inevitably lead to scarring. The precise alloimmune mechanisms involved remain unknown.

There are two risk factors identified as being strongly predictive of the development of obliterative bronchiolitis—the frequency of early acute rejection and cytomegalovirus serological status. Recipients with more than two episodes of acute rejection in the first 3 months post-transplant have a threefold or higher risk of developing obliterative bronchiolitis than those with no acute rejection. Any cytomegalovirus serological positivity confers an increased risk of developing obliterative bronchiolitis, with cytomegalovirus-negative recipients who receive organs from a cytomegalovirus-positive donor being at greatest risk.

Natural history

Obliterative bronchiolitis confers an increased risk of death, with the hazard ratio increasing with worsening bronchiolitis obliterans syndrome status. Patients in bronchiolitis obliterans syndrome grade 3 have a risk of dying six times higher than those in bronchiolitis obliterans syndrome 0. Once acquired, bronchiolitis obliterans syndrome usually progresses quickly, with a mean time for progression to the next stage or death of only 150 days. This is more pronounced in patients with frequent early acute rejection who are at risk of an even greater acceleration of their disease. The main cause of death in patients with obliterative bronchiolitis is infection. Inevitably, bronchiectasis develops in association with the obliterative bronchiolitis, with organisms such as pseudomonas and aspergillus becoming

problematic.

Treatment

There are no controlled trials to guide treatment of this condition. In some cases, the disease arrests spontaneously. Augmented immunosuppression increases the risk of infection and is not usually effective. Most units now change immunosuppression early in the disease, substituting tacrolimus for cyclosporin, or mycophenolate for azathioprine. In advanced disease, numerous treatments such as methotrexate, phototherapy, and total lymphoid irradiation have been tried, but no consensus exists regarding the best course of action. If the disease progresses despite the above changes, immunosuppression is reduced in an attempt to minimize the impact of infections.

Specific infections

Cytomegalovirus

Before the introduction of ganciclovir, cytomegalovirus pneumonitis had a mortality rate of 50 per cent in cytomegalovirus-naive lung transplant recipients. This led to the matching of cytomegalovirus-negative recipients with cytomegalovirus-negative donors to prevent primary (donor acquired) infection. Ganciclovir therapy (both treatment and prophylaxis) has proven very effective in reducing both the morbidity and mortality associated with this infection.

Prophylaxis is effective in both delaying the onset of clinical infection and reducing the severity of subsequent infective episodes. In lung transplant recipients, cytomegalovirus most commonly causes pneumonitis. Cytomegalovirus syndrome describes an illness characterized by fever, malaise, and leucopenia, and may accompany target organ infections such as pneumonitis or hepatitis. Treatment is with intravenous ganciclovir (10 mg/kg/day). In cases of ganciclovir intolerance or resistance, foscarnet is used. Many patients will have cyclosporin related renal dysfunction and appropriate dose adjustments are necessary. Ganciclovir causes bone marrow suppression and severe leucopenia can occur in association with the low white cell count caused by cytomegalovirus. Antiviral therapy should be continued, and in this setting the addition of granulocyte colony stimulating factor is usually effective. Cytomegalovirus retinitis is uncommon in lung transplant recipients and requires specialist ophthalmology review and follow-up.

Aspergillus

Aspergillus infection occurs in pulmonary and extrapulmonary forms. Extrapulmonary disease is always invasive. There are several forms of pulmonary infection, and significant differences in the timing and pattern of aspergillus infection related to the type of transplant. In single and bilateral lung transplants where the bronchial anastomosis is relatively ischaemic, aspergillus related problems tend to occur early (most within the first 3 months). In addition, there is a very high risk of developing an airway problem if aspergillus is present in this setting. By contrast, in heart–lung transplantation, the tracheal anastomosis is not ischaemic (due to a collateral blood supply from the coronary arteries), and most aspergillus related problems occur later with the onset of obliterative bronchiolitis.

Aspergillus infection of any sort must be diagnosed and treated early. Airway manifestations and early invasive parenchymal disease have a good prognosis. Late-stage or disseminated disease is usually fatal. Treatment with systemic amphotericin in high doses is used. Liposomal amphotericin B is the preferred therapy because of its much improved side-effect profile compared with the conventional preparation (CAB). This is very evident in the setting of cyclosporin induced renal dysfunction which severely limits therapy with CAB. Treatment starts at a single dose of 5 mg/kg/day. It is well tolerated and can be given via a peripheral line.

The role of azoles (primarily itraconazole) as primary treatment of aspergillus infection in this population is not established. Itraconazole is generally reserved for prolonged treatment following a course of liposomal amphotericin B, or where long-term prophylaxis is required. The latter situation usually arises when aspergillus is repeatedly isolated in the setting of an airway complication, or in the presence of obliterative bronchiolitis.

Pneumocystis

Pneumocystis infection is now an uncommon occurrence following the introduction of specific (cotrimoxazole) prophylaxis. Pneumocystis pneumonia in lung transplant recipients presents in a very different manner from pneumocystis pneumonia in AIDS patients, and if not recognized can be fatal. The onset is often insidious, with a low-grade febrile illness and mild to moderate dyspnoea, often only on exertion. Chest radiograph may be normal or show subtle alveolar shadowing, usually in the upper lobes. High-resolution computed tomography scanning shows a ground-glass pattern. Severe hypoxaemia and gross radiographic changes are uncommon. Transbronchial biopsies typically show a granulomatous pneumonitis. On occasions, the histology mimics acute rejection and if special staining is not performed the organisms will be missed. In addition, in distinct contrast to pneumocystis pneumonia in AIDS, the organism load in lung transplant recipients is very low. Pneumocysts are not usually recovered from bronchoalveolar lavage fluid, and can be very difficult indeed to find in biopsy tissue. Repeated transbronchial biopsies may be necessary to diagnose the condition. Treatment is the same as that employed in HIV infected patients, although very high-dose therapy is usually not required with the low organism loads.

Mycobacterial infection

Tuberculous mycobacterial and non-tuberculous mycobacterial disease occur at an increased frequency in lung transplant recipients when compared with the general population. Occult and old mycobacterial disease is sometimes found unexpectedly in explanted organs. In single lung transplantation, disease may remain in the native lung.

With previous inadequately or untreated tuberculous mycobacterial infection, prophylaxis with isoniazid should be considered. The use of rifampicin as a chemoprophylactic agent is not advisable because of the profound interaction with cyclosporin. If full treatment is required, standard robust antituberculous regimens are indicated, and since rifampicin has the profound effect of inducing hepatic metabolism, cyclosporin doses must be adjusted accordingly (dose increases of four- to fivefold are usually required).

Non-tuberculous mycobacterial infections tend to occur later in the post-transplant course than tuberculous mycobacterial disease. Treatment is based on ethambutol and rifampicin with the addition of a macrolide (clarithromycin or azithromycin) and ciprofloxacin. There are no data to guide the choice or length of treatment, but a minimum of 12 months' therapy is usually required, depending on the organism. Intolerance of medication is a significant problem that often limits treatment options in the longer term.

Gastrointestinal complications

Gastrointestinal problems are common after lung transplantation. They often relate to the side-effects of medication and are usually limited to upper gastrointestinal symptoms and/or diarrhoea. All patients receive antibiotics post-transplant and *Clostridium difficile* should be considered in the differential diagnosis of any case of diarrhoea or large bowel problems. Cytomegalovirus (discussed above) is the only other common infective gastrointestinal complication.

Upper gastrointestinal motility problems are common in recipients with cystic fibrosis and are exacerbated by vagus nerve damage during the procedure. All patients are prone to constipation because of immobility and drug therapy such as narcotic analgaesia. Regular laxative therapy should be used throughout the perioperative period. Cystic fibrosis patients are particularly prone to this complication, manifesting as distal intestinal obstruction syndrome. This life-threatening complication is managed aggressively with oral gastrograffin.

Bowel perforations are a catastrophe requiring urgent laparotomy for diagnosis and treatment. The signs of acute abdomen may be modified or absent in patients on steroids, and a high index of suspicion is needed to ensure rapid diagnosis and appropriate intervention. Gastrointestinal lymphoma often presents with small bowel perforation.

Pancreatitis affects a small number of patients and, unless related to gallstones, is usually fatal. Drugs such as azathioprine and prednisolone, and cardiopulmonary bypass are recognized risk factors. a_1-antitrypsin-deficient and cystic fibrosis recipients are also at increased risk. Treatment is along standard lines but there is usually rapid progression to multiorgan failure and death.

Neurological complications

Most of the neurological problems encountered post-transplant are related to cyclosporin toxicity and respond to dose reduction. Tremor and headache are very common, peripheral neuropathy less so. Diffuse cerebral oedema has occurred in a number of patients and been attributed to an idiosyncratic reaction to cyclosporin. Recipients with cystic fibrosis are particularly prone to seizures, particularly in the setting of high cyclosporin levels and/or hypertension (also a side-effect of cyclosporin). Infection of the central nervous system and lymphoma should always be considered in the differential diagnosis of central neurological symptoms.

Malignancy

Solid organ and lymphoid malignancies occur at an increased frequency, affecting up to 4 per cent of recipients. Lymphoproliferative disorders are related to the intensity of immunosuppression, and are driven by replication of Epstein–Barr virus. Most cases are focused in the allograft and most occur in the first 12 to 18 months post-transplant. Classification of these disorders is problematic. Some are clearly a polyclonal lymphocyte proliferation that usually respond to a reduction in immunosuppression and aciclovir therapy. Other cases present as lymphoma (non-Hodgkin's) and are treated with standard chemotherapy regimens. There are many cases where the disorder falls between these two extremes and treatment decisions are often very difficult. In these cases, histology is not a reliable guide to clinical behaviour or response to treatment. Patients are usually given a 1 to 2 month trial of aciclovir and reduced immunosuppression, with either non-response or progression indicating the need for chemotherapy. Reduction of immunosuppression involves decreasing cyclosporin levels by 30 to 50 per cent, stopping azathioprine, and reducing prednisolone to 10 mg or less per day. There are, however, no evidence-based data to support these recommendations, which are based on clinical experience. The prognosis of these disorders is surprisingly good, especially if confined to a single organ system. Most respond to reducing immunosuppression. In those requiring chemotherapy, complications of the treatment are largely responsible for the morbidity and mortality seen. Patients diagnosed with advanced disease invariably have a poor outcome.

The commonest solid organ tumours seen are cutaneous malignancies (squamous or basal cell carcinoma). With early diagnosis and treatment they carry a very good prognosis. By contrast, other solid organ malignancies (lung, gastrointestinal tract, etc.) carry a very poor prognosis, usually resulting in death within 3 to 6 months of diagnosis.

Airway complications

The bronchial anastomosis is prone to problems, with most units experiencing an airway complication rate of around 10 per cent. The bronchial anastomosis is devoid of its normal bronchial arterial supply, relies on retrograde perfusion from the pulmonary arteries, and is therefore relatively ischaemic. Bronchial artery revascularization procedures are time-consuming, technically demanding, and not widely performed. Complications range from minor narrowing of the bronchus, to severe narrowing requiring surgical intervention, to dehiscence and death. Bronchial stenoses are treated with dilatation and/or stenting.

The situation in heart–lung transplantation is completely different. The tracheal anastomosis has a collateral blood supply derived from the coronary arteries. The airway is well vascularized and serious airway/anastomotic problems are rare.

Outcome

Many studies have shown that lung transplantation confers significant survival and quality of life benefits to the majority of recipients. In experienced units, survival figures of better than 80 per cent at 1 year and 50 per cent at 5 years are now achieved for all types of transplant and underlying disease category. For those surviving the first year, the adjusted 5-year survival figure is 60 to 70 per cent.

The main cause of death in the first 12 months is infection (predominantly bacterial). Acute rejection rarely causes death directly. Its main impact is as a risk for the development of obliterative bronchiolitis, which is the main factor determining long-term survival in the majority of lung transplant recipients.

Survival is usually associated with markedly improved lung function and this translates into an improved functional capacity. As an example, in our own cystic fibrosis recipient group, FEV_1 improved from a mean of only 21 per cent predicted pretransplant, to 88 per cent predicted at 1 year post-transplant. Many patients are able to return to work and live a near normal life. Several female lung transplant recipients have undergone normal pregnancies without specific transplant related complications.

Conclusion

Lung and heart–lung transplantation offer the only therapeutic option for many patients with a variety of endstage pulmonary and cardiopulmonary diseases. With increasing experience and the development of more effective immunosuppression, survival figures continue to improve. The limiting factor in providing transplants is the critical shortage of donor organs.

18.1 Joints and connective tissues: introduction

Jonathan C. W. Edwards

Modern medicine has moved away from diseases with Latin names towards concepts of disordered physiology. Discussion is increasingly of airflow obstruction, insulin resistance, or reduced ejection fraction. Rheumatology has been behind in this move. Terms such as rheumatoid arthritis and osteoarthritis remain popular and may do so for a few years more. A more physiological approach must come, but old habits die hard.

Five major components of joints are involved in disease: cartilage, bone, tensile tissues (ligament and tendon), and, in diarthrodeal joints, synovium and synovial fluid. Building an understanding of the structure and function of these tissues not only lays down a scientific basis for joint disease, but is also directly relevant to the clinic, providing a framework for explanation and reassurance for patients, which, arguably, is the rheumatologist's main function.

An emerging theme in joint physiology is that biophysics, neurophysiology, and immunoregulation are simply facets of a seamless whole of tissue homeostasis. Disease often arises when interactions between these elements of homeostasis break down.

Cartilage

The primary function of hyaline cartilage is the generation and maintenance of skeletal shape. Most hyaline cartilage ossifies during growth but small amounts are retained in the nose, ribs, and joints. Loss of articular hyaline cartilage reveals two local functions. Spongy bone collapses once cartilage is lost, indicating a force distributing function. The bone margin also remodels progressively in response to changing mechanical stimulation, demonstrating that articular cartilage retains a 'shape memory' function, reflecting its relative resistance to remodelling in response to stress.

Although hyaline cartilage is often seen as adapted to low friction, many human joints (and most avian) function perfectly with fibrocartilaginous surfaces. Fibrocartilage replaces hyaline cartilage following loss, so hyaline cartilage might be considered redundant in this respect.

Cartilage loss

Loss of hyaline articular cartilage is the commonest major joint problem. Loss may occur either by fragmentation, with formation of fissures and the release of debris into the joint, or by resorption. If any central concept survives the debate about what osteoarthritis means, it is cartilage fragmentation under load. Cartilage wear occurs at points of loadbearing. Resorption of cartilage occurs in inflammatory disease and involves replacement of cartilage at the articular margin by fibrovascular 'pannus'. The two processes often coexist.

A major problem with the concept of 'osteoarthritis' is the confusion of events leading up to cartilage fragmentation and the events put in train once fragmentation has started. The events leading to fragmentation are many and affect different joints to differing extents. Dysplasia, heritable biochemical defects, metabolic changes, heritable tendencies to new bone formation, non-physiological usage, obesity, and prior damage from inflammatory disease all contribute. However, it is not clear if all of these factors belong to the concept of osteoarthritis, or whether some represent 'primary' and others 'secondary' disease. In most cases the factors inducing cartilage fragmentation are not understood. The idea that changes in the subchondral bone lead to altered loading on cartilage and subsequent failure is currently popular. This is almost certainly true in Paget's disease, but perhaps more subtle bony changes in middle age underlie many 'primary' cases. It would certainly be the best explanation for the sequential appearance of Heberden's nodes over a period of months in the hands of women who use them rather little.

The events which follow as cartilage fragments are well documented in animal models of non-physiological use, and now in models of excessive bone formation. Changes in glycosaminoglycan composition occur early, with subsequent failure of the collagen framework and disintegration. Disintegration usually starts at the cartilage surface, but there are also examples of cartilage fracturing away from subchondral bone. A major unknown is the role of chondrocyte death in this sequence. Chondrocyte death precedes collagen disruption in at least some cases and could be the critical irreversible event in joints such as the hip.

Resorption of hyaline cartilage is prominent in both septic and aseptic arthritis. Again, several pathways contribute, most involving enzymes. However, chondrocyte death may also play a role here, since most published micrographs of cartilage being resorbed show significant numbers of dead chondrocytes. Toxic factors such as reactive oxygen species and depletion of nutrients may damage cells. Reactive oxygen species and proteolytic enzymes may also attack extracellular matrix. Enzymes may act locally at the surface of cells in pannus activated by cytokines, or indiscriminately, if released into synovial fluid, as may apply to neutrophil elastase.

Chondrocytes also show evidence of degrading their own matrix, both in inflammatory and mechanical disease. Metalloproteinases induced by cytokines such as interleukin 1 and tumour necrosis factor-a are likely mediators. Disruption of collagen by collagenases or gelatinases is likely to be the critical irreversible event. However, depletion of glycosaminoglycan by stromelysin or aggrecanase may make the collagen susceptible to mechanical damage through loss of swelling pressure. Mobilization of aggrecan may also occur through changes in non-covalent interactions involving hyaluronan and binding proteins such as TSG-6 (the product of tumour necrosis factor-senstive gene 6).

Bone

New bone formation commonly occurs in reaction to cartilage fragmentation. However, bone overgrowth has a wider significance. In many joints, subchondral bone remodels gradually over decades, with flaring at the margin and changes in articular congruity. This occurs in the absence of any prior failure of cartilage. In the ninth decade osteophytes are commonplace. One of the major obstacles to effective management of 'hard tissue problems' is the lumping together of new bone formation with loss of (cartilage) joint space as 'degenerative change' in radiographic assessment. The physician cannot reassure the patient with a clear explanation if he or she is not in possession of the facts.

New bone formation

The commonest articular problem attributable to new bone formation is probably pain from impingement of the under surface of the acromion on the rotator cuff tendon of the shoulder. Irritation of the medial collateral ligament of the knee is also common. Compression of other structures occurs, with carpal tunnel syndrome and sciatica being obvious examples.

Very little is known about the factors responsible for the rate of growth of periarticular bone. There is a documented familial element for some sites. A degree of physical stress is probably necessary, in that flaccid limbs may retain a lifelong adolescent bony outline. There is, however, no clear relationship to the degree of use.

A different form of new bone formation occurs at ligament insertion sites. Generalized forms are termed diffuse idiopathic skeletal hyperostosis or Forestier's disease.

These patterns of new bone formation may restrict movement, yet may protect against pain.

Tensile tissues—ligament, tendon, and enthesis

Apart from trauma and tenosynovitis (see synovium), tensile tissue problems are focused at entheses—the attachments of ligament, tendon, or aponeurosis to bone. Entheses are variable, containing fibrocartilaginous and hyaline cartilage elements, and undergo structural change at the cessation of growth, which may influence disease onset. Entheses provide routes for vascularization of the tensile tissue.

Enthesopathy is the central lesion of the seronegative spondarthropathies. Two patterns can be separated—axial and peripheral. Axial enthesopathy affects spinal ligaments and the sacroiliac joint. Peripheral enthesopathy affects ligaments around peripheral joints, the plantar ligament origin, and the Achilles tendon insertion.

Axial enthesopathy is strongly associated with the B27 major histocompatability complex class I allotype. This may reflect an unusual immunological microenvironment in tissues under tension. The same sites which overstretch in Marfan's syndrome become inflamed in ankylosing spondylitis: entheses, the lung apices, the aortic root, the ciliary body, and the sacral root sheaths. Several of these sites are favoured by intracellular infections such as tuberculosis and brucellosis, suggesting that major histocompatability complex class I mediated events, such as cytotoxicity, are inhibited there, perhaps to avoid inflammatory resorption of tensile matrix. Inhibition may be mediated by local production of factors such as transforming growth factor-b. Structural differences between B27 and other allotypes are emerging which raise the possibility that local inhibition of class I associated events at sites such as entheses may be defective in the case of B27.

Synovium

Synovium comprises a superficial intimal cell layer and a subintima, which can consist of any type of connective tissue. The intima, unlike epithelium, is an incomplete and loosely arranged layer of modified macrophages and fibroblasts.

Why such a seemingly trivial tissue should be the major target for several autoimmune and inflammatory disorders may appear puzzling. However, tracing the evolution of synovium reveals some clues. Prior to the development of the jaw in cartilaginous fishes the endoskeleton was a semirigid rod of no immunological interest. Primitive immunity and leucocyte activity is likely to have focused on coelomic (serosal) cavities. Splanchnopleura remains the site of lymphocyte origin in mammals. Cartilaginous fish developed cavities within the skeleton, lined by a new tissue—synovium. Synovial intima and serosae share the expression of a complement regulatory protein, decay-accelerating factor and the immunoglobulin IgG receptor FcgRIIIa, suggesting a shared pattern of immunoregulation. Bone marrow and endoskeletal leucocytopoiesis developed later in teleosts, with bone marrow stroma derived from the same perichondrial stock as synovium. Bone and synovial stromal cells therefore share many features, including readiness to express the adhesion molecule VCAM-1. Thus, the cells of the intimal layer show marked immunological specialization. Intimal macrophages may be adapted to an 'early warning' response to immune complexes, in terms of FcgRIIIa expression, and the fibroblasts have an enhanced capacity to support lymphocyte survival via VCAM-1 and decay-accelerating factor. This combination may make the tissue particularly susceptible to autoimmune disease.

Just as tensile stress may regulate the enthesial immunological microenvironment, other stresses may contribute to the synovial environment. Macrophage FcgRIIIa expression appears to be induced at sites of shearing, not only in synovium but also in dermis over bony prominences, matching the distribution of rheumatoid nodules. Hence biophysics and immunology are inseparable.

Functions of synovium

Functions of synovium are not easily defined because removal of synovium causes few problems. It regenerates rapidly. Misconceptions about synovium, such as the existence of 'Haversian glands' have flourished. Largely as a result of the work of J. R. Levick, it has become clear that the dynamics of synovial fluid are unique and quite different from glandular secretion. Other functions have also been reappraised with the general conclusion that synovium has to be understood on its own terms, not by analogy with other tissues.

Functions of synovium are summarized below.

Disconnection

Unlike other connective tissues, synovium maintains a plane of disconnection which allows movement between rather than within solid tissues. This involves the maintenance of a non-adherent tissue surface. The best example of failure of this function is adhesive capsulitis of the shoulder, in which synovium becomes adherent to itself.

Low friction

Synovium contributes to low friction between cartilage surfaces and between synovial surfaces. Three molecules are important: water, hyaluronan, and a glycoprotein, lubricin. Water is a good lubricant, but cannot alone maintain a film between surfaces under load. Hyaluronan is not a lubricant but a film-maintaining agent. It is a carbohydrate polymer which adds viscosity and elasticity to water making it almost impossible to squeeze a film from between two surfaces. Lubricin is a true lubricant, reducing friction to an extremely low level.

Although changes in synovial fluid in disease probably alter lubricating efficiency, this may have little clinical relevance. In the short term joints appear to function well despite dilution of synovial fluid with exudate. The value of the sophisticated lubricating function of normal synovial fluid is that it reduces long-term articular surface wear to zero. The same collagen molecules are present on the surface 50 years after they were put there. Persistent presence of exudate in joints might facilitate wear, but preserved cartilage in reactive arthritis argues against even this. Attempts to modify the properties of synovial fluid are of doubtful value.

Deformable packing

The articular surfaces of most joints are incongruent. The intervening space is packed with synovium. Synovial fluid fills the tiniest crevices, with a film thickness of 40 µm in many places. With joint movement synovium has to deform with minimal resistance. How this is done remains totally unknown. Loss of this deformability is at least as important a source of disability as bone or cartilage damage in inflammatory arthritis, and can be devastating in children. It deserves serious study.

Chondrocyte nutrition

Cartilage is avascular, and chondrocytes must derive nutrition via the subchondral plate or from synovium. The synovial route is most accessible, although there is no proof that cartilage cannot survive without synovium. Synovectomy is not followed by cartilage death. There is also no evidence that synovium is structurally adapted to the nutrition of cartilage since its vasculature is similar when lining tendons, which have their own vascular supply.

It is commonly suggested that synovial fluid is important in transferring nutrients from synovium to cartilage. In fact, synovial fluid impairs nutrient transfer by acting as a diffusion gap. Without it much of the cartilage would be in contact with vascular synovium. During movement synovial fluid may facilitate nutrition of surfaces which do not come in to contact with synovium, but the fluid capacity is small and routes through solid tissue may be effective. The only likely clinical relevance of synovial fluid in nutrition is that large effusions, particularly those containing fibrin, may impair diffusion from synovium to cartilage leading to ischaemia.

Control of synovial fluid volume and composition

The combined action of muscles and lymphatic 'hearts' normally returns free tissue fluid to the circulation. Since synovial surfaces are permeable to water and there is no active pumping of water into synovial cavities, joints might be expected to be dry. The constant presence of a small volume of synovial fluid appears to be due to hyaluronan. Water from plasma transudate can enter the synovial cavity freely, but once in the cavity is mixed with hyaluronan secreted by intimal fibroblasts. If water molecules leave the joint without hyaluronan molecules, the concentration of hyaluronan at the tissue surface rises until it is so great that it obstructs the further flow of water. This curious process, known as solute polarization, means that a given amount of hyaluronan traps a certain amount of water in the synovial space. The volume can increase with inflammatory exudate, but cannot decrease unless the synovium ruptures (well recognized in disease). Chronic leakage through fistulae

between synovium and lymphatics is probably also common in rheumatoid joints, and may explain why they often show synovial thickening but are dry on aspiration.

Synovitis and synovial lymphoid metaplasia

Synovial tissue responds to acute stimuli in a similar way to other tissues. Vasodilatation, oedema, hyperalgesia, and granulocyte accumulation occur in response to pyogenic infection or crystals. Synovium may be hyper-responsive: accumulations of crystals cause little inflammation at other sites. Synovial cavities are also reputed to be good sites for induction of an immune response to injected foreign antigen.

A peculiar feature of acute synovitis is that cell migration is polarized and segregated in relation to the cavity. Granulocytes pass rapidly into the fluid compartment and are sparse within the tissue. Mononuclear cells remain largely in the tissue and macrophages accumulate at the tissue surface. This leads to a thickening of the intima, previously misnamed 'hyperplasia'. The differential distribution of cells is partly explained by intimal fibroblast expression of VCAM-1, the ligand for which, a4b1 integrin, is present on mononuclear but not polymorphonuclear leucocytes. There is also a difference in the behaviour of macrophages and lymphocytes. Macrophages accumulate in the intima but lymphocytes are confined to the subintima. The reasons for this remain unclear.

Prolonged stimulation of synovium leads to a pattern of infiltration peculiar to the tissue. In addition to the features above, both T and B lymphocytes accumulate in the subintima and generate follicles, and the stroma becomes colonized by plasma cells. The tissue effectively becomes a hybrid between bone marrow and lymph node, contributing to the rubbery or 'boggy' feel characteristic of chronic synovitis. The likely reason for this is, again, the readiness with which synovial fibroblasts express VCAM-1. Synovial fibroblasts as a whole show enhanced expression of VCAM-1, and also decay-accelerating factor and complement receptor 2, in response to tumour necrosis factor-a *in vitro*. This suggests that the high-level expression of VCAM-1 and decay-accelerating factor by intimal fibroblasts in normal tissue reflects a combination of a general responsiveness of synovial cells and an unidentified local intimal stimulus. VCAM-1, decay-accelerating factor, and complement receptor 2 are utilized by lymphoid stromal cells to support lymphocyte survival.

It is likely that the formation of lymphoid tissue in synovium is a stereotyped response to the generation of proinflammatory cytokines such as tumour necrosis factor-a. The source of cytokine is likely to be different in different clinical syndromes. In what we call rheumatoid arthritis the characteristic feature of early synovitis is an increase in size, number, and activation of intimal macrophages, suggesting preferential activation of these cells. This is consistent with the initiating stimulus being small immune complexes capable of crossing endothelium and interacting with FcgRIIIa-expressing macrophages. Extra-articular features can be explained in the same way. The most consistent and specific immunological abnormality in rheumatoid arthritis remains the presence of IgG rheumatoid factors, probably formed from IgG oligomers. In systemic lupus other small immune complex species may have a similar effect. However, tissue damage is more limited, perhaps because IgG rheumatoid factor-secreting plasma cells can generate both antibody and antigen locally in synovium, whereas plasma cells secreting the autoantibodies of lupus only produce antibody.

In the seronegative spondarthropathies increasing evidence that the primary lesion is at the enthesis suggests that peripheral synovitis is secondary to cytokines generated at contiguous entheses. This would explain the relatively mild degree of intimal macrophage activation seen. The net result of lymphoid metaplasia may be very similar, although the precise lymphocyte populations involved may be biased by the (unknown) nature of the underlying immune response.

Pain

A structural approach to joints risks overlooking the essence of rheumatic disease—pain. Synovium, tensile tissues, and bone are innervated by pain fibres and there is growing knowledge of their physiology. However, the relationship between pain and events measurable in the terms described above remains about as ineffable as that between the music of Pablo Casals and the motion of a string of catgut. Prostanoids, central nervous system sensitization, depression, hopes and fears, cultural patterns, holidays, and personality interactions are all essential to an effect which can be simultaneously intractable and responsive in an instant to a word or facial expression. A cyclo-oxygenase inhibitor at night may be essential to face the next day, but the best analgesics may remain explanation and trust. Diagnostic terms such as fibromyalgia are often devised to fudge difficult concepts and tend rapidly to lose value. Appropriately, pain is becoming a discipline in its own right.

Applications to therapy

The growing understanding of the biology of joints has contributed to rational therapy in two ways. It has provided rationales for empirically derived current practices, and has generated new therapeutic avenues.

Articular cartilage has little useful capacity for repair. The best treatment for damaged cartilage, as for teeth, may be what we use now—replacement by non-living material. Attempts to induce cartilage regeneration are probably futile and have the disadvantage of needing to maintain a living material. The main remaining problem is osseo-integration of non-living materials. Dentists have achieved a good solution with titanium but optimum materials for joint prostheses are still under review.

Development of rational physical therapies has been slow, owing to our lack of understanding of the relationship between movement and homeostasis in soft connective tissues. Many studies have demonstrated that exercise reduces pain and improves outcome in arthritis, but the reasons are unclear. Physiotherapeutic techniques tend to remain based on pseudophysiological concepts and are rarely validated by well designed trials. The same applies to techniques of 'joint protection' in which specific actions are discouraged to reduce deformity. Pragmatic management of diseased joints by experienced therapists has a major part to play for patient groups whose psychomotor development is limited—especially children and those with central nervous system disease or trauma. For the average adult with arthritis it is less clear that there is justification for more than sympathetic encouragement to exercise.

The discovery of cyclo-oxygenase inhibition confirmed that aspirin and indomethacin were logical agents to use to reduce pain and stiffness due to inflammatory oedema. It explained why these agents have no long-term effect on inflammation, since cyclo-oxygenase products mediate vasodilatation, pain, and oedema rather than cell influx. Cyclo-oxygenase 2 inhibitors follow this path but their place has yet to be evaluated.

Logical treatment of chronic inflammatory disease depends on whether it is the inevitable result of a genetically determined low inflammatory threshold or an acquired immune response. The former is probably important in ankylosing spondylitis and some forms of juvenile arthritis. These conditions may best be treated by long-term modulation of balances in cytokine and growth factor levels but, as yet, we do not know which molecules should be the best targets. In the meantime, suppression of inflammatory cell function by methotrexate remains the main practical, if not very sophisticated, option. This suppressive approach is also currently the mainstay of therapy for disorders such as rheumatoid arthritis which appear to represent an acquired adaptive immune response. Until recently, synovitis has been suppressed by drugs with unknown and probably disparate modes of action. Intramuscular gold and penicillamine appear only to be effective in rheumatoid arthritis. Sulphasalazine is of benefit in inflammatory bowel disease and seronegative spondarthropathies affecting peripheral joints. Methotrexate and azathioprine have a broad spectrum of action. However, none of these agents has a good risk–benefit profile. Rational suppression of synovitis has come with agents which neutralize tumour necrosis factor-a. Antitumour necrosis factor-a antibodies and soluble receptor fusion proteins have been used to mop up tumour necrosis factor-a with very good results. A similar approach has been used for interleukin 1. Anticytokine therapies appear to be broadly safe but are costly, and there is rapid relapse after withdrawal.

There is an increasing view that disorders such as rheumatoid arthritis, based on an acquired immune response, should be amenable to long-term cure if the immune system can be 'reprogrammed' to 'forget' the autoimmune response. Gold is probably the only agent in current use which occasionally induces complete remission that persists indefinitely after drug withdrawal. Rational 'reprogramming' has been attempted with high-dose chemotherapy, followed by stem cell rescue, but the mortality rate for this procedure is significant and long-term results are awaited. Hopes that anti-CD4 therapy might induce a state of tolerance which would abolish the autoimmune response have not been realized, and long-term T-cell depletion has been a problem. B-lymphocyte depletion is currently under study and has shown some promising results, but further information is needed. A combination approach may well be necessary. At least results so far give grounds for optimism that safe definitive therapy may not be a decade away.

18.2 Clinical presentation and diagnosis of rheumatic disease

Anthony S. Russell and Robert Ferrari

'Medicine is a first-rate profession for a second-rate intellect.' Whilst we may not fully agree with that statement from a first-class iconclast (George Bernard Shaw), we do agree that with experience it is possible to discipline the mind to follow routine pathways to arrive at a correct diagnosis and therefore a valid treatment plan. In modern medicine, rheumatologists are almost unique in relying heavily on the patient's history and physical examination before applying a relatively restricted number of valid tests to clarify the diagnosis.

Pitfalls occur at every stage of the diagnostic process. The first trap is the referral note or phone call from the primary care physician, conveying their impression of the case, plus laboratory results which may or may not be of relevance. This information is obviously important but must never be blindly accepted as fact. After all, the patient has been referred for a second opinion, which should be truly unbiased and not merely an automatic repetition of the views of the referring doctor. For example: 'This man has refractory gout which is not responding to treatment and his uric acid level is high. Allopurinol has not helped him and after 5 days he still cannot walk because of pain and swelling in his right foot.' The referring physician's clinical assumption that the patient has gout may be incorrect, and the plasma uric acid level could well be irrelevant. Furthermore, if the clinical assumption is correct, then the treatment is inappropriate. Therefore, whilst at no time hinting to the patient that aspersions are being cast on the referring physician's assumptions, the consultant must start from the very beginning, taking a careful history. This should include any previous or family history of such attacks, a general history for systemic disease, or any cause for secondary gout. There should be a comprehensive physical examination, commencing with inspection of the affected part. The correct diagnostic process can be laid out as in the algorithm (a term which we use for expediency) for monarticular arthritis, but note that algorithms can only be initiated at some distance down the diagnostic pathway (Fig. 1).

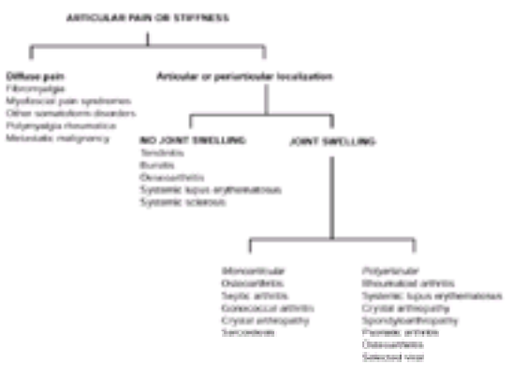

Fig. 1 An algorithm for rheumatology diagnosis.

General approach

The diagnostic process thus begins with the referral consultation note, followed by observation of the patient as they come in, their gait, demeanour, attire, and whether they are alone or accompanied. These, together with the presenting complaint and the initial features of the history, allow the development of an intuitive approach where the physician attempts to define aspects of the disorder and to arrive at a diagnosis (Table 1). The subsequent interview and examination are used to provide feedback and to support or refute those intuitive diagnoses; some observations necessitating a complete rethink of the process. Sometimes this rethink may relate to results of investigation or the development of new clinical features. Central to this diagnostic process is the classification into systemic rheumatological problems, localized—usually structural—problems, or functional somatic syndromes—perhaps best thought of as biopsychosocial disorders, an ungainly term, but one which emphasizes that biological, psychiatric, and social factors are all important. While there is obvious overlap between these categories, we believe it provides a useful framework for proceeding, partly because it allows for a positive diagnostic and therapeutic approach to this latter group, rather than simply regarding them as a group of patients where other diagnoses need to be excluded.

Some physicians feel insecure in a rheumatological diagnosis because of a lack of confidence in their rheumatological examination. This is unfortunate, because although the examination will provide important information, we believe that the principal diagnostic pointers come from a good history. The initial interview also provides a useful way of getting to know the patient and their environment. It is important, by open-ended questioning, to find out not only the details of the problem(s), but what the patient's fears and perceptions are, and especially, in a chronic disorder, what led them or their physician to seek a consultation at this time. This format also allows the patient to become at ease, and make them confident that you are truly listening. Specific directed questions are also of importance, both to elicit less frequent complaints, for example photosensitivity, xerophthalmia, recurrent miscarriage, and to elaborate on misleading terms. Thus, patients often describe 'hip pain', meaning pain in the buttocks, rarely due to hip disease; 'weakness' may reflect true neuromuscular disease, but more commonly reflects pain, for example in the shoulders or hip, or simply exhaustion or fatigue. These distinctions are crucial, and will be reviewed below (Table 2).

One of the key questions in rheumatology is 'where is the pain?', but it must be followed up with, 'and do you have pain anywhere else?'. Sometimes the answer to this, eventually, is 'all over', which by itself is very suggestive of a chronic pain syndrome. Instruments such as a pain diagram where the patient is asked to shade in areas that are painful, and also to indicate their intensity, may present a vivid pictorial representation of this. We find these useful, particularly for demonstrating the diagnostic value of this response.

When confronted with the patient who 'hurts all over', the next set of questions will often readily yield the diagnosis. The patient with diffuse pain should be asked to list all their other symptoms: a lengthy list indicates fibromyalgia or another functional somatic syndrome, and hearing extreme descriptions of individual symptoms is the next best clue. Indeed, after this, examination confirming lack of joint swelling and the presence of tender points provides ready and simple confirmation of the diagnosis, avoiding unnecessary consideration of other conditions in most cases. By contrast, when the patient fails to give a lengthy list of other symptoms, the less common causes of diffuse (poorly localized) pain should be sought. Be wary of those who complain of weight loss: this is rarely one of the long list of symptoms of fibromyalgia patients, and its presence in someone suspected of having fibromyalgia mandates a complete history and emphasis on the physical examination to look for another process. Conditions to be carefully considered in this context include polymyalgia rheumatica and metastatic bone disease (see below).

