While thrombosis and thrombocytopenia are dramatic complications of heparin, they are rare. The most common complication of heparin therapy is haemorrhage, which may occur in any tissue. In general, the longer the aPTT, the greater the likelihood of haemorrhage. Heparin may also aggravate haemorrhage from structural lesions, such as colonic carcinoma or gastric ulcer. For this reason, bleeding from the gastrointestinal, respiratory, or urinary tract in patients on heparin should prompt a search for a potential source of the bleeding.

The question of how to maintain adequate anticoagulation in an individual with thrombosis who cannot take heparin is an important one. Alternatives to heparin include warfarin, other antithrombotic agents such as dextran, ancrod, novel antithrombin inhibitors such as hirudin or its synthetic analogues, prepared by recombinant technology or peptide synthesis, low-molecular-weight heparinoids, and the peptide inhibitor of thrombin, argatroban. Argatroban is easiest to use since therapy is monitored using the aPTT, in a manner analogous to heparin. Hirudin and its analogues are effective, but monitoring is with a special assay using the snake venom, ecarin, because of the very high affinity of hirudin for thrombin. Low-molecular-weight heparinoids have a risk of cross-reaction with the

heparin-dependent antibody. The clinical situation largely determines which agent is used. For example, if gastrointestinal bleeding from an ulcer or polyp occurs on preventative doses of heparin (so-called 'mini-dose' heparin), the easiest course may be simply to discontinue the heparin. In the case presented, the presence of a recent deep vein thrombosis and the complicating arterial occlusion are indications to continue antithrombotic treatment.

22.6.3 Disorders of platelet number and function

Kathryn E. Webert and John G. Kelton

Introduction

Platelets are the smallest of the circulating blood cells and their numbers in healthy individuals range from 150 × 10^9/litre to 450 × 10^9/litre. Platelets are released from the megakaryocytes in the bone marrow and circulate for 5 to 10 days before being cleared by the cells of the reticuloendothelial system. Disorders of platelet number and function are frequently encountered in medical patients.

Platelets are discoid cells that average 4 μm in diameter. The external membrane is a glycocalyx surface covering a phospholipid bilayer. Penetrating the membrane and traversing the platelet is a tubular system termed the open canalicular system. This system is continuous with the surface membrane and acts as a conduit for the release and uptake of substances. The platelet cytoskeleton is composed of three filamentous systems consisting of microtubules, microfilaments, and intermediate filaments. These tubules maintain the platelet's shape and participate in shape change, a complex process that occurs following platelet activation.

Platelets contain a number of organelles including alpha-granules, dense granules, lysozymes, peroxisomes, and mitochondria. The alpha-granules are the most numerous platelet granules (approximately 50 granules per platelet) and contain proteins synthesized by megakaryocytes, including b-thromboglobulin, platelet factor 4, thrombospondin, and von Willebrand factor. Alpha-granules also contain plasma-derived proteins such as fibrinogen, albumin, immunoglobulin G (**IgG**), and factor V. On the alpha-granule membrane are a variety of proteins including P-selectin and glycoprotein IIb/IIIa. Dense granules are far fewer in number than alpha-granules (four to eight per platelet) and are smaller. Dense granules are important for platelet activation and contain adenosine triphosphate, serotonin, calcium, magnesium, pyrophosphate, and granulophysin. Their membranes also contain a number of platelet proteins including P-selectin, glycoprotein Ib, and glycoprotein IIb/IIIa. Lysosomal granules contain proteolytic enzymes.

Platelet surface structures

Penetrating the platelet membrane are platelet glycoproteins. Most of these glycoproteins can be classified as one of five supergene families: integrins, leucine-rich glycoproteins, immunoglobulin domain molecules, selectins, and quadraspanins. The integrin family is the most common with glycoprotein IIb/IIIa being the most abundant integrin. Glycoprotein IIb/IIIa, also known as $a_{IIb}b_{3,}$ is present in high numbers (40 000 to 50 000 surface copies per platelet) and is the key binding site for platelet aggregation. Glycoprotein Ib/IX complex is the second most abundant platelet glycoprotein with an average of 20 000 surface copies per platelet. Glycoprotein Ib is a binding site for von Willebrand factor. A variety of other platelet glycoproteins are present in lower numbers such as glycoprotein Ia/IIa, the receptor for collagen. Finally, platelets carry 400 to 4000 copies of an IgG crystallizable fragment receptor, which is important in heparin-induced thrombocytopenia.