Systemic disorders

These include rheumatoid arthritis, other polyarthritides, systemic lupus erythematosus, polymyalgia, vasculitides, etc. Pointers to this type of disorder are malaise, anorexia, weight loss, rashes, fever, and multifocal symptoms including a description of actual joint swelling or persistent sensory motor deficits. Rheumatoid arthritis may begin as a monarticular problem, and although there are ways, even here, to approach a probable diagnosis, it may require more prolonged observation to establish this with certainty, obviously coupled with empirical management of symptoms. Even though the systemic disorders are typically widespread they are multifocal—that is a widespread focal problem in different joints. By contrast, pain 'all over' or 'from my head to my toes' suggests fibromyalgia, as indicated previously.

Unfortunately, patients' observations and descriptions of joint swelling are often unreliable and are particularly frequent, for example, in fibromyalgia where, by

definition, it does not occur (unless there is a second disease process going on). There is little point in going through all the diagnostic questions about rheumatoid arthritis and risk factors for gout in a patient who has never had documented swelling. However, if swelling is present on examination, then a further list of questions is aimed at making a specific diagnosis. This means that in practice it is not uncommon for rheumatologists to immediately examine the hands if the patient says that they hurt, and on seeing swelling, return to diagnostic questions about the polyarthritides to expand on a presumptive diagnosis, for example of rheumatoid arthritis.

Inflammatory arthritides are usually associated with morning stiffness of over 30 min, and the patterns of joint involvement (Table 3) and acuteness of presentation may help indicate the likely diagnosis (see Fig. 1). Specific questions directed to associated disorders are important, for example bowel disturbance, rectal bleeding, urethritis, mucosal lesions, conjunctivitis, psoriasis, etc.

Ensure that 'sun sensitivity' is not fatigue, headache, or cholinergic urticaria, but a true photosensitivity. Vague circulatory changes and cold hands are so common in the background population that this is of no help. A diagnosis of Raynaud's requires an extension of this to include at least pallor, usually followed by reactive hyperemia. Even this may occur in 5 per cent of the population without other disease. Always remember to question the validity of previous diagnoses: who made them, and on what grounds?

An important diagnosis in the over-55 age group is polymyalgia rheumatica. Patients may report fatigue and sometimes weight loss. The erythrocyte sedimentation rate is usually very high. Here the problems are located especially around the limb girdles and are associated with marked morning stiffness and sometimes systemic features. The erythrocyte sedimentation rate is virtually always substantially elevated, although this is very non-specific. Commonly the examination may be normal, and muscle tenderness is uncommon. In younger individuals with similar symptoms a somatoform disorder is more likely. Myositis itself is not usually painful, and weakness is the predominant complaint, as it is for myopathies.

Metatastic bone disease is less common. Patients with this condition usually have weight loss and fatigue as well as nocturnal 'bone pain', symptoms which should lead to enquiry about any previous malignancies and risk factors for malignancy.

Although in one sense a focal problem, a patient with a single, hot, swollen joint is best considered as having a systemic disorder. The critical issue here is to decide whether or not the joint is infected. Because of the risk of infection the same initial decision process is involved in a patient with known rheumatoid arthritis who has an acute monarticular 'flare'. If examination confirms an acute synovitis, i.e. not merely tenderness or a periarticular lesion such as cellulitis or erythema nodosum, then joint aspiration and fluid analysis and culture are the most important investigative procedures to be undertaken. Elements of the history are helpful, for example the development 2 to 5 days postoperatively of pain and swelling in the hallux points to gout, and in the knee or wrist to pseudogout. If gonococcus is a possibility then, as culture of joint fluid may be negative, cultures from other sites are equally important. However, the most important point is to remember that even in seemingly classical situations, aspiration remains advisable to achieve a definitive diagnosis.

So-called 'diagnostic criteria' are generally designed not for diagnosis of the individual patient but for classification of groups of patients, for example for studies or reports. They are, however, useful in providing an *aide-mémoire* to direct questions regarding specific features. Thus: the symmetric arthritis of rheumatoid arthritis, the photosensitivity and serositis of systemic lupus erythematosus, the widespread pain above and below the waist of fibromyalgia, the lack of important pain in myositis, the good response of spondylitis to therapy with non-steroidal anti-inflammatory drugs, etc. are all reinforced as important points to record.

Focal disorders

Here the patient presents with pain or other symptoms in one area, although there may be some radiation or spread. For these it is important to know the relevant anatomy and patterns of referral. Some of these are listed in Table 4 together with diagnostic pointers. To recognize meralgia paraesthetica, for example, one has to know of the existence and supply of the lateral cutaneous nerve of the thigh. A diagnosis of tendonitis should not be made unless it is associated with the name of the specific tendon or, if diffuse, with a systemic disease such as rheumatoid arthritis that can induce this. Too often it is an inappropriate attempt at diagnostic specificity in the presence of vague symptoms; diffuse pain and tenderness are often better considered under the functional section below.

Focal problems can be divided into truly articular and periarticular disorders. It must be remembered that they can be early manifestations of a systemic disease— see Table 5—and this illustrates why an inflammatory lesion is best regarded *ab initio* as a systemic problem.

Diffuse muscle pains are common. In the elderly, where radiological changes of osteoarthritis, particularly of the spine, are frequent, the pains may inappropriately be attributed to 'widespread osteoarthritis'. In general this is a diagnosis to be avoided. It does occur, for example in haemochromatosis, epiphyseal dysplasias, etc., but should be confirmed by clear-cut joint tenderness and decreased range of movement. However, the elderly may accumulate a number of focal disorders, for example unilateral osteoarthritis of the knee, a frozen shoulder on the right, postural cervical pain, and an osteoporotic fracture of the dorsal spine, the combination of which may simulate a systemic disease.

Functional somatic syndromes

Functional somatic syndromes are common in rheumatological practice, and are often badly managed because physicians tend to focus on organic disease. We are much more likely to be chagrined at missing the rare secondary deposit as a cause of thigh pain than by initially failing to recognize a patient whose somatic symptoms reflect depression or other emotional distress. We are subject to WHIMS (the 'what have I missed syndrome') that encourages repeated and fruitless investigation in this group to eventually arrive at a diagnosis by exclusion.

It is possible and beneficial to make the diagnosis after a good history and examination. Common symptoms are fatigue, weakness, sleep difficulties, headache, muscle aches, joint pains (plus a description of swelling), paraesthesiae, problems with memory and concentration, gastrointestinal symptoms including nausea, and alternating constipation and diarrhoea, and even irritable bladder. Such symptoms have been termed 'idioms of distress' and may be presented with a characteristic hyperbole. Thus, the pain is 'excrutiating' like 'red hot pokers in the back—you know' (as if this were an everyday experience for physicians). Apart from this, excrutiating pain is seen with fractures, septic/crystal arthritis, or nerve involvement. Patients with rheumatoid arthritis or osteoarthritis, however severe, don't normally use this terminology.

Patients with a functional somatic syndrome may also have arrived at a diagnostic label for their illness: repetitive strain injury, chronic whiplash, side-effects of silicone breast implants, candida hypersensitivity, and Gulf War syndrome to name but a few. We would also include fibromyalgia, chronic fatigue, irritable bowel syndrome, and others. It is possible, as has been suggested, that fibromyalgia (for example) may represent a central disorder of pain perception, perhaps associated with altered levels of substance P or nerve growth factor. We are unconvinced, but in any event this could be equally true of individuals with depression, with dysfunctional personalities, etc., and does not affect the overall approach to these disorders, amongst which there is considerable symptomatic overlap. All of these symptoms are common in the healthy population, and it may be more fruitful to ask oneself why the patient has presented to a physician, and at this time, rather than why they have headaches or fatigue in the first place.

Examination

The ability to detect joint swelling is important, but we are referring to obvious changes—if they are merely 'possible' or subtle, then rely more on the history for diagnostic pointers. A distinction between bony swelling and soft tissue/effusion is important and will often be of diagnostic significance.

Contrary to common belief, evident warmth of a joint (or redness) is unusual and would point to infection or crystal synovitis. The knee is normally somewhat cooler than the thigh or foreleg, and a lack of this coolness may actually be a sign that an observed knee swelling is inflammatory.

Careful palpation should allow one to distinguish between joint line tenderness, seen in arthritis, tenderness in between joints, as in an acute flexor tendonitis, periarticular tenderness, for example in lateral epicondylitis, and diffuse muscle tenderness, seen in some patients with local or generalized fibromyalgia (and very, very rarely in myositis).

The tender points found in fibromyalgia and many other somatoform diagnoses reflect a lowered pain threshold, and it has been suggested that they can be thought of as a 'sed(imentation) rate for emotional distress'. Nevertheless, they may provide diagnostic reassurance to the physician as other aspects of the examination are negative. In particular, joint swelling does not occur—although it is frequently referred to and described by the patient. The physician's observations are important

here, because if swollen joints are found, then some disease process is going on that may also need assessment, perhaps in addition to fibromyalgia.

With some exceptions, physical signs in rheumatology have not yet been subjected to assessments of their validity or positive predictive value. Thus, the stress tests for sacroiliac inflammation, while often described, are of no value. Tinel and Phalen's (sustained palmar flexion of the wrist for 60 s may induce finger paraesthesiae) signs have become modified and integrated into an approach to improve their use in the diagnosis of carpal tunnel compression. Adson's manoeuvre is also of little value. Palpation of tender muscle bands is subject to great intra- and interobserver error, and the relevance of tender trapezius or gluteal muscles in the diagnosis of postural/mechanical neck and back pain, although clinically probable, remains unproven. Even the classic 'limitation of straight leg raising' has a relatively poor sensitivity and specificity. Crossed straight leg raising appears quite specific, but is relatively insensitive. A great deal still needs to be done here.

Investigations

As physicians we are trained to order tests to help throw light on, and perhaps confirm, a diagnosis. We very commonly use them inappropriately. Thus, the idea of a 'rheumatology screen', so popular with some physicians, is entirely inappropriate. There are far, far more healthy people in the population who have a positive test for rheumatoid factor, antinuclear antibodies, or HLA-B27 than there are those with significant disease. Thus, for any test to be useful diagnostically, a Bayesian approach considering the pretest probability of diagnosis is critical, or to put it simply, the result must be taken in context. If the outcome, positive or negative, cannot affect the diagnostic probability, then the test should not normally be ordered. Otherwise, we subject the patient to unnecessary tests and often, when the results are positive, unreasonable anxiety that may take months and a specialty consultation to assuage. This does not include tests done for reasons other than diagnosis, for example to establish a baseline prior to treatment, or to obtain prognostic information, etc.

Diagnostic tests are sometimes ordered for the false reassurance a negative result provides in the presence of an insecure history and/or physical examination. Unfortunately, a false positive may occur and can be disastrous. Particular caution is therefore advised in ordering tests, or further consultations, to reassure 'the patient', especially those with a somatoform disorder. Negative findings generally fail to reassure, and indeed may heighten anxieties: a negative test is interpreted as puzzling and means that the problem is not yet solved. Similarly, if treatment, such as rest, does not improve the situation, the implication is that the disorder is too bad, not that the treatment was inappropriate. In fibromyalgia, for example, acknowledging and legitimizing the patient's distress and complaints is important. But although the patient may want a diagnostic label, and whilst this seems reasonable, labelling has been shown to increase disability and labels should not be applied that can be used to validate the 'sick role', i.e. they must come with reassurance and explanation. This reassurance will only be perceived as helpful rather than dismissive if the physician has initially taken care to legitimize and accept the validity of the complaints. The goal of treatment becomes the recognition and management of factors increasing symptoms and the focus on coping and improving functional status rather than curing 'the disease'.

Treatment

For many rheumatic diseases therapy has advanced enormously in the past 20 years, but the patient will not benefit if the correct diagnosis is not made. Thus, with allopurinol gout should rarely be an active problem, but patients are frequently still admitted to hospital for antibiotics because the correct diagnostic approach of synovial fluid aspiration has not been performed, or because the fluid has been allowed to clot so that crystals are not seen, or because crystals were not looked for, etc. The therapies for rheumatoid arthritis and ankylosing spondylitis, for example, have all progressed, but not to the stage of a cure. Thus, rheumatologists spend a lot of time informing and 'educating' patients. Many of these educational endeavours, when put to the test, have been shown not merely to convey retained information, but to actually alter behaviour and outcomes. It is always rewarding if we can 'fix' a problem, for example by prescribing antimalarials for palindromic arthritis, but all too often the additional role of the rheumatologist is supportive—to inform, to reassure where possible, and to provide continued advice and encouragement.

18.3 Clinical investigation

Michael Doherty and Peter Lanyon

Introduction

Disease 'markers' are pathological or physiological characteristics of an individual that assist in determining the diagnosis, the current activity of disease, or the expected prognosis of the condition in that individual (Fig. 1). Some markers relate to just one of these elements; others may relate to two or occasionally all three.

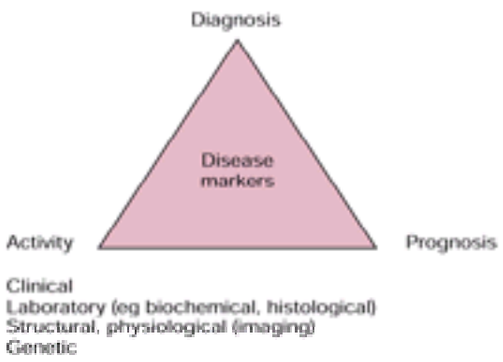

Fig. 1 Markers may be used for diagnosis, assessment of disease activity, or prognosis.

Clinical markers are derived from enquiry and examination of the patient. For many common rheumatic disorders clinical assessment alone gives sufficient information for patient diagnosis and management. In some situations, however, particularly with inflammatory, metabolic, or multisystem disease, a search for additional investigational markers may be warranted. It is important to emphasize that the requirement for and selection of investigations, as well as their subsequent interpretation, is principally determined by the clinical assessment. Investigations are an adjunct, never a substitute, for competent clinical assessment. There is no place for a battery of 'screening tests'. Investigational markers may include:

- Laboratory markers (biochemical, haematological, microbiological, histological) sought through investigation of body fluids and tissues.
- Structural and physiological markers, mainly assessed by imaging (radiography, scintigraphy, magnetic resonance imaging, ultrasound).
- Genetic disease susceptibility and prognostic markers—these hold promise for the future but at present only have clinical application to rare monogenic disorders.

When considering any investigation the following deliberations are pertinent:

- 'Is this the most appropriate investigation to answer the clinical question?' This may depend on various factors, for example the sensitivity and specificity of the marker being sought, its predictive value (which takes into account disease prevalence as well as the sensitivity and specificity), the cost and availability of the investigation, the pros and cons of invasive versus non-invasive tests.
- 'Will the result of this test alter the diagnosis or clinical management of the patient?' It is easy to initiate more investigations than are really required.
- 'Will I be able to interpret and act on the results of this test?' Tests should only be ordered if the implications of either a normal or abnormal result are understood.

In common rheumatological practice the investigations that are of most use in diagnosis are synovial fluid analysis and the plain radiograph. Confirmation of clinically assessed inflammatory disease activity and its response to treatment is mainly by the full blood count and either direct or indirect measures of the acute phase response. These investigations are therefore given special prominence in this chapter. The usefulness of other investigations will be discussed in the context of specific clinical scenarios.

Synovial fluid analysis

This is the key investigation to confirm the diagnosis of the two curable rheumatic diseases—septic arthritis and gout. Other crystal-associated arthropathies and intra-articular bleeding are also diagnosed in this way. Synovial fluid analysis is thus the pivotal investigation for an acute monoarthritis, especially with overlying erythema.

Synovial fluid can be obtained from almost any peripheral joint and only a small volume is required for diagnostic purposes. Aspiration of large joints should be no more uncomfortable than venepuncture. The patient should be informed of the purpose and nature of the procedure and positioned on a couch in a comfortable and relaxed position with full exposure of the relevant joint. The risk of introducing sepsis is negligible as long as sterile equipment and the same sensible precautions used for venepuncture are employed.

Macroscopic appearance

Normal synovial fluid is present in small volume, contains very few cells, is clear, colourless, to pale yellow, and has high viscosity due to macromolecular hyaluronate (Fig. 2 and Plate 1). In general, with increasing joint inflammation the volume increases, the total cell count and proportion of neutrophils rises (causing turbidity), and the viscosity lowers (due to degradation of hyaluronate by protease). However, there is such overlap between arthropathies that these features are of little diagnostic value. Frank pus or 'pyarthrosis', due to very high neutrophil counts, should always lead to exclusion of sepsis but can occur with any florid synovitis such as acute crystal synovitis or rheumatoid. High concentrations of urate or cholesterol crystals may result in white synovial fluid—joint 'milk'.

Fig. 2 Different macroscopic appearances of synovial fluids: (a) on the left, clear straw-coloured fluid from an osteoarthritic knee (easy to read writing behind it); (b) less viscous, turbid (high cell count) 'inflammatory' fluid from a rheumatoid knee; and (c) uniform bloodstaining (haemarthrosis) due to acute pseudogout. (See also Plate 1.)

Non-uniform bloodstaining of synovial fluid is common and reflects inconsequential needle trauma to synovial vessels. Uniform bloodstaining (haemarthrosis) most commonly occurs in association with florid synovitis but may also result from a bleeding diathesis, trauma, or pigmented villonodular synovitis. A lipid layer floating above bloodstained fluid is diagnostic of intra-articular fracture.

Gram stain and culture

If sepsis is suspected synovial fluid should be sent for urgent Gram stain and culture. Placement in blood culture bottles in addition to a sterile universal container increases positive yields, especially of anaerobes. If gonococcal sepsis or uncommon organisms are suspected, especially in immunocompromised patients, it is advisable to discuss this with the microbiologist so that the optimal cultures can be established and molecular techniques of antigen detection used if appropriate. Although a positive result on Gram staining is found in over 50 per cent of cases of adult septic arthritis (predominantly *Staphylococcus aureus*), a negative result does not exclude infection. If there is a strong clinical suspicion of sepsis the patient should be given intravenous antibiotics pending the results of the synovial fluid, blood, and other culture results.

Crystal identification

Accurate identification of common synovial fluid crystals requires a compensated polarized light microscope and an experienced observer. Monosodium urate and calcium pyrophosphate crystals may be seen by ordinary light microscopy but confident identification resides in their light characteristics as well as their morphology. Analysis is best performed on fresh unrefrigerated synovial fluid taken into a plain container to avoid problems of crystal dissolution, postaspiration crystallization, and artefacts from tube additives. If only a few drops are obtained these should be placed straight onto a clean microscope slide and a second slide or coverslip placed on top. Even with an apparently 'dry tap' it is worth expelling the contents of the needle onto a slide as a very small amount of fluid is sometimes obtained and may be diagnostic. Urate crystals are long and needle-shaped and show a strong intensity with negative birefringence (Fig. 3 and Plate 2). Pyrophosphate crystals are smaller, rhomboid in shape, usually less numerous than urate, and have weak intensity and positive birefringence (Fig. 4 and Plate 3).

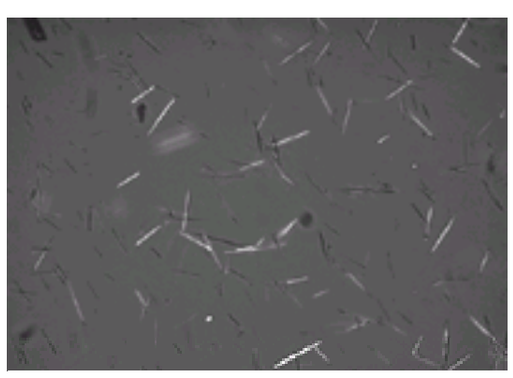

Fig. 3 Monosodium urate crystals viewed by compensated polarized light microscopy (×400) showing bright birefringence (negative sign) and needle-shaped morphology. (See also Plate 2.)

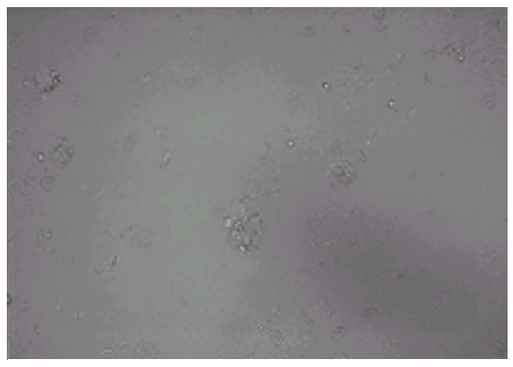

Fig. 4 Calcium pyrophosphate crystals viewed by polarized light microscopy (×400) showing weak birefringence (positive sign), scant numbers, and a predominantly rhomboid morphology. These are clearly more difficult to detect than urate crystals. (See also Plate 3.)

Although usually identified in the setting of acute synovitis, crystals are also often present in fluid aspirated from the joint after the attack has settled. Aspiration of an asymptomatic first metatarsophalangeal joint (gout) or knee (gout, pseudogout) may therefore permit confirmation of a suspected diagnosis. This is particularly important in gout because of the possible implications of life-long hypouricaemic therapy. The diagnosis can also be made by analysis of a tophus aspirate.

Plain radiography

In conjunction with a full history and examination this remains the single most useful imaging technique for assessment of rheumatic disease. Although a radiograph is a static record of predominantly past events, it can demonstrate visually alterations that reflect the underlying pathological processes of rheumatic disease (for example cartilage and bone erosion, bone remodelling, calcification). The abnormalities that may be seen on a plain film include:

- soft tissue swelling—seen as altered skin contours and displaced fat planes and intracapsular fat pads (fat appears dark on a radiograph)
- decreased or increased bone density (localized or generalized; Table 1)
- joint erosion (non-proliferative or proliferative marginal erosion, central erosion)
- joint-space narrowing (osteoarthritis—focal; inflammatory arthritis—generalized)
- new bone formation (osteophyte, enthesophyte, syndesmophyte)
- periosteal reaction (Table 2)
- calcification (cartilage—chondrocalcinosis; synovium, capsule, ligament, tendon, muscle, fat, vascular, skin)
- bone cysts and radiolucent lesions (Table 3)
- intra-articular osteochondral bodies
- deformity.

Although most of these abnormalities taken individually have low specificity, various combinations of some of these features, together with their targeting of certain joint sites (Fig. 5), result in characteristic patterns of abnormality and distribution that have high diagnostic specificity. The distribution of joint involvement, of course, is usually apparent following clinical assessment of the patient, and joints to be investigated by radiography will usually be selected on this basis. An important exception, however, is seronegative spondarthropathy where sacroiliac involvement is often asymptomatic and is difficult to detect clinically. For suspected seronegative spondarthropthy an anteroposterior view of the pelvis and a lateral thoracolumbar spine view (i.e. two films) are usually sufficient to show sacroiliitis and syndesmophytes if these are present.

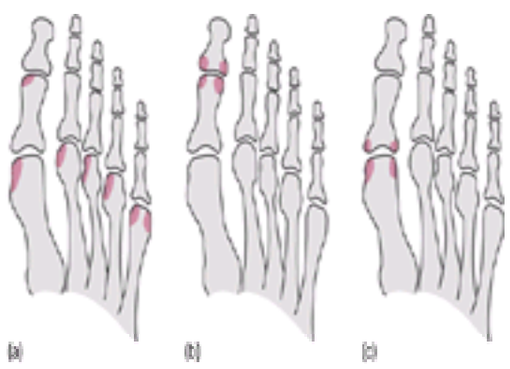

Fig. 5 Diagram to show different target sites of involvement in the forefoot for (a) rheumatoid arthritis, (b) psoriatic arthritis, and (c) osteoarthritis.

Radiographs should be selected to answer specific questions. For example, to address the question of whether a patient with chronic inflammatory polyarthritis affecting hands, elbows, neck, knees, and ankles has erosive disease typical of rheumatoid, posteroanterior views of hands and feet (i.e. two films), but not radiographs of all symptomatic joints, are appropriate. This is because rheumatoid erosions appear first in wrists and the small joints of hands and feet, and may first affect the metatarsophalangeal joints, even if they are relatively asymptomatic. However, if the degree of structural damage in one large joint is a principal cause for concern then a radiograph of that particular joint should obviously be taken. For most joints a single (two-dimensional) view is sufficient (for example anteroposterior view of pelvis, posteroanterior view of both hands, posteroanterior view of both feet), although two views are required for some (for example posteroanterior standing view of both knees plus individual lateral or bilateral skyline patellofemoral view). Thus selection of radiographs will often differ for purposes of diagnosis or disease assessment.

Erosions

An important hallmark of inflammatory arthropathies is cartilage and bone erosion. Intracapsular bone erosion first occurs at the 'bare areas' of the joint margin ('marginal erosion') where bone is exposed directly to inflammatory synovium without the protection of overlying cartilage. Loss of the sharp cortical line, the 'dot-dash' appearance, is the first radiographic sign that precedes more definite scalloping of the bony contour (Fig. 6). Cartilage erosion also commences at the joint margin and slowly works centrally, resulting in relatively late loss of interosseous distance or 'joint space'. Both rheumatoid disease and the seronegative spondarthropathies (especially psoriatic and chronic reactive arthritis) cause marginal erosions. In rheumatoid disease, however, the aggressive synovitis overwhelms any reparative response, presenting a very atrophic appearance ('non-proliferative erosions'; Fig. 6 and Fig. 7) with no new bone or periosteal reaction and only juxta-articular osteopenia (a sign of inflammation) and soft tissue swelling as accompanying early radiographic features. By contrast the seronegative spondarthropathies are characterized by a degree of low-grade inflammation that permits some reparative response. Such inflammation results in a tendency to fibrosis, calcification, and ossification. Marginal erosions in these arthropathies are therefore commonly accompanied by fluffy new bone formation ('proliferative erosions'; Fig. 6 and Fig. 8) with normal or increased periosteal and bone density rather than osteopenia. The fact that different joints are targeted in these conditions, and the common accompanying involvement of entheses—fibrous insertions of tendons, ligaments, or capsule into bone—further assists differentiation in most cases.

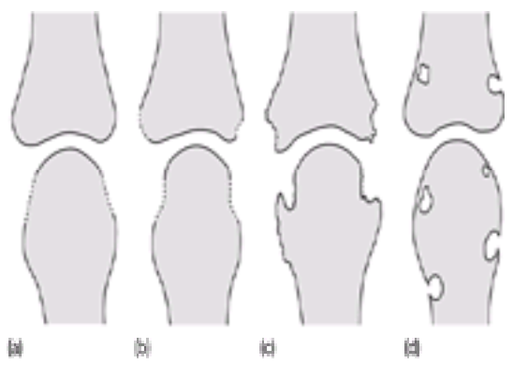

Fig. 6 Diagram of metacarpophalangeal joint showing (a) early dot-dash erosion, (b) the later definite non-proliferative erosion of rheumatoid arthritis, (c) the proliferative erosion of psoriatic arthritis, and (d) the intra- and extracapsular 'pressure erosions' of gout.

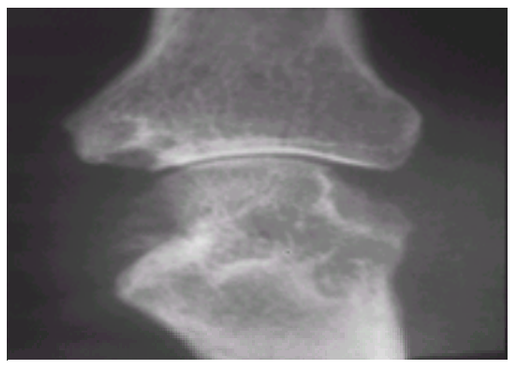

Fig. 7 Radiograph of metacarpophalangeal joint showing late non-proliferative marginal erosions of rheumatoid arthritis, more obvious proximally than distally (reflecting the more proximal than distal distribution of synovium in small finger joints) and eventual global loss of cartilage.

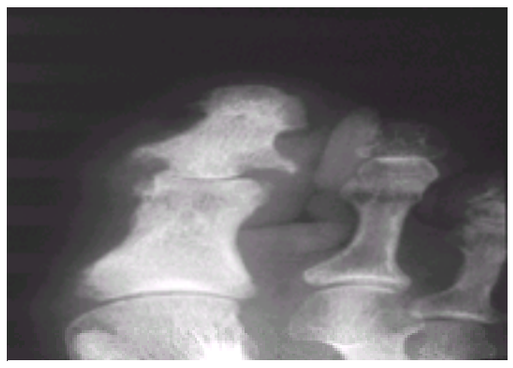

Fig. 8 Radiograph of the hallux showing proliferative erosions and cartilage loss of the interphalangeal joint, and associated increased bone density ('ivory phalanx') typical of psoriatic arthropathy.

In early septic arthritis the radiograph is often normal, apart from osteopenia and soft tissue swelling, for 1 to 2 weeks. However, erosion proceeds rapidly and results in generalized loss of joint space with loss of cortical integrity centrally (central erosion) as well as marginally. In chronic gout bony defects develop slowly as massive crystal concretions ('tophi') causing pressure necrosis to surrounding bone; such 'pressure erosions' (Fig. 6) occur at extracapsular as well as intracapsular sites and are unaccompanied by osteopenia.

Osteoarthritis

The features of osteoarthritis, by far the most common joint disease, are highly characteristic and contrast with those of inflammatory arthropathy. The two cardinal features are narrowing and osteophytes. By contrast to inflammatory arthropathies, joint space narrowing is focal rather than widespread within the joint, mainly targeting the maximum load-bearing region (Fig. 9). Bony osteophyte is most noticeable at the margins of the joint but also occurs centrally and as periosteal osteophyte ('buttressing') at sites such as the femoral neck. Subchondral sclerosis, or increased density of bone is also common, principally below the site of maximal narrowing. Additional features include subchondral 'cysts', osteochondral ('loose') bodies within the synovium, and an increased association with chondrocalcinosis. In contrast to inflammatory arthritis, the bone density is normal or increased and marginal erosions are not a feature.

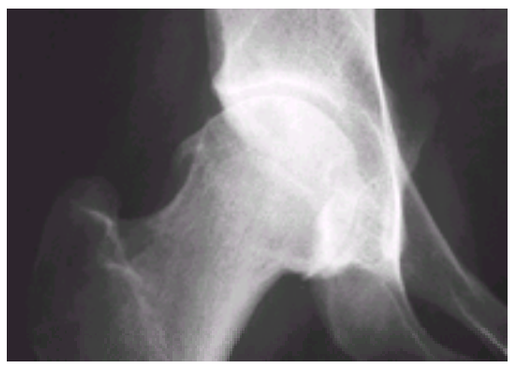

Fig. 9 Radiograph of the hip to show changes of osteoarthritis, specifically superior joint space narrowing, subchondral sclerosis, marginal osteophyte, and cysts.

Calcification

Calcification can affect any locomotor tissue. Calcification of fibro- and hyaline cartilage (chondrocalcinosis) is most commonly due to calcium yrophosphate crystals, less commonly to apatite or other basic calcium phosphates. This can occur as an isolated phenomenon (mainly age-associated, rarely as a result of metabolic or familial disease predisposition) or in association with structural changes of osteoarthritis (chronic 'pyrophosphate arthropathy'). Less commonly pyrophosphate crystals also cause calcification of the synovium and capsule, and linear tendon calcification (mainly hip adductors, Achilles, triceps).

Periarticular calcification is usually apatite. Isolated periarticular calcification mainly affects central sites such as the shoulder (supraspinatus tendons) or hip (abductor tendons), appearing as single dense concretions with rounded contours, as opposed to the linear calcification of pyrophosphate. Shedding of these crystal deposits can result in severe, self-limiting inflammation (acute calcific periarthritis) with reduction or loss of the radiographic calcification.

Spotty, multiple calcification of soft tissues (calcinosis) mainly targets peripheral and intermediate sites such as the finger pulps, wrists, and forearms and is a feature of connective tissue disease, most commonly CREST syndrome (**C**alcinosis, **R**aynaud's, o**E**sophageal dysmotility, **S**clerodactyly, **T**elangiectasia). Calcinosis requires distinction from small blood vessel calcification (increased in diabetes and chronic renal failure) which has a thin, meandering tramline appearance, sesamoids, and solitary dense calcified phleboliths. Myositis ossificans is rare and appears as dense sheets of calcification mainly at proximal sites such as the hip. Fine reticular or linear calcification of subcutaneous fat and muscle may follow young onset derma-tomyositis.

Other imaging

Arthrography

Injection of positive (iodinated) or negative (air) contrast, or a combination of both, can help delineate the soft tissue outline of a joint or other tissue space (for example bursa). The main use of plain film arthrography is at the knee to demonstrate a ruptured popliteal ('Baker's') cyst as a cause of calf pain and swelling. It is also commonly used with either computed tomography (**CT**) or magnetic resonance imaging (**MRI**) to provide better anatomical assessment.

Scintigraphy

Scintigraphy is a cheap, readily available technique that delivers only a very small amount of radiation. It involves gamma camera imaging following an intravenous injection of radioisotope, usually $^{99}Tc^{m}$ diphosphonate. Early 'flow' images obtained immediately postinjection, or a little later when the isotope is in the soft tissues ('blood pool' phase), reflect vascularity and will show, for example, the increased perfusion of inflamed synovium, Pagetic bone, or hypervascular primary or secondary bone tumour (Fig. 10). 'Delayed' images, taken a few hours after injection, indicate bone remodelling due to localization of the diphosphonate to sites of active bone turnover. Although non-specific and lacking high spatial resolution, the major advantage of scintigraphy is its high sensitivity for detecting important bone and joint pathology that may not be apparent on plain radiographs. It is particularly useful, following a normal or inconclusive plain radiograph of the presenting painful region, as the second imaging investigation to detect the following:

- bone metastases (at the presenting site and at clinically occult sites)
- bone or joint sepsis (at the presenting site and at clinically occult sites)
- early osteonecrosis (at the presenting site and at clinically occult sites)
- stress fracture
- reflex sympathetic dystrophy (algodystrophy)
- hypertrophic osteoarthropathy.

Scintigraphy is also useful in delineating the extent and current activity of Paget's disease of bone.

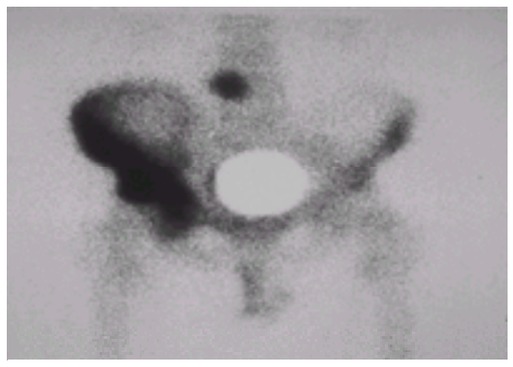

Fig. 10 Bone scan demonstrating secondary deposits of prostate cancer. The presenting painful lesion was in the right hemipelvis and the plain pelvic radiograph was normal. The spinal lesion (and two others not shown on this photograph) were asymptomatic.

Computed tomography

Computerized reconstruction of multiple radiographic scan sections can give detailed information on anatomy, especially of bone, allowing three-dimensional visualization of structures such as the spinal canal and facet joints. Its principal use is therefore in assessing areas of complex anatomy such as the spine or pelvis where plain radiographs may be inadequate (for example to investigate stenosis of the spinal canal). Drawbacks, however, include limited soft tissue resolution and exposure to a considerable radiation dose; in many situations it is has now been superseded by MRI.

Magnetic resonance imaging

The ability of MRI to image the anatomy and biochemistry of soft tissue as well as bone means that it provides detailed information not only on structure but also on the pathophysiology of all locomotor tissues. Further advantages include its capacity for multiplanar imaging (for example coronal, axial, sagittal, oblique) and its safety, without radiation exposure. The physics of MRI is complex. When a patient is placed in the magnetic field of the scanner the protons in the body align along the central axis of the field. Application of a radiofrequency pulse or 'sequence' causes the protons to spin in phase with each other. When the pulse is stopped the protons return to random spinning and 'dephase'. As they do so they emit a signal that is converted to an image by computer manipulation. In general, T_1-weighted short sequences are useful for defining anatomy, and T_2-weighted long sequences are useful for assessing pathology. Other sequences are selected for special purposes, for example the short tau inversion recovery sequence (**STIR**) is used to image marrow since it suppresses fat and makes the marrow appear dark. MRI, with or without enhancement with gadolinium, is particularly useful in detecting and assessing the following:

- early osteonecrosis (at the presenting site and the contralateral clinically occult site)
- intervertebral disc disease, root entrapment, and spinal cord compression
- osteoarticular and soft tissue sepsis
- osteoarticular and soft tissue malignancy
- internal mechanical derangement of joints (particularly the knee)
- assessment of soft tissue and periarticular pathology (for example early synovitis, rotator cuff tears, bursitis, tenosynovitis).

The choice between three-phase scintigraphy and MRI for detection of conditions such as early osteonecrosis, where both have excellent sensitivity (scintigraphy 90 per cent, MRI 100 per cent), will depend on practical issues such as ease of access, musculoskeletal reporting expertise, and local cost.

Ultrasonography

This is a safe and accessible technique for confirming soft tissue changes such as a hip joint effusion, popliteal cyst, or thickened Achilles tendon. Limited resolution, however, makes it inferior to CT or MRI for defining anatomical abnormality.

Blood tests for inflammation and systemic disease

The full blood count, erythrocyte sedimentation rate, and C-reactive protein may show changes that indicate the presence of inflammation somewhere in the body. These changes are very sensitive but are non-specific. They are mainly used as a semiquantitative measure to complement the clinical assessment of inflammatory disease and its response to treatment.

The systemic response to injury that results in these changes is summarized in Fig. 11. At any site of injury or inflammation macrophages and monocytes release soluble intercellular signalling polypeptides (cytokines) including interleukin 1, interleukin 6, and tumour necrosis factor-a. Some of these cytokines enter the systemic circulation and exert effects on the hypothalamus, bone marrow, and liver. These combined systemic effects are called the acute phase response, even though they accompany chronic as well as acute inflammation. Interleukin 6 is the main cytokine to influence the liver, causing increased production of certain acute phase proteins (including fibrinogen and C-reactive protein) but decreased production of other negative acute phase reactants (such as albumin and transferrin).

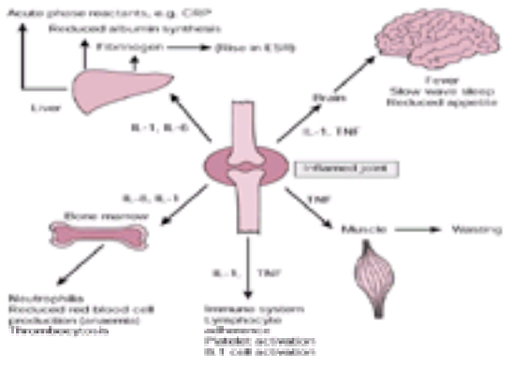

Fig. 11 Diagram to show the important elements of the acute phase response.

Much of the acute phase is beneficial for body defence and adaptation to injury, especially for dealing with the two major complications of injury that threaten life—haemorrhage and sepsis. For example, the thrombocytosis and increased serum levels of clotting factors facilitate haemostasis; neutrophilia and the increased serum levels of complement, immunoglobulin, and C-reactive protein (an opsonin) combat infection; and the anaemia and low serum transferrin levels result in diminished delivery of iron to bacteria and parasites.

Of all the acute phase proteins C-reactive protein shows the greatest shift from very low to very high levels, often representing a several hundred-fold increase in concentration. In addition C-reactive protein closely mirrors the current degree of inflammation, rising rapidly at its onset and falling as inflammation subsides, such that it is therefore the single most useful direct measure of the acute phase response. Interestingly, some rheumatic diseases—specifically lupus, systemic sclerosis, and dermatomyositis—associate with only modest or no elevation of C-reactive protein despite unequivocal pathological evidence of inflammation and tissue damage. The reason for this remains unclear, but patients with such disease are capable of mounting a typical acute phase response, for example in response to infection. In a patient with lupus or scleroderma gross elevation of C-reactive protein should therefore suggest an incidental cause such as sepsis. Some clinical features of active systemic lupus and infection overlap, and in this situation the C-reactive protein can prove a useful test.

The erythrocyte sedimentation rate is an old established indirect measure of the acute phase response. It mainly reflects the degree of rouleaux formation. Normally our circulating erythrocytes do not clump together because of the net balance of three electrical forces (Fig. 12):

- weak attractant van der Waal's forces resulting from red cells being bodies
- a strong repellent net negative surface charge, or zeta potential, due mainly to membrane sialic acid residues, and
- an attractant dielectric constant resulting from the charge characteristics of the plasma constituents.

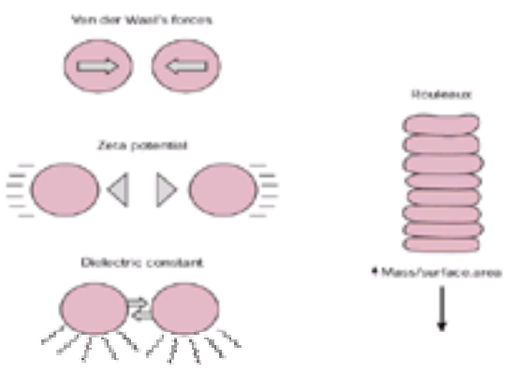

Fig. 12 Diagram showing the balance of three electrical forces that influence clumping of erythrocytes. Rouleaux sediment faster than individual erythrocytes.

In health the zeta potential far exceeds the sum of the two attractant forces, so that erythrocytes electrostatically repel each other and remain single. However, during the acute phase response the change in plasma protein concentrations leads to an increase in dielectric constant. Fibrinogen is particularly important in this respect. Although its increase in concentration is relatively modest, fibrinogen is a very asymmetric molecule that exerts a major electrical charge effect. The resulting increase in dielectric constant is sufficient to overcome the zeta potential so that rouleaux form more readily. Rouleaux have a higher ratio of mass per surface area so sediment faster than single red cells. This property is measured in the erythrocyte sedimentation rate. In the Westergren test system a 200 mm capillary tube is filled with the patient's blood. After 1 h the clearance of red cells from the top is measured. If there is little rouleaux formation the discrete red cells sediment only slowly and the clearance is small (less than 5 to 10 mm). However, if there is significant rouleaux formation the clearance is greater and the erythrocyte sedimentation rate in the first hour is elevated. Therefore in a patient with an acute phase response the erythrocyte sedimentation rate and C-reactive protein are both elevated, the erythrocyte sedimentation rate lagging behind the C-reactive protein in terms of speed of change.

The erythrocyte sedimentation rate, however, may be elevated for reasons other than the acute phase response. Immunoglobulins are very symmetrical molecules and their modest increase in concentration during the acute phase response has relatively little effect, compared with fibrinogen, on the dielectric constant. However, large increases in immunoglobulin concentration (for example in multiple myeloma or associated with autoimmune diseases such as Sjögren's syndrome) will increase the dielectric constant and lead to rouleaux formation. In this situation the patient may have a high erythrocyte sedimentation rate but normal or relatively low C-reactive protein. Such discordance between the erythrocyte sedi-mentation rate and C-reactive protein should lead to consideration of hypergammaglobulinaemia and myeloproliferative disease and to direct measurement of serum immunoglobulins.

In addition to the changes reflecting an acute phase response, the full blood count may show other alterations that are non-specific in themselves but which, taken in the context of the clinical features, may be characteristic of certain rheumatic diseases or their complications (Fig. 13). For example, neutrophilia may be seen in systemic vasculitis, and neutropenia in lupus. Furthermore, many of the slow-acting drugs used to control chronic inflammation have toxicity on the bone marrow so that the full blood count is often included in the routine monitoring of such treatment.

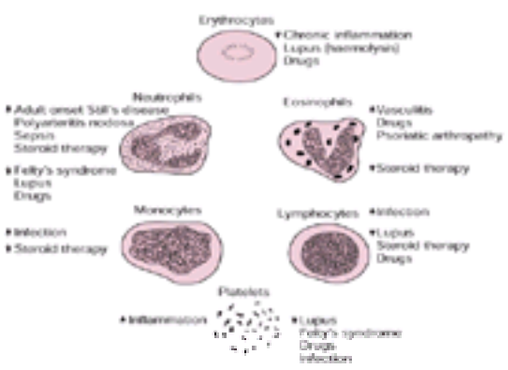

Fig. 13 Diagram showing some of the non-specific changes that may occur in individual elements of the full blood count in patients with systemic rheumatic disease.

Taken together, therefore, the full blood count, erythrocyte sedimentation rate, and C-reactive protein can be a useful complement of tests in the major rheumatic diseases to:

- assess inflammatory disease activity
- assess response to disease-suppressing treatment
- detect certain disease complications, and
- screen for drug toxicity.

However, it is important to appreciate that although an elevated acute phase response is consistent with inflammatory rheumatic disease, it is non-specific; also that the degree of elevation is often proportional to the amount or 'burden' of inflammatory tissue, for example isolated small joint synovitis in rheumatoid arthritis may not be sufficient to cause a detectable acute phase response, but this does not mean that inflammatory disease is not present.

Immunological tests

There are an increasing number of autoantibodies that can be detected from a serum sample by clinical laboratory services. Production of some of these is a common, age-related phenomenon that may be exaggerated by the presence of chronic inflammation. Their mere presence, therefore, often has low diagnostic specificity and little clinical relevance. If present in high concentrations, however, their disease specificity usually increases, so that it is always important to know how much antibody is present (the titre or concentration in units) rather than just whether it is detectable. For some autoantibodies (for example c-ANCA (antineutrophil cytoplasmic antibody)) their titre, if initially high, may be used to monitor the activity of the associated disease; only a few antibodies (for example anti-dsDNA) have high diagnostic specificity. Again, the correct choice and interpretation of these tests will depend on detailed knowledge of the patient. Different detection and assay systems exist for many of these autoantibodies and close liaison with the local immunology service is required.

Rheumatoid factor

The definition of a rheumatoid factor is an antibody directed against a specific region of the Fc (crystallizable) fragment of human IgG. The antibody itself may be of any immunoglobulin class, although IgM anti-IgG is the rheumatoid factor that is most commonly measured in the first instance. One of the traditional methods used to detect IgM rheumatoid factor is to coat latex beads with human IgG. If the patient's serum is then added to the test system the pentameric IgM antibody binds to the IgG causing the latex particles to flocculate producing a positive 'latex fixation test'. The amount the patient's serum must be diluted before this flocculation is lost is then determined; the higher this 'titre' the higher is the concentration of antibody present. Although 'rheumatoid factor' was so named because it was first detected in the sera of patients with rheumatoid arthritis, it also occurs in association with a variety of other conditions as well as in some normal adults (Table 4). It therefore has low diagnostic specificity, particularly in the elderly, and is not a 'test for rheumatoid arthritis'. In terms of sensitivity, it is present in the majority of patients with erosive rheumatoid disease but may only appear after many months or years of disease, once the diagnosis is beyond dispute. It is therefore of little value in making a diagnosis of rheumatoid arthritis, being neither sufficient nor necessary: rheumatoid arthritis is predominately a clinical diagnosis, based on detecting the presence of synovitis (capsular swelling, joint line tenderness, stress pain). However, if present in high titre at the onset of rheumatoid arthritis it associates with a poorer prognosis. IgG rheumatoid factor has greater specificity for major rheumatic disease, but the above caveats still remain. One situation where a negative rheumatoid factor is of diagnostic significance is in a patient with arthritis and nodules. As a general rule all patients with nodular rheumatoid are seropositive so that in this situation other causes of 'arthritis plus nodules' must be considered, for example tophaceous gout or hypercholesterolaemia.

Antinuclear antibody

An antinuclear antibody is any autoantibody directed against one or more components of the nucleus. Immunofluorescence microscopy after serum has been applied to a nucleated tissue substrate (for example rodent organs) or human cell lines (e.g. Hep 2) is the standard method of detection, and four main patterns of staining are reported. As with rheumatoid factor, the higher the titre of antinuclear antibody the greater its significance, but a high titre does not necessarily imply more severe disease. The specificity and sensitivity also vary according to the antigen preparation used in the test system and whether the antinuclear antibody measured is IgG or IgM. However, the tests are not universally standardized, and again, liaison with the laboratory is important in order to determine which cut-off titre is considered to be 'abnormal'. The many causes of a positive antinuclear antibody are outlined in Table 5. The commonest reason to undertake an antinuclear antibody test is in a patient with suspected lupus. For lupus, the antinuclear antibody has high sensitivity (97 to 100 per cent), but because the specificity is very low (10 to 40 per cent) a positive result does not make the diagnosis; by contrast, a negative antinuclear antibody virtually excludes it.

If a screening serum antinuclear antibody test is positive most laboratories will then attempt to determine the specific antigenic determinants. Some of these determinants are soluble and can be extracted from the nucleus, hence 'extractable nuclear antigens' (ENA), although many of the antigen–antibody specificities in human disease remain to be discovered. Compared with the antinuclear antibody, antibodies against specific nuclear antigens may have higher specificity for certain diagnoses or for certain patterns of system involvement within the same disease. For example, antinuclear antibody directed against double-stranded DNA is highly specific for lupus. Unfortunately, it is present in only a minority of patients and those in whom it is positive often have classic severe lupus (for example with renal involvement) and a clear clinical diagnosis.

Antibodies to 'Sm' antigen occur almost exclusively in systemic lupus erythematosus and may imply a poorer disease prognosis. Antitopoisomerase 1 and anticentromere antibodies are found exclusively in diffuse and limited scleroderma respectively. Antibodies to 'Ro' antigen occur predominantly in Sjögren's syndrome and systemic lupus erythematosus and associate with a high frequency of photosensitive rashes and a risk of neonatal heart block. Antibodies to RNP (ribonucleoprotein) are found in systemic lupus erythematosus, but also in a variety of other conditions, including scleroderma, myositis, mixed connective tissue disease, and rheumatoid arthritis. Although these antibodies may associate with disease subsets, there is little evidence that they are involved in disease pathogenesis.

The antiphospholipid syndrome, defined by the occurrence of arterial and venous thromboses, recurrent fetal losses, and thrombocytopenia in the presence of antiphospholipid antibodies, occurs in lupus and other autoimmune diseases and also in subjects with no other underlying disease. Antiphospholipid antibodies can be detected in assays for anticardiolipin antibodies (predominantly directed against a2 glycoprotein 1) and in phospholipid-dependent coagulation studies to detect lupus anticoagulants (prolonged Activated Partial Thromboplastin Time (APTT) which fails to correct with the addition of normal serum). Antiphospholipid antibodies also occur in a wide variety of rheumatic, infectious (bacterial, viral, protozoal) and malignant conditions, although in these situations they are not usually associated with thromboses.

Further information on these tests can be found in Chapter 13.14 and Chapter 18.10.2.

Tests for specific clinical situations

Chronic inflammatory disease at a single site

Patients with unexplained inflammatory disease at a single locomotor site (monoarthritis, bursitis, tenosynovitis, osteitis) should be considered for biopsy. The timing for this will vary according to how florid the lesion appears, but in general this should be undertaken for any undiagnosed lesion that has persisted for 6 months. The reason is to determine or exclude specific disease that can only be diagnosed by this means (Table 6). Although these conditions are uncommon or rare they require a specific treatment approach, rather than a continuing empirical symptomatic one. The commonest site for unexplained inflammatory monoarthritis is the knee, followed by the wrist and small hand joints. Arthroscopic biopsy is ideally used for larger joints (for additional information from direct visualization and guided biopsy), open biopsy for smaller joints and periarticular lesions. Tissue should be examined histologically and sent for culture, including mycobacteria. Apart from the specific conditions in Table 6, histopathology has no role in the diagnosis or management of most common rheumatic disease.

Investigation of suspected muscle disease

There are three principal investigations for the diagnosis and monitoring of muscle disease: serum creatine kinase, electromyography, and muscle histology. None are 100 per cent sensitive so that each may be normal despite abnormality detected by one or both of the others. Although creatine kinase is the most indirect measure it is readily available and commonly measured in the first instance. It is important to realize that elevation of the creatine kinase may result from a variety of causes (Table 7) and certain racial groups (e.g. Afro-Caribbean) have higher 'normal range' values. Electromyography or muscle biopsy will usually be undertaken next, the

choice depending on local availability and expertise. How much information on diagnosis and disease activity has been gained from the first two tests will then often determine whether the third is also undertaken. The one used for subsequent monitoring of disease activity will be that which was most helpful in confirming the diagnosis.

Electromyography measures the action potentials produced at rest and during voluntary contraction. Normal muscle is electrically silent at rest. On slight contraction motor-unit potentials of 500 to 1000 μV in amplitude and 4 to 8 ms in duration are recorded. On maximal contraction, as many motor units as possible are recruited and an interference pattern develops. With inflammatory polymyositis the electromyography may show a diagnostic triad of:

- spontaneous fibrillation
- short-duration action potentials in a polyphasic disorganized outline, and
- repetitive bouts of high-voltage oscillations produced by contact of diseased muscle with the needle.

Muscle histology can readily be obtained from a needle muscle biopsy sample. This is a relatively simple procedure requiring a local anaesthetic, small skin incision (no stitches required), an appropriate muscle biopsy needle, and no subsequent limitation of activity: it can easily be repeated serially for subsequent monitoring of response to treatment. The quadriceps is usually chosen, although the deltoid or other muscles can also be biopsied this way. The two or more small cores of tissue obtained by the needle need to be transported rapidly to the laboratory to be correctly orientated prior to freezing and sectioning. Immunohistochemical staining in conjunction with plain histology gives considerable information concerning primary and secondary muscle and neuromuscular disease. Although open biopsy will yield more tissue than needle biopsy, only a small amount of muscle is actually required and serial open biopsy is clearly problematic.

For further discussion of the investigation of muscle disease, see Chapter 24.22.4.

Investigation of suspected vasculitis

The clinical features of vasculitis often relate to specific organ involvement (ear, nose, and throat, neurological, renal, respiratory) but may be non-specific (malaise, weight loss, night sweats). In view of the potential toxicity of appropriate treatment, further investigation is always required. In terms of laboratory tests, simple measures such as a urine dipstick test and microscopy should not be overlooked, as the prognosis of many of these diseases is dictated by renal involvement. Antineutrophil cytoplasmic antibodies (**ANCA**) were initially detected in patients with glomerulonephritis. These antibodies are directed against enzymes present in neutrophil granules. Two main patterns of immunofluorescence are distinguished, cytoplasmic and perinuclear. The majority of c-ANCAs and p-ANCAs are specific for the enzymes proteinase 3 and myeloperoxidase respectively. These two patterns have been correlated with particular disease manifestations, for example c-ANCA with Wegener's granulomatosis and p-ANCA with microscopic polyangiitis. However, positive ANCAs occur in a variety of other settings, including malignancy and infections (bacterial and HIV infection) as well as other autoimmune diseases (inflammatory bowel disease, rheumatoid arthritis, lupus, pulmonary fibrosis). Therefore, the diagnosis of these conditions cannot be made or refuted on the ANCA test alone. Other evidence should be obtained by biopsy of an appropriate organ (nose, kidney, muscle, skin) or angiography.

For further information see Chapter 20.10.3.

Investigation of multiple regional pain

In most patients who present with widespread musculoskeletal pain the diagnosis is made from clinical examination alone, for example widespread rheumatoid disease. In some cases, however, there may be little to detect on clinical examination to explain the widespread pain. In most cases the diagnosis will be fibromyalgia. This is confirmed clinically by the appropriate symptoms (for example widespread pain, non-restorative sleep, marked fatigue, 'tension' headache, 'irritable bowel' symptoms, anxiety and depression, poor memory and concentration, urinary frequency) and the presence of widespread hyperalgesic tender sites and negative control sites (see Chapter 18.4). However, a number of other conditions may present similarly with multiple regional symptoms and few, if any, physical findings. In this situation, a limited screen (Table 8) is justified to detect conditions that have a specific treatment approach.

18.4 Back pain and regional disorders

Simon Carette

Low back pain

Introduction

Low back pain is one of the commonest symptoms and was the fifth leading reason for all visits to doctors' surgeries in the United States in 1990. Between 60 and 80 per cent of adults will suffer from at least one episode of back pain during their lifetime. Acute back pain is usually self-limiting, and the majority of subjects do not seek medical advice. Of those who do, more than 90 per cent will be back to work within 2 months, independent of the treatment received, including those in whom the acute episode results from a work-related injury for which compensation might be available. The 5 to 10 per cent of patients who remain disabled after this time represent a difficult therapeutic challenge due to the influence of psychological and social factors on the continuation of pain. This small percentage of patients is responsible for more than 75 per cent of the total costs of low back pain to our society, estimated to be between 1 and 2 per cent of the gross national product in most industrialized countries.

Significant risk factors for the occurrence of back pain include older age, heavy labour (in particular jobs requiring lifting in an awkward position), lower education and income, smoking, and obesity. Long-distance driving and whole-body vibration such as experienced by lorry drivers is a well-known risk factor for disc herniation. Prior episodes of back pain are strong predictors of recurrence. A number of psychosocial risk factors, or so-called 'yellow flags', predict poor outcomes. These include beliefs that back pain is harmful or potentially severely disabling, resulting in fear/avoidance behaviour and reduced activity levels, excessive reliance on aids and appliances, depressed mood, withdrawal from social interaction, and job dissatisfaction.

Many structures of the back, including the muscles, ligaments, discs, bones, and zygoapophyseal and sacroiliac joints are innervated and can therefore be a source of pain. However, in more than 90 per cent of patients presenting with low back pain, it is extremely difficult—if not impossible—to identify precisely the anatomical source of the pain on the basis of history and physical examination. These patients should be diagnosed as suffering from 'non-specific low back pain'. A host of clinical entities such as muscle strain, degenerative disc disease, facet syndrome, myofascial pain syndrome, segmental instability, minor intervertebral displacement, iliolumbar syndrome, piriformis syndrome, etc. have been described within this broad category based on the localization of pain and tenderness, reproduction of symptoms by specific manoeuvres, radiological features, or pathophysiological hypotheses. Unfortunately, the signs and manoeuvres described for each of these clinical syndromes lack sensitivity and specificity and are not reproducible even by experienced clinicians. Moreover, the claim that any of these entities is responsible for the pain in a given patient can very rarely be validated. For example, it is hazardous to ascribe pain to degenerative disc disease or apophyseal joint osteoarthritis when it has been shown that individuals with similar radiological changes can be completely asymptomatic. The only way to determine if the discs, or zygoapophyseal or sacroiliac joints are the source of pain in a given patient is through injection studies done under stringent, controlled conditions (see below).

Clinical approach o the diagnosis of low back pain

In evaluating a patient presenting with low back pain, the physician should not try to differentiate between the various elusive entities responsible for non-specific back pain but rather should focus on determining if the patient needs emergency surgery, has sciatica with signs of nerve root compression, or has an underlying medical cause of back pain (infectious, inflammatory, metabolic, tumoural, or visceral) (Table 1).

Is this a surgical emergency?

Cauda equina syndrome and an expanding vascular aneurysm are two extremely rare but important conditions to recognize since both are surgical emergencies. In the first instance, the patient will usually present with low back and/or buttock pain, associated with bilateral sciatica, neurological symptoms in the lower extremities, and urinary and/or bowel incontinence. Physical examination may show bilateral weakness, sensory losses, saddle anaesthesia, decreased reflexes in the legs, and decreased rectal tone. Diagnostic procedures (magnetic resonance imaging (**MRI**), computed tomography (**CT**) scan, or myelogram) should be performed on an emergency basis if bowel and bladder control are to be preserved. Central disc herniation is the most common cause of the syndrome, followed by tumours and epidural abscesses.

An aortic aneurysm can be responsible for a dull, gnawing back pain due to direct compression of the aneurysm on the lumbar vertebrae. They are typically seen in elderly patients, especially white men, and physical examination may reveal a pulsating abdominal mass and decreased pulses in the lower extremities. Diagnosis is most important because rupture or dissection of the aneurysm can be fatal in 15 to 70 per cent of cases in various series. In this instance, the patient presents with a sudden, excruciating tearing abdominal or back pain radiating to the groin, buttocks, or thighs with haemodynamic compromise (hypotension, tachycardia, and shock). Up to 30 per cent of ruptured aneurysms are initially misdiagnosed. Preventive surgery (before rupture or dissection) is the optimal treatment.

Does the patient have sciatica and/or neurological signs?

Sciatica can be defined as pain radiating below the knee. It is a rare symptom, being reported by only 1 per cent of patients with back pain, but its presence is usually associated with an identifiable aetiology. Typically, sciatica results from compression of the spinal nerve originating between L4 and L5 (L5 nerve root) and/or L5 and S1 (S1 nerve root) by a herniated disc, bone, or a combination of the two (spinal stenosis). Tumours, infections, or epidural haemorrhage can very rarely produce similar symptoms and signs. The pain in a patient with a herniated disc tends to be aggravated by prolonged sitting as well as any manoeuvre that increases intrathecal pressure such as sneezing, coughing, or defaecation. It is often associated with paraesthesiae and weakness in the distribution of the involved nerve.

Patients with spinal stenosis are usually older and typically complain of pain and/or paraesthesiae in one or both buttocks, thighs, and/or legs that develop on standing or walking and are relieved by 15 to 20 min rest ('neurological claudication'). These patients often walk with the trunk flexed since extension aggravates their symptoms by worsening nerve impingement. The neurological examination is most often normal or shows non-specific abnormalities, such as reduced or absent ankle reflexes. Differentiating neurological from vascular claudication can be difficult since both problems occur in the same age category. Typically, pain from vascular claudication is relieved faster with rest than that of neurological claudication.

Does the patient have an underlying medical cause for their back pain?

The history is by far the most important diagnostic step in the search of potential medical aetiologies of low back pain. A number of clues or 'red flags' should be looked for systematically. These include the presence of fever, chills, night sweats, weight loss, and nocturnal pain that should direct the clinician towards the possibility of neoplasia or infection. An insidious onset of back pain accompanied by significant early morning stiffness in a young individual suggests a spondylarthropathy and should prompt the clinician to enquire about the family history and undertake a detailed review of the ocular (conjunctivitis, iritis), cutaneous (psoriasis, mouth ulcers, balanitis, keratoderma blennorrhagica), gastrointestinal (diarrhoea, haematochezia, abdominal pain), genitourinary (urethritis), and musculoskeletal (peripheral arthritis, dactylitis, enthesitis, heel pain) systems. Risk factors for neoplasia (previous or current history of malignancy), infection (history of tuberculosis, AIDS, intravenous drug abuse, or recent genitourinary procedures), and metabolic bone diseases (previous fractures, menopause, corticosteroid

intake, history of anorexia nervosa) should also be looked for in patients suspected of having a medical problem underlying their back pain.

What are the key signs to look for in the physical examination?

A good examination of the lumbar spine and relevant nerves can be accomplished in less than 5 min if it is done systematically (Table 2). A full physical examination must be completed in patients suspected of having a medical cause for their back pain. The diagnostic utility of the many physical manoeuvres described to identify zygapophyseal and sacroiliac joint pain has been refuted when validated against diagnostic blocks with local anaesthetic. Waddell has described a number of non-organic physical signs (Table 3). When a patient has three or more of these signs, this suggests that psychological factors or secondary gains may be involved.

The classification of non-specific low back pain

In 1987, the Quebec Task Force on Spinal Disorders proposed a classification of activity-related spinal disorders in 11 mutually exclusive categories based on pain localization, neurological examination, paraclinical examinations, and response to treatment. The first four categories are divided according to duration of symptoms and work status as both of these factors can influence management (Table 4).

Who should be investigated and how?

There are now clinical guidelines available from the United States, the United Kingdom, Australia, The Netherlands, Israel, and New Zealand to help physicians manage patients with acute back pain. No such guidelines exist for chronic back pain. There is a general agreement that the initial assessment should focus on the detection of 'red flags' suggestive of a medical aetiology and that the vast majority of patients with back pain do not need any investigations. Recommendations for ordering a plain radiograph in a patient presenting with back pain include the following: age over 50, fever, weight loss, significant trauma, previous history of neoplasia, use of corticosteroids, drug or alcohol abuse, neurological symptoms and signs, particularly if widespread, night pain, morning stiffness (in which case a pelvic rather than a lumbar radiograph is recommended to detect sacroiliitis), and the persistence of pain after 1 month of conservative therapy.

All other tests should be restricted to patients in whom a medical aetiology is suspected from the history and physical examination, and patients with abnormalities on neurological examination who do not improve with conservative management. Ordering blood tests and imaging in any other situation can hardly be justified since not only are these tests unhelpful but they contribute significantly to medical costs. In addition, as many as 25 to 50 per cent of asymptomatic individuals have been shown to have abnormalities such as disc herniation on CT scans and MRI.

The sedimentation rate is the most useful blood test in patients suspected of having spinal infection since it is elevated in up to 80 per cent of cases. Neutrophilia and anaemia are also commonly seen in patients with neoplasia and infection. Laboratory evaluation of patients with osteoporosis and/or pathological fractures should include serum calcium, phosphorus, alkaline phosphatase as well as serum and urine immunoelectrophoresis (to detect myeloma), particularly if the sedimentation rate is elevated.

Many radiologists consider MRI to be the imaging modality of choice for the diagnosis of lumbar disorders. It provides a unique non-invasive means of studying the spine and is unsurpassed for imaging soft tissues. It is particularly helpful in the evaluation of spinal cord tumours, as well as infections of the spine, including discitis, epidural, and paraspinal abscesses. Computed tomography is superior to MRI for the evaluation of bony structures and therefore is the modality of choice for spinal stenosis, particularly when combined with myelography. Plain myelography is rarely used today except in patients who have contraindications to MRI or CT (claustrophobia in particular). The diagnostic accuracy of MRI, plain CT, and CT myelography is comparable for the assessment of nerve root compression due to disc herniation. While MRI is non-invasive and involves no radiation to the patient, the much lower cost of plain CT makes it an excellent choice in this context. CT-guided percutaneous biopsy is commonly used to obtain histological material from patients with tumour mass or infection.

As mentioned previously, injection studies done under fluoroscopic guidance are the only means of diagnosing back pain of discal, zygoapophyseal, or sacroiliac joint origin. When normal discs are injected with contrast material, the individual does not experience pain. A provocative discography should be considered positive only if the injection reproduces the patient's pain and no pain is experienced during the injection of adjacent discs. In a recent report, 40 per cent of subjects with chronic low back pain attending a large specialist spinal centre satisfied this strict definition and demonstrated a radial fissure on CT. Similarly, between 10 and 15 per cent of subjects report a significant improvement in their pain when their zygoapophyseal joints or their sacroiliac joints are injected with a local anaesthetic but not with isotonic saline. When taken together, these figures suggest that the anatomical source of pain can be established in as many as 70 per cent of patients with non-specific back pain by using these invasive techniques. However, the impact of this approach on patient management is unclear, since no treatment has yet been demonstrated to be effective for these specific entities.

Radionuclide bone scintigraphy with technetium-99m is helpful in conditions characterized by increased bone turnover. These include bone metastases, fracture, Paget's disease, and infections. Gallium-67 binds to polymorphonuclear leucocytes and can he helpful in the evaluation of vertebral osteomyelitis and sacroiliac septic arthritis. Typically, bone scans are negative in patients with multiple myeloma which is characterized by lytic lesions.

Neurophysiological studies are rarely indicated except in patients in whom it is difficult to distinguish between a neuropathy, radiculopathy, or plexopathy. Fibrillations in the paraspinous muscles are the most common and earliest findings seen in radiculopathy. Their presence indicates a lesion proximal to the vertebral foramen and excludes a plexopathy.

How best to manage patients with low back pain?

Surgical emergencies

As mentioned earlier, cauda equina syndrome and a ruptured vascular aneurysm are the only two conditions that must be managed surgically on an emergency basis.

Sciatica and neurological deficits

About 90 per cent of patients with a herniated lumbar disc will improve significantly with limited rest, analgesics, and anti-inflammatory drugs. The role of epidural steroids remains unclear. They may afford short-term improvement in leg pain but they do not reduce the need for surgery. Indications for surgery include persistent disabling buttock and/or leg pain despite 2 to 3 months of conservative management, and/or severe or progressive worsening neurological deficit whilst on treatment. Surgery may also be indicated in patients with neurological claudication due to spinal stenosis, but only after all attempts with conservative management have failed. Patients with spinal stenosis who are more incapacitated by back pain than by neurological claudication probably should not be operated on, since surgery is rarely effective and may even worsen back pain.

Medical back pain

Primary and secondary tumours of the spine can be treated by surgery, radiotherapy, or chemotherapy, while antibiotics with or without surgical drainage are the treatment for discitis and osteomyelitis. Postural exercises and non-steroidal anti-inflammatory drugs remain the cornerstone of treatment for patients with spondylarthropathies. While the efficacy of most non-steroidal anti-inflammatory drugs has been demonstrated, indomethacin and phenylbutazone are the two most effective in resistant cases (because of the risk of agranulocytosis and aplastic anaemia, in the United Kingdom phenylbutazone is only available for the treatment of ankylosing spondylitis when other therapy has failed or is unsuitable). Sulfasalazine and methotrexate are helpful for the peripheral arthritis associated with spondylarthropathies but they have no role in the treatment of the spinal disease. The treatment of metabolic bone diseases is beyond the scope of this chapter.

Non-specific low back pain

A number of systematic reviews of randomized controlled trials of the most common interventions have recently been published and form the basis of the recommendations found in the many guidelines published in the past 10 years. For acute back pain, patients should be advised to stay as active as possible. There is strong evidence for the effectiveness of analgesics, non-steroidal anti-inflammatory drugs, and muscle relaxants. Exercise therapy in the acute phase is ineffective. A very important objective at this stage is to reduce the likelihood of patients progressing to chronicity, not least because there are only a few modalities, including manipulation, back schools (programmes using cognitive, physical, and motivational methods to educate patients on how to manage their back problem), and exercise

therapy that have been show to be beneficial in patients with chronic back pain. The early identification of psychosocial risk factors or 'yellow flags' is essential. Screening questionnaires have been developed to help clinicians with this task. Cognitive and behavioural approaches must be used in high-risk patients in an attempt to influence positively some of these factors. Patients with persistent back pain after 6 months represent a very difficult therapeutic challenge, particularly if they have not returned to work. At this stage, their chance of going back to their previous job is only 50 per cent, while after 1 year of absenteeism it decreases to 25 per cent. Health professionals have a major role to play in preventing this unfortunate outcome.

Neck pain

Neck pain is a very common symptom. In a recent large epidemiological survey from Norway, 34.4 per cent of adult respondents reported troublesome neck pain in the previous year, with 13.8 per cent reporting pain lasting more than 6 months. As for low back pain, neck pain can rarely be attributed to a specific anatomical source and the vast majority of patients presenting with this symptom should be diagnosed as suffering from 'non-specific neck pain' or 'cervical spinal pain of unknown origin', rather than applying non-validated diagnostic labels. Trauma, in particular acceleration–deceleration (whiplash) injuries, increasing age, lower education, and psychosocial factors are the most common risk factors associated with the development of neck pain.

The clinical approach to the patient with neck pain should follow the same principles as described for low back pain. Signs of nerve root and/or spinal cord compression should always be looked for, particularly in patients complaining of associated pain, numbness, or weakness in their upper and/or lower extremities. Older patients with cervical spinal stenosis due to severe osteoarthritis may present with wasting and lower motor neurone weakness in the arms or hands and spastic weakness and sensory disturbance in the legs.

A number of diseases from the pharynx (pharyngitis, retropharyngeal abscess), larynx (laryngitis), trachea (tracheitis), thyroid (acute thyroiditis), lymph nodes (lymphadenitis), carotids (carotidynia), lungs (Pancoast tumor), heart (myocardial infarction), pericardium (pericarditis), aorta (dissecting aneurysm), and diaphragm (subphrenic abscess) can refer pain to the neck and should be considered. These conditions will usually have other clinical manifestations to alert the physician to the proper diagnosis. The neoplastic, infectious, inflammatory, and metabolic conditions enumerated in Table 1 can also affect the cervical spine. In addition, rheumatoid arthritis and diffuse idiopathic skeletal hyperostosis should be considered in the differential diagnosis as both can involve the cervical spine and cause spinal cord compression.

A special task force recently proposed a classification of cervical disorders associated with whiplash injuries which takes into account both the severity and duration of symptoms (Table 5). Although the classification was designed to address problems related to whiplash injuries, it can be very useful in classifying and guiding management of patients presenting with non-specific neck pain unrelated to trauma.

Investigation of patients with neck pain—who and how

Guidelines are only available for patients presenting with whiplash injuries. Patients with grade I whiplash-associated disorder do not usually require radiographic evaluation. Those with grade II to IV whiplash-associated disorder need a baseline radiological examination consisting of plain films with anteroposterior, lateral, and open-mouth views. Radiographs are usually unhelpful in patients with non-specific neck pain. Degenerative changes in the discs and zygoapophyseal joints increase with age and do not correlate with symptoms of neck pain. CT is helpful for evaluating the bony structures of the neck but it must be combined with myelography to adequately visualize the neural tissues. Therefore MRI is usually preferred in most cases with spinal cord or nerve root compromise. Fifty per cent of patients with chronic neck pain after motor vehicle accidents respond to diagnostic zygoapophyseal joint injection, suggesting that these joints are responsible for their pain.

Management of patients with neck pain

The majority of treatments recommended for the management of patients with neck pain have not been evaluated in a scientifically rigorous manner. Those that have been have shown very little, if any, evidence of efficacy. These include soft cervical collars, zygoapohyseal joint injections, and acupuncture. Patients with acute neck pain should be encouraged to maintain their usual level of activity. There is evidence that non-narcotic analgesics, non-steroidal anti-inflammatory drugs, mobilization, and manipulation are effective, while the promotion of rest and soft collars tends to prolong disability. Surgery is only indicated for patients with severe radiculopathy not responsive to 2 to 3 months of conservative management. There is no consensus as to how to best manage patients with chronic neck pain.

Regional pain disorders

Regional musculoskeletal pain disorders, defined as painful conditions in a specific region of the body, are extremely common occurrences. A number of clinical entities have been described for the shoulder, elbow, wrist and hand, hip, knee, ankle, and foot regions (Table 6). Most of the regional pain disorders can usually be identified through a careful history and directed physical examination, although recent research indicates that interobserver diagnostic agreement is only moderate for the conditions related to the shoulder region, particularly in patients complaining of severe or chronic pain, and those with bilateral involvement. Paraclinical investigations are not usually required for the diagnosis of most regional pain disorders.

In a patient presenting with regional pain, one should aim to determine whether the pain has its origin in the bones and joints, periarticular soft tissues (tendons, bursa, and fascia), nerve roots and peripheral nerves, or blood vessels or if it is referred from distant musculoskeletal or visceral structures. Lesions of the periarticular soft tissues account for most causes of regional pain disorders. Plain radiographs are helpful in delineating soft tissue calcifications which may or may not be related to the pain presented by the patient. Ultrasonography and MRI are of equal value in confirming a diagnosis of tendon rupture in the shoulder, knee, or ankle regions.

The principles of management include temporary rest, analgesics or non-steroidal anti-inflammatory drugs, local corticosteroid injections, thermal modalities, orthotics, and graded flexibility and strengthening exercises.

Diffuse musculoskeletal pain

Between 8 and 10 per cent of the adult population report suffering from chronic diffuse musculoskeletal pain and about half of these satisfy the classification criteria for fibromyalgia. The aetiology of fibromyalgia is unknown. Patients who seek medical help suffer from more psychological distress than those who don't. Although the pain is felt primarily in the muscles, the muscles show no histological or metabolic abnormalities other than those associated with physical reconditioning. There is evidence that substance P levels are increased in the cerebrospinal fluid of patients with fibromyalgia, thus supporting the hypothesis that the pain may be of central origin. Management which includes patient education, cognitive-behavioural approaches, regular aerobic training, and low-dose tricyclic agents is generally unsatisfactory.

18.5 Rheumatoid arthritis

R. N. Maini

Historical background

The first clinical description of rheumatoid arthritis in the medical literature is generally accorded to Landry-Beavais (1800), although Garrod was the first to use the term in his book published in 1859. Whether rheumatoid arthritis existed in Western Europe in olden times is debated by scholars of medical history: descriptions of chronic deforming arthritis suggestive of rheumatoid arthritis in classical writings of Galen and others have, for example, been ascribed to chronic polyarticular gout. The suggestion has been made that rheumatoid arthritis was imported to Europe after the discovery of the New World in the fifteenth century, where it pre-existed as evidenced by examination of archaic Amerindian skeletal remains. The possibility that rheumatoid arthritis spread from the New World in recent times is not only of historical interest but has also led to speculation suggesting the importance of environmental factors in its causation.