Thrombopoiesis

Pluripotent stem cells produce precursors of the red and white cells and the platelets. The platelet precursor is the megakaryocyte. Megakaryocytes undergo repeated nuclear replication without cytoplasmic division. This produces very large cells with four to 12 times the nuclear material of other cells of the body. Platelets bud off the cytoplasm of the megakaryocytes and are released into the circulation. The mean platelet volume can be measured on a cell counter and is approximately correlated with the number of nuclei in the megakaryocyte. Thrombocytopenia leads to increased proliferation of megakaryocytes and large platelets.

The primary regulator of megakaryopoiesis and platelet production is thrombopoietin. Thrombopoietin, an erythropoietin-like hormone, is primarily produced in the liver, with secondary sites including the kidney, bone marrow, brain, smooth muscle cells, and testes. The receptor for thrombopoietin, c-Mpl, is present on stem cells, megakaryocytes, and platelets. Binding of thrombopoietin to c-Mpl activates a variety of pathways resulting in the proliferation of megakaryocyte progenitors, an increased rate of megakaryocyte maturation, an increase in megakaryocyte nuclear mass and ploidy, and increased platelet release. The circulating level of thrombopoietin is primarily determined by the platelet mass. Platelets bind the thrombopoietin, internalize it, and degrade it. Consequently, less is available to stimulate platelet production. When the platelet count falls, less thrombopoietin is bound to platelets resulting in increased circulating levels of thrombopoietin and increased platelet production. Platelet production is also regulated by a number of other cytokines including interleukins 6 and 11.

The role of platelets in haemostasis

Platelets play a critical role in haemostasis. When the wall of the blood vessel is damaged, platelets adhere to exposed collagen and other components of the subendothelium. The key receptor is glycoprotein Ib linked to the vessel wall through von Willebrand factor. Other adhesive receptors include glycoprotein Ia/IIa, which binds collagen. The adhesion of the platelets to the vessel wall results in platelet activation. Agonists such as thrombin or adenosine diphosphate are released from their granules. The prostaglandin pathway is also activated during platelet activation; arachidonic acid is released from the platelet membrane where it is converted by a number of enzymes into platelet activating agents including thromboxane A_2. A key, rate-limiting step in this pathway is catalysed by the cyclo-oxygenase enzyme. Aspirin, an antiplatelet agent, irreversibly inactivates this enzyme. Following platelet activation, glycoprotein IIb/IIIa undergoes conformational changes making it able to bind fibrinogen. This process is termed platelet aggregation and results in the formation of the haemostatic plug. Activated platelets also contribute to the clotting cascade by serving as the phospholipid membrane surface needed for many reactions leading to thrombin generation, especially the activation of factor X by a complex of factors IXa and VIIIa and the activation of prothrombin by a complex of factors Xa and Va.

Disorders of platelet number

Thrombocytopenia

Thrombocytopenia is defined as a reduction in the number of circulating platelets to less than the laboratory's normal count (typically < 150 × 10^9/litre). Bleeding is uncommon unless the platelet count falls below 10–20 × 10^9/litre or unless there is an abnormality in platelet function.

Classification of thrombocytopenia

It is convenient to classify disorders of thrombocytopenia into problems of underproduction, increased destruction, and sequestration (Table 1). Since megakaryocytes originate from stem cells it is rare to see a deficit in platelet production without abnormalities also occurring in other cell lines. Although isolated underproduction of platelets can occur, isolated thrombocytopenia usually suggests increased platelet destruction. Platelet sequestration is usually due to splenomegaly and can cause isolated thrombocytopenia, but also causes mild leukopenia or anaemia.

History and physical examination of the thrombocytopenic patient

The physician must investigate the risk of the thrombocytopenia as well as determine the underlying cause. It is important to elicit the duration of the haemostatic impairment to determine if the patient has recently ingested an antiplatelet agent such as aspirin or alcohol, which interferes with platelet function and can trigger bleeding.

The history should be guided by the potential mechanism of thrombocytopenia. For example, if increased destruction is considered, then the patient should be questioned about drugs including prescription drugs, over-the-counter medications, herbal remedies, and illicit drugs. Secondary associations of thrombocytopenia, which include systemic lupus erythematosus, human immunodeficiency virus (**HIV**) infection, and lymphoproliferative disorders (Table 2), will lead to other questions. Finally, one should obtain information about any family members with a history of thrombocytopenia or bleeding disorders.