The concept of rheumatoid arthritis as a disease entity continues to evolve with advances in knowledge of the multiple causes of chronic inflammatory joint diseases. Thus improved microbiological, immunological, and epidemiological methods have led to a reclassification of certain forms of chronic arthritis, which in the past may have been labelled as rheumatoid arthritis. These include arthritis caused by infections, such as rubella, parvovirus, and borrelia (Lyme disease), or due to biological responses to non-viable products of micro-organisms ('reactive' arthritis) such as yersinia, salmonella, and chlamydia. Diseases of uncertain aetiology, for example the spondyloarthropathies, sarcoidosis, and chronic arthritis associated with systemic lupus erythematosus, primary Sjögren's syndrome, and other connective tissue diseases, have all been recognized as distinct from rheumatoid arthritis in the relatively recent past.

Definition

Rheumatoid arthritis has been defined as a chronic systemic inflammatory disorder characterized by deforming symmetrical polyarthritis of varying extent and severity, associated with synovitis of joint and tendon sheaths, articular cartilage loss, erosion of juxta-articular bone, and in most patients, the presence of IgM rheumatoid factor in the blood. In some patients systemic and extra-articular features may be observed during the course of the disease, and rarely prior to joint disease. These include anaemia, weight loss, vasculitis, serositis, mononeuritis multiplex, interstitial inflammation in lungs and exocrine salivary and lacrimal glands, as well as nodules in subcutaneous, pulmonary, and scleral tissues.

The American College of Rheumatology (**ACR**) has developed and revised criteria for the classification of rheumatoid arthritis based on a hospital population of patients with established active disease (Table 1). These combine a constellation of clinical, serological, and radiological features and have become widely accepted for epidemiological and clinical studies. These criteria distinguish active rheumatoid arthritis from other forms of inflammatory arthritis with a diagnostic sensitivity and specificity of about 90 per cent. However, they are of less value in prevalence studies, which should ideally include patients with inactive rheumatoid arthritis.

The classification criteria are too restrictive to diagnose rheumatoid arthritis reliably early in its presentation, since not all the required features may be present at this stage of evolution. Moreover, a minority of patients presenting with polyarthritis who satisfy the classification criteria for rheumatoid arthritis may later differentiate into other disease types or follow a self-limiting course.

Epidemiology

Criteria and methods for diagnosis of rheumatoid arthritis have varied in different epidemiological studies: some have been based on retrospective analysis of hospital records and others on prospective observation of patients attending hospitals where clinical examination, rheumatoid factor tests, and radiography have been employed. Questionnaires and clinical examination, with or without tests for rheumatoid factor and radiography, have also been used in population studies. However, in recent years the more widespread use of ACR criteria, including a version with a modified format for use in population studies, has introduced a measure of standardization. Based on studies carried out in various parts of the world, some generalizations can be made about the occurrence of rheumatoid arthritis amongst different ethnic populations.

Given the inherent variability in the methodology employed it is not surprising that estimates of the incidence of rheumatoid arthritis in the United States and Europe vary. In a recent study the incidence was 54 per 100 000 in women and 24.5 per 100 000 in men. The incidence increased sharply to a maximum in women over the age of 45 and in men continued to rise into the seventh decade (Fig. 1). A declining trend in the incidence of rheumatoid arthritis amongst females has been observed in recent years.

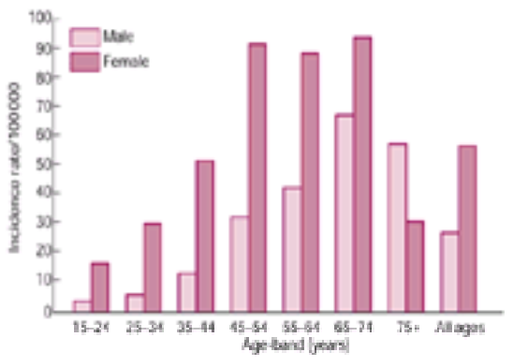

Fig. 1 Age-specific incidence applying modified ACR criteria for rheumatoid arthritis in a United Kingdom population registered in 1990 in whom multiple assessments were made over a 5-year period. Any one of seven criteria may be positive only once during this period. Data from: Wiles N *et al*. (1999). Estimating the incidence of rheumatoid arthritis: Trying to hit a moving target? *Arthritis and Rheumatism* **42**, 1339–46.

The prevalence of rheumatoid arthritis has been consistently assessed as being between 0.8 and 1.1 per cent of the adult population in cross-sectional studies in United States and Western Europe, and translate into higher prevalence rates in the elderly female population. Lower rates of 0.2 to 0.3 per cent have been reported in China and Japan. The prevalence of rheumatoid arthritis amongst the black population is low in rural South Africa (approximately 0.2 per cent) and virtually non-existent in parts of Nigeria. By contrast, prevalence rates of almost 1 per cent have been observed amongst black populations in urban South Africa and in the United States. A strikingly high prevalence rate of over 5 per cent has been noted amongst certain American Indian tribes in the United States, for example the Pima and Chippewa Indians. Differences in both genetic and environmental factors are likely to impact on these variations in incidence and prevalence rates, as are differing access to medical facilities, population age structures, and mortality. Such data are therefore of limited value in providing direct insight into aetiology, but are invaluable in directing research questions and allocating health resources.

Aetiology

Genetic factors

The initiating cause of rheumatoid arthritis remains unknown. A prevalence of 12 to 15 per cent in genetically identical (monozygotic) twins observed in Finland and Great Britain, compared with 4 per cent in non-identical (dizygotic) twins, and between 0.5 to 1 per cent in the general population, strongly favours multigenic influences. It also argues for an environmental trigger.

Advances in molecular genetics have permitted genotyping to confirm an association between the occurrence of rheumatoid arthritis and allelic polymorphisms of genes on the short arm of chromosome 6 that code for a hypervariable region of the b chain of HLA-DR molecules. The critical expressed pentapeptide sequence (glutamine–arginine or lysine–arginine–alanine–alanine) of amino acid residues 70 to 74 has been located to the helical wall of the antigen-binding cleft of the HLA-DRb chain by molecular structural studies (Fig. 2). This pentapeptide region is also referred to as the 'shared epitope' because of its detection by a specific monoclonal antibody. The sequence is present, for example, on HLA-DR4 subtypes Dw4 and Dw14, and HLA-DR1 subtype Dw1, coded by DRB1*0401,*0404, and 0101 genes, respectively. The shared sequence and corresponding allelic genes have been detected in a frequency of up to 90 per cent in patients with rheumatoid arthritis of Western European descent. Their association with rheumatoid arthritis supports the hypothesis that these particular HLA-DR molecules present antigens to T-cell receptors and activate pathogenic reactions.

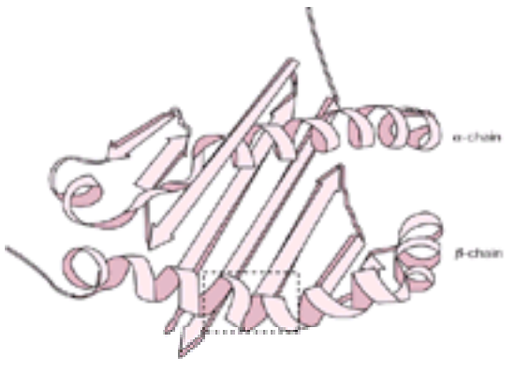

Fig. 2 Ribbon diagram of HLA class II molecule, demonstrating the antigen-binding cleft. The floor consists of a b pleated sheet and the walls are helical structures. The rectangle delineates the hypervariable region of the b chain containing the shared epitope (amino acid residues 70 to 74).

By contrast, HLA-DR4 subtypes, of which Dw10 and Dw13 are examples (coded by DRB1*0402 and *0403 genes, respectively), are negatively associated with rheumatoid arthritis. These subtypes are characterized by a substitution of the basic amino acids glutamine and arginine in positions 70 and 71 by acidic amino acids aspartic and glutamic acid. These alterations are sufficient to alter the specificity of binding such that a different set of antigens binds to the HLA cleft. Another possibility is that specific shared epitope sequences influence T-cell receptor interactions with the HLA-DRb alpha helix independently of peptide . It is proposed that signals delivered to T cells are therefore different and lead to the activation of regulatory pathways that serve a protective function.

It is estimated that major histocompatibility genes confer 30 to 50 per cent of the genetic component of susceptibility to rheumatoid arthritis. However, the presence of DRB1*04 susceptibility genes also correlates with seropositive, erosive, and extra-articular disease. Homozygosity for DRB1*0401 or DRB1*0404, or when they are combined with each other or with DRB1*0101 (as compound homozygotes), appears to correlate with more severe disease, increasing the absolute risk ratio up to 1 in 7 (relative risk of 49). These data have been interpreted as indicating that the shared epitope encoding genes may be more useful as markers of disease severity in established rheumatoid arthritis than as markers of disease susceptibility.

It is intriguing to note that the HLA-DR B1 allele *0405—coding the shared epitope in a different HLA-DR4, Dw15 subtype—is increased in Japanese patients, whilst the DRB1*1402 gene coding HLA-DR6, Dw16 is increased in Yakima American Indians. However, other population studies, for example in black American individuals with rheumatoid arthritis, show no increase in frequency of the gene coding the shared epitope, thus casting some doubt on the hypothesis that it is an essential aetiological factor.

Recent studies have sought positive or negative correlation between disease severity and gene polymorphisms detected by nucleotide sequencing or microsatellite mapping. Using such techniques, associations with polymorphic alleles of candidate genes coding molecules involved in the pathogenesis of rheumatoid arthritis, such as tumour necrosis factor-a (**TNF-a**), a pro-inflammatory cytokine, and interleukin 10 (**IL-10**), an anti-inflammatory cytokine, have been described.

Environmental factors

The similarity of clinical features of rheumatoid arthritis and polyarthritis caused by infectious agents such as rubella, parvovirus B19, and Epstein–Barr virus (**EBV**), and reports of immune hyperactivity to their antigens in rheumatoid arthritis, continues to fuel interest in a potential role for such organisms in initiating rheumatoid disease. In one recent study, for example, the B19 antigen VP-1 was specifically expressed in active lesions in synovium with rheumatoid arthritis but not in osteoarthritis or controls. In other studies, EBV-specific or rubella-specific lymphocytes have been detected in joints with rheumatoid arthritis. However, the arthritis caused by such known infections is almost always sporadic and self-limiting, and the clustering of new cases that one might expect if rheumatoid arthritis was an infectious disease has not been reported. Moreover, corroboration of claims by independent studies is still lacking, hence these theories of causation remain

speculative.

In attempts to define a role for environmental factors in the aetiology of rheumatoid arthritis, epidemiological studies have sought differences in the incidence or prevalence of the disease in genetically similar populations exposed to urbanization, different socio-economic conditions, lifestyles, and known industrial noxious agents. In South Africa, one study found a higher point prevalence of rheumatoid arthritis in Bantu people residing in an urban township area—similar to that recorded for white people in Western countries—compared with Bantu in a rural community. However, in another study, black people living in urban Manchester, United Kingdom, had a lower prevalence of rheumatoid arthritis than white people and the low prevalence of rheumatoid arthritis amongst Chinese people living in urban Hong Kong was no higher than that observed in rural areas. These apparently contradictory data reflect the problems inherent in assessing the relative importance of genetic and environmental factors in heterogeneous populations in a disease with variable expression. The data on correlation with social class are also conflicting. Cigarette smoking, on the other hand, was associated with an increased risk of rheumatoid arthritis in two prospective population studies and in a twin study. Claims of an increased risk have also been made in people exposed to silica dust, organic solvents, and mineral oils.

It is possible that a decline in the incidence of rheumatoid arthritis amongst women noted in Rochester, United States, in the period 1950 to 1975 and in a general practice register in the United Kingdom in the decade following 1976 are indicative of a change in environmental pressures or in lifestyle. Epidemiological studies demonstrating a relationship between the birth weight of babies and future development of cardiovascular disease and premature death have drawn attention to the possibility that the environment of the growing fetus may be as important as environmental factors to which an adult might be exposed.

Host factors

A number of observations implicate sex hormones and prolactin in susceptibility to, or protection from, rheumatoid arthritis. Thus females have a higher incidence of rheumatoid arthritis, which is especially marked before the menopause. Exposure to the oral contraceptive pill confers a level of protection and postpones the onset of rheumatoid arthritis. Pregnancy is associated with suppression of disease, and the incidence of rheumatoid arthritis is increased following parturition and during lactation. Testosterone levels are reported to be low in males with rheumatoid arthritis, and the incidence of disease increases with advancing age when levels of male sex hormones are on the decline. Interconnections between the hypothalmic–pituitary axis, hormones, and cytokines have been described, suggesting possible mechanisms whereby these may influence the evolution of rheumatoid arthritis.

Pathology and pathogenesis

Pathology

Joints

The rheumatoid disease process in the joints is characterized by synovitis, an inflammatory effusion and cellular exudate into the joint space, and by damage to tendons, ligaments, cartilage, and bone in and around articulating surfaces of the joint. Long tendons whose sheaths are lined by synovial membrane, such as in the palms, wrists, ankles, and feet, may also be involved by the inflammatory process and cause malfunction due to damage, rupture, and fibrosis.

In health the synovial membrane (the intima) is a film of one or two cells lining the capsule and its circumferential attachment to the periosteum at the cartilage–bone junction of the joint (Fig. 3). The normal synovial membrane consists of type A and B cells, without a basement membrane and lying on a bed of loose connective tissue and a network of small blood vessels (the subintima). Type A cells have morphological and phenotypic features of macrophages. Type B cells are of mesenchymal origin and share many, but not all, of the phenotypic features of typical tissue fibroblasts and are hence referred to as fibroblast-like synoviocytes.

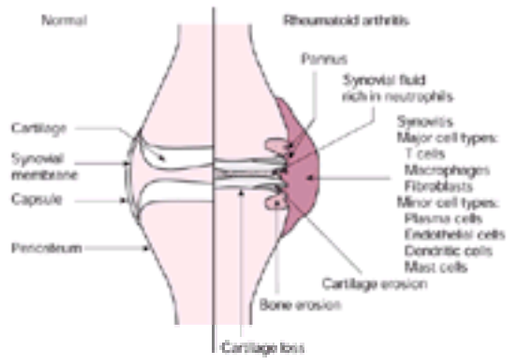

Fig. 3 The pathology of rheumatoid arthritis, normal joint (left) and rheumatoid joint (right).

In established rheumatoid arthritis the synovial membrane typically becomes enormously thickened and assumes a villous appearance. The diseased tissue now consists of an intima that is several (2 to 10) cell layers deep and coated by a film of fibrin. Type A cells predominate over type B cells and tend to lie in the more superficial part of the intima. The sublining layer (subintima) is also greatly expanded by newly formed blood vessels and infiltrating mononuclear cells, including T lymphocytes, lymphoblasts, B cells, plasma cells, monocytes, macrophages, dendritic cells, and synoviocytes (Fig. 3). The cellular infiltrate usually has a recognizable architecture, comprising perivascular aggregates of CD4+ T cells (Fig. 4 and Plate 1). Interaggregate areas show a mixed inflammatory cell population, including dendritic cells and macrophages expressing HLA class II, CD8+ T cells, activated B cells, and plasma cells. The aggregates may be organized into prominent lymphoid follicles, some of which display germinal centre formation.

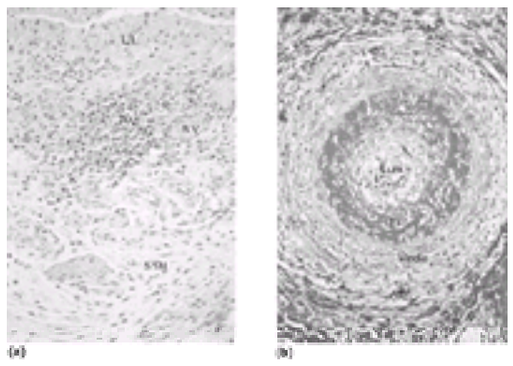

Fig. 4 Histology of rheumatoid arthritis. (a) Rheumatoid arthritis synovitis. L.L., lining layer; P.V., perivascular aggregate of lymphocytes and macrophages; B.V., blood vessel; SYN, synoviocytes; (haematoxylin and eosin staining). (b) Small vessel arteritis. Lum., lumen; Int., Intima; P.V., perivascular inflammation; Adv., adventitial tissue. Arterial wall shows a thrombosed vessel with intimal hyperplasia, destruction of internal elastic lamina, and mononuclear cell infiltration of media and perivascular tissue (methylene blue and safranine staining) (See also Plate 1).

The surface of the thickened synovial membrane is bathed in an inflammatory synovial fluid containing a predominance of polymorphonuclear cells, but also CD4+ and CD8+ lymphocytes, dendritic cells, macrophages, and synoviocytes. The synovial fluid is rich in pro-inflammatory cytokines and immune complexes containing rheumatoid factor. It is a site of local complement consumption, resulting in low haemolytic complement activity, low C3 and C4, and increased complement breakdown products.

The destructive lesion in the joint typically occurs at the circumferential attachment of the joint capsule, just below and adjacent to the articular cartilage and subchondral bone. Here the intima of the adjacent hypertrophic synovial membrane creeps over the cartilage, and tissue rich in blood vessels, macrophages, and synoviocytes (termed 'pannus') invades and destroys variable parts of articular cartilage and subchondral bone. The cells at the cartilage–pannus junction consist of synoviocytes and macrophages, whereas the pannus invading subchondral bone is enriched in osteoclasts. The connective tissue matrix of cartilage adjacent to pannus tissue becomes depleted of proteoglycans and collagen type II as a result of enzymatic degradation and lack of regeneration. A number of enzymes responsible for degradation of cartilage matrix have been demonstrated in the joint with rheumatoid arthritis, including the collagen-degrading matrix metalloproteinases I, III, and XIII, neutrophil-derived cathepsins L and D, and collagenase, as well as aggrecanase that degrades proteoglycans. The matrix in which chondrocytes are embedded becomes depleted, with loss of chondrocyte numbers, suggesting that matrix degeneration is secondary to degradative effects mediated by both pannus and chondrocyte activity or cell death. There may also be a reparative response in the later stages of disease, as suggested by the presence of fibrous tissue replacing areas of destroyed cartilage and bone in some joints removed at surgery.

Extra-articular disease

Extra-articular features associated with rheumatoid arthritis comprise essentially two types of lesion: the first involves arterial walls and the second leads to extravascular lymphocyte–macrophage granuloma formation.

Of those lesions involving arterial walls, two types of pathology are described. The first type is a bland fibro-intimal hyperplasia, without obvious inflammatory changes, resulting in vascular occlusion. This lesion is typically observed in digital vessels of patients with long-standing disease and is associated with collateral blood vessel formation. It correlates with a history of benign, intermittent nail-fold infarcts that develop in winter months. By contrast, the second type of lesion has a polyarteritic pathology and is observed in patients with rheumatoid systemic vasculitis and a poor prognosis. Medium- and small-sized arteries of the limbs, peripheral nerves, and organs are involved, but renal vessels are spared. Histopathological examination of involved vessels reveals lymphocytic, histiocytic, and inflammatory cell infiltration of the medial and perivascular area, disruption of the internal elastic lamina by fibrinoid necrosis, and proliferation of the vessel wall intima with intravascular thrombosis and occlusion (Fig. 4(b)).

Extravascular nodule formation in areas subject to pressure or friction is the characteristic granulomatous lesion of rheumatoid arthritis. Nodules consist of a central core of fibrinoid eosinophilic material surrounded by a palisade of histiocytes, occasional giant cells, and an outer layer of lymphocytes, fibroblasts, and fibrous tissue. Extravascular granulomatous inflammation, with or without nodule formation, has been documented on the surface of the pleura, pericardium, and endocardial valves. As is the case with systemic vasculitis and Felty's syndrome, the occurrence of nodules correlates with seropositive disease and the carriage of HLA-DRb1*04 alleles.

Pathogenesis

Although the initiating cause of rheumatoid arthritis remains uncertain, there has been considerable progress in understanding the cellular and molecular mechanisms involved in chronic inflammation and tissue damage (Fig. 5).

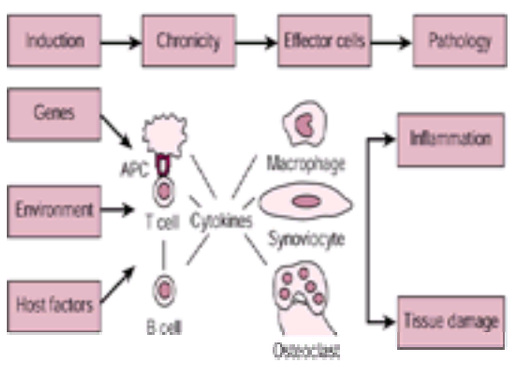

Fig. 5 Aetiopathogenesis of rheumatoid arthritis. In this simplified diagram the four steps in the aetiopathogenesis of rheumatoid arthritis are shown: (a) the induction phase involving interactions among genetic, environmental, and host factors; (b) the chronicity phase dependent upon immunological reactions; and (c) the effector phase of pathology mediated by macrophages, synoviocytes, osteoclasts, and cytokines, which leads to (d) pathology, namely inflammation and tissue damage.

The discovery of rheumatoid factor in the blood of patients with rheumatism over half a century ago led to the immunological hypothesis of disease pathogenesis. Since rheumatoid factor is an autoantibody directed against epitopes on the constant domains of the Fc portion of IgG1, the concept that rheumatoid arthritis is an autoimmune disease gained credibility. However, IgM rheumatoid factor occurs in a variety of other diseases in the absence of joint pathology. In the case of rheumatoid arthritis, rheumatoid factor complexes are present in synovial fluids, and IgG-producing B cells, whose rearranged immunoglobulin gene sequences implicate antigen stimulation, are present in inflamed synovium. B cells in rheumatoid joints also synthesize antibodies to some cartilage components such as collagen type II, although these are not disease specific. By contrast, recent research has shown a highly disease-specific antibody directed against citrullinated peptides in the serum of patients. It seems possible that autoantibodies could interact with complement and Fc receptors expressed on cells in the rheumatoid joint and so contribute to inflammation. Since IgG antibodies are implicated, T-cell help might be required.

The predominance of CD4+ T cells in proximity to antigen-presenting cells in the rheumatoid joint suggests their involvement in perpetuating the immune response. This is also supported by the association of rheumatoid arthritis with HLA class II genes and the beneficial response to T-cell-depleting therapies (lymphophoresis, cyclosporin, and some anti-CD4 monoclonal antibodies). For example, it has been proposed that as a result of molecular mimicry between epitopes on infectious agents and endogenous antigens an immune response is initiated which, by a phenomenon known as 'epitope spreading', overcomes tolerance mechanisms and results in autoimmunity. Alternatively, macromolecules in cells undergoing apoptopic cell death may become modified by oxidative or enzymatic damage and provide neoantigens to which autologous T cells are not tolerant. Candidate autoantigens under current investigation include proteins derived from cartilage, citrullinated peptides, and peptides derived from HLA class II molecules. However, an autoantigen that drives the immune response in rheumatoid arthritis has not yet been identified.

CD4+ T cells in joints appear to be of T_{H1} type, bearing memory and activation markers such as CD45 RO+, CD45B dim+, VLA-4+, CD69+, and HLA class II+. However, whether these T cells are antigen activated is debated since they do not appear to show significant T-cell receptor oligoclonality and do not display the full functional characteristics of such cells, for example the production of IL-2 and interferon-g. Moreover, T cells in joints do not proliferate but increase in number by recruitment and accumulation. It seems possible that T cells are conditioned and activated by cytokines such as IL-15, TNF-a, IL-6, and IL-10 produced by rheumatoid tissues. Cell membrane contact between macrophages and cytokine-activated T cells may also be a key event in driving production of the pivotal cytokine TNF-a (see below).

Cytokines are protein messenger molecules that transmit signals from one cell to another by binding to their specific receptors on the surface of cell membranes. Their activity is usually restricted to adjacent cells in the local milieu. Cytokines are normally produced and exported as soluble molecules into the fluid phase, although some cytokines, such as TNF-a, are also active as molecules displayed on the surface of the producer cells. Expression of mRNA and protein of a large number of cytokines is reported in rheumatoid synovial tissue. These molecules regulate a diverse range of functions relevant to an understanding of the pathogenesis and clinical features of rheumatoid disease. Both pro- and anti-inflammatory cytokines, chemokines, and mitogenic factors are produced, but pro-inflammatory mediators predominate during active phases of disease.

Of the pro-inflammatory cytokines, IL-1 and TNF-a are of key importance in the pathogenesis of rheumatoid arthritis (Fig. 6). They are intimately involved in activation of the cytokine network, leucocyte recruitment and activation, the local immune response, angiogenesis, and fibroblast proliferation. IL-1 and TNF-a also regulate production of a number of mediators of connective tissue damage by synoviocytes, including matrix metalloproteinases and prostaglandins. Furthermore, these cytokines activate osteoclasts that are implicated in bone damage. TNF-a is produced mainly by type A cells of macrophage lineage in the intima, subintima, and the cartilage–pannus junction. The p55- and p75-TNF receptors are coexpressed by cells in the vicinity. The hypothesis that TNF-a is a dominant pro-inflammatory

mediator in the cytokine dysequilibrium observed in the rheumatoid synovium has gained considerable support. In particular, TNF-a regulates production of IL-1 and together these two cytokines orchestrate rheumatoid inflammation and damage. The identification of TNF-a as a molecular target for therapy has been validated by clinical trials of biological inhibitors of TNF-a and their recent application in rheumatological practice.

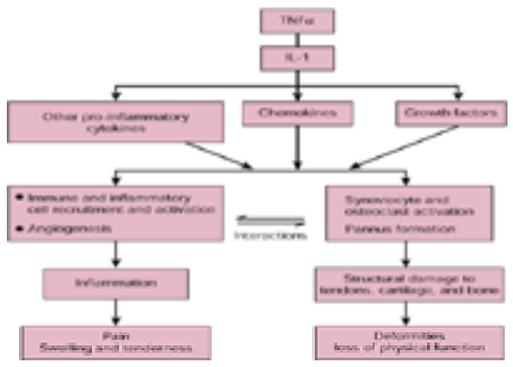

Fig. 6 The role of tumour necrosis factor-a in the pathogenesis of inflammation and structural damage to tendons and bone in rheumatoid arthritis.

Examples of the importance of TNF-a as a mediator of rheumatoid disease include the following observations after treatment with infliximab, a monoclonal anti-TNF-a antibody.

1. There is a reduction in the cellularity of the rheumatoid synovial membrane associated with a reduction in the number of tissue macrophages and lymphocytes.
2. There is evidence that the reduced cellularity is associated with a reduction of cytokine-induced vascular adhesion molecules—intracellular adhesion molecule-1 (ICAM-1), E-selectin, and vascular cell adhesion molecule-1 (VCAM-1)—as well as chemokines such as IL-8 and monocyte-chemoattractant protein-1 (MCP-1).
3. There is reduction in synovial vascular density and neovascularization (avb3 staining of blood vessels), associated with a fall in the concentration of circulating vascular-endothelial growth factor, a major cytokine implicated in new vessel formation.
4. There is direct evidence of reduced retention in joints of autologous ^{111}indium-labelled polymorphonuclear cells (Fig. 7).
5. There is a reduction of serum IL-6 concentrations within 6 h of a single infusion of the anti-TNF-a antibody, followed within 24 h by a reduction in markers of acute-phase response including C-reactive protein, serum amyloid A protein, and erythrocyte sedimentation rate.
6. There is a reduction in the circulating concentrations of pro-matrix metalloproteinase-1 (pro-MMP-1) and pro-MMP-3 in blood. Matrix metalloproteinases are implicated in cartilage and bone degradation and there is clinical trial evidence that anti-TNF-a markedly retards radiographic signs of cartilage loss and bone erosions.

Many other cytokines and chemokines are potential therapeutic targets. Clinical trials have been conducted with anti-TNF-a, anti-IL-1, anti-IL-6, and human recombinant IL-10 and IL-11. So far, anti-TNF-a has been approved for the treatment of rheumatoid arthritis, and in the United States, the IL-1 antagonist, human recombinant IL-1 receptor antagonist (IL-1ra) has been approved.

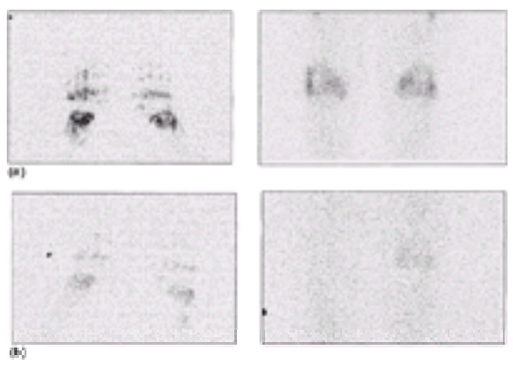

Fig. 7 Gamma camera images of the hands and knees of a patient with rheumatoid arthritis. Images were taken 22 h after a bolus injection of autologous radiolabelled (^{111}indium) granulocytes (a) before and (b) after a single 10 mg/kg intravenous bolus of anti-TNF-a antibody (infliximab). There was a reduction in signal after treatment. (Images kindly provided by P. C. Taylor.)

Clinical features

Presentation

The onset of rheumatoid arthritis is frequently insidious and the principal symptoms are pain and stiffness, mainly of peripheral joints, with associated swelling. Prolonged stiffness of joints on waking and following inactivity is usual and may last an hour or more. There is progressive decline in physical function and ability to perform daily activities. Fatigue and lethargy are common and there may also be low-grade fever and weight loss. Symptoms are persistent in affected joints, although there may be some day to day variation in severity. As the disease evolves, further joints may become involved and some may remit, but ultimately the distribution of arthritis becomes permanently established.

Other patterns of disease presentation are also recognized. Up to one-third of patients present with an explosive or subacute onset of arthritis, leading to severe immobility. In a minority of patients a migratory polyarthritis flitting from joint to joint is observed. This is referred to as 'palindromic rheumatism' and may be a recurring pattern over months before chronic polyarthritis becomes established. About 10 per cent of patients present with features of the syndrome of polymyalgia rheumatica, characterized by prominent limb-girdle pain, stiffness, and painful movement of the neck, shoulders, and hips. Persistent inflammatory arthritis of a single joint such as the knee, wrist, ankle, shoulder, or hip may be the only rheumatological symptom and can antedate the onset of polyarthritis by months or years.

In some patients bilateral diffuse swelling of the fingers and hands may be a presenting complaint, often associated with symptoms of carpal tunnel syndrome. Synovitis of tendon sheaths of the dorsal extensors of the wrist and of flexor tendons in the palm and wrist may be present with concurrent joint signs, but may also occur as a prominent clinical feature in the absence of polyarthritis. Swelling of the ankles with pitting oedema is commonly seen in active rheumatoid arthritis. Lymphoedema of the forearm or lower limb is observed less frequently.

Rarely, the initial manifestations of rheumatoid arthritis are confined to extra-articular disease. Examples include subcutaneous nodules, one or more nodules in the thorax presenting as pulmonary lesions on a chest radiograph, pleurisy with pleural effusion, pericarditis, episcleritis, and vasculitis.

Joint distribution

The expression of rheumatoid arthritis shows interindividual variation with respect to the anatomical sites and numbers of involved joints. For example, some patients have mainly small joints affected, whilst others show simultaneous involvement of small and large joints. The hip and shoulder joints may be spared in some, whilst in others they bear the brunt of the disease. The actual numbers of diseased joints can vary from three or four to over 50. Diseased neck joints may be asymptomatic until, in the late stages, neurological complications alert the physician to subluxation of the cervical spine or the atlantoaxial joint.

In over 80 to 90 per cent of patients, one or more of the metacarpophalangeal and proximal interphalangeal joints of the hand and the metatarsophalangeal joints are involved. Other frequently involved sites include the wrists, glenohumeral joints of the shoulders, knees, and the elbow joints, followed by the mid-tarsal, acromioclavicular, interfacetal, and atlantoaxial joints of the cervical spine and hip joints. The temporomandibular, sternoclavicular, and cricoarytenoid joints are involved in about a third of patients.

Symmetrical involvement of the joints is usual, but joint damage and deformity may be asymmetrical and related to overuse or traumatic injury. Conversely, neurological paralysis of a limb results in joint protection.

In addition to involvement of diarthrodial joints, the rheumatoid process frequently involves tendon sheaths of hands, wrists, shoulders, and ankles.

Features of joint disease

Hands and wrists

In active rheumatoid disease, soft tissue swelling and tenderness of metacarpophalangeal and proximal interphalangeal joints is observed (Fig. 8 and Plate 2). Thickening and nodularity of flexor tendons in the palms may be palpable and tenosynovitis can be a cause of 'triggering' of the fingers. Wasting of the interossei is prominent and fist closure restricted. Flexor tendonitis and wrist synovitis may be associated with signs and symptoms of median nerve compression (carpal tunnel syndrome).

Fig. 8 The hands of a person suffering from rheumatoid arthritis. Features to note include symmetrical soft tissue swelling of the second and third metacarpophalageal joints, early swan-neck deformity of the left ring finger, ulnar deviation at the metacarpophalageal joints, and wasting of the small muscles of the hand. In addition, several small rheumatoid nodules are present. (See also Plate 2.)

Ulnar deviation and volar subluxation of the digits and wrists may develop later. Other recognized deformities include Boutonnière (button hole) flexion deformity of the proximal interphalangeal joint and 'swan-neck' deformities of fingers due to hyperextension of the proximal interphalangeal joint and flexion at the distal interphalangeal joint.

Diffuse synovial swelling may be pronounced at the dorsal aspect of the wrist and the ulnar styloid may become dorsally subluxed. The carpus may drift in a volar direction such that supination of the hand is restricted. In this late stage, the extensor tendons appear stretched across a shrunken carpus ('the bowstring' sign). Extensor tendons may occasionally rupture, most commonly affecting the little or ring fingers.

Nail-fold and finger-tip infarcts and splinter haemorrhages indicate digital vascular occlusive disease. Palmar erythema is common but not specific for rheumatoid arthritis.

Elbows and shoulders

Physical signs in early stages include swelling, limitation of movement, and inability to flex or extend the elbow. Later, pronation and supination are restricted, and the head of the proximal radioulnar joint may dislocate. Olecranon bursitis and subcutaneous nodules around the elbow are common. In the shoulder, aside from glenohumeral joint synovitis, there may be accompanying subacromial bursitis and rotator and biceps tendon involvement.

The neck

Rheumatoid involvement of the apophyseal joints of the neck can cause pain, stiffness, and restricted movement. Loss of stability in the spine may occur at several levels and be associated with symptoms and signs of radicular or cord compression. Subluxation of the atlantoaxial joint diagnosed by plain radiography or magnetic resonance imaging occurs in 6 per cent of the rheumatoid population and up to 30 per cent of patients who are admitted to hospital. It may be asymptomatic, but when severe tends to occur in patients who also suffer from severe generalized disease and advanced disability, and is a recognized cause of quadriplegia and sudden death.

The knees

Involvement of the knees is common, and chronically active synovitis is associated with irreversible destruction and rapid deterioration in functional capacity. In early stages especially, high pressure in the knee joint on active flexion, for example during squatting, can lead to joint rupture and leakage of inflammatory fluid into the calf. This complication simulates signs and symptoms of a calf deep vein thrombosis: it can be diagnosed by arthrography using contrast medium, or by ultrasonography of the knee. A chronic effusion in the knee joint may also be associated with a posterior popliteal (Baker's) cyst and occasionally this extends into the medial aspect of the calf.

Ankles and feet

Inflammation of the metatarsophalangeal joints is common and results in subluxation of the metatarsal heads and, ultimately, claw- or hammer-toe deformities. The soft tissue pad that is normally positioned underneath the metatarsal heads becomes displaced such that the heads of the metatarsal bones become painful to walk on. Patients may describe this as feeling as if they were walking on marbles or stones. Involvement of the tarsal and subtalar joints may result in flattening of the arches of the foot and valgus deformity of the hindfoot. These deformities cause difficulties with footwear, and where shoes rub the feet there is a tendency for callosities to form.

Hips

The hips are less often involved, but there may be erosions in severe cases with remodelling of the acetabulum (protrusio acetabuli). There may also be secondary degenerative disease at the hip. Total hip replacement is generally a highly successful treatment for endstage hip disease.

Extra-articular disease

Nodules

Nodules occur in 25 to 30 per cent of patients with rheumatoid arthritis and are associated with seropositive disease. Common sites for subcutaneous nodules include

the elbow, ischial tuberosity, heel, and dorsum of fingers. Multiple, small, rapidly evolving nodules can occur in those on methotrexate treatment (Fig. 8). Nodules in the pleura may present as single or multiple round shadows on a routine chest radiograph.

Systemic vasculitis

Rheumatoid vasculitis occurs in patients with seropositive and nodular disease. It presents with a severe systemic illness characterized by fever and weight loss. Associated clinical features are consequent upon occlusion of medium- to small-sized arteries. These include Raynaud's phenomenon, nail-fold and digital infarcts, and gangrene, skin ulceration, mononeuritis multiplex, scleromalacia perforans, and occlusion of arteries to visceral organs. The latter include coronary, pulmonary, coeliac axis, and cerebral vessels. In some patients vasculitis may present as a skin rash associated with necrotizing polyangiitis of small cutaneous blood vessels.

Fibrosing alveolitis and obliterative bronchiolitis

Physiological abnormalities in lung function tests indicative of airways and interstitial disease may be present without symptoms. In a proportion of patients with rheumatoid arthritis, more frequently male than female, dyspnoea of insidious onset, physical signs, characteristic lung function abnormalities, a chest radiograph, and high-resolution computed tomography may reveal characteristic features of chronic fibrosing alveolitis. More rarely, acute pneumonitis may be the presenting feature with rapid deterioration and development of respiratory failure. Patients with fibrosing alveolitis are usually seropositive, have a high frequency of antinuclear antibodies, and may also exhibit evidence of multisystem disease, including vasculitis.

Obliterative bronchiolitis can be associated with rheumatoid arthritis. It is usually rapidly progressive, but some patients follow a chronic protracted course that may respond to corticosteroid and immunosuppressive therapy.

Serositis

Past evidence of pericardial and pleural inflammation is common at autopsy and may be discovered by imaging techniques in asymptomatic patients. Both may present with clinical symptoms, generally following a benign course with resolution associated with disease-modifying antirheumatoid drugs (**DMARDs**) or corticosteroid therapy. Rare cases of constrictive pericarditis have been reported. Typically, pleural effusions are exudates with a high protein content and cellular exudate enriched in lymphocytes, but also containing polymorphonuclear cells and macrophages. A low level of complement activity relative to blood concentrations and a low glucose concentration (usually less than 1.4 mmol/l) is of diagnostic value.

Eye complications

Scleritis, episcleritis, scleromalacia perforans, corneal melt, and keratoconjunctivitis sicca have all been described and need evaluation and treatment by a specialist.

Amyloidosis

Secondary amyloidosis due to deposition of amyloid AA fibrils in blood vessels and parenchyma of kidneys, liver, spleen, and gastrointestinal tract has been described in the tissues of 10 to 15 per cent of patients examined at autopsy, or in the blood vessels in the submucosa of rectal and gingival biopsies. Proteinuria, nephrotic syndrome, or renal failure are less common and have a poor prognosis unless detected and treated before irreversible renal failure has occurred. Effective treatment of rheumatoid arthritis with suppression of the acute-phase response with DMARDs and corticosteroids prevents progression and may reverse the disease. In patients with a continuing acute-phase response despite the standard DMARD therapy, treatment with chlorambucil is reported to be of some benefit. Imaging of radionuclide-labelled serum amyloid P protein in the spleen and kidneys may be used to monitor treatment.

Osteoporosis

Juxta-articular osteoporosis is a common feature of radiographs of affected joints and is related to local disease activity. However, decreased bone mineral density of the spine and pelvis has been described in patients with active severe rheumatoid arthritis. This is likely to reflect the response of bone metabolism to prostaglandins and catabolic cytokines such as IL-6, IL-11, and the receptor for activition of NF_b (RANK)-ligand, which increase osteoclast activity. This is distinct from immobility-associated or corticosteroid-induced osteoporosis, although these factors may be additive in individual patients. It has been suggested that increased mobility following low-dose prednisolone may be beneficial and reverse, rather than aggravate, corticosteroid-induced osteopenia.

Felty's syndrome

Felty's syndrome is characterized by a combination of seropositive rheumatoid arthritis, neutropenia, and splenomegaly. Lymphadenopathy, leg ulcers, and nodular hyperplasia of the liver have been described. Patients with severe neutropenia are liable to bacterial infections. Some patients also develop anaemia and thrombocytopenia. In a variant of Felty's syndrome, an expansion of large granular lymphocytes is found in the blood: these are cytotoxic CD8+ lymphocytes and may present as clonally expanded cell populations.

Myocardial disease

Myocardial disease due to diffuse fibrosis or granulomatous lesions is recognized in rheumatoid arthritis, although the more frequently recognized association is with coronary artery disease. Systemic vasculitis may also involve coronary vessels. Aortic incompetence due to valvular thickening and nodule formation or dilation of the ascending aorta have been described.

Neurological complications

A number of compression neuropathies may occur in rheumatoid arthritis. These include compression of the median nerve at the wrist, the ulnar nerve and posterior interosseous branch of the radial nerve at the elbow, and posterior tibial nerve at the level of the knee or ankle. It is important to recognize and confirm these neuropathies by nerve conduction studies since surgical decompression usually cures symptoms.

A mild, symmetrical, sensory peripheral neuropathy involving the hands and legs in a 'glove and stocking' distribution also occurs in rheumatoid arthritis. This is distinct from the rarer and more severe sensorimotor mononeuritis multiplex associated with wrist and foot drop and usually due to vasculitis of vasa nervora, when other features of a systemic vasculitis and extra-articular disease may be present. In some patients, however, no vascular pathology is demonstrable and the cause of axonal degeneration is not understood.

Rheumatoid involvement of the transverse ligament and odontoid process of the atlantoaxial joint may lead to posterior subluxation or upward movement of the odontoid and cause cervical cord compression. Cord compression may also occur due to rheumatoid damage at lower levels of the cervical spine. Compression is a recognized cause of tetraparesis and sudden death. Surgical stabilization of the neck can be successful but cannot always be recommended in patients with associated severe disability and poor health status.

Infections

Patients with rheumatoid arthritis are susceptible to local and systemic bacterial and opportunistic infections. Infections of joints and respiratory and urinary tracts, skin ulcers, and septicaemia are all described, and infections are one of the causes of increased mortality in rheumatoid arthritis. Endogenous disease-related immunosuppressive mechanisms are thought to play an important part. In Felty's syndrome, neutropenia compromises host defence. Drugs for treating rheumatoid arthritis such as cytotoxic and immunosuppressive agents may also be contributory factors.

Clinical course, progression, and outcome

Clinical course

Disease activity

The course of the disease activity fluctuates over time, partly due to the endogenous mechanisms of disease and partly as a result of effective therapy. Recurring periods of weeks or months of exacerbation of symptoms, described as 'flares', alternate with periods of relative quiescence of disease. In about 10 to 20 per cent of patients, the disease continues unabated throughout.

The key clinical features of disease activity in rheumatoid arthritis are pain, fatigue, stiffness of joints on waking, swelling, tenderness of joints on palpation, restriction of joint motion, and loss of physical functional capacity. Joint deformities become apparent as the disease progresses. Symptoms are assessed by taking a history in descriptive terms, but also by attempting to quantify their severity. These measurements have been incorporated into various criteria for assessment of disease activity and response to therapy, developed and validated, for example, by the American College of Rheumatology and the European League Against Rheumatism.

Swelling of joints due to synovial thickening may be detected by palpation as a 'spongy' or 'boggy' feel. Concomitant effusion can be demonstrated by fluctuation. In later stages of disease, subluxed surfaces of bones (such as the heads of metacarpals in the hands, the styloid of the ulna, and distal radius at the wrist) can give the appearance of bony swelling. Tenderness is elicited by digital pressure or squeezing of a joint. The classic signs of inflammation, such as redness and increased temperature overlying joints, are not usually prominent, although readily demonstrable by thermography. Active and passive movement of joints through their anatomical range of motion elicits restriction of movement associated with pain.

Functional capacity can be assessed by testing grip strengths using an inflatable bag attached to a sphygmomanometer, walking time over a standard distance, and by standard health assessment questionnaires (such as the Stanford questionnaire). The degree, quantity, and severity of pain is recorded as experienced by the patient, graded on a visual analogue scale of 1 to 10. The duration of morning stiffness is recorded in minutes. A 'global assessment' of disease activity on a visual analogue scale of 1 to 10 as judged by the patient and physician may also be used as a quantitative measurement of disease activity over time.

Structural damage

The rheumatoid disease process leads to structural damage to the cartilage, bone, and associated joint structures. This is cumulative and irreversible and appears to be related to the severity of inflammatory activity over time. In later stages of disease, loss of normal joint architecture and mechanical derangement also contribute to the perpetuation of symptoms and secondary inflammation. Serial radiographs of the hands and feet are employed to assess structural damage to joints.

Prognosis

The longer-term health status of patients presenting to hospital clinics with recent-onset rheumatoid arthritis has been documented in a number of studies. Functional deterioration occurs rapidly. In one study, half the patient population was moderately disabled in 2 years and severely disabled by 10 years. The most marked deterioration occurs in those patients with the most compromised functional capacity in early disease. These data are compatible with the proportion of patients at work whose disease-associated disability prevents continuing employment: around 20 per cent of patients stop work in the first 2 years, increasing to 30 per cent within 5 years, 50 per cent in 10 years, and 90 per cent prior to retirement age. A low level of manual work, job flexibility, and higher educational and psychosocial status are amongst the determinants that correlate best with the ability to continue work.

Patients with rheumatoid arthritis have a higher than expected prevalence of other serious illnesses and an increased mortality compared with the general population. In one study approximately 20 per cent reported concurrent disorders, and iatrogenic disease is not uncommon. In a 35-year follow-up study on 3501 patients, mortality was twice that of a control population, resulting in a shortening of life by 7 to 10 years. Rheumatoid arthritis itself may contribute to premature death in up to 20 per cent of patients as a result of complications such as fibrosing alveolitis, vasculitis, secondary amyloidosis, cardiac disease, or transection of the cord due to cervical spinal subluxation. More frequently, death is the consequence of comorbid conditions or complications of therapy. These include infection, gastrointestinal haemorrhage or perforation, cardiovascular and cerebrovascular disease, renal failure, and lymphoproliferative diseases.

Survival rates of about 50 per cent at 5 years have been recorded in a subset of patients with polyarticular disease, poor functional status, or extra-articular disease (Fig. 9).

Prognostic factors

A number of prognostic factors have been identified in cohorts of patients with rheumatoid arthritis that herald rapid functional deterioration and premature death. These include more than 30 affected joints, a persistently raised level of acute-phase proteins, lower socio-economic status, early development of functional incapacity, a positive rheumatoid factor, cryoglobulinaemia, and in Northern European patients, the presence of the HLA-DRb*04 genes. However, on an individual patient basis, none of these factors are reliably predictive, either singly or in combination.

Remission

Remission has been defined by the American College of Rheumatology as an absence of joint symptoms and signs, duration of morning stiffness less than 15 min, freedom from fatigue, and an erythrocyte sedimentation rate less than 30 mm/h for females and 20 mm/h for males, for 2 consecutive months. Remission of disease is seen in a small proportion of patients, especially in the initial stages of disease. More usually, remission follows in approximately 20 per cent of patients treated with a disease- modifying antirheumatoid drug.

Diagnosis and stages of disease

Recent-onset and established disease

A diagnosis of rheumatoid arthritis is likely if three or more symmetrically distributed joints are found to be swollen and tender for more than 6 weeks in a patient with a

positive rheumatoid factor test and elevated erythrocyte sedimentation rate or serum concentration of C-reactive protein. However, not all these features are necessarily present at the early stages of disease, at which point arthritis is best termed 'undifferentiated'. The broad spectrum described in the 'presentation' section may cause considerable difficulty in making a definitive diagnosis

With the passage of time, the emergence of other features such as subcutaneous nodules, radiographic evidence of joint space narrowing, juxta-articular osteopenia, and bony erosions add further certainty to the diagnosis.

The ACR criteria (Table 1) may not be fulfilled for 6 to 12 months, by which time the pattern of joint involvement and a chronic disease course are usually evident. Prognostic factors declare themselves and the patient is regarded as having reached the stage of established disease.

Differential diagnosis

In patients with recent onset of symptoms of arthritis, the following disorders should be considered in the differential diagnosis.

Polyarthritis associated with connective tissue disease

Systemic lupus erythematosus may present with chronic non-deforming polyarthritis, but features such as Raynaud's phenomenon, photosensitivity, rashes, alopecia, haemolytic anaemia, leucopenia, thrombocytopenia, and renal or neurological involvement are detectable sooner or later, and diagnostic antinuclear antibodies (anti-ds-DNA, anti-Sm and others) are present. Other connective tissue diseases such as systemic sclerosis, polymyositis, mixed connective tissue disease, 'overlap' syndromes, and primary Sjögren's syndrome may also present with marked polyarthralgia or polyarthritis which mimics rheumatoid arthritis. In many such patients the presence of rheumatoid factor can further confuse the diagnosis. Careful clinical examination and measurement of marker autoantibodies directed against nuclear and cytoplasmic antigens will usually permit recognition of the underlying disorder. In some cases the diagnosis may only unfold after a period of weeks or months of a disorder best labelled 'undifferentiated connective tissue disease'.

Infection-related polyarthritis

The polyarthritis of rubella or other microbial agents, such as parvovirus B19 and *Borrelia burghdorferi*, and reactive arthritis associated with genitourinary or gastrointestinal infections can all cause diagnostic difficulty. A positive diagnosis is made by microbiological tests on relevant body fluids and serological tests for the detection of IgM antibodies or a rising titre of IgG antibodies to the suspected micro-organism in sequential serum samples taken over 2 weeks.

Spondyloarthropathies

Peripheral joint disease can be seen in conjunction with ankylosing spondylitis, psoriasis, and inflammatory bowel disease. Clinical examination of the spine, skin, and nails, radiological examination of the bowel using double-contrast enema or small bowel enema, endoscopy, and biopsy may reveal the underlying diagnosis. A high proportion of patients are HLA B27 positive.

Osteoarthritis

Osteoarthritis may present with inflammatory symptoms and signs but is readily distinguished by its different joint distribution (proximal and distal interphalangeal joints, carpometacarpal joints of the thumb) and radiographs that show joint space narrowing, subchondral new bone formation, osteophytes, and subchondrial cysts. Where there is pre-existing osteoarthritis, the superimposition of rheumatoid arthritis can be difficult to distinguish.

Other conditions

In late middle-aged and elderly patients the clinical presentation of polyarticular chronic pyrophosphate arthropathy may be difficult to distinguish from rheumatoid arthritis. The former diagnosis may be suspected where there is an atypical distribution of synovitis together with periarticular complications. Chronic pyrophosphate arthropathy may be associated with a modest acute-phase response and low-titre rheumatoid factor, but can usually be distinguished from rheumatoid arthritis on the basis of typical radiographic appearances and the finding of calcium pyrophosphate dihydrate (CPPD) crystals in synovial fluid aspirates. Rarely, rheumatoid arthritis and chronic pyrophosphate arthropathy may coexist.

Other diagnoses to be considered include hypermobility syndrome, polyarticular gout, psoriatic arthritis, haemochromatosis, sarcoidosis, sickle-cell disease, primary amyloidosis, and paraneoplastic disease.

Laboratory tests

Laboratory studies are an integral part of the management of patients with rheumatoid arthritis and are employed for diagnosis, evaluation of prognosis, assessment of disease activity, response to therapy, and monitoring toxic effects of drugs. Only routinely used tests are considered here.

The measurement of rheumatoid factors is useful in the early stages of assessment of a patient with suspected rheumatoid arthritis. Tests using sensitized sheep erythrocytes (Rose–Waaler) in an agglutination test give better diagnostic specificity than agglutination of human IgG-coated latex particles. Automated tests using nephelometry or enzyme-linked immunosorbent assays are being increasingly used. All assays have to be standardized against a reference standard and may be expressed in international units. A positive result is one that exceeds concentrations (or titres) observed in less than 5 per cent of normal controls, or the value set by an international reference standard, and is observed in about 70 per cent of patients at some point in their disease course. In a patient with recent-onset polyarthritis, a positive rheumatoid factor is moderately specific for rheumatoid arthritis but can also be observed in patients with other connective tissue diseases such as systemic lupus erythematosus and primary Sjögren's syndrome. A repeat test may be positive after an initial test is negative and is therefore necessary before a patient can be categorized as having seronegative rheumatoid arthritis. A significant titre of rheumatoid factor is associated with a poor prognosis and extra-articular disease.

Measurement of erythrocyte sedimentation rate (Westergren method) and serum C-reactive protein are extensively used. High values correlate with disease severity and a reduction is one criterion of response to therapy. Persistently elevated C-reactive protein concentrations correlate with deforming erosive disease.

Patients with active rheumatoid arthritis show haematological abnormalities as a consequence of disease-related mechanisms, such as the overproduction of cytokines suppressing the bone marrow, immune complexes increasing the clearance of polymorphonuclear cells in Felty's syndrome, and hypersplenism reducing platelet counts. A high level of disease activity is associated with a normocytic normochromic anaemia, polymorphonuclear leucocytosis, and thrombocytosis. These abnormal values tend to return to normal as the inflammatory component of disease responds to therapy.

Active disease may also be associated with a raised serum alkaline phosphatase and a low serum albumin. Serum chemistry is otherwise normal. Serum immunoglobulin and complement C3 and C4 levels may be elevated.

Non-steroidal anti-inflammatory drug (**NSAID**) therapy may cause microcytic iron-deficiency anaemia from blood loss from the gastrointestinal tract. A low serum ferritin level suggests iron deficiency, but this is not a reliable guide in cases of rheumatoid arthritis as serum concentrations may be elevated as part of an acute-phase response. Corticosteroids may be responsible for increased polymorphonuclear cell counts and decreased lymphocyte counts. Many DMARDs show dose-related bone marrow toxicity, and sulphasalazine, D-penicillamine, azathioprine, and gold can cause unexpected agranulocytosis due to hypersensitivity, unrelated to the dose administered.

Of the commonly used drugs, methotrexate, sulphasalazine, azathioprine, and leflunomide are hepatoxic and can cause elevation of liver enzymes and alkaline phosphatase. Repeated monitoring is advisable: persistent or highly raised values should prompt further investigation or discontinuation.

Imaging

Radiographs of hands and feet can be used to assess the presence and progression of cartilage loss and bone erosions (Fig. 10). Standardized measurements (the

Larsen or Sharp scoring methods) have been devised to quantify these measures. Changes seen in the hands and feet correlate with radiological changes in other affected joints, showing a linear progression after the initial 1 to 2 years. The erosion count correlates with physical function. Radiographs of affected joints are used for the assessment of integrity and damage. Flexion views of the cervical spine are suitable for demonstration of atlantoaxial subluxation and cervical instability. Arrest or retardation of radiographic change is considered to be a marker of good control of disease.

Fig. 10 Hand radiographs taken soon after symptom onset (left panel) and 12 years into established disease (right panel), showing extensive structural damage especially in the metacarpophalangeal, interphalangeal, carpal, and wrist joints.

Magnetic resonance imaging (**MRI**) and computed tomography (CT) are valuable in assessing neck pathology and pressure on the cervical cord. MRI and high-frequency ultrasound examination are sensitive methods to evaluate synovitis and early change in cartilage and bone, but their place in routine management is not yet established. Dual emission x-ray absorptiometry (DEXA) scanning is in routine use for the assessment of bone mineral density.

Management

Aims of treatment

These are:

1. to relieve symptoms and signs of disease;
2. maintain physical function;
3. prevent structural damage to joints and associated structures;
4. restore and maintain quality of life that permits the pursuit of normal work, domestic, and social life;
5. reduce the comorbidity and increased mortality associated with the disease and therapies; and
6. correct abnormal laboratory-based values of haemotopoietic function, acute-phase proteins, and other markers of disease process.

Achievable goals of current therapy

Considerable progress has been made in developing effective therapies for the relief of symptoms and signs of disease. However, despite the best therapies in current use, the goals of halting structural damage and maintaining a normal quality of life have not yet been realized, although significant progress has been made. The realistic aims, therefore, are to maximize gains whilst minimizing toxicity of drugs (an optimum risk:benefit ratio) and to operate within the pharmacoeconomic constraints (cost–benefit and cost–utility) that apply in the setting in which the patient is being treated.

The costs of treatment of rheumatoid arthritis over the lifetime of a patient are considerable. They include direct and indirect costs that are cumulative and incremental as the disease progresses. Direct costs include those in the primary and hospital sectors of medical and allied health professionals, hospital admissions, drugs, surgery, aids, and appliances. Indirect costs include those arising from loss of economic productivity and earnings, unemployment and disability benefits, the cost of maintaining mobility, and domestic help and daily care for the severely disabled. Patients with rheumatoid arthritis become debilitated by pain and fatigue and may experience psychological depression, anxiety, and loss of self-esteem, which require additional medical treatment and psychological support. Iatrogenic diseases caused by anti-inflammatory and other drugs add further socio-economic burdens over the long term. These considerations have been used as an argument for the aggressive use, within safe limits, of drugs and new therapies that offer rapid relief of symptoms and signs, retardation of structural damage, and maintenance of functional capacity.

The physician has to be able to evaluate these factors and, because of the variability of disease expression and progression, individualize and agree the treatment plan with each patient. It is prudent to re-evaluate and revise the goals from time to time as the prognosis and response to therapy unfolds.

General principles

The heterogeneous and variable course of chronic rheumatoid arthritis presents a complex management problem, with each patient requiring an individualized approach for an optimum outcome. Nevertheless, the general principles that may aid the physician's task are summarized below.

Ascertainment of the severity of disease determines the appropriate choice of drugs. Evaluation of the extent of joint and extra-articular involvement, the level of disease activity, and its progression are judged by clinical examination, laboratory tests, and the rate of progression of radiographically determined damage to joints. The full extent may only unfold over months or years of follow-up. Patients with severe and active disease will require more aggressive medical treatment than those with mild disease.

The main aim is to control disease activity as rapidly as possible. Response to therapy should be monitored to ensure efficacy, using quantifiable clinical and laboratory indices of inflammatory activity and impact on the progression of damage to joints. A lack of response to initial therapy should trigger a change in the management plan and consideration of alternative strategies at intervals of 3 to 6 months. A thorough knowledge of the scope and limitations of treatment modalities is essential in the art of management.

In early rheumatoid arthritis the goal should be to achieve disease remission. With aggressive and continuing use of available therapeutic agents there is evidence that it is possible to achieve this in 20 to 40 per cent of patients over a period of 1 to 2 years. Since low or absent disease activity correlates with retardation of joint damage, the benefit of treatment is likely to be most marked in the early phase of disease.

Remission is rare in established rheumatoid arthritis of more than 2 or 3 years duration. Nevertheless, minimizing disease activity by attention to a measurable response to therapy remains at the core of the management plan. Controlled clinical trials support the concept that optimum use of drugs can ameliorate symptoms and signs and retard progression of joint damage and disability even in later stages of disease.

At all stages of disease, irrespective of its severity, drug therapy constitutes only one part of the whole management plan. Other essential elements include measures such as patient education, psychological and employment counselling, setting appropriate levels of rest and exercise, coping with tasks of daily living, and maintaining mobility, access to splints, aids, and appliances for the disabled, and access to social and financial benefits. In addition, successful pharmacological intervention requires the patient's informed consent in instituting therapeutic decisions and involving the patient and other carers in monitoring of drug toxicity. The provision of holistic care thus requires team work and co-ordination between the treating physician and other medical and health-care professionals, including specialist nurses, physiotherapists, occupational therapists, and social workers.

Surgical treatment plays an important role in relieving intractable symptoms and restoring loss of physical function and mobility due to damage to joints, tendons, and

associated soft tissues. It is also indicated in the treatment of secondary complications such as entrapment of peripheral nerves at the wrist and elbow and cervical cord compression due to instability of the cervical spine.

Evidence base and profile of drugs used in the treatment of rheumatoid arthritis

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are widely used for treating symptoms of rheumatoid arthritis. They act by inhibiting the enzymes cyclo-oxygenase I and/or II, which act on lipid substrates in cells, converting them to prostanoids. Tissues such as the gastric and duodenal mucosa, blood vessels, and platelets constitutively express cyclo-oxygenase I, which in the gastroduodenal mucosa regulates the production of prostaglandins, including prostaglandin E_2, that exert a protective effect on its integrity by reducing acid secretion and increasing the secretion of mucus and bicarbonate. Cyclo-oxygenase I-induced prostaglandin E_2 promotes platelet aggregation and its prothrombotic effects. By contrast, cyclo-oxygenase II is mainly induced in macrophages and polymorphonuclear cells at sites of inflammation by pro-inflammatory cytokines such as IL-1 and TNF-a. NSAIDs that inhibit both cyclo-oxygenase I and II activity therefore compromise the gastroprotective effect of cyclo-oxygenase I, whilst simultaneously exerting a therapeutic effect by inhibiting the production of inflammatory prostanoids. Selective or specific cyclo-oxygenase II inhibitors should in theory block inflammation without gastropathic effects.

The conventional and currently widely used NSAIDs are inhibitors of both cyclo-oxygenase I and II. In the United States they are responsible for admission to hospital of over 1 per cent of patients with rheumatoid arthritis per year for complications such as peptic ulceration, gastric haemorrhage, and perforation, and account for a twofold increase in death over expected rates. It is claimed that the least gastrotoxic are ibuprofen and nabumetone, with naproxen and diclofenac carrying intermediate risk, followed by drugs with a high risk such as fenoprofen, ketoprofen, indomethacin and piroxicam, and azapropazone (see Table 2 for dose ranges).

For patients who develop dyspepsia and/or NSAID-induced gastropathy, or elderly patients who have a high risk of gastroduodenal side–effects, concomitant administration of prostaglandin analogues (such as misoprostol) or proton-pump inhibitors (such as omeprazole or lansoprazole) is recommended, and NSAIDs are best avoided for patients with a history of peptic ulcers. Eradication of *Helicobacter pylori* infection results in long-term healing of pre-existing gastric and duodenal ulcers, but whether it decreases dyspepsia or ulceration caused by NSAIDs is uncertain.

Drugs such as meloxicam and etodolac that act by selective or specific inhibition of cyclo-oxygenase II and thus spare cyclo-oxygenase I have fewer gastropathic effects. Two highly cyclo-oxygenase II selective inhibitors, celecoxib and rofecoxib, possessing no significant cyclo-oxygenase I inhibitory activity at anti-inflammatory therapeutic doses, have been recently introduced. Clinical trials have demonstrated their improved safety profile in respect to endoscopically detectable gastroduodenal ulcers, upper gastrointestinal haemorrhage, and perforation when compared with conventional NSAIDs. Although the inhibition of platelet function by NSAIDs that inhibit cyclo-oxygenase I is associated with serious gastrointestinal haemorrhage in susceptible individuals, certain of these drugs, such as low-dose aspirin, appear to be beneficial in the prevention of strokes and coronary thrombosis, a property not shared by selective cyclo-oxygenase II inhibitors.

NSAIDs are valuable in controlling joint pain and stiffness but have insignificant effect on factors mediating joint damage. There is little difference in the efficacy of available NSAIDs at optimal doses. Preferred NSAIDs have the most favourable risk:benefit ratio at low cost and are administered once or twice daily at doses that achieve 8- to 12-h activity to ensure compliance, alleviation of symptoms during nocturnal sleep, and on waking in the morning.

All NSAIDs can cause fluid retention and oedema by a renin–angiotensin-dependent mechanism that may also aggravate congestive cardiac failure and systemic hypertension. Patients with impaired renal function, cirrhosis of the liver, and decreased plasma volume from any cause are at risk from developing NSAID-induced renal toxicity. It is claimed that sulindac may be safer than other NSAIDs in patients with renal failure.

NSAIDs, especially indomethacin, may cause side-effects involving the central nervous system such as headache, dizziness, anxiety, disorientation, and drowsiness. Rarely, use of NSAIDs may be associated with aseptic meningitis. NSAIDs may aggravate asthma and cause hypersensitivity reactions. Blood dycrasias and an increase in serum concentration of liver enzymes and alkaline phosphatase are described. Drug interactions may decrease the efficacy of some concomitantly prescribed therapies, for instance antihypertensives and lithium, and potentiate the effects of others, for instance anticoagulants, anti-epileptics, and oral hypoglycaemics. NSAIDs decrease the excretion of methotrexate but do not appear to increase its toxicity in the dose range used to treat rheumatoid arthritis. They also increase plasma concentrations of cyclosporin and FK-506 and hence may increase the risk of renal toxicity.

Disease-modifying antirheumatoid drugs (DMARDs)

DMARDs, also classified as slow-acting antirheumatoid drugs (SAARDs) because of the lag period of some weeks before their anti-inflammatory effect becomes apparent, are the current cornerstone of drug therapy for rheumatoid arthritis (Table 3). Drugs in this category include: the antimalarials, hydroxychloroquine or chloroquine sulphate; sulphasalazine; weekly low-dose oral or parenterally administered methotrexate; weekly injections of gold aurothiomalate or gold aurothioglucose; leflunomide; cyclosporin; azathioprine; and D-penicillamine. Drugs such as gold, antimalarials, and methotrexate were introduced for use in rheumatoid arthritis by serendipity. Others, such as azathioprine, cyclosporin, and lefluomide, were developed as immunosuppressive agents for preventing transplant rejections and subsequently used to curb the aberrant immunological response in rheumatoid arthritis. The mechanism of action of these drugs in rheumatoid arthritis is complex and still incompletely understood. Inhibitory effects on inflammatory pathways, immune responses, and cell activation have been described in experimental systems and clinical studies.

Clinical trials have demonstrated superior efficacy of all these drugs over placebo in controlling symptoms and signs in patients previously treated with only NSAIDs in early and established rheumatoid arthritis. In addition, compared with placebo, sulphasalazine, methotrexate, and leflunomide appear to retard progression of structural damage as assessed by serial radiographs of the hands and feet in controlled trials lasting 6 to 12 months.

A meta-analysis of clinical trials of commonly used DMARDs has been analysed for efficacy and toxicity relative to each other and to placebo treatment. Methotrexate, sulphasalazine, injectable gold, and D-penicillamine have the best and equal efficacy in the short term compared with placebo. The antimalarials (hydroxychloroquine and chloroquine) and azathioprine appear to be less efficacious in this analysis. The toxicity profile shows a different rank order. Antimalarials are least toxic, followed by methotrexate and sulphasalazine in an intermediate range, and injectable gold, azathioprine, and D-penicillamine at the most toxic end of the spectrum. Methotrexate and sulphasalazine emerge with the best balance between efficacy and toxicity. Since leflunomide was introduced recently it was not included in this meta-analysis, but its efficacy and toxicity profile is similar to methotrexate and sulphasalazine.

Remission of rheumatoid arthritis on DMARD therapy has been described in approximately 20 per cent of those with early disease treated with methotrexate or sulphasalazine as single agents. However, in one example of a follow-up study fewer than 1 in 10 of 18 per cent that achieved remission (i.e. around 2 per cent of the original cohort) sustained it for longer than 3 years. Remissions are rare in patients who have progressed to a stage of physical disability and whose radiographs show bony erosions.

Conclusions from short-term randomized clinical trials do not reflect the effectiveness of DMARDs in controlling disease activity in the longer term. Incomplete responses, relapses, and adverse events are common and account for discontinuation of antimalarials, gold salts, D-penicillamine, sulphasalazine, and azathioprine in the majority of patients in 1 to 3 years. By contrast, responses to methotrexate appear to be more durable in follow-up studies of large cohorts of patients with rheumatoid arthritis, with about 50 per cent continuing therapy at 5 years. Data on long-term effectiveness, tolerability, and toxicity of leflunomide are not yet available.

Combinations of DMARDs have been used in the expectation that their different modes of action might provide added efficacy. However, a meta-analysis showed that there was marginal benefit at the doses and combinations used prior to 1994, especially in the reduction of number of tender joints, with increased toxicity when compared with single agents. Several subsequent randomized controlled trials have demonstrated significantly improved efficacy of combination therapy, without increased toxicity: some examples are given below.

In one trial lasting 2 years, a combination of oral methotrexate (7.5 to 17.5 mg/week), sulphasalazine (0.5 g twice daily), and hydroxychloroquine (200 mg twice daily) showed superior control of symptoms and signs compared with methotrexate alone or a combination of sulphasalazine and hydroxychloroquine. Patients enrolled in this trial with advanced disease had already failed to respond to DMARD monotherapy.

In a further study on patients with disease of less than 2 years duration, the introduction of a combination of methotrexate, sulphasalazine, and hydroxychloquine not

only controlled symptoms better but, at the end of 2 years, had induced remission in 37 per cent compared with 21 per cent of patients on sulphasalazine or methotrexate alone.

In another trial lasting 24 weeks, patients with active disease despite methotrexate (mean dose 12.5 mg/week) showed improvement in their signs and symptoms when cyclosporin at 2.5 to 5 mg/kg daily was added, compared with the addition of placebo. Similarly, in an open-label study, the addition of leflunomide at 20 mg daily enhanced the efficacy of ongoing methotrexate treatment in patients whose disease activity was not well controlled, but was associated with greater toxicity.

Corticosteroids

Corticosteroids are potent anti-inflammatory agents and are most efficacious in treating symptoms and signs of rheumatoid arthritis and for amelioration of systemic features, but their use is limited by toxicity related to dose and duration of exposure. The circumstances in which use of corticosteroids has been established and those in which it is debated are described below.

In patients in whom loss of function and disease activity is restricted to a few joints, local corticosteroid therapy can be most effective. This indication may arise in those whose rheumatoid disease is limited to a few joints, or in patients with an incomplete response to NSAID and DMARD therapy. Several alternative corticosteroid preparations are available, the dose being dependent on the size of the joint. Depot methyl prednisolone (dose range 4 to 40 mg) or triamcinolone acetonide (dose range 2.5 to 40 mg depending on size of joint) are suitable alternatives. Repeat injections may be necessary, but more than three per joint per year should be avoided.

Corticosteroid administered orally in courses lasting a few weeks to months (such as prednisolone at 7.5 to 10 mg daily), or in the form of 'pulse therapy' (such as depot methyl prednisolone at 80 to 120 mg by intramuscular injection), is a suitable adjunctive therapy in patients in whom the benefit of DMARDs is not yet established. Longer-term, more or less indefinite, treatment with low-dose prednisolone is necessary in patients with moderate to severe disease, especially associated with refractory anaemia that is not controlled with currently used antirheumatoid drugs. Long-term low-dose prednisolone retards the progression of rheumatoid bone erosions in radiographs of hands and feet and, hence it is claimed, deterioration of physical function. Whether this benefit is outweighed by the side-effects and morbidity of corticosteroid therapy is debatable. Higher doses of corticosteroids are indicated in the treatment of severe extra-articular disease.

Prevention of corticosteroid-induced osteoporosis and reduction in risk of fractures requires adequate prophylaxis with calcium and vitamin D intake (for example, daily intake of 1000 mg of calcium and 800 IU of vitamin D). In susceptible patients, or those on doses exceeding the equivalent of 7.5 mg of prednisolone daily, measurement of bone mineral density is used to identify and monitor management. Bisphosphonates may be required in addition to calcium and vitamin D, and hormone replacement therapy is recommended in perimenopausal women.

Biological therapy

The identification of TNF-a as a key mediator of rheumatoid inflammation has led to the development of anti-TNF agents that have been introduced recently into clinical practice. Other targeted therapies are in advanced clinical trials, including recombinant IL-1 receptor antagonist (rIL-ra) that inhibits the activity of IL-1, an important pro-inflammatory cytokine. In clinical trials treatment with rIL-ra has shown significant improvement of signs and symptoms and retardation of radiographic progression of joint damage.

Non-pharmacological measures and support

Specialist physicians co-ordinate the management of patients with rheumatoid arthritis using a team of health professionals. The support provided improves the patient's ability to cope with pain, disability, daily activities, and the prospect of continuing work and retaining independence.

Education and counselling is helpful in preparing patients for the likely consequences of their disease, and its development over time. It also allows the patient to participate fully in making informed decisions about taking and monitoring drugs and retaining control. Studies have demonstrated the benefit of this approach in minimizing costs of medical care and improved outcomes.

Bed rest and the use of resting splints is helpful during the very acute stages of joint disease, but should always be accompanied by daily passive joint movements and appropriate isometric exercises to avoid contractures, muscle atrophy, and osteoporosis, and to retain joint function. Exercise initiated under supervision and maintained by patients on a regular basis does not accelerate joint damage, diminishing pain and promoting a sense of well being in those in whom fatigue is a major feature of active disease.

For patients with disability, aids and appliances can be helpful in undertaking daily tasks and leisure activities such as dressing, turning keys and taps, cooking, lifting, domestic tasks, and gardening. Adjustments in the home are helpful, such as use of cushions and chairs with high seats in the bathroom and toilet. For the very disabled, learning techniques for transfers from bed to chair, chair to the toilet, and the installation of chairlifts and use of wheelchairs need expert help and advice.

Maintenance of mobility requires attention to foot care, podiatry, comfortable shoes, a walking stick or elbow crutches, and specially adapted motor vehicles to get to work and for social purposes.

Disabled people have certain privileges in employment and may qualify for disability allowances. Some may benefit from retraining for suitable work. The health-care team needs to recognize that chronic illness and disability places increased pressure on spouses and family, who generally end up as carers of the patient with rheumatoid arthritis: support and counselling should therefore extend to them.

Dietary manipulation, such as exclusion of certain foods and beverages, has enjoyed popularity and in some patients appears to be beneficial, but there is little evidence that most such diets are of value. Fasting followed by a vegetarian diet was shown to be of benefit in a Norwegian study, but the durability of effect is unknown. Diets rich in fish oils and omega fatty acids appear to be of some benefit. As excessive weight accelerates joint damage and increases the risk of complications when undergoing essential surgery, obese patients should be encouraged to lose weight.

Management strategies

Mild disease

Definition

Mild disease may be defined as rheumatoid arthritis with limited joint involvement, low disease activity, and without markers of poor prognosis. Such patients will typically show most of the following features: involvement of less than six or seven individual joints and sparing of weight-bearing joints; pain readily controlled with NSAIDs; less than 15 min of joint stiffness on waking or following inactivity; lack of extra-articular disease; minimally elevated erythrocyte sedimentation rate or concentration of C-reactive protein; negative rheumatoid factor test; a normal haematological profile; little or no impairment of physical function; and ability to undertake activities of daily living, maintaining employment and enjoying non-strenuous social and leisure activities. Radiographs of hands and feet show a lack of significant osteopenia, joint space narrowing, and bony erosions at baseline and annual follow-up. The disease course may be punctuated by self-limiting exacerbations of symptoms and signs. Patients with mild disease constitute a small proportion of patients referred to specialist clinics but are more numerous in the community and in the primary care setting.

Drug treatment

This consists of a judicious use of non-steroidal anti-inflammatory drugs. Corticosteroid injections into individual affected joints, tendon sheaths, and bursas for persistent swelling, tenderness, or loss of normal range of movement can be very effective. Follow-up assessment is necessary to ensure that the disease has not altered to a more severe pattern. DMARDs are indicated in those with recurrent or persistent symptoms and signs, deformities, or radiographic evidence of structural damage. Hydroxychloroquine or sulphasalazine are used initially. If the decision to embark on the use of DMARDs is made, the aims and management strategy are

the same as for patients with moderate or severe disease.

Moderate and severe disease

Definition

This is defined as rheumatoid disease that has evolved into an unremitting pattern of polyarthritis with evidence of significant functional impairment and joint damage. With increasing severity most of the following features are present: 10 to 30 swollen and tender joints; frequent involvement of proximal joints of the upper and lower limbs; moderate to severe pain; inactivity and morning stiffness exceeding 1 h in duration; prominent fatigue; elevated erythrocyte sedimentation rate and/or C-reactive protein concentrations; low haemoglobin concentration; polymorphonuclear leucocytosis and thrombocytosis; and positive rheumatoid factor test. Deformities of joints are apparent early in the course of disease and radiographs of hands, feet, and affected joints already show loss of joint space and subchondral erosions within 2 years of presentation. Such patients show a significant impairment in daily activities and restricted ability to perform domestic and work-related tasks and to enjoy social and leisure activities.