Physical evaluation focuses on evidence of haemostatic impairment and signs of an underlying cause of the thrombocytopenia. Many patients with thrombocytopenia are asymptomatic. Only at low platelet counts will one see petechiae, which are tiny, red collections of red cells found on dependent parts of the body and sites of trauma. Petechiae are specific for thrombocytopenia. Large bruises or purpura can be observed on the limbs and trunk and have a lower specificity. The risk of bleeding increases progressively from asymptomatic patients, to patients with petechiae and purpura, to patients who have mucous membrane bleeding, which is typically manifest by blood blisters in the mouth. Blood blisters usually occur on the bite margins of the oral mucosa and on the tongue. They indicate that the patient is at significant risk for bleeding and treatment is urgently required. The physical examination should focus on the examination of the joints, lymph nodes, spleen, and liver since abnormalities indicate a secondary cause of the thrombocytopenia.

Laboratory evaluation of the thrombocytopenic patient

One of the most important first steps is to review the peripheral blood film looking for pseudothrombocytopenia. Pseudothrombocytopenia is a laboratory artifact that causes spontaneous platelet agglutination and results in platelet clumps in the peripheral smear. Automated determination of the platelet count will be inaccurate, as the machine will not recognize the larger platelet aggregates as platelets. Pseudothrombocytopenia commonly occurs because of agglutination of the patient's platelets in ethylenediaminetetra-acetic acid. This disorder occurs in 0.1 per cent of blood samples and is caused by a clinically insignificant autoantibody that agglutinates platelets at low calcium concentrations. This can be avoided by using an anticoagulant other than ethylenediaminetetra-acetic acid to collect the blood sample.

The patient's haemoglobin and white blood cell count should be evaluated. Cytopenias involving other cell lines are suggestive of disorders involving the bone marrow such as myeloproliferative or myelodysplastic diseases. The platelet count helps to determine the patient's risk of bleeding. Patients with mild thrombocytopenia (platelet count > 50×10^9/litre) have a low risk of bleeding. Patients with severe thrombocytopenia (platelet count < 20×10^9/litre) have a higher risk of bleeding and can experience spontaneous bleeding. The peripheral smear may lead to the diagnosis of the condition causing the thrombocytopenia. Fragmented red cells or schistocytes may be seen in thrombotic thrombocytopenic purpura, haemolytic uraemic syndrome, disseminated intravascular coagulation, and renal graft rejection. Leukoerythroblastic changes in the peripheral smear, such as teardrop-shaped red blood cells, nucleated red blood cells, and immature white cells suggest infiltration of the bone marrow. The presence of abnormal circulating cells such as lymphoblasts or myeloblasts suggests a malignant process. Typical changes on the peripheral smear such as megaloblastic red blood cells and hypersegmented neutrophils suggest vitamin B_{12} or folate deficiency. The finding of atypical lymphocytes should cause one to consider the diagnosis of a viral infection. Finally, the finding of giant platelets on the peripheral smear suggests the diagnosis of certain congenital thrombocytopenias. Examination of the bone marrow should be considered if the aetiology of the thrombocytopenia is uncertain after the initial evaluation. Additionally, one should perform a bone marrow examination when abnormalities are seen on the peripheral blood smear or when multiple blood cell lineages are affected. The finding of normal or increased numbers of megakaryocytes in the marrow is supportive of a diagnosis of peripheral destruction or sequestration of the platelets. Other laboratory investigations that may be indicated include antinuclear antibody, rheumatoid factor, thyroid stimulating hormone, and testing for HIV infection.

Disorders of increased platelet destruction

Disorders of increased platelet destruction can be subdivided into two major categories: immune and non-immune. Non-immune causes include disseminated intravascular coagulation, and a variety of schistocytic or haemolytic anaemias such as thrombotic thrombocytopenic purpura. For the majority of thrombocytopenic disorders caused by non-immune mechanisms, the underlying cause is apparent and the patient's clinical presentation indicates the correct diagnosis (i.e. fever and clinical septicaemia suggest infectious causes of thrombocytopenia, fragmentation haemolysis suggests thrombotic thrombocytopenic purpura or haemolytic uraemic syndrome).

Immune mediated platelet disorders

Immune mediated disorders can be caused by autoantibodies, for example idiopathic thrombocytopenic purpura; alloantibodies, exemplified by post-transfusion purpura; and immune complexes, as demonstrated in heparin-induced thrombocytopenia. The majority of immune mediated platelet disorders are caused by IgG antibodies that bind to the platelet membrane.

Autoimmune thrombocytopenia

Autoimmune thrombocytopenia is mediated by antibodies that bind to individual platelet glycoproteins, most frequently glycoprotein IIb/IIIa. The autoimmune thrombocytopenia is classified as primary if there are no underlying conditions and secondary if it is associated with a systemic disease.