Drug treatment

The aim of drug treatment is to achieve rapid control of disease activity and, if possible, remission of disease. This requires simultaneous or sequential use of drugs belonging to different classes, for instance NSAIDs, DMARDs, corticosteroids, and biological therapies as discussed below.

NSAIDs are used at optimal doses for control of pain and stiffness (Table 2), those most commonly given in practice being naproxen, diclofenac, and indomethacin. Many physicians prefer to administer these drugs in slow-release preparations in the morning and before retiring to bed at night. In the elderly, cyclo-oxygenase II-selective NSAIDs may be preferable, or else the simultaneous use of a gastroprotective agent, most commonly proton pump inhibitors. In addition, simple analgesics such as 0.5 to 1 g of paracetamol every 6 h may be required for relief of pain.

DMARDs should be used in all patients (Table 3), the two most commonly employed being sulphasalazine and methotrexate, provided there are no contraindications. These are given as single drugs in incremental doses over 3 to 4 months to the maximum recommended or tolerated dose. If a clear-cut reduction in disease activity (or remission) is not observed with one of these drugs, then monotherapy with leflunomide, azathioprine, or injectable gold may be attempted. Alternatively, other DMARDs are added at this stage. Commonly used DMARD combinations include: methotrexate and hydroxychloroquine; methotrexate, sulphasalazine, and hydroxychloroquine; and methotrexate and cyclosporin. The choice of therapy is ultimately determined by evaluation of risks of toxicity, efficacy, durability, and direct and indirect costs of treatment. There is no consensus on the most effective combination regimen. Meticulous monitoring of toxic effects is necessary.

In practice over 50 per cent of patients with moderate or severe disease require corticosteroid therapy. If continuing long-term use appears necessary, the aim should be to reduce the dose to the equivalent of 5 to 7.5 mg of prednisolone daily by more aggressive use of DMARDs, or consider anti-TNF therapy.

Despite good initial responses to currently available DMARD treatments, a proportion—probably 10 to 15 per cent of hospital patients—show continuing disease activity and progressive disability. Randomized, placebo-controlled trials of two anti-TNF biological agents have shown these to be efficacious in such cases, and they became available in 2000, although their high cost is likely to restrict widespread use. The two anti-TNF-a drugs licensed for use in rheumatoid arthritis are infliximab (a chimeric monoclonal anti-TNF-a monoclonal antibody) given in combination with methotrexate, and etanercept (a soluble dimeric molecule consisting of a TNF receptor linked to the constant domains of Fc-IgG). Infliximab is given intravenously at a dose of 3 mg/kg over 1 h every 8 weeks to patients already receiving methotrexate therapy once a week. Etanercept given as 25 mg subcutaneously twice weekly is efficacious as monotherapy or when added to methotrexate. Symptoms and signs are rapidly alleviated in approximately 60 to 70 per cent of patients (Fig. 11) in clinical trials. Durable responses are being reported for up to 2 years, with a small increase in upper respiratory infections but without an increase in serious adverse events. Continuing therapy is needed and relapse of disease follows withdrawal.

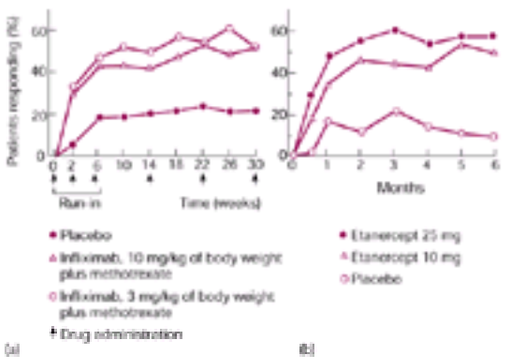

Fig. 11 Anti-TNF therapy. (a) Efficacy of combination of infliximab and methotrexate compared with methotrexate and placebo. Percentage of patients achieving a clinical response of a 20 per cent change from baseline as defined by the American College of Rheumatology 20 (ACR20) criteria. Patients were treated with methotrexate (10 to 35 mg/week) and either placebo, 3, or 10 mg/kg infliximab administered intravenously at time points indicated, in a patient group unresponsive to DMARDs with active disease despite methotrexate therapy (Maini *et al*. 1999). (b) Efficacy of etanercept compared with placebo. ACR 20 results in patients treated with two doses of etanercept or placebo injections administered subcutaneously twice weekly over a 6-month period in a population unresponsive to DMARDs. (Reproduced from Moreland *et al*. (1999), with permission.)

The combination of infliximab and methotrexate has also been reported to inhibit or even reverse significantly progression of joint damage at the end of 1 year in most patients as assessed by serial radiographs. By contrast, damage continues in the control group of patients with an incomplete response to methotrexate. In another study in rheumatoid arthritis, etanercept was found to be more effective than methotrexate in controlling progression of bone erosions, assessed by radiographs of the hands and feet at baseline and the end of 1 year. These data imply that anti-TNF therapy could preserve physical function and quality of life in the long term and hence prove to be cost-effective.

The efficacy of anti-TNF agents represents an important advance in therapy, although their efficacy and safety beyond 2 years of continuous therapy under controlled trial conditions is not yet established. Post-marketing surveillance of adverse events to infliximab and etanercept following exposure of approximately 300 000 patients to date have drawn attention to concerns arising from rare, but significant numbers of cases of sepsis, tuberculosis, fungal, and opportunistic infections. These infections are compatible with the consequences of blockade of the postulated role of TNF in host defence mechanisms. Based on these reports, regulatory authorities in the United States and Europe have advised that anti-TNF therapy is contraindicated in the presence of active serious infections and, in the case of infliximab, latent untreated tuberculosis. Other rare adverse events have included demyelinating syndromes (hence it is advisable not to treat patients with a history of multiple sclerosis), lupus syndrome, and bone marrow depression. Based on reports of an unexpected number of deaths in a phase II clinical trial of infliximab in the treatment of severe congestive cardiac failure, use of infliximab is not advisable for the treatment of patients with rheumatoid arthritis in moderate or severe congestive cardiac failure. Provided suitable screening and monitoring practices are in place, the favourable risk to benefit profile of anti-TNF therapy does not alter the indication for its use in the treatment of moderate to severe rheumatoid arthritis with persistent disease activity despite best available, but also potentially toxic and immunosuppressive, standard therapy. The high cost of anti-TNF drugs has, however, limited access to this treatment in some countries.

Extra-articular disease

Effective treatment of rheumatoid arthritis generally reduces the risk of developing severe extra-articular disease. Systemic rheumatoid vasculitis is potentially a life-threatening complication and may be aggravated by coincidental infection, such as cutaneous ulcers. After due attention to confirming the diagnosis and excluding and treating infections with appropriate antimicrobial drugs, therapy with high-dose corticosteroids and cyclophosphamide is favoured by many specialists, although no randomized placebo-controlled trial data are available. One regimen recommends intravenous methylprednisolone at 1 g daily for 3 days, simultaneously with an initial single pulse of intravenous cyclophosphamide (10 to 15 mg/kg) in a fully hydrated patient to prevent bladder toxicity. Cyclophosphamide is repeated every 3 to

4 weeks, subject to a satisfactory clinical response or lack of toxicity, up to a total dose of 10 to 12 g in a cycle of treatment. Alternatively, oral cyclophosphamide at 2 mg/kg (maximum dose 150 mg daily) may be used. Oral high-dose prednisolone is continued until clinical response is observed or toxic effects occur, when it is rapidly tapered to a maintenance dose, generally about 15 mg daily. Similarly, cyclophosphamide is substituted by the less toxic azathioprine at 1.5 to 2 mg/kg daily or methotrexate at 15 mg/week.

Similar regimens have been used for severe fibrosing alveolitis and for severe scleritis and corneal melt in conjunction with local therapy. Occasional patients with Felty's syndrome and hypersplenism that do not respond to DMARDs benefit from splenectomy, and their neutropenia may respond to recombinant human granulocyte colony-stimulating factor. Keratoconjunctivitis sicca and dry mouth due to secondary Sjögren's syndrome respond to local measures including artificial tears, dental hygiene, and saliva substitute.

18.6 Spondyloarthropathies and related arthritides

J. Braun and J. Sieper

Introduction and definitions

The spondyloarthropathies are a heterogenous group of inflammatory rheumatic diseases with predominant involvement of axial and peripheral joints and entheses. In addition to these, the various spondyloarthropathies share other characteristic clinical features, for example anterior uveitis and Crohn-like gut lesions. Symptoms in subsets of spondyloarthropathies can overlap, for example psoriatic skin lesions in Reiter's syndrome, and patients can move from one subset to another, for example from reactive arthritis to ankylosing spondylitis.

The various names which have been and are still used for the spondyloarthropathies include seronegative spondarthropathies, spondarthritis, spondylarthropathy, spondyloarthropathy, and spondyloarthritis. There is no substantial difference between them. The prefix seronegative, referring to the general absence of rheumatoid factors in the spondyloarthropathies, is historical and redundant. The term spondyloarthropathy is preferred in this chapter. The spondyloarthropathies are not modern diseases, with ankylosing spondylitis first having been described in 1649 (Table 1).

Epidemiology

The mean age at onset is 20 to 40 years, with a slight preponderance of males in most subsets of spondyloarthropathy. Next to rheumatoid arthritis, the spondyloarthropathies are the most frequent inflammatory rheumatic diseases (Table 2), with ankylosing spondylitis and undifferentiated spondyloarthropathy being the most common subsets. The overall prevalence of spondyloarthropathies in patients presenting with back pain to general practitioners' surgeries in the United Kingdom has been estimated at 5 per cent.

The spondyloarthropathies are associated with the major histocompatability complex class I antigen HLA B27, and the prevalence of spondyloarthropathies in any population correlates with that of HLA B27. The magnitude of association differs between the subsets (Table 3) and has been mainly shown for ankylosing spondylitis, but in Inuit populations Reiter's syndrome is more frequent.

Pathogenesis

In all forms of spondyloarthropathy there is a strong genetic association with the major histocompatability complex class I antigen HLA B27, as shown in Table 3. The overall influence of genes in the pathogenesis of ankylosing spondylitis has been estimated to be 95 per cent, leaving only 5 per cent to other causative factors such as environmental influences. HLA B27 is responsible for about one-third of the total genetic load: 25 subtypes are now recognized by polymerase chain reaction technology, three of which are not associated with ankylosing spondylitis, or are associated less strongly. There is weaker association of spondyloarthropathies with

HLA B60 and HLA DR1, and possibly also tumour necrosis factor-a polymorphisms. Further genes have not yet been identified.

The relevance of HLA B27 to disease pathogenesis is not known: several models have been proposed to explain tissue tropism, the aberrant immune response to certain bacteria, and the HLA B27 association of the spondyloarthropathies (Table 4).

The classical arthritogenic peptide model is backed by the demonstration of HLA B27-restricted CD8+ T-cell clones in the synovial fluid of patients with reactive arthritis. Immunodominant peptide motifs and peptides have been described, but their pathogenetic relevance is not yet clear. Lipopolysaccharide and RNA of bacteria associated with reactive arthritis and a CD4+ T-cell response directed against bacterial antigens have been detected in reactive arthritis, but it is not clear whether this immune response is beneficial or arthritogenic. At the humoral and the cellular level, molecular mimicry (partial sequence homologies at the protein and DNA level) between bacterial antigens and self structures has been described, mainly of the HLA B27 molecule. It also seems possible that patients with HLA B27+ spondyloarthropathies have deficient immune reactivity, for example diminished ability to secrete tumour necrosis factor-a, or a synovial T_{H2} response (secretion of too little interferon-g, too much IL-4, IL-10) making elimination of bacteria difficult. Presentation of HLA B27-derived peptides themselves by HLA class II molecules, or even by HLA class I molecules, has been proposed as an explanation of the association of HLA B27 with disease.

Clinical features

The characteristic clinical features of the spondyloarthropathies are listed in Table 5.

Diagnosis

Five subsets of spondyloarthropathies can be distinguished on clinical grounds: ankylosing spondylitis, reactive arthritis/Reiter's syndrome, psoriatic arthritis, arthritis associated with inflammatory bowel diseases, and undifferentiated spondyloarthropathy.

Diagnostic criteria for spondyloarthropathies are shown in Table 6. Inflammatory back pain is one of the main clinical criteria used. To diagnose this requires four of the following five to be present: insidious onset, onset before the age of 45 years, duration of more than 3 months, morning stiffness, and relief by exercise but not by rest. Other features of possible relevance include waking up at night, alternating buttock pain, initially deep localization, response to non-steroidal anti-inflammatory drugs (**NSAIDs**), other clinical signs of spondyloarthropathies (enthesitis, arthritis, anterior uveitis, family history), elevated acute phase reactants (C-reactive protein, erythrocyte sedimentation rate), and the presence of HLA B27. Note, however, that HLA B27 can never make a diagnosis but increases the probability of an underlying spondyloarthropathy by about tenfold.

Differential diagnosis

The leading clinical symptom of inflammatory back pain may be pain in the lower back radiating to the thighs. Hence an important initial differential diagnosis is sciatica, particularly if symptoms are not insidious but begin abruptly. In inflammatory back pain radiation is more often bilateral than unilateral, rarely extends below the knees, almost never into the foot, and is not associated with paraesthesia. Cough impulse pain may be present. Diagnostic procedures for the detection of disc herniation by magnetic resonance imaging (**MRI**) or computed tomography (**CT**) can be misleading since disc prolapses are found in as many as 30 per cent of normal individuals.

Diffuse idiopathic skeletal hyperostosis or Forestier's disease, a severe radiographic spondylosis, can be difficult to distinguish from spondyloarthropathy. Scoliosis is not usually a marked feature of anklylosing spondylitis. Sacroiliitis occurs in a number of other rheumatic and infectious diseases, as shown in Table 7. The differential diagnosis of peripheral arthritis of the lower limbs includes Lyme arthritis, sarcoidosis (Löfgren's syndrome), gout, and undifferentiated oligoarthritis. The differential diagnosis of enthesitis includes epicondylitis and fibromyalgia, and that of dactylitis is erysipela and infection.

Prognosis

There are no good studies, but the following seem to be poor prognostic factors: hip arthritis, limitation of lumbar spine movements, dactylitis, oligoarthritis, young age at onset (less than 16 years), poor efficacy of NSAIDs, and an erythrocyte sedimentation rate of more than 30 mm in the first hour.

Ankylosing spondylitis

Ankylosing spondylitis is a chronic inflammatory rheumatic disease that mainly affects the axial skeleton, starting in the sacroiliac joints and often progressing to the spine, but peripheral joints, enthesial structures, the anterior uvea, and the aorta can also become affected.

The diagnosis is made on the basis of significant radiological changes in the sacroiliac joints, the typical clinical history of inflammatory back pain and stiffness, and evidence of limited spinal movement and/or chest expansion on physical examination.

Epidemiology

The age of onset is commonly in the twenties, but ankylosing spondylitis can begin in childhood, or considerably later (over the age of 50). The male:female ratio is about 2:1 to 3:1. Approximately 90 per cent of Caucasian ankylosing spondylitis patients are HLA B27-positive. The risk of developing ankylosing spondylitis is increased tenfold in HLA B27-positive individuals, rising to 25 to 30 per cent if a first-degree relative or dizygotic twin is affected, and to 50 to 60 per cent in monozygotic twins. Reactive arthritis, psoriasis, and inflammatory bowel disease are additional, partly independent risk factors.

Immunopathology and pathogenesis

The leading features of ankylosing spondylitis are spinal inflammation and ankylosis, but their cause is unknown. The association of ankylosing spondylitis with bacterial infections is less clear than in reactive arthritis. Antibodies to *Klebsiella pneumoniae* are more frequently detected in patients with ankylosing spondylitis than in healthy controls, but similarly often in patients with Crohn's disease and first-degree relatives of those with ankylosing spondylitis. This finding is probably explained by increased gut permeability, and its predominant clinical association is with peripheral (not axial) arthritis.

The sacroiliac joint is the structure most frequently involved in the initial phase of disease. If biopsy is performed, T cells and macrophages are seen to be the predominant infiltrating cells, with CD4+ and CD8+ T cells both present. The reason for this tropism is unclear. The fact that sacroiliac and spinal joints are affected in diseases caused by mycobacteria and other microbes may argue for a pathogen-triggered pathogenesis in ankylosing spondylitis. However, bacteria associated with reactive arthritis have not been detected in the sacroiliac joints.

Clinical features

The most common initial symptom is inflammatory back pain, commonly in the lower back and the buttocks. Early in the course of disease there may be no limitation of spinal movement or chest expansion. As it progresses, there is restriction of lateral flexion, forward flexion, and extension. There is often a flattening of the lumbar lordosis, or an inability to reverse this on forward flexion. With more advanced disease a thoracic kyphosis develops, with concomitant restriction of thoracic rotation and chest expansion due to inflammation and ankylosis of the costovertebral and costotransverse joints. In severe cases movements of the cervical spine are also restricted in all planes, with dramatic limitation of lateral flexion. The combination of cervical stiffness and severe thoracic kyphosis can lead to difficulties with forward vision. An example of a young patient with severe progressive disease is shown in Fig. 4 and Plate 3. Severe spinal disease is more frequent in men than in women. There is no evidence that pregnancy has a significant impact on the course of the disease.

Fig. 4 30-year-old man with rapidly progressive ankylosing spondylitis (disease of 5 years duration). (See also Plate 3.)

Peripheral joint involvement occurs in 30 to 50 per cent of cases at some time. About 20 to 30 per cent of patients have acute peripheral arthritis of the lower limbs, often with joint effusions as the first symptom, this being especially marked in children. This situation is difficult to differentiate from reactive arthritis. Joint involvement is usually oligoarticular and often asymmetrical. The joints most often involved are the knees, ankles, hips, shoulders, wrists, temporomandibular joints, sternoclavicular joints, manubriosternal joints, costovertebral joints, zygapophyseal joints, and symphysis pubis. Small joints are rarely affected.

Enthesitis occurs at the heel at the insertion of the Achilles tendon (Fig. 1) and the plantar fascia (Fig. 2), and at the iliac crests, the ischial tuberosities, the greater trochanters, and other sites. The diagnosis is often difficult if no swelling is apparent, in which case ultrasound can be revealing. Dactylitis of fingers and toes is uncommon in ankylosing spondylitis, being seen most often in psoriatic arthritis.

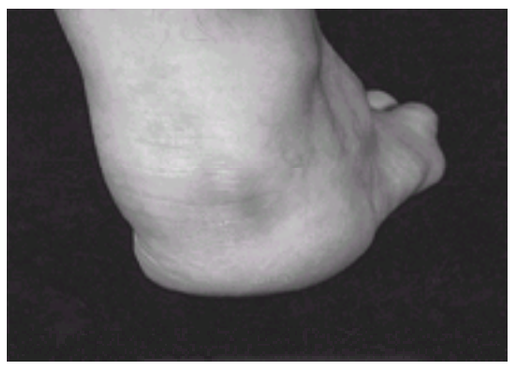

Fig. 1 Enthesitis at the insertion of the Achilles tendon in a patient with reactive arthritis. (See also Plate 1.)

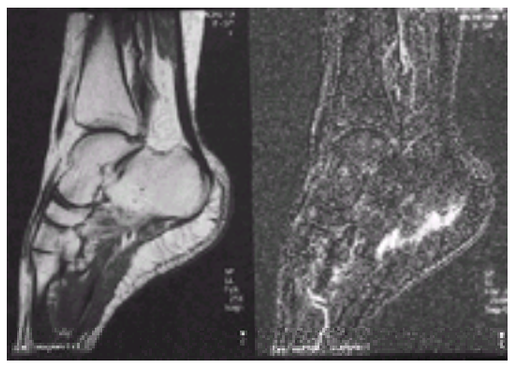

Fig. 2 Magnetic resonance image showing inflammation of the plantar fascia in a patient with undifferentiated spondyloarthropathy.

Fig. 3 Dactylitis of the third finger of the right hand in a patient with undifferentiated spondyloarthropathy. (See also Plate 2.)

Physical examination of the spine and thoracic cage

The physical examination is important in the evaluation of patients with ankylosing spondylitis, in particular to quantitate flexibility of the spine and thoracic cage. The following measurements are useful, but it should be stressed that the values expected of normal individuals are dependent on age and physical training:

1. Schober test (modified):
   - Ventral: with the patient standing upright, a line is drawn across the lumbar spine connecting the two posterior superior iliac spines. Marks are made in the midline over the spine 10 cm cranial and 5 cm caudal to this horizontal line. The patient then bends with legs straight and the distance is measured again. It normally increases by more than 3 cm.
   - Lateral: the distance between the longest finger tip and the floor is measured in the upright position. This is repeated when the patient tries to flex laterally towards the ground as far as possible, normally moving by more than 10 cm.
2. Thoracic excursion. The circumference of the thorax is measured in the fourth intercostal space after maximal inspiration and expiration. It normally alters by more than 3 cm.
3. Occiput/wall distance. In the upright position the patient leans backwards against a wall, and should normally be able to touch the wall with their occiput.
4. Chin/sternum distance. The chin is maximally bent towards the sternum, and should normally be able to touch it.
5. Cervical rotation. The head is rotated to the left and right sides with the angles of rotation measured (normally more than 50°).

6. Intermalleolar distance. The patient tries to stand with their feet together: the malleoli should normally touch.

Physical examination for extra-articular organ involvement

Acute anterior uveitis can occur at any time in the course of disease and is seen in 20 to 30 per cent of patients. It is typically unilateral, but either eye may be affected in separate episodes. Recurrent attacks are common. Aortic regurgitation secondary to aortitis occurs in about 1 per cent of ankylosing spondylitis patients, most frequently in advanced disease, and may be associated with atrioventricular block. Probably on the basis of a restrictive pulmonary defect due to limited chest expansion, apical pulmonary fibrosis occurs in no more than 1 per cent of the patients, especially those with advanced disease. A cauda equina syndrome may complicate severe longstanding disease, with resultant disturbance of the bladder and bowel function. Lumbar diverticulae are seen in myelographic examinations.

Diagnosis

The 1984 modified New York criteria for ankylosing spondylitis are shown in Table 8.

There is a significant diagnostic delay in women (8 years) and in men (5 years). The most probable reason is that back pain is a very frequent complaint, and that primary care and general physicians are often not trained to distinguish inflammatory back pain from other causes of back pain.

Laboratory features

The erythrocyte sedimentation rate and the C-reactive protein are raised in 30 to 50 per cent of patients, with moderate correlation to overall disease activity. Less commonly, serum IgA levels are raised. Mild to severe normochromic normocytic anaemia occurs.

Radiological features

Sacroiliac radiography

Dependent on stage, severity, and duration of disease, there are sacroiliac joint abnormalities in almost all patients. The radiological changes are graded from 0 (normal), through I (minimal changes), II (sclerosis, some erosions), III (severe erosions, pseudodilatation of joint space, limited ankylosis), to IV (ankylosis) (Fig. 5). They are critical for the diagnosis of ankylosing spondylitis and for the differentiation from undifferentiated spondyloarthropathy, but it must be noted that significant inter- and intraobserver variability has been reported—particularly concerning grades I and II—which creates diagnostic problems and confusion. Sclerosis, joint space narrowing, and even synchondrosis occur in healthy elderly individuals. Oblique and other special views are generally not significantly better than normal anteroposterior pelvic radiographs, but can be helpful in a few cases.

Fig. 5 Radiographic sacroiliitis, stage IV in both joints, in a 28-year-old man with ankylosing spondylitis.

Sacroiliac MRI and CT

In early ankylosing spondylitis sacroiliac radiographs may be normal. In clinically suspicious cases dynamic MRI of the sacroiliac joints can be helpful in providing objective evidence of sacroiliitis (see undifferentiated spondyloarthropathy). Active inflammation can be demonstrated by enhancement after application of a contrast agent (gadolinium DTPA) or by special magnetic resonance sequences such as short tau inversion recovery (STIR) or other fat saturation techniques which optimize the visualization of oedematous areas (Fig. 6). Computed tomography of the sacroiliac joints is superior to normal radiographs for documenting bony changes such as erosions and ankylosis. The sacroiliac joint is accessible to biopsy under CT guidance.

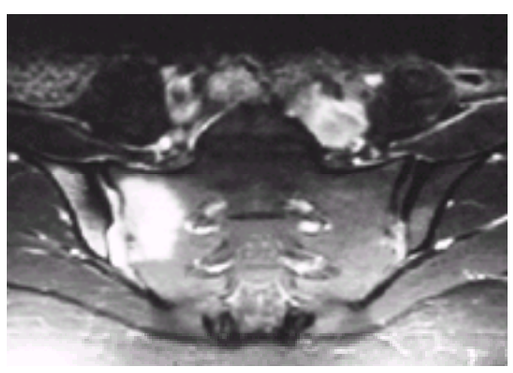

Fig. 6 Dynamic MRI showing right-sided acute sacroiliitis.

Spinal radiography

The characteristic spinal lesion in advanced disease is the syndesmophyte—a bony proliferation originating from an inflammatory area at the ligamentous/discal attachment to the vertebral edge. This early ankylotic structure predominantly grows cranially to fuse with the next vertebral body and has to be distinguished from the spondylophyte, which mainly grows laterally and typically indicates degenerative vertebral disease.

In ankylosing spondylitis the earliest spinal lesions are frequently in the lower thoracic and upper lumbar spine, sometimes preceded by squaring of the vertebrae seen on lateral films. The zygapophyseal joints are frequently involved at all stages. Anterior spondylitis is indicated by lateral spinal radiographs showing hypersclerotic corners (Romanus lesion, Fig. 7). Spondylodiscitis (Anderson lesion) is revealed by erosion of the disc and vertebra with a hypersclerotic lining. In later stages calcification of the anterior and the posterior ligaments occurs, eventually leading to the characteristic 'bamboo spine' (Fig. 8).

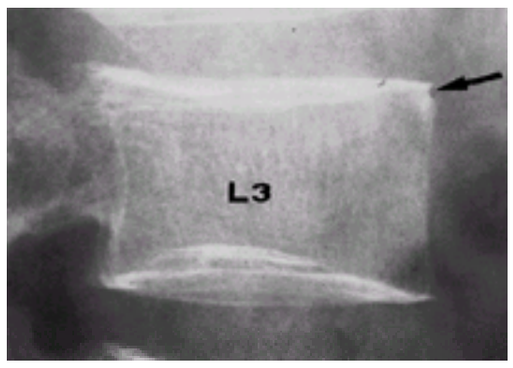

Fig. 8 Radiographic anterior spondylitis (arrow) in a 42-year-old man with ankylosing spondylitis.

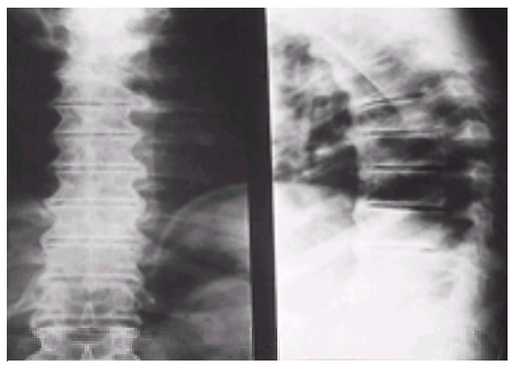

Fig. 8 Spinal radiograph showing classical bamboo spine.

Spinal MRI

Early spinal inflammation (spondylitis, spondylodiscitis) can be detected by dynamic MRI, which can be useful for localizing inflammation in the spine in the early stages when plain radiographs are normal.

Treatment

Although there is no cure for ankylosing spondylitis, several treatments are available. The main therapeutic options are as follows:

1. Acute anti-inflammatory therapy: NSAIDs, local corticosteroids, systemic corticosteroids.
2. Disease-modifying therapy: sulphasalazine, methotrexate(?), gold(?), hydroxychloroquine(?).
3. Anti-resorptive therapy: bisphosphonates (pamidronate)

Non-steroidal anti-inflammatory drugs are better than analgesics and can be used in combination with them. Diclofenac (50–150 mg, and higher in extreme cases), meloxicam (7.5–15 mg), and indomethacin (50–150 mg) are commonly given. Thalidomide and phenylbutazone are reserved for severe cases when other agents have failed. The novel Cox-2 specific agents (rofecoxib 12.5–25 mg, celecoxib 100–200 mg) may be useful. The main risk of NSAIDs is gastrointestinal side-effects: 25 per cent of patients suffer these, ranging from dyspepsia to peptic ulceration and (rarely) bleeding, perforation, and death. It is important to provide patients with proper information about possible symptoms, and prophylactic therapy with proton pump inhibitors or misoprostol is indicated in those at particularly high risk (older age, history of ulcer, disability, comorbidity).

Most patients with ankylosing spondylitis do not respond to small doses of corticosteroids. Transient high-dose steroid treatment has been tried in extreme cases with additional symptoms of inflammatory bowel disease. In our experience, mainly female and HLA B27-negative ankylosing spondylitis patients respond to low-dose corticosteroid therapy.

Sulphasalazine is given in a dosage of 2 to 3 g/day, when effects may be seen after 2 to 4 months. The influence on peripheral joint disease is more significant than for axial symptoms, but this may be due to the preferential study of patients with longstanding disease. Sulphasalazine should mainly be given to patients with early, active disease.

The antitumour necrosis factor-a antibody infliximab in a dosage of 5 mg/kg, which has also been found to be effective in Crohn's disease and rheumatoid arthritis, has been used with significant success in open pilot studies in severe ankylosing spondylitis and recently also in a randomized placebo controlled trial.

The aim of physiotherapy is to maintain and enhance function by improving mobility and muscle strength. Patients affected by spinal stiffness should have physiotherapy on a regular daily basis. Hip replacement is indicated for those with severe hip involvement, and osteotomy can be indicated in cases where visual problems are due to severe kyphosis.

Prognosis

The established myth is that 'patients with ankylosing spondylitis generally do well'. However, one-third are severely disabled and experience intense pain and impairment of health to a comparable degree as those with rheumatoid arthritis. Ankylosing spondylitis does not burn out: disease activity and pain are independent of the duration of the disease. Since the disease usually starts in the second or third decade of life, patients with ankylosing spondylitis typically suffer its effects for many years. The mortality of patients with ankylosing spondylitis may be slightly increased: possible causes of premature death are amyloidosis, NSAID gastropathy (ulcers, bleeding), vertebral fractures, and cardiac or respiratory complications.

Reactive arthritis/Reiter's syndrome

For further information see Chapter 18.7.2.

Undifferentiated spondyloarthropathy

Definition

The term undifferentiated spondyloarthropathy (uspondyloarthropathy) was introduced and defined by the European Spondylarthropathy Study Group in 1991. Terms such as incomplete Reiter's syndrome, syndrome of enthesopathy and arthritis, HLA B27-positive oligoarthritis, and others had been used previously. Patients with uspondyloarthropathies have the typical clinical features of spondyloarthropathies but do not fit into any of the other defined categories. The fact that patients with a clinical picture of peripheral oligoarthritis but without spinal symptoms are also classified/diagnosed with uspondyloarthropathies by the European Spondylarthropathy Study Group criteria can be confusing in some cases. It is possible that uspondyloarthropathies may represent an early form of another spondyloarthropathy subset, or be a genuine spondyloarthropathy subset of their own.

Epidemiology

The prevalence of uspondyloarthropathies is not known precisely, but the frequency is not much less than that of ankylosing spondylitis. They are commoner in men. About 70 per cent of patients are HLA B27-positive. In some contrast to other spondyloarthropathies, late onset disease has been reported.

Clinical features

The main clinical features are inflammatory back pain, asymmetric peripheral arthritis, predominantly of the lower limbs, enthesitis, dactylitis, and anterior uveitis.

Diagnosis

The diagnosis of a uspondyloarthropathy requires inflammatory back pain and/or peripheral arthritis of the lower limbs and at least one other characteristic feature in addition—enthesitis, a positive family history for spondyloarthropathy, psoriasis, or inflammatory bowel disease. Dactylitis, anterior uveitis, and HLA B27 are not part of the European Spondylarthropathy Study Group criteria, but are part of Amor's criteria, and may be taken to indicate uspondyloarthropathy in single cases. Radiographs are not essential for a diagnosis, but in clinically suspicious cases MRI of the sacroiliac joints can be helpful in providing objective evidence of sacroiliitis.

The differential diagnosis of asymmetric peripheral arthritis of the lower limbs in spondyloarthropathies comprises Lyme arthritis, sarcoidosis, gout, osteoarthritis, atypical rheumatoid arthritis, and connective tissue diseases and other rarer conditions.

Treatment

Non-specific therapy with NSAIDs, intra-articular steroid injections, transient immobilization, ice packs, and physiotherapy is similar to that of other arthritides. Sulphasalazine may be effective, but no therapeutic trials with disease-modifying agents has been performed in uspondyloarthropathies.

Prognosis

Knowledge of the long-term prognosis in uspondyloarthropathies is limited. In about 30 to 50 per cent of cases a transition to ankylosing spondylitis has been reported over many years.

Psoriatic arthropathy

Definition

All kinds of arthritis occurring in association with psoriasis can be regarded as psoriatic arthritis, but it is clear that there can be considerable variability in arthritic manifestation. Many patients can be classified as having a spondyloarthropathy, but some are affected in a manner more closely resembling rheumatoid arthritis, and there are other unique forms such as arthritis mutilans. Different forms of psoriasis are associated with different forms of arthritis.

Epidemiology

Psoriasis is common, with a prevalence between 1 and 3 per cent of the population. Arthritic symptoms occur in 20 to 40 per cent of these patients, with the axial skeleton affected in 15 to 25 per cent, such that the overall prevalence of psoriatic arthritis is somewhere around 0.1 to 0.3 per cent. The peak age of onset of psoriatic arthritis is between 20 and 40 years: juvenile disease is rare. Both sexes are equally affected, but women more frequently get polyarthritis and men more often have spinal involvement.

Pathogenesis

Familial aggregation and high concordance rates in monozygotic (70 per cent) compared with dizygotic twins (20 per cent) suggest that there is a clear genetic factor in psoriasis and psoriatic arthritis. About 30 per cent of patients give a clear history of affected first-degree relatives. The genetic impact is thought to be multifactorial. Psoriasis is associated with HLA B13, B17, B37, and HLA DR7. The strongest association is with Cw6 (RR = 24). HLA associations of psoriatic arthritis are with HLA B38 and B39 (peripheral arthritis), with HLA DR4 (symmetric polyarthritis) and HLA B27 (spondylitis).

The importance of genetic linkage may lie in determination of the immunological response to particular antigens, and there has been much interest in the possible role of streptococcal infection. A proliferative response of skin and synovial T cells to streptococcal antigens has been detected in psoriatic arthritis, but also in rheumatoid arthritis, and the (immuno)histology is similar in the two conditions, although some differences have been described.

Koebner's phenomenon is described in psoriasis, when plaques arise at sites of skin injury, scratches, and scars, but the role of trauma in psoriatic arthritis is not clear. Drugs can exacerbate and trigger psoriasis: most well known are b-adrenergic blocking agents, antimalarials, and lithium; and withdrawal of corticosteroids can induce a skin flare; but the relevance of these factors to psoriatic arthritis is uncertain.

Clinical features

Psoriatic arthritis has been divided into five subgroups: distal interphalangeal (overlapping, most common), asymmetrical (spondyloarthropathy-like), symmetrical (rheumatoid arthritis-like), mutilans (unique, rare, Fig. 9 and Plate 4), and spinal (ankylosing spondylitis-like). It must be stressed, however, that these subgroups are not clearcut. In a recent study, when patients were evaluated over a period of 8 years, the initial classification pattern changed significantly over time, and finally only two categories remained: peripheral disease without axial involvement (70 per cent) and axial involvement with or without peripheral arthritis (30 per cent). The latter was correlated with duration of the disease and magnitude of joint involvement. Erosions were found in 70 per cent of the patients.

Fig. 9 Severe psoriatic arthritis (arthritis mutilans). (see also Plate 4.)

Psoriasis precedes joint disease in the majority of cases (70–80 per cent), both occur simulataneously in 15 per cent, and in about 10 per cent arthritis comes first. There is poor correlation between onset, severity, and activity of psoriatic skin lesions and arthritis. More than 80 per cent of patients with psoriatic arthritis have nail dystrophy, while this is the case in only 20 per cent of those with uncomplicated skin disease. Nail dystrophy, ranging from some to many nail pits and horizontal (not longitudinal) ridging to onycholysis, occurs most often in those with distal interphalangeal involvement. In some patients the involvement of interphalangeal joints and

nails is closely correlated, with both appearing on the same finger(s). Acute anterior uveitis occurs mainly in those with radiological sacroiliitis and ankylosing spondylitis.

Different types of psoriatic skin involvement lead to different types of arthropathy. Most frequent is the common psoriasis vulgaris, but a type of skin disease that frequently affects the palms of the hands and soles of the feet with many psoriatic plaques is also seen: pustolosis palmaris et plantaris. This type is associated with the SAPHO syndrome (see below), which is related to the spondyloarthropathies but has unique features that justify the designation as a separate subset of these disorders.

A severe form of psoriatic arthritis can occur in HIV-infected patients, although is not clear whether HIV increases the overall prevalence of psoriatic arthritis. Severe peripheral enthesitis (predominantly of the heel) and dactylitis are characteristic. Knee arthritis can be rapidly destructive. Axial inflammation is less frequent.

There is a classical overlap between psoriatic arthritis and reactive arthritis in the form of keratoderma blenorrhagicum—a desquamating psoriasis-like lesion mostly occurring on the soles of the feet in patients with Reiter's syndrome.

Psoriatic arthritis often improves during pregnancy. There is no adverse effect of the disease on mother or child.

Diagnosis

Scaling erythematous papules and plaques on the scalp and extensor aspects of the extremities, often surmounted by a silvery white micaceous scale that is easily removed, are suggestive of psoriasis. Elbows and knees are often affected. The diagnosis of psoriatic arthritis is based on the presence of these characteristic skin lesions, which are not always obvious. Less accessible areas such as the navel, perineum, and scalp need to be examined carefully. The patient should be asked whether they have a family history of psoriasis or psoriatic arthritis.

Since psoriasis is a frequent disease, it must be remembered that a patient with psoriasis can have an attack of gout or another form of arthritis. The diagnosis of psoriatic arthritis should be considered in those without skin lesions if there is distal interphalangeal joint involvement, dactylitis, the involvement of a whole finger or toe, tendon sheaths and bone of an affected limb, and/or typical radiographic changes.

Laboratory and radiological features

Acute phase reactants are often raised. HLA determinations including HLA B27 do not provide diagnostic help in those with psoriatic arthritis, but in HLA B27-negative patients who appear to have ankylosing spondylitis, psoriasis should always be searched for. The presence of rheumatoid factor does not formally exclude a diagnosis of psoriatic arthritis, there being a background prevalence of rheumatoid factor positivity, but a positive result should always make the physician consider the diagnosis carefully.

The distribution of radiological changes reflects clinical involvement, with the interphalangeal joints involved earlier than larger joints. A characteristic lesion in advanced cases is the so-called pencil-in-cup deformity (Fig. 10), which evolves by resorption of the distal end of a phalanx or metacarpal with uniform deep erosion of the end of the corresponding distal phalanx. In some cases the joints can be completely destroyed and invisible on the radiograph.

Fig. 10 Radiograph of the hands showing destructive psoriatic arthritis.

Radiological grounds for thinking the diagnosis more likely to be psoriatic arthritis than rheumatoid arthritis are distal interphalangeal joint involvement, asymmetric joint involvement, marginal erosions with adjacent bone proliferation (whiskering), osteolysis, periostitis, proliferative new bone formation, and ankylosis. Radiological sacroiliitis is a finding in 20 to 40 per cent of patients. The axial disease in psoriatic arthritis can be indistinguishable from that in primary ankylosing spondylitis, but in psoriatic arthritis the following are more likely: asymmetrical sacroiliitis, less zygapophyseal joint involvement, fewer, coarser, and asymmetric syndesmophytes, and bony bridging that is more often asymmetrical. Psoriatic arthritis syndesmophytes can be indistinguishable from spondylophytes typical of diffuse idiopathic skeletal hyperostosis (Forestier's disease).

When scintigraphy is used to detect the extent and localization of arthritis, an increased uptake of the isotope ^{99}Tc can frequently be detected in the sternoclavicular and manubriosternal joints—this is not necessarily associated with clinical symptoms.

Treatment

Many patients improve with the use of NSAIDs and intra-articular steroids, especially in the case of large joint involvement or flexor tenosynovitis. However, 20 to 40 per cent of patients will not improve and need to be treated with disease-modifying antirheumatic drugs. Sulphasalazine 2 to 3 g daily is often effective against arthritis. Methotrexate 7.5 to 40 mg daily is also good for arthritis, and even better for the skin. Intramuscular gold and azathioprine can be tried. Antimalarials and penicillamine are not used; the former may exacerbate psoriasis. Cyclosporin A is given in severe cases. There is limited information on the use of combination therapy. Systemic corticosteroids are limited to extreme cases of arthritis: psoriasis usually flares when they are withdrawn.

Local skin therapy has no effect on joint symptoms. Etretinate is not clearly beneficial for arthritis and may cause arthralgias and many other adverse reactions. The role of physiotherapy is similar to that in other spondyloarthropathies, and there are no special considerations for surgical intervention in psoriatic arthritis, apart from the fact that the presence of florid skin lesions close to a joint is a relative contraindication to surgery.

Prognosis

Severe psoriasis can lead to significant disability. There are only limited data from long-term studies in psoriatic arthritis. In cross-sectional studies 10 to 20 per cent of patients with psoriatic arthritis were in a poor functional class; the HLA antigens HLA B27, HLA B39, and DQw3 have been associated with such an outcome.

Arthritis associated with inflammatory bowel disease

Definition

An arthropathy with various clinical symptoms occurring in association with Crohn's disease and ulcerative colitis is termed arthritis associated with inflammatory bowel disease. Other forms of arthropathy occurring in association with enteropathy are Morbus, Whipple's disease, and arthritis after intestinal bypass surgery.

History

A relationship between gut and joint disease was postulated in 1922 when Smith treated arthritis patients with segmental bowel surgery. Bargen and Hench in 1929 and 1935 described arthritis in association with ulcerative colitis and Crohn's disease. Moll and Wright included arthritis associated with inflammatory bowel disease in the concept of spondyloarthropathies in 1973. Mielants and Veys described Crohn-like gut lesions in all subsets of spondyloarthropathy in 1984.

Epidemiology

The prevalence of Crohn's disease and ulcerative colitis is between 0.05 and 0.1 per cent of the population, generally higher in Whites and Jews. The peak occurrence of both diseases is between 15 and 35 years, but it may appear in every decade of life; both sexes are equally involved. Arthritis associated with inflammatory bowel disease occurs in 10 to 30 per cent of patients with inflammatory bowel disease; in general more frequently in Crohn's disease than in ulcerative colitis, and more often in patients with colonic involvement and in those with extended bowel disease.

There is a genetic predisposition for inflammatory bowel disease with documented familial aggregation for both Crohn's disease and ulcerative colitis. The association with HLA B16, HLA B18, and HLA B62 is not strong. The peripheral arthritis of inflammatory bowel disease is not associated with HLA B27, but axial inflammation is (50 per cent). The patient with inflammatory bowel disease who is, by chance, HLA B27-positive, is at high risk of developing spondylitis. The relative frequency of sacroiliitis and ankylosing spondylitis in inflammatory bowel diseases varies between 2 and 20 per cent or more, partly depending on the sensitivity of the diagnostic imaging procedure. Four per cent of patients with ankylosing spondylitis develop overt inflammatory bowel disease, while 60 per cent have microscopically detectable Crohn-like gut lesions.

Pathogenesis

The pathogenesis of inflammatory bowel disease and arthritis associated with inflammatory bowel disease is not known. One hypothesis is of an aberrant immune response to gut bacteria, with gut inflammation leading to increased permeability, allowing bacteria to cross the mucosal border and get access to joints. There is some evidence from the HLA B27 transgenic rat model that gut and joints are closely linked: susceptible rats get both colitis and arthritis once they have left a germfree environment.

Clinical features

Patients with ulcerative colitis and Crohn's disease typically present with bloody diarrhoea and abdominal pain, and in severe cases with fever, weight loss, and fatigue. For further details of gastrointestinal and other non-rheumatological presentations, and criteria for diagnosis, see Section 14.

Similar to the other spondyloarthropathies the arthritis is mostly asymmetric and predominantly affects the lower limbs. The arthritis is migratory, often transient, but tends to recur. It does not frequently become chronic but may be associated with erosive disease in some patients. Flaring of gut symptoms is often associated with arthritis, especially in ulcerative colitis. In Crohn's disease, patients experience significantly fewer joint symptoms after colectomy.

Two types of arthropathy were distinguished in a recent study of almost 1500 patients with inflammatory bowel disease, essentially on the basis of the number of joints involved and importantly without knowledge of spinal radiographs. Pauciarticular disease (type I, fewer than five joints involved) affected 3.6 per cent of patients with ulcerative colitis and 6 per cent of those with Crohn's disease and was acute and self-limiting, with episodes lasting 4 to 5 weeks, in 83 and 79 per cent of the cases. Polyarticular disease (type II, five or more joints) affected 2.5 per cent of patients with ulcerative colitis and 4 per cent of those with Crohn's disease and was associated with persistent symptoms in 87 and 89 per cent of the cases.

The onset of peripheral arthritis is associated with exacerbations of colitis, but there is no link between enteric and spinal symptoms. Acute anterior uveitis occurs in 10 per cent of patients with inflammatory bowel disease. It is associated with axial involvement and with HLA B27. Compared with other spondyloarthropathies, the type of uveitis is somewhat different in inflammatory bowel diseases: posterior uveitis and scleritis may occur. The most common skin lesion in arthritis associated with inflammatory bowel disease is erythema nodosum, occurring in association with exacerbation of enteritis.

Diagnosis

Most arthritic symptoms occurring in patients with inflammatory bowel disease can generally be attributed to spondyloarthropathies. However, as in psoriasis, patients can have more than one disease (osteoarthritis, etc.). As many as 50 to 60 per cent of all patients with ankylosing spondylitis have gut lesions resembling those in Crohn's disease, but the majority are asymptomatic. Clinically apparent ankylosing spondylitis often precedes Crohn-like symptoms. This spectrum of diseases clearly and typically belongs to the spectrum of spondyloarthropathies. The differentiation (if needed) will rarely cause problems since one disease is usually predominant. Along with psoriasis, inflammatory bowel disease should always be looked for in HLA B27-negative patients who appear to have ankylosing spondylitis.

Treatment

Treatment of inflammatory bowel diseases is always the first consideration and will probably influence the peripheral arthritis. Treatment with NSAIDs may be effective for arthritis and spondylitis but can exacerbate the bowel disease. There are few data on the use of disease-modifying antirheumatic drugs. Sulphasalazine is effective in ulcerative colitis and other spondyloarthropathies and may, accordingly, be used in arthritis associated with inflammatory bowel disease. Azathioprine is effective in Crohn's disease and can be tried to treat severe and chronic joint disease. Corticosteroids are the therapy of choice in acute inflammatory bowel disease and will generally help arthritis, but they should not be used for mild and transient joint symptoms.

Prognosis

Patients with inflammatory bowel disease have increased mortality due to peritonitis and sepsis. By contrast, the prognosis of arthritis associated with inflammatory bowel disease is generally good. Joint destruction is a rare event. Patients may have ankylosing spondylitis at presentation of inflammatory bowel disease, or develop this later.

SAPHO syndrome

Definition

The acronym SAPHO stands for **S**ynovitis, **A**cne, **P**ustolosis palmaris et plantaris, **H**yperostosis, and **O**steitis. French workers proposed SAPHO as a unifying diagnosis for several idiopathic bone and skin diseases, thereby combining over 50 different terms published in the literature (including pustulotic arthro-osteitis, chronic multifocal osteomyelitis, Tietze syndrome (German), and acquired hyperostosis syndrome). Their description of the common symptoms and overlapping features of this heterogenous group of rheumatic joint, bone, and skin diseases has led to better recognition of the relatively rare condition.

There is an argument that SAPHO simply represents a subset of psoriatic arthropathy; also that it might not really belong to the spondyloarthropathies at all. Only 43 per cent of patients with SAPHO fulfilled the European Spondylarthropathy Study Group criteria for spondyloarthropathies, and only 1 in 19 was HLA B27-positive in one follow-up study.

Pathogenesis

The pathogenesis is unclear. Some authors think that it is similar to that of reactive arthritis. *Propionibacterium acnes*, which can induce arthritis in animals, has been detected in acne lesions and grown from osteitic lesions in some cases. However, cultures are negative in the vast majority of cases, and antibiotics are ineffective.

Diagnosis

There are no evaluated diagnostic criteria for SAPHO. Most convincing clinically is the combination of a classical skin symptom—such as pustolosis or significant acne (acne conglobata and acne fulminans or hidradenitis suppurativa)—with a characteristic joint or bone lesion such as arthritis of the sternoclavicular joint, osteitis, or hyperostosis in the anterior chest wall.

Diagnosis is important to avoid unnecessary biopsy procedures, but can be very difficult, especially in those without typical skin lesions. The most important differential diagnoses are bacterial osteomyelitis and malignancy. The pattern of joints affected differs from other rheumatic diseases: the sternoclavicular joint (Fig. 11 and Fig. 12 and Plate 5), the clavicle, the ribs, and the mandible are frequently involved by arthritis, osteitis, and/or hyperostosis. Sacroiliitis, mostly unilateral, occurs in one-third of patients.

Fig. 11 Arthritis/hyperostosis of the left sternoclavicular joint in a 52-year-old man with SAPHO syndrome. (See also Plate 5.)

Fig. 12 Radiograph showing severe osteitis of the left sternoclavicular joint in a 35-year-old woman with SAPHO syndrome.

Treatment

Analgesics, NSAIDs, and intra-articular steroids are usually effective. In severe cases systemic corticosteroids should be considered. Immunosuppressive agents can be added if the steroid dose cannot be tapered to less than 10 mg/day. Sulphasalzine, azathioprine, and methotrexate have been tried successfully in some cases. Radiation therapy can also be effective in refractory cases. No controlled studies have been performed.

Prognosis

The course of disease is very variable. Initially, occurrence of several flares per year is common. Further progress is usually favourable, but complications such as axillary vein and C8 compression can occur. Some patients may develop ankylosis and few progress into ankylosing spondylitis.

Other enteric arthropathies

Whipple's disease

Whipple's disease is a rare systemic disease which usually involves the small intestine (see Chapter 14.9.6). The associated arthritis is often symmetric and polyarticular, and may antedate the intestinal complaints by years. It is not usually destructive. Axial involvement occurs but is not typical.

Arthritis associated with coeliac disease

For a description of coeliac disease (gluten-sensitive enteropathy) see Chapter 14.9.3. The joint manifestations show a striking response to a gluten-free diet, which strongly suggests a causal relationship. The pattern of arthritis is very variable and overt bowel symptoms are absent in half of cases, making diagnosis difficult. The lumbar spine, hips, knees, shoulders, elbows, wrists, and ankles are most frequently affected, often symmetrically. The arthritis is not destructive. HLA B8 and DR3 are frequently found in the patients. The pathogenesis is unclear.

Arthropathies associated with collagenous colitis

Collagenous colitis is a chronic diarrhoeal disease characterized by a normal or near-normal mucosa endoscopically and a thick subepithelial collagen layer. More than half of patients with this disorder have some form of arthritis and use NSAIDs regularly.

Arthropathies associated with intestinal bypass surgery

Arthritis has been reported in 5 to 50 per cent of patients in the first 3 years after jejunoileal bypass surgery. A symmetric peripheral polyarthritis involves the knees, wrists, metacarpophalangeal and metatarsophalangeal joints, elbows, proximal interphalangeal joints, and ankles and is usually non-destructive. Almost half of those affected also have vesicopustular skin lesions. No specific HLA association has been found, but two previosly healthy HLA B27-positive patients developed spondylitis. Bacterial overgrowth of the blind loop is critical for pathogenesis.

18.7.1 Pyogenic arthritis

Anthony R. Berendt

Introduction

Pyogenic arthritis, which may be acute or chronic, describes infection and resulting inflammation in a joint, native or prosthetic. It should not be confused with postinfectious (reactive) arthritis (discussed in Section 18.8). As with other musculoskeletal infections, failings in diagnosis or management may have long-term functional consequences, and clinicians should therefore know when to consider the diagnosis and obtain expert help.

Aetiology

Acute pyogenic arthritis may be primary (by haematogenous spread), or secondary (to trauma, surgery, or arthrocentesis). Organisms that cause primary septic arthritis are usually aggressive pathogens capable of causing a bacteraemia, seeding the joint, and multiplying within it, hence they are also common causes of septicaemia, with *Staphylococcus aureus* dominating in most circumstances. The causes of secondary and chronic septic arthritis are more diverse because they include skin and environmental flora, together with lower-grade pathogens, as well as all the causes of acute infection.

Table 1 in Chapter 19.2 shows the common pathogens involved in both pyogenic arthritis and osteomyelitis.

Epidemiology

The incidence of pyogenic arthritis has been estimated at 7 in 100 000: this is highest in children and the elderly, and more common in males. The increased incidence in the elderly probably reflects a higher prevalence of potential sources of bacteraemia such as urinary tract infection, skin ulceration, pneumonia, and hospitalization with intravenous and/or urinary catheterization. Infection complicates some 0.5 to 2 per cent of total joint replacements, but the true prevalence of prosthetic joint infection is unknown.

Pathogenesis and pathophysiology

In primary septic arthritis, organisms must exit the bloodstream and access the joint. In the case of *S. aureus*, invasion of endothelial cells can occur through interactions between bacterial fibronectin-binding proteins and cell surface-associated fibronectin. This triggers integrin-dependent uptake of bacteria and may be a key first step in bacteraemic seeding.

S. aureus releases a number of toxins and proteases thought to affect host defences. It also expresses numerous cell wall-associated adhesins that mediate attachment to the matrix proteins associated with cell surfaces, cartilage, and bone. Animal models demonstrate that T-cell dependent inflammation plays a central role in damage to articular cartilage following an acute inflammatory response. In these models immunomodulation (for example with corticosteroids) can substantially reduce arthritis, but at the expense of host survival if antibiotic therapy is not also given. Thus the host response appears to reduce the risk of bacteraemia and death, but at the cost of joint damage. If not fatal through septicaemia, untreated septic arthritis generally causes joint destruction or fusion, sometimes with sinus formation and persistent infection (see Fig. 1(a) and (b)).

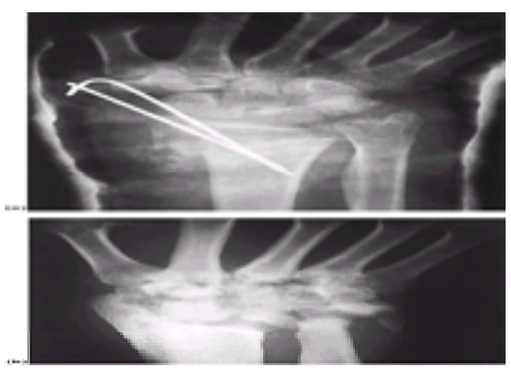

Fig. 1 (a) A Colles fracture fixed with percutaneous K wires. (b) A few months later, after *S. aureus* infection associated with the K wires has led to septic arthritis in the wrist, the wrist joint is completely destroyed.

In a prosthetic joint, the presence of foreign material impairs local antibacterial defences. Bacteria adhere to plastic or metal (in some cases via fibronectin) and in this state become relatively resistant to the action of antibiotics and to phagocytosis. Ineffective but chronic inflammation causes pain and triggers bone loss, with subsequent mechanical loosening.

Clinical features

Patients typically present with fever and an acutely painful joint. The joints involving the long bones are most commonly affected (knee, hip, shoulder, elbow, wrist, and ankle). There may be bacteraemia (in some series up to 70 per cent), giving prostration, vomiting, or hypotension. Infants localize pain poorly and commonly present refusing to use the affected limb. Adults may be unable to localize pain if a sternoclavicular, acromioclavicular, sternocostal, or manubriosternal joint is involved. Infections in these locations often present as chest wall pain. Sacroiliac joint infection presents as buttock or low back pain and may mimic hip or spine pathology.

Clinical examination reveals a joint that is swollen, warm to the touch, tender on palpation, and painful, frequently exquisitely so, on active or passive movement. To minimize pain, the patient will often nurse the joint in a neutral position. A joint effusion is usually present and this may be accompanied by synovitis, depending on the duration of the history. Erythema, not usually prominent, may signal the presence of bursitis.

Septic arthritis must be distinguished from other acute monoarthropathies, notably gout, pyrophosphate arthropathy, and haemarthrosis. Rheumatoid and reactive arthritis can initially present with involvement of only a single joint. Infection is most commonly monoarticular, but multiple joints can be involved. In the patient with

known inflammatory arthritis, polyarticular infection may be mistaken for a flare in the underlying disease.

Prosthetic joint infection may present as an acute wound infection, a periarticular abscess, an acute arthritis or with loosening of the implant (as pain). The differential is from superficial wound infection, haemarthrosis, periprosthetic fracture or dislocation, and aseptic loosening. A sinus discharging in or near the operative scar represents infection of the prosthesis until proved otherwise.

Pathology

The synovial fluid contains polymorphs and the synovium shows an acute inflammatory response with a fibrinous exudate on its surface, which may be ulcerated. A chronic synovitis may develop, with a lymphocytic and mononuclear infiltrate. Late changes include chondrolysis and the development of subarticular osteomyelitis. Tissue from infected prosthetic joints shows a polymorph infiltrate accompanied by chronic inflammatory changes representing a reaction to foreign materials.

Laboratory diagnosis

The criterion for diagnosis of pyogenic arthritis is the isolation of a recognized pathogen from samples of synovium or synovial fluid obtained through biopsy or aspiration. Infected synovial fluid is generally turbid or purulent. It should be sent for Gram stain, semiquantitative or quantitative white cell count, examination under polarized light for pyrophosphate or uric acid crystals, and culture. If tuberculosis, brucellosis, or fungi are suspected, the laboratory should be advised so that the sample can be appropriately processed. For suspected *Neisseria gonorrhoeae*, urethral, endocervical, throat, and rectal swabs should also be obtained for microscopy and culture.

Blood cultures should always be obtained. The white cell count, C-reactive protein, and erythrocyte sedimentation rate are usually raised, but can also be elevated during flares of inflammatory arthritis or acute crystal arthropathy. Their value is probably greatest in following the response to treatment. Measurement of serum uric acid may be elevated in gout, but cannot be used to establish or refute this diagnosis. Serological tests may be of retrospective value in diagnosing *Borrelia burgdorferi* (Lyme disease) and *Brucella* spp. Detection of bacterial nucleic acid in joints remains a research technique.

Plain radiographs can show fracture, effusion, chondrocalcinosis, bone destruction, or loss of joint space. An effusion may be seen acutely, but bony changes appear slowly. If seen at presentation they either indicate chronic infection or represent underlying arthritis. A radiograph at presentation provides a useful baseline for subsequent comparisons. The role of CT scan or magnetic resonance imaging is to demonstrate or exclude surgical disease in the joint or neighbouring bone (Fig. 2). Ultrasound scanning may assist in this and in distinguishing between effusion and synovitis, allowing diagnostic samples to be obtained more reliably.

Fig. 2 Marked synovitis, but no osteomyelitis, in a 10-year-old with group A streptococcal infection of the knee.

Treatment

Acute septic arthritis poses a threat to the joint and is an orthopaedic or rheumatological emergency. Treatment should generally be in an inpatient hospital setting. Patients with suspected chronic septic arthritis may initially be managed as outpatients, but most eventually require surgical intervention.

After obtaining blood cultures and (when possible) synovial fluid, acute pyogenic arthritis should be treated promptly with intravenous antibiotics active against aerobic Gram-positive cocci and Gram-negative organisms. Appropriate regimens would be cefuroxime (or another antistaphylococcal cephalosporin) or a high-dose semisynthetic antistaphylococcal penicillin (flucloxacillin, dicloxacillin, or nafcillin), with or without an aminoglycoside. Patients allergic to b-lactams, or with risk factors for methicillin-resistant *S. aureus*, should receive vancomycin, usually with an aminoglycoside, until culture results are obtained. Treatment can then be modified.

Urgent consultation with an orthopaedic surgeon is advised. Arthroscopic washout has largely replaced arthrotomy, reducing morbidity. Surgery can sometimes be avoided altogether by aspiration once or twice daily until clinical response is evident, but may still be needed if there is clinical deterioration or failure to settle within 5 days. This type of treatment can be applied to children or adults, particularly when anaesthesia is thought to carry high risks. Whether delaying surgery in this way gives worse outcomes than immediate washout is unknown, but there is consensus on the need for prompt surgery on the hip and shoulder joints. The reflection of the capsular vessels up the necks of the humerus and femur makes them vulnerable to thrombosis and subsequent avascular necrosis of the femoral or humeral head. If this occurs, joint destruction, with or without chronic infection of the dead bone, is inevitable.

The optimal duration and mode of administration of antibiotics is unknown. In uncomplicated infection 2 to 3 weeks is adequate, depending on the pathogen (shorter for streptococci, longer for *S. aureus* and aerobic Gram-negative rods). In children it is possible to convert to oral therapy within 48 to 72 h of defervescence, provided that there has been a rapid clinical response. This strategy requires the organism to be sensitive to a reliably bioavailable oral antibiotic, the parents or carers to understand clearly the importance of adhering to the antibiotic regimen, and the clinician to monitor clinical progress carefully. Some authorities treat adults with an oral regimen provided that similar criteria are met, but intravenous antibiotics may be preferred when there has been accompanying bacteraemia or where there are concerns about bony involvement, absorption of antibiotic, or adherence. Many patients are suitable for intravenous therapy at home, provided this is properly organized and supervised.

Chronic septic arthritis has generally led to joint destruction by the time the patient presents. Surgical debridement, arthrodesis, or joint replacement may be necessary, the latter after a considerable interval free of infection. Surgery is commonly required in prosthetic joint infection, although such problems can occasionally be treated successfully with retention of the implant. Antibiotic treatment is usually prolonged in chronic or prosthetic joint infection.

Prognosis

If diagnosed and treated promptly, the prognosis of acute native joint infection is good, with many patients making a complete recovery. Some joint damage is likely when the diagnosis is made late. Infection in young children may lead to disturbance of the growth plate around the infected joint, causing deformity. Mortality is low in uncomplicated septic arthritis, higher when it is complicated by *S. aureus* bacteraemia (up to 20 per cent) and highest in multijoint disease (50 per cent). Recurrence is uncommon and generally indicates a persisting surgical focus in relation to the joint.

Outcomes are less favourable in prosthetic joints, which can be salvaged in 30 to 70 per cent of cases where the prosthesis is retained. Infection can be eradicated in up to 90 per cent of cases with revision surgery, but with very much poorer results when revision surgery for infection is itself complicated by further infection. This and the need for expert surgical and microbiological input, as well as the considerable comorbidity such patients often have, makes the management of infected prosthetic joints a formidable challenge.

Prevention and control

There are no proven means of preventing primary pyogenic arthritis. Secondary cases can be prevented by meticulous attention to infection control measures whenever a joint is aspirated or operated on, and by thorough cleaning and debridement when a joint is contaminated through trauma.

Occupational, quality of life, and psychosocial aspects

The pain of acute pyogenic arthritis generally resolves within the first 1 to 2 weeks of successful treatment, but stiffness and swelling usually persist for very much longer. Chronic infections have significant effects on quality of life through pain and poor function. This is most prolonged and severe in prosthetic joint infection.

Areas of uncertainty needing further research

Further understanding of pathogenesis could potentially offer new targets for therapy or prevention, while diagnostic sensitivity could be improved by robust, well-evaluated molecular methods. Numerous aspects of treatment, including the role of surgery and the duration and route of administration of antibiotics, await clarification in prospective studies, both for native and prosthetic joint infections.

18.7.2 Reactive arthritis

J. S. H. Gaston

Introduction and historical perspective

The term 'reactive arthritis' was introduced in 1969 by Aho in Finland, where the combination of a high prevalence of HLA B27 and gastrointestinal infection by *Yersinia* afforded opportunities for studying the disease. However, the condition was first recognized in the eighteenth and nineteenth centuries as an arthritis which followed dysentery or venereal disease, and there were descriptions by Hans Reiter and other contemporaries of the disease amongst troops affected by dysentery in the trenches of the First World War. The term 'Reiter's disease' has been used extensively since that time, but is now less favoured for several reasons: Reiter was not the first to describe the disease; he erroneously attributed it to spirochaetal infection; and the triad which makes up Reiter's disease—arthritis, conjunctivitis, and urethritis/cervicitis— is not a clinically meaningful subgroup within reactive arthritis.

Definition

The term reactive arthritis is sometimes used rather loosely to cover any form of arthritis which follows infection, and would then include postviral arthritides, rheumatic fever, Lyme disease, and other forms of arthritis which do not generally have clinical features in common. This usage is not helpful and the term 'postinfectious arthritis' is to be preferred, with this all-embracing term then subdivided into different clinical syndromes, one of which is reactive arthritis (Table 1). Viewed in this way, reactive arthritis is seen as one of the seronegative spondyloarthropathies (ankylosing spondylitis, psoriatic arthritis, arthritis associated with inflammatory bowel disease), sharing clinical and immunogenetic features with those diseases. Other postinfectious arthropathies lack these common features.

In the absence of agreed and validated diagnostic or classification criteria for reactive arthritis, Table 2 presents a useful working classification of those patients who could reasonably be considered to have reactive arthritis. This takes as its starting point the classical pattern of arthritis and typical extra-articular features (Table 3) which are commonly seen after infection by five organisms—*Salmonella*, *Yersinia*, *Campylobacter*, *Shigella flexneri*, and *Chlamydia trachomatis*. The same clinical syndrome (i.e. arthritis and extra-articular signs) is also seen, but more rarely, following many infections, especially of the gastrointestinal tract, for example by *Clostridium difficile*, but genitourinary infections with *Ureaplasma* and respiratory infection with *Chlamydia pneumoniae* can probably also act as triggers of reactive arthritis. The other large group of patients are those who have asymmetric oligoarthritis without extra-articular features, but with definite laboratory evidence of preceding infection by one of the five major reactive arthritis-associated bacteria. Laboratory diagnosis of infection is given priority over symptoms as a classification criterion because infection may be clinically silent. *Chlamydia* is notorious for this, particularly in women, whilst in *Yersinia* infection, arthritis is inversely correlated with the severity of gastrointestinal symptoms. Positively identifying the triggering infection often poses practical problems. Patients in whom arthritis (with or without extra-articular signs) develops after symptomatic episodes of gastrointestinal or genitourinary infection are therefore usually regarded as having reactive arthritis, even when no triggering organism can be identified, although the diagnosis is inevitably less secure in these cases. Improvement in methods for diagnosing preceding infection should decrease the size of this group, and may well show reactive arthritis to be the commonest cause of inflammatory oligo- or monoarthritis in young adults.

Epidemiology

This has been best studied in outbreaks of food poisoning where the proportion of infected patients developing arthritis can be accurately assessed. However, in such studies the proportion going on to develop reactive arthritis varies widely (0–21 per cent). The incidence of clinically significant arthritis is generally low in community surveys of infected patients and high in patients whose infection is severe enough to require hospital referral, but careful population studies of *Campylobacter* infection have shown a high incidence (7–16 per cent) of musculoskeletal symptoms not severe enough to need rheumatological attention. As in other forms of spondyloarthropathy, the influence of HLA B27 on incidence is important: 60 to 80 per cent of patients with reactive arthritis presenting to rheumatology clinics will be B27 positive, but amongst those with mild disease the figure drops to 30 per cent, compared with the population prevalence of 7 to 10 per cent. Thus B27 is associated mainly with the severity and persistence of arthritis, rather than its incidence.

Pathogenesis

There is mounting evidence that, following infection of the gut or genitourinary tract, organisms reach the joints. They may arrive intact, when they can be detected by using the polymerase chain reaction, or as antigenic material (proteins, lipopolysaccharide) which can be demonstrated by immunofluorescence and immunoblotting techniques in synovial macrophages and polymorphs. This process can continue for months or even years, suggesting that some of the infections, for example *Yersinia*, persist as continuing sources of antigens/organisms. Elevated and persistent titres of IgA antibody to these organisms in reactive arthritis compared with uncomplicated infection also favour the idea of persistence. These findings emphasize that the distinction between septic and postinfectious arthritis has become blurred, since viable organisms can be detected in the joint in various forms of postinfectious arthritis, including Lyme disease and reactive arthritis, although they may be difficult or impossible to culture from synovial fluid or synovium.

Within the joint, cellular immune responses to the bacteria responsible for triggering the reactive arthritis are readily detected, particularly by CD4+ helper T lymphocytes, but also CD8+ T cells. Interestingly, although the association with HLA B27 is often taken to imply that CD8+ T cells are the principal effector cells in the disease, observations on reactive arthritis in HIV-positive patients show that they present with arthritis at stage I infection, when numbers of CD4+ T cells are less depressed. By contrast, arthritis can be relatively quiescent in full-blown AIDS. Both CD4+ and CD8+ lymphocytes produce proinflammatory cytokines such as interferon-g which could potentially drive joint inflammation by secondary effects on synoviocytes.

There are several hypotheses about how HLA B27 could influence the course of reactive arthritis, particularly its severity and persistence. For instance, infection may generate a B27-restricted response by CD8+ T cells to a bacterial peptide which crossreacts with a component of the joint, i.e. infection triggers autoimmunity by 'molecular mimicry'. No such autoimmune response has yet been demonstrated. Alternatively, B27 may adversely affect the efficiency with which the immune system clears the triggering organism. In this case disease does not require autoimmunity, but is primarily driven by persistent bacterial antigens. Lastly, B27 might affect the immune response to the triggering organism qualitatively, for example by allowing hyper-responsiveness to particular antigens, or biasing the immune response in favour of the production of proinflammatory cytokines.

Clinical features

Preceding illness

A history of urethritis (dysuria or discharge) and diarrhoea must be sought specifically, there being no reason for patients to automatically link these occurrences with their arthritis. The interval between infection and arthritis is variable but is not usually more than 3 weeks. However, by the time a rheumatologist is consulted, many weeks may have passed and the triggering illness be forgotten, particularly if symptoms were mild. Note that urethritis may be triggered by gastrointestinal infection: if this possibility is forgotten minimally symptomatic gastrointestinal infection and prominent urethritis may cause diagnostic confusion.

Arthritis

The clinical picture in reactive arthritis is usually an asymmetric oligoarthritis (generally fewer than six joints), predominantly affecting the lower limbs (Table 4). However, any joint can be affected, and a proportion of patients have monoarthritis only. Affected joints are often hot and markedly swollen, with septic arthritis and crystal-induced arthritis being the most likely differential diagnoses. Dactylitis, similar to that seen in psoriatic arthritis, also occurs. Many patients complain of low back or buttock pain, suggesting involvement of the sacroiliac joint. Arthritis is usually at its worst early in the course of the disease, but new sites can be affected after several months and relapses are not uncommon, even in those in whom disease eventually settles completely. The presence of enthesitis (inflammation of ligamentous and tendinous insertions) in addition to arthritis is helpful diagnostically, with plantar fasciitis and involvement of the Achilles tendon insertion the commonest sites.

Extra-articular features

In acute severe disease patients have constitutional symptoms of malaise, fatigue, and fever. More useful diagnostically are the specific extra-articular signs listed in Table 3 and illustrated in Fig. 1, Fig. 2, and Fig. 3. The fact that these extra-articular features are common to other forms of spondyloarthropathy greatly strengthens the case for including reactive arthritis in this disease family, and for delineating reactive arthritis as a distinct syndrome within the postinfectious arthritides. Extra-articular features are more common in those with severe joint involvement. Conjunctivitis is often transient and no longer present by the time the patient presents. More persistent eye inflammation or painful eyes should raise the question of an acute anterior uveitis rather than a simple conjunctivitis and prompt full ophthalmological assessment. Circinate balanitis is usually asymptomatic and needs to be looked for specifically in uncircumcized males. Oral ulceration is usually asymptomatic. Keratoderma blennorrhagica is histologically identical to psoriasis; it is most commonly seen on the soles of the feet, but can also involve the hands or trunk. Erythema nodosum is associated with *Yersinia* infection, but is otherwise uncommon in reactive arthritis. Aortitis and cardiac conduction disorders have been described but are rare.

Fig. 2 Circinate balanitis in reactive arthritis. (By courtesy of Dr C. J. Eastmond.)

Fig. 3 Keratoderma blennorrhagica in reactive arthritis. (By courtesy of Dr C. J. Eastmond.)

Differential diagnosis

The differential diagnosis of reactive arthritis is summarized in Table 5. The principal concerns in acute disease are septic arthritis, crystal arthropathies, and other forms of postinfectious arthritis such as Lyme disease, poststreptococcal arthritis, or gonococcal arthritis. In chronic disease it may be difficult to distinguish reactive arthritis from other forms of spondyloarthropathy, especially in those with inflammatory bowel disease, and many patients in whom no infectious trigger can be implicated are classified as having an 'undifferentiated' spondyloarthropathy.

Laboratory features

General

The principal aims of investigation are to exclude important differential diagnoses and to identify the triggering organism. Abnormalities in the early stages when

arthritis is most active are those of a pronounced acute inflammatory response with elevation of erythrocyte sedimentation rate and C-reactive protein, the latter often very marked (more than 100 mg/litre). Rheumatoid factor and antinuclear antibodies are absent. Positive antineutrophil antiplasmic antibodies have been described, but the antibodies are not directed against proteinase-3 or myeloperoxidase and the test is not useful diagnostically. Septic arthritis and crystal arthropathies are best excluded by aspiration of synovial fluid followed by culture and microscopy. Blood cultures should be performed and serum urate checked. A chest radiograph may reveal hilar lymphadenopathy, suggesting the diagnosis of sarcoidosis, although *Yersinia* can cause both reactive arthritis and a sarcoid-like illness. Throat swab and antibodies to streptococcal antigens may produce evidence of poststreptoccocal arthritis, which does not generally share extra-articular features with reactive arthritis.

Microbiological

Stool should be cultured for pathogens associated with reactive arthritis, although cultures are often negative after gastrointestinal symptoms have settled—despite the recent evidence that persistent infection contributes to pathogenesis. *Chlamydia* infection must be sought in sexually active patients, particularly when there is no clear history of gastroenteritis. Formal referral to a department of genitourinary medicine is often helpful. Patients are not infrequently infected with both *Chlamydia* and *Gonococcus*. This can cause confusion, but gonococcal arthritis differs from reactive arthritis with its characteristic rash and absence of the classical extra-articular features. *Chlamydia* can be cultured from urethral or cervical swabs or from urine, and *Chlamydia* antigens can be demonstrated by enzyme-linked immunosorbent assay techniques or by direct immunofluorescence tests. The latter are highly sensitive, in principle able to detect one organism per smear, but they require highly skilled technicians. Polymerase chain reaction techniques achieve similar sensitivity, and can be used on urine specimens, addressing the natural reluctance of many patients with reactive arthritis (or other conditions) to undergo routine urethral and vaginal instrumentation.

The possibility of spondyloarthropathy in the context of HIV infection also needs to be considered, although this appears rare in developed countries. By contrast, large numbers of reactive arthritis cases, often related to dysentery, have recently emerged amongst the HIV-infected population in Africa, where the disease was previously unknown.. Nevertheless, HIV testing should be considered, particularly in patients with unusually severe disease and with relevant risk factors.

Immunological

When the triggering organism cannot be demonstrated directly, infection can be inferred on the basis of immune responses. However, this evidence needs to be interpreted cautiously, since in many cases the findings simply imply immunological memory for the organism in question and do not demonstrate a clear relationship between infection and arthritis. For enteric pathogens, specific IgM antibodies may be demonstrated and these, along with IgG, form the basis of the agglutination tests which are widely used. Rising IgG titres may also be helpful. However, when patients present several months into their illness, IgM may no longer be evident and IgG titres stable. In these circumstances high and persistent IgA titres to organisms such as *Salmonella* and *Yersinia* may be helpful. The possibility of using antibody responses to particular bacterial antigens diagnostically is currently under investigation. Serological diagnosis of *Chlamydia* infection is particularly difficult because of high levels of infection with *Chlamydia pneumoniae* in the community, an organism which shares several highly conserved antigens with *Chlamydia trachomatis*.

Lastly, cellular immune responses to triggering organisms can be demonstrated, particularly in the synovial fluid. Again, these only demonstrate T-cell memory for the organism and do not demonstrate causality—patients with, for instance, rheumatoid arthritis and incidental *Salmonella* infection, will have *Salmonella*-specific T cells in their synovial fluid. Currently such tests are used in research rather than diagnostically.

Radiology

In the acute stages of disease, radiology is not diagnostically helpful, with soft tissue swelling and occasionally periarticular osteoporosis at affected joints being the only abnormalities. Radionuclide scintigraphy can be useful for demonstrating acute sacroiliitis and may show the full extent of acute synovitis and enthesitis, but is not usually required for clinical management. Radiological changes are confined to the minority of patients with persistent disease (more than 1 year's duration). The principal features are erosion of affected joints, including the sacroiliac, and new bone formation manifested as periostitis of metatarsal and metacarpal bones and 'enthesophytes', such as plantar spurs. In the spine paravertebral ossification can be seen in the lumbar region: this is asymmetric and differs from the classical changes of ankylosing spondylitis. Erosive changes are also seen at sites of enthesitis such as the calaneum.

Treatment

Evidence-based therapies for reactive arthritis are lacking, so that consensus opinion is the current guide. In the acute phase affected joints should be rested until they improve substantially. This often requires emphasizing to young, active patients involved in sports, and alternative forms of exercise should be considered. Synovial effusions should be aspirated and when septic arthritis has been excluded will respond well to injection with long-acting corticosteroids. If *Chlamydia* infection is established or thought likely, patients require conventional treatment with short-term antibiotics, but there is no evidence that this has any effect on the progress of reactive arthritis. Enteric infections do not require antibiotics in their own right. Uveitis requires formal ophthalmological assessment and treatment with local steroids. Physiotherapy and advice on exercise is helpful, with quadriceps function needing particular attention in view of the frequent involvement of the knees.

There are two major unresolved treatment issues in reactive arthritis. Firstly, the place of disease-modifying drugs. Sulphasalazine and methotrexate are useful in spondyloarthropathies generally, and on this basis have been used in reactive arthritis, but without controlled trials confined to this condition alone. The frequency with which the disorder is self-limiting makes controlled trials of second-line agents difficult. The second issue is whether long-term antibiotics confer any benefit. In a controlled trial, a subset of patients with evidence of *Chlamydia* infection benefited from prolonged tetracycline, but subsequent trials using ciprofloxacin, mainly in *Yersinia*-associated reactive arthritis, have been negative. Nevertheless, since persistent infection is implicated in our current understanding of pathogenesis, further work on antibiotics is being undertaken, particularly of agents which might be able to treat quiescent or slow-growing bacteria which are refractory to agents that target bacterial cell division.

Psychological and quality of life issues

Reactive arthritis commonly affects young, fit adults who have not previously experienced any form of prolonged illness or disability. The danger is that the rheumatologist, all too used to the gloomy prognosis of rheumatoid arthritis, may treat reactive arthritis, where there is a high likelihood of complete resolution of disease, too lightly. Patients need to be given a realistic prognosis, i.e. that symptoms are likely to persist at some level for 6 to 12 months, although in the latter stages these are usually very mild compared with those experienced in the first 4 to 8 weeks. Exacerbations during this time are not uncommon and do not imply that the disease will not eventually resolve. The chances of the patient developing chronic arthritis are less than 10 per cent. Patients benefit from continuing psychological and clinical support throughout the course of their illness, with rapid access to joint aspiration and intra-articular steroid injection when there is recurrent joint swelling.

Current areas of uncertainty

Current uncertainties concern classification criteria and management strategies. Both may be resolved by developing more secure diagnostic techniques for identifying the triggering infection. Improved treatment is likely to come from either additional evidence about the importance of persistent infection and how to eliminate it, or from discovery of the immune responses responsible for maintaining joint inflammation, whether these are directed against a bacterial antigen or an autoantigen. If a target antigen can be identified, specific immunomodulation strategies will then be relevant.

Reactive arthritis differs from other forms of human inflammatory arthritis in having a clearly defined onset and being triggered by known infectious agents. Genetic influences that result in a minority of infected individuals developing arthritis are being investigated. These include HLA B27, but it is likely that other genes are also involved. Genome screening now being applied to ankylosing spondylitis may throw up likely candidates.

18.8 Osteoarthritis

Paul H. Brion and Kenneth C. Kalunian

Introduction

Osteoarthritis is the commonest form of arthritis, detectable radiographically in 80 per cent of patients over the age of 55. Symptomatic osteoarthritis of the knee (pain with radiographic abnormalities) was noted in 6.1 per cent of adults aged 30 and over in the Framingham Study, and the frequency is comparable in the United Kingdom. Approximately 20.7 million people in the United States have physician-diagnosed osteoarthritis. Whilst some may be asymptomatic, many have significant pain and disability, with one study finding that osteoarthritis accounts for 12.3 per cent of all those with limitation of activity. The prevalence of osteoarthritis is likely to increase, paralleling the increase in the absolute and relative number of people who are over 65 years of age. The social impact of this disease is enormous, accounting for more dependency in walking and stair climbing than any other disease. The estimated annual cost associated with osteoarthritis in the United States is $15.5 billion in 1994 dollars, which approaches 1 per cent of the gross national product, with more than 50 per cent of the costs due to work loss.

Definition

Osteoarthritis was described by Solomon as

> A chronic disorder characterized by softening and disintegration of articular cartilage, with reactive phenomena such as vascular congestion and osteoblastic activity in the subarticular bone, new growth of cartilage and bone (osteophytes) at the joint margins, and capsular fibrosis. Osteoarthritis is not accompanied by any systemic illness, and although there are sometimes signs of inflammation, it is not primarily an inflammatory disorder.

Alternative definitions exist, including those based on symptoms, physical findings, and radiographic and arthroscopic findings. The presence of joint symptoms plus evidence of structural change generally defines clinical osteoarthritis, whereas many studies use radiographic assessment alone as the primary means of identifying the condition. Most clinical investigators use the Kellgren and Lawrence scale for grading osteoarthritis of the knee, which defines osteoarthritis on the basis of osteophytes, the presence of which relates well with the presence of knee symptoms. The American College of Rheumatology has developed classification criteria for the presence of osteoarthritis based on the joint involved (Table 1, Table 2, and Table 3): these are based on clinical criteria alone, clinical and laboratory criteria, and clinical plus radiographic criteria. Initially, only the clinical and radiographic criteria were validated; more recently, Klashman and colleagues have validated the other methods. However, the clinical and radiographic criteria have the best specificity (86 per cent) compared with the clinical and laboratory criteria (75 per cent) and clinical criteria alone (69 per cent). Kawasaki and colleagues have shown that the non-radiographic criteria have adequate interobserver reproducibility for outpatients complaining of knee pain with a wide spectrum of rheumatic diseases; however, sensitivity and specificity are lower than those reported by Klashman and colleagues.

Risk factors and epidemiology

A multitude of risk factors exist for the development of osteoarthritis of the knee. These include being female, increasing age, obesity, family history, increased bone density, trauma, and certain occupational exposures (Table 4).

Age is considered the strongest associated risk factor for the development of osteoarthritis in many studies. The National Health and Nutrition Examination Survey found a prevalence of osteoarthritis of only 0.1 per cent in people aged 25 to 34 years, compared with over 80 per cent in those aged 55 to 64 years. This increased incidence occurs in osteoarthritis of the hands, back, hip, and knees.

Gender differences in osteoarthritis are complicated. There is an overall higher prevalence in women, in whom the disease more often involves multiple joints. However, before the age of 50 years there is a higher prevalence and incidence in men, whereas after 50 years the reverse applies, with increasing female predominance as age increases. There is a plateau or decline in both genders by the age of 80 years. The gender- and age-related differences in prevalence parallel the effect of postmenopausal oestrogen deficiency in increasing the risk of osteoarthritis. Other probable factors that help explain the increase in the incidence and prevalence of osteoarthritis with age include a decreased responsiveness of chondrocytes to growth factors that stimulate repair, an increase in the laxity of ligamentous structures, and a decrease in proprioceptive responses.

Although racial differences in osteoarthritis of the hip are conflicting, the higher relative weight of African-American women may predispose them to higher rates of osteoarthritis of the knee. There are few data available for other racial differences in osteoarthritis of the knee among the population of the United States. Several studies have confirmed that inheritance is a risk factor for osteoarthritis: individuals are at higher risk of developing the condition if their parents had it, especially if the parental disease was polyarticular or had its onset in middle age or earlier. The role of inheritance may be more important among women than men. Numerous extended families with high rates of early onset severe osteoarthritis have been characterized in which the condition has been linked to an autosomal dominant mutation in type 11 procollagen. Although the majority of cases of osteoarthritis of the hand are inherited, the percentage for osteoarthritis of the knee is smaller, perhaps because osteoarthritis of the knee often develops more as a result of repeated mechanical insults.

The incidence of osteoarthritis is lower in the setting of osteoporosis: bone density in osteoarthritis patients is greater than in age-matched controls, even at sites distant from the affected joints. Most studies linking osteoarthritis with high bone density are cross-sectional. Although osteoarthritis and high bone density are both linked to obesity, the association of osteoarthritis with high bone density is independent of body mass index. It has been suggested that osteophyte formation rather than cartilage loss is linked to high bone density, which suggests the presence of a circulating bone growth factor in those with osteophytes; possibilities include insulin-like growth factor type 1, platelet-derived growth factor, fibroblast growth factor, transforming growth factor-b, and colony-stimulating factor.

Oestrogen deficiency has been implicated as a risk factor for the development of osteoarthritis as evidenced by the high incidence of osteoarthritis after the menopause. Several studies suggest that oestrogen replacement therapy reduces the risk of osteoarthritis of the hip and knee. Both the Study of Osteoporotic Fractures and the Framingham Study have reported a strong inverse relationship between oestrogen replacement therapy and osteoarthritis among those undergoing long-term oestrogen replacement therapy.

Reactive oxygen species have been implicated in the development of osteoarthritis, and antioxidants may prevent or delay the onset of osteoarthritis. In the Framingham Study, those in the lowest tertile of vitamin C intake had a threefold greater risk of progression of osteoarthritis of the knee, joint space loss, and onset of knee pain compared with subjects with a higher intake. However, the effects of b-carotene and vitamin E against disease progression were inconsistent. No effect of serum 25-hydroxy-vitamin D was seen on incident osteoarthritis; however, among subjects with radiographic osteoarthritis at baseline, those who were in the lowest tertile of serum 25-hydroxyvitamin D had a higher rate of radiographic progression compared with those in the highest tertile.

Local biomechanical factors such as trauma or repetitive joint use are risk factors for osteoarthritis. In animal models, a change in biomechanics that occurs after injury leads to increased shear stress on local areas of cartilage, possibly causing osteoarthritis. In humans, traumatic injury to joints is a common cause of osteoarthritis, and Kellgren and Lawrence found that a history of previous trauma could be elicited in approximately 40 per cent of men and approximately 20 per cent of women aged 55 to 64 years with osteoarthritis of the knee. In the Framingham Study, men with a history of major trauma to the knee had a five-fold increased risk

of osteoarthritis of the knee, whilst women with a similar history had a greater than three-fold increased risk. Trauma that causes damage to a cruciate ligament and/or a meniscus has been associated with subsequent development of osteoarthritis of the knee, perhaps through concurrent damage to articular cartilage. With regard to repetitive use, occupations that require kneeling and squatting are associated with a higher prevalence of osteoarthritis of the knee, but heavy physical work is less consistently associated. The level of physical activity increases the risk of developing osteoarthritis. In the Framingham Study, physical activity (generally consisting of walking and gardening in this population) was found to correlate directly with the risk of developing radiographic osteoarthritis of the knee in elderly subjects followed for 8 years. Those with high levels of these activities had a threefold increase in the risk of osteoarthritis compared with sedentary controls. Elite athletes have higher rates of incidence of osteoarthritis of weight-bearing joints compared with controls, probably because athletic activities often involve both increased risk of injury and repetitive use.

Several longitudinal studies suggest that increased weight is a risk factor for the development of osteoarthritis of the knee, and that overweight patients with established osteoarthritis of the knee are at greater risk of developing progressive disease compared with those who are not overweight. The associations between obesity and osteoarthritis of the knee are significantly greater for women than men and are not affected by adjustments for concurrent diseases. Data from the Chingford Study showed that patients in the highest weight tertile had an odds ratio of 6.17 for radiographic osteoarthritis of the knee compared with the lowest weight tertile. For every two-unit increase in body mass index (approximately 5 kg), the odds ratio for radiographic osteoarthritis of the knee increased by 1.36. A follow-up study of incident osteoarthritis of the knee in women with unilateral disease found the tertile with the highest body mass index had a relative risk of 4.69 for developing osteoarthritis in the contralateral knee compared with patients in the lowest body mass index tertile. Similar findings exist for osteoarthritis of the hand and hip, but the association is less robust. The importance of obesity cannot be understated as this may be a modifiable risk factor. A possible mechanism for the effect of obesity on osteoarthritis of the knee is increased force across the weight-bearing joint, which induces cartilage breakdown by altered walking mechanics. However, obesity may also have effects through metabolic intermediaries.

Quadriceps weakness has been associated with radiographic osteoarthritis of the knee. Muscular strength may be required to stabilize the knee, distribute force, or lessen the effect of an impact load, and maintenance of muscular strength may be important in decreasing the incidence of osteoarthritis of the knee and its progression and disability due to established disease. Proprioceptive sensation, which declines with age, is impaired in elderly patients with osteoarthritis of the knee, suggesting that poor proprioception may contribute to functional impairment in these patients.

Pathogenesis and pathological features

The pathogenesis of osteoarthritis remains controversial. Once thought of as a normal consequence of aging, the complex nature of this disease is only now being understood. Current theories suggest that osteoarthritis results from an imbalance in catabolic and anabolic processes that lead to progressive cartilage damage and destruction. Increased catabolism may be the result of acute injuries such as an acute meniscal tear or of chronic microtraumatic events. Initially, anabolic processes such as proteoglycan synthesis maintain balance with catabolic processes and damage to cartilage is repaired. However, with time and age, anabolic processes decline and progressive cartilage damage ensues.

Histological changes in osteoarthritis are complex. Early stages are characterized by increased water content and cartilage swelling. This swollen cartilage is believed to be more susceptible to injury and may lead to fragmentation of the articular surface. Fragmented cartilage is less able to withstand biomechanical insults, resulting in further deterioration. Chondrocytes become activated and proinflammatory cytokines such as interleukin 1 and tumour necrosis factor-a are synthesized. These cytokines increase the synthesis of degradative proteases such as collagenase, gelatinase, and stomelsin. As cartilage destruction progresses, proteoglycan content becomes reduced. Cartilage becomes thinned, fragmented, and proteoglycan depleted.

Reparative processes may initially lead to joint stabilization, but ultimately contribute to progression of the disease. Fibrocartilage may be synthesized in response to loss of the more durable hyaline cartilage. Fibrocartilage may be denuded bone, improving joint mechanics and protecting the subchondral bone. However, fibrocartilage is less able to withstand mechanical loading. The subchondral bone is exposed to increased force relative to that of hyaline cartilage. The synthesis of fibrocartilage, while a temporary improvement, is ultimately less efficient than hyaline cartilage. Subchondral bony changes such as sclerosis and osteophyte formation develop.

The gross pathological findings of osteoarthritis include cartilage loss and reactive bone formation. Cartilage loss occurs primarily in areas of joint loading and may be related to repetitive mechanical insults. Cartilage loss may be best visualized arthroscopially when findings include cartilage softening, fibrillation, and thinning. Areas of complete cartilage loss may be seen. More commonly, the clinician will recognize these findings as radiographic joint space narrowing. Similarly, bony changes may be seen on pathological specimens or arthroscopically. Arthroscopic findings include osteophyte projections and subchondral bone visualized through denuded cartilage. The classic radiographic bony changes include osteophyte formation and subchondral bony sclerosis and cysts.

Clinical features

Precise definition of clinical osteoarthritis has remained elusive since radiographic findings and symptoms may diverge. In addition, osteoarthritis may be categorized by the joint area involved or as being idiopathic or secondary to other disorders. An essential element to diagnosis of osteoarthritis is the correct attribution of symptoms to the affected joint. Initial evaluation of soft tissue abnormalities such as bursitis, tendonitis, and ligamentous strain should be performed. In addition, consideration of neurological or underlying bone abnormalities should be entertained when appropriate.

A thorough history and physical examination should be performed to evaluate for secondary forms of osteoarthritis. These include developmental, mechanical, or biochemical abnormalities known to increase the risk for osteoarthritis. These forms tend to present earlier in life (for example congenital hip abnormality), in atypical joints (for example calcium hydroxyapatite) or as more inflammatory in nature (for example calcium pyrophosphate deposition disease).

Idiopathic osteoarthritis may occur localized to one body area or as a more generalized disease. Common areas of involvement include the hands, hips, knees, and spine. Less commonly, osteoarthritis involves the shoulders, wrists, ankles, feet, and jaw.

Pain is the predominant symptom of osteoarthritis, usually mild to moderate in nature and increasing with joint use and at the end of the day. Pain is generally improved with rest and moderation of activity. Severe disease may cause pain at rest or at night. The source of pain may be the underlying bone, the joint capsule, or surrounding structures. Cartilage is avascular and without nerves and not itself a source of pain.

Stiffness may occur but is generally limited to less than 30 min in duration (gelling phenomenon). It is typical in the morning or after any prolonged rest (theatre sign). Effusions may occur, but warmth and soft tissue swelling is rare and suggests another diagnosis.

Physical examination reveals tenderness to palpation, bony thickening (osteophyte formation), small effusions, and crepitus. Specific joint findings also occur. Typical in the hand are bony enlargement of the proximal interphalangeal joints (Bouchard's nodes) and the distal interphalangeal joints (Heberden's nodes). The first carpometacarpal joint may be involved causing a 'squared appearance' of the lateral aspect of the hand (in anatomical position) (Fig. 1). Involvement of the foot yields bunions, and of the knee pronounced valgus and varus deformities, Baker's cyst or locking suggesting meniscal damage. Early hip findings include limited internal and external rotation. Back findings include pain: true osteoarthritis occurs at the apophyseal joints; degenerative disc disease and diffuse idiopathic skeletal hyperostosis are distinct entities.

Fig. 1 Osteoarthritis of the hand. Note squaring of first carpometacarpal (CMC) joint and evidence of a Heberden's node on the third distal interphalangeal joint.

In an effort to standardize the diagnosis of osteoarthritis, the American College of Rheumatology formed a subcommittee to define osteoarthritis of the knee, hip, and hand. Clinical, laboratory, and radiographic findings were evaluated by an expert panel and statistical analysis, to yield classification criteria with acceptable sensitivity and specificity values. These instruments should be used with caution in individual patients but provide a framework for analysis (see Table 1, Table 2, and Table 3).

Common clinical mimics of osteoarthritis include rheumatoid arthritis, calcium pyrophosphate deposition disease, and infectious monoarticular arthritis.

Hand osteoarthritis may be confused with rheumatoid arthritis as both cause pain and visible swelling. Less commonly hip or knee arthritis may present as diagnostic challenges. Hand osteoarthritis typically involves the proximal interphalangeal and the distal interphalangeal joints; the 'swelling' is not true swelling but hard, bony thickening due to osteophyte formation; and stiffness is limited. By contrast, rheumatoid arthritis typically involves the proximal interphalangeal, metacarpophalangeal, and carpal joints, sparing the distal interphalangeals. True swelling occurs and is soft with palpation. Multiple joints are involved, symptoms of systemic inflammation occur, and rheumatoid factor is usually positive. In rheumatoid arthritis radiographs demonstrate symmetric joint space narrowing, bony erosions, minimal sclerosis, and minimal osteophyte formation.

Calcium pyrophosphate deposition disease is difficult to differentiate from idiopathic osteoarthritis because the two may coexist. Typical distributions for this disease include the knees, wrist, shoulder, and metacarpophalangeals. Patients may have more prolonged stiffness and pain and swelling may occur. Radiographs with evidence of chondrocalcinosis strongly suggest calcium pyrophosphate deposition disease, but the presence of crystals on arthrocentesis is the gold standard for diagnosis.

Infectious monoarthritis can occasionally mimic osteoarthritis. The distinction is more difficult with subacute infections, such as fungal or mycobacterial. If there is clinical suspicion, radiographs and arthrocentesis should be performed.

Investigation

Laboratory tests, if performed, reveal normal sedimentation rates and non-inflammatory synovial fluid. Radiographic findings include asymmetry, joint space narrowing, subchondral sclerosis, subchondral cysts, and the hallmark osteophyte (Fig. 2, Fig. 3, Fig. 4, and Fig. 5).

Fig. 2 Osteoarthritis of the hand. Note changes in the distal interphalangeal joints and proximal interphalangeal joints as well as the base of the thumb (carpometacarpal). These changes are typical for osteoarthritis of the hand. Note the loss of joint space, bony sclerosis, and the presence of osteophytes. The bony changes seen in the distal interphalangeal and proximal interphalangeal joints would manifest as Bouchard's and Heberden's nodes on clinical examination.

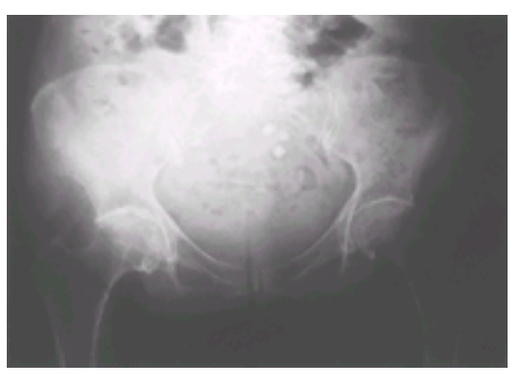

Fig. 3 Hip radiograph demonstrating osteoarthritis. Note joint space narrowing and sclerosis.

Fig. 4 Bilateral knee osteoarthritis. Note the asymmetric joint space narrowing, bony sclerosis, and the presence of osteophytes.

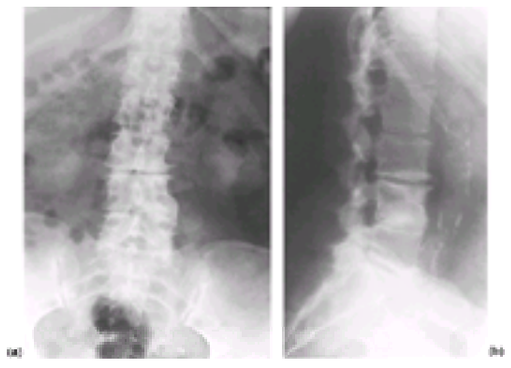

Fig. 5 (a) and (b) Lumbar spine arthritis. Note the changes of degenerative disc disease as narrowing and large osteophytes. Although often called osteoarthritis these changes are not true osteoarthritis. True osteoarthritis occurs at the facet joints. Sclerosis is seen in the inferior facet joints.

Treatment

Traditional treatments

Treatment modalities for all forms of osteoarthritis, listed in Table 5, remain limited. Traditional therapies include analgesics, non-steroidal anti-inflammatory drugs (**NSAIDs**), intra-articular corticosteroid injections, intra-articular hyaluronic acid injections, topical agents, tidal lavage, arthroscopic irrigation, and total joint replacement. With the exception of joint replacement, none of these therapies address the underlying problem of cartilage damage. Newer therapies include weight loss and exercise, both of which have been difficult to maintain over long periods of time. Emerging therapies such as tetracycline, cytokine modulators, and inhibitors of metalloproteinases may potentially alter the progression of osteoarthritis. Nutritional supplements such as glucosamine, chondroitin sulphate, soybean, and avocado products have been reported to provide better long-term analgesia than NSAIDs, and some of these agents may alter the progression of osteoarthritis and repair cartilage damage. However, the efficacy of these emerging therapies and nutritional supplements has not been studied adequately in controlled trials.

Weight loss

Weight loss, while effective, is difficult to achieve and maintain. Evidence suggests that a weight loss of 4.5 kg (10 lb) over 10 years may decrease the risk of developing contralateral knee osteoarthritis by 50 per cent. Studies demonstrating improvement in disease outcome are more controversial. However, given potential benefits in osteoarthritis as well as the additional health benefits of a normal body mass index, obese patients should be encouraged to lose weight.

Exercise and psychosocial support

Physical therapy and exercise are advocated in osteoarthritis for a variety of reasons. Improvements in flexibility and muscle strengthening may decrease joint loading, preventing further damage. They have been demonstrated to improve functional outcome and pain scores in clinical trials. In addition, they provide a sense of self-determination, an adjunct for weight loss, improve depressive symptoms, and decrease patient disability. Obstacles include expense and the lack of motivation to continue exercising after a programme has been completed.

The role of psychosocial support may be significant. Telephone calls providing contact and education have been demonstrated to improve pain and functional status. Education and support improve feelings of frustration, minimize dependency, and improve coping mechanisms.

Simple analgesics

Analgesics such as acetaminophen and paracetamol provide analgesic relief comparable with that of NSAIDs. The lower relative risk of complications has favoured their use over that of NSAIDs, especially in older populations. Typical daily doses of acetaminophen are 4 g (3 g in elderly patients). These agents may be associated with liver problems and interactions with other drugs such as warfarin. Narcotic analgesics are generally avoided because of potential complications including constipation, sedation, addiction, and impairment of balance.

Non-steroidal anti-inflammatory agents

NSAIDs remain a cornerstone of osteoarthritis treatment. Availability, dosing schedule, cost and individual side-effect profile influence the choice of a particular agent. The associations of NSAIDs with peptic ulcer disease and renal insufficiency are well established. Less common side-effects include rash, hepatic dysfunction, platelet dysfunction, and central nervous system effects. NSAIDs with specific cyclo-oxygenase-2 (Cox-2) inhibiting activity have become popular because of their decreased dosing frequency, decreased platelet effects, and—most importantly—decreased incidence of gastrointestinal ulceration compared with traditional NSAIDs.

Corticosteroids

Intra-articular corticosteroids may be effective in decreasing joint pain associated with osteoarthritis. Dosage varies depending on patient body size, comorbidity, and the joint involved. They have multiple side-effects, including risk of infection, bleeding, and (possibly) cartilage damage. To minimize the risk of complications, injections should be limited to three to four per year in any given joint.

Hyaluronic acid

The use of hyaluronic acid preparations (Hyalgan™, Synvisc™) has become popular in recent years. These agents are reported to increase viscosity by replacing depleted hyaluronic acid, which occurs in osteoarthritis. Multiple studies demonstrate efficacy similar to NSAIDs, and the risk profile for side-effects is better than that of NSAIDs.

Joint lavage

Irrigation of osteoarthritic joints has been proposed as a method of relieving joint pain by removing debris or inflammatory cytokines, but remains controversial. Livesley compared arthroscopic irrigation with physical therapy and found that the arthroscopic group experienced significant improvement in pain that was sustained over 12 months. Ike and colleagues compared medical management plus joint lavage without arthroscopy with medical management alone in a multicentre, randomized prospective study: significant improvements in pain and stiffness occurred in the group receiving irrigation. Ravaud and colleagues evaluated the efficacy of joint lavage and intra-articular steroid injection in osteoarthritis of the knee. Patients who underwent joint lavage had improved significantly at 6 months; those only given corticosteroids had early improvement but no long-term benefit. Kalunian and colleagues studied the effectiveness of visually guided arthroscopic irrigation in early osteoarthritis of the knee unresponsive to conservative management. Patients received 3 litre or minimal (< 250 ml) arthroscopic irrigation, the former having an effect on pain as measured on two rating scales.

Surgery

Surgical intervention is generally reserved for patients who have failed conservative management including analgesics, physical therapy, and intra-articular injection. Prescribed treatments include synovectomy, repair of meniscal tears, realignment osteotomy, and total joint replacement. Total joint replacement removes the affected structure and is the only known 'cure' for osteoarthritis to date, providing marked pain relief and functional improvement.

Aids and appliances

A joint that is unstable and painful can be made more stable and less painful by appropriate aids. Wheelchairs and other appliances may make it possible for a patient to maintain their independence. Walking sticks can be very effective, and for a painful hip or knee should be held in the contralateral hand to transfer weight from the affected joint. If the main problem is instablility, the stick should be held in the hand that inspires most confidence. Splinting to correct instability, correction of valgus or varus deformity at the knee or ankle, use of a rocker sole to ease hallux rigidus pain, or a heel raise if the legs are of unequal length, can all allow significant reduction of symptoms, as can the simple recommendation of shoes with good shock-absorbing soles. These simple and apparently mundane issues should not be ignored by the physician.

Other therapies

Glucosamine and chondroitin sulphate

Many patients with osteoarthritis feel that glucosamine salts and chondroitin sulphate improve symptoms and there are abundant data to support these claims, but studies generally involve small numbers of subjects. There are, however, few data to suggest that these supplements repair cartilage damage.

Glucosamine, an aminomonosaccharide, is present in almost all human tissues, but particularly in articular cartilage where it is an intermediate substrate in the synthesis of glycosaminoglycan and proteoglycans. Exogenous glucosamine salts significantly enhance chondrocyte synthesis of glycosaminoglycans, collagen, and DNA. Both glucosamine hydrochloride and glucosamine sulphate are rapidly absorbed after oral administration and are not toxic, even at high oral doses.

Several double-blind studies have compared glucosamine to placebo for periods ranging from 5 to 38 weeks in patients with osteoarthritis of the knee, showing that glucosamine produces significant improvements in pain. Vaz found that glucosamine was as effective as ibuprofen in osteoarthritis of the knee: those receiving ibuprofen had greater initial improvement in pain than those randomized to receive glucosamine, but by 4 and 8 weeks the situation had reversed. Qie and colleagues compared glucosamine with ibuprofen in 178 subjects with osteoarthritis of the knee: both significantly reduced knee symptoms, but glucosamine was better tolerated. In a randomized, controlled, double-blind trial involving 329 patients with medial femerotibial osteoarthritis, Rovati and colleagues found that 3 months of glucosamine was more effective than standard NSAID therapy and placebo, and that the safety of glucosamine did not differ from placebo but was significantly better than NSAIDs.

Reginster and colleagues recently presented data regarding the chondroprotective effects of glucosamine sulphate. This randomized, double-blind, placebo-controlled study included 212 patients with osteoarthritis of the knee, who received either oral glucosamine sulphate 1500 mg/day or placebo. Weight-bearing anteroposterior radiographs of each knee were taken at enrolment, year 1, and year 3 and analysed for joint space narrowing: this progressed by 0.24 mm in the placebo-treated group, while the glucosamine-treated group had preservation of the joint space (–0.12 mm progression). The authors concluded that glucosamine sulphate may be a disease-modifying agent. Criticisms of the study include the use of traditional radiographs rather than fluoroscopically guided semiflexed views, which have better reliability in progression studies.

Chondroitin sulphate is a long-chain polymer of a repeating disaccharide. It is the predominant glycosaminoglycan found in articular cartilage and differs from glucosamine in that it stimulates glycosaminoglycan and proteoglycan synthesis by both extracellular and intracellular mechanisms, whereas glucosamine utilizes only intracellular mechanisms. By virtue of its long chains, chondroitin sulphate competitively inhibits enzymes that degrade proteoglycans, and this may be its mechanism of action, with increased availability of substrates for formation of articular matrix another possibility. It is 70 per cent absorbed after oral ingestion, with affinity for synovial fluid and articular cartilage.

In a randomized controlled trial comparing 3 months of treatment with chondroitin sulphate with placebo, the chondroitin sulphate group demonstrated significant reductions in clinical symptoms. Chondroitin sulphate has also been compared with NSAIDs in patients with osteoarthritis of the knee. In one study, patients treated with chondroitin sulphate had statistically significant decreases in pain by 3 months of therapy, with an overall 72 per cent decrease in concomitant usage of NSAIDs. In another study, patients treated with an NSAID showed prompt reduction in clinical symptoms that reappeared after discontinuation of the NSAID, whereas those given chondroitin sulphate had a therapeutic response that appeared later but lasted for up to 3 months after treatment was discontinued.

The combined use of glucosamine and chondroitin sulphate in the treatment of osteoarthritis has become popular: they have been reported to work synergistically in forming glycosaminoglycans, inhibiting degradative enzymes, and stimulating cartilage metabolism and matrix production. In a randomized double-blind placebo-controlled trial of 93 patients with osteoarthritis of the knee, subjects were randomized to receive glucosamine hydrochloride 1000 mg and chondroitin sulphate 800 mg twice daily orally or placebo. There was significantly greater improvement in the glucosamine and chondroitin sulphate treatment group compared with controls, with a significant drop in requirement for pain medication. A National Institutes of Health sponsored multicentre randomized study is under way comparing glucosamine, chondroitin sulphate, the combination of glucosamine and chondroitin sulphate, and placebo in patients with osteoarthritis of the knee: this will involve more than 1000 patients treated for 4 months.

Tetracyclines, interleukin 1 antagonists, and collagenase inhibitors

Tetracyclines have been demonstrated to inactivate matrix metalloproteinases such as collagenase, stromolysin, and gelatinase. Dog models using doxycycline reduce the incidence of osteoarthritis. A National Institutes of Health sponsored multicentre randomized, placebo-controlled trial of doxycycline is under way.

Other agents demonstrating efficacy in osteoarthritis include use of diacerein and avocado/soybean extracts. Diacerin is an oral agent with analgesic properties, hypothesized to have an effect in osteoarthritis by inhibiting synthesis and activity of interleukin 1 and demonstrating cartilage preservation in an animal model. Human studies have demonstrated improvements in pain and function in hip osteoarthritis, as well as an NSAID-sparing effect. Similarly, avocado and soybean unsaponifiables are believed to exert their effects through interleukin 1. Clinical studies have demonstrated an NSAID-sparing effect and improvement in functional index and pain.

Ro 32–335 (Trocade) is an orally active collagenase inhibitor that has demonstrated chondroprotection by radiographic criteria in a mouse osteoarthritis model. Bay 12–9566 is a stromelysin-1 (MMP-3) inhibitor which demonstrated efficacy both dog and guinea pig meniscetomy models. Further studies of these compounds are needed. Future strategies for chondroprotection include manipulation of tumour necrosis factor, nitrous oxide, and insulin-like growth factor.

18.9 Crystal-related arthropathies

S. C. O'Reilly and M. Doherty

Introduction

Diversity and terminology

A large number of crystals have been associated with acute synovitis, chronic arthropathy, or periarticular syndromes (Table 1). In practice only monosodium urate monohydrate, calcium pyrophosphate dihydrate, and basic calcium phosphates (mainly hydroxyapatite) are commonly encountered.

The taxonomy of these conditions is not universally agreed. Difficulties arise from our poor understanding of pathogenesis, historical extrapolation from gout to other crystal-related conditions, and multiple terms for the same clinical syndrome. Possible relationships between crystals and disease are outlined in Fig. 1. A 'crystal deposition disease' is defined as a pathological condition associated with mineral deposits which contribute directly to the pathology. This is probably the situation for all manifestations of gout, for acute syndromes associated with calcium pyrophosphate dihydrate, and for acute apatite periarthritis. However, the role of non-urate crystals in chronic arthropathy is unclear and confounded by the following observations:

1. Most crystals lack disease specificity and occur in a variety of clinical settings, often unaccompanied by symptoms or other abnormality.
2. Crystal deposition may coexist with other rheumatic disease, most commonly osteoarthritis, and often follows rather than precedes articular damage.
3. Combined deposition of several crystal species is common ('mixed crystal deposition').

For descriptive purposes, confusion may be avoided by specifying the crystal, the site of involvement, and the clinical syndrome (for example, chronic urate olecranon bursitis, acute pyrophosphate arthritis of the knee).

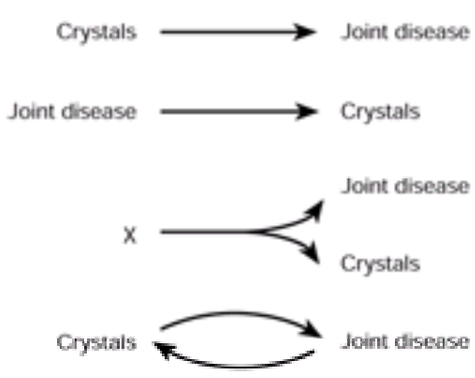

Fig. 1 Possible relationships between crystals and joint disease.

Crystal deposition and clearance

Many factors determine crystal formation and dissolution (Fig. 2). High solute concentrations alone are often insufficient to initiate crystal formation, and the presence of nucleating factors that aid initial particle formation and the balance of growth-promoting and inhibitory factors are probably more important. Little is known of such tissue factors, although they may in part explain:

1. the characteristic, limited distribution of different crystals;
2. the frequency of mixed crystal deposition (via epitaxial nucleation and growth of one crystal on another); and
3. non-specific predisposition to crystal formation in osteoarthritic tissues (via accompanying alterations in proteoglycan, collagen, and lipid).

Formation of crystals *in vivo* is a dynamic process, although usually slow. At any time the crystal load will depend on the rate of formation, the rate of dissolution, and trafficking of crystals away from their site of formation (via 'shedding' from preformed deposits with secondary uptake by synovial and other cells).

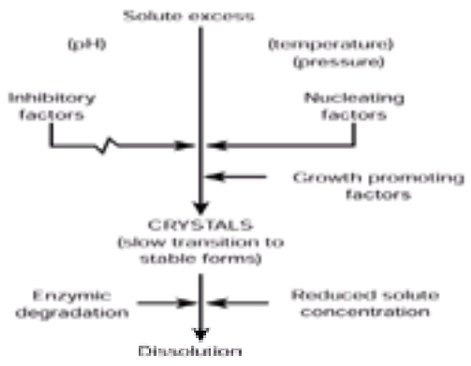

Fig. 2 Factors affecting crystal formation.

Crystal-induced inflammation and tissue damage

Crystals implicated in joint disease are stable, hard particles that exert biological effects via surface-active and mechanical properties. With respect to acute inflammation, they are all markedly phlogistic agents in a wide range of *in vitro* and *in vivo* systems. Surface-active interaction has been demonstrated with:

1. humoral mediators: for example complement activation via classical and alternative pathways; activation of Hageman factor;
2. cell-derived mediators: for example superoxide production and release of lysozymes, chemotactic factor, and lipoxygenase-derived products of arachidonic acid by neutrophils; release of interleukin I, interleukin 6, and tumour necrosis factor by monocytes and synoviocytes;
3. cell membranes: for example membranolysis of lysosomes, erythrocytes, and neutrophils; non-lytic platelet and neutrophil secretory responses.