Primary autoimmune thrombocytopenia (idiopathic thrombocytopenic purpura)

Idiopathic thrombocytopenic purpura (ITP) is one of the most common autoimmune disorders that physicians manage. Idiopathic thrombocytopenic purpura is a disorder of both children and adults. In young children, frequently under the age of 5, the disease presents abruptly with dramatic evidence of haemostatic impairment. At least 80 per cent of children will have a spontaneous remission of their disease. Girls and boys are affected equally. In contrast, 80 per cent of adults who present with idiopathic thrombocytopenic purpura will have chronic disease. The disorder is typically seen in young and middle-aged adult women.

Adults with idiopathic thrombocytopenic purpura can present in one of three ways. Many patients will be asymptomatic and will have thrombocytopenia discovered incidentally. Other patients will give a history of easy bruising that may have occurred for many years and, frequently, worsened with ingestion of a substance which interferes with platelet function, such as aspirin or alcohol. Finally, patients may have an acute onset of petechiae, purpura, and mucous membrane bleeding.

Treatment of idiopathic thrombocytopenic purpura

The most important decision is whether the patient requires any treatment. If the patient has mild or moderate thrombocytopenia (platelet count > 50×10^9/litre) and no history of haemostatic impairment, we would monitor this patient with periodic platelet counts every few weeks. These patients usually maintain a consistent platelet count that tends to drop only if the patient has an immune stimulus such as an infection. The decision is more difficult in patients with more severe thrombocytopenia (platelet count (20–50) $\times 10^9$/litre) and who have modest signs of haemostatic impairment such as occasional bruising. We often do not treat these patients, but would alert the patient that the platelets should be raised before a haemostatic challenge such as a tooth extraction or surgery. Patients with severe thrombocytopenia (platelets < 10×10^9/litre) usually require treatment, especially if they have clinical signs of haemostatic impairment. The first line of treatment is corticosteroids, typically prednisone (1 mg/kg). Corticosteroids are effective in two-thirds of patients, but have predictable side-effects (Cushing's syndrome, hypertension, diabetes mellitus, osteoporosis). Corticosteroids should be given for as short an interval as possible, tapering the dose once the platelet count has reached haemostatically safe levels (> 100×10^9/litre). Patients who have a relapse of their thrombocytopenia may require more definitive treatment such as splenectomy.

Reticuloendothelial blockade through high-dose intravenous immunoglobulins (1 g/kg delivered over 6 h on two consecutive days) or anti-D in a rhesus positive individual (75 µg/kg) will result in a more rapid rise in the platelet count than corticosteroids and are indicated when platelets must be urgently raised. The major disadvantage of these treatments is that they are significantly more expensive than corticosteroids; however, they have fewer side-effects. There is a strong correlation between the response of a patient to high-dose intravenous immunoglobulins and response to a subsequent splenectomy. At least 80 per cent of patients

will respond to reticuloendothelial blockade with the peak platelet count occurring in about a week and lasting for 4 to 8 weeks.

Splenectomy

Splenectomy should be considered for patients who require ongoing medical management. Patients needing splenectomy should be vaccinated 2 weeks prior to the procedure with pneumococcal, meningococcal, and probably *Hemophilus influenzae* vaccines. The platelet count should be raised to safe levels prior to the procedure. Because of its reduced morbidity and significantly shortened hospital stay, laparoscopic splenectomy is the preferred approach. Splenectomy will result in a long-term remission or cure in about two-thirds of patients.

Second-line therapies

As many as one-third of patients will not respond to splenectomy and will require an alternative therapy. Danazol, an attenuated anabolic steroid, will induce a dose-dependent rise in platelet count in some refractory patients. The typical dose ranges from 200 to 1200 mg/day. Unfortunately, it has adverse effects including liver enzyme abnormalities and virilization. Vincristine or vinblastine have been used in refractory patients. However, if a rise in platelet count does occur, it is generally transient. Hence, the drug needs to be given repeatedly, which invariably causes dose-dependent neurotoxicity. Patients with refractory idiopathic thrombocytopenic purpura who require ongoing therapy may need aggressive immunosuppression that includes oral chemotherapy such as cyclophosphamide or azathioprine, intermittent high-dose intravenous immunoglobulins, or intermittent corticosteroids.

Emergency treatment of idiopathic thrombocytopenic purpura

Patients with idiopathic thrombocytopenic purpura who have severe bleeding require aggressive therapy including platelet transfusions, high-dose intravenous immunoglobulins, and high-dose corticosteroids, in addition to standard resuscitation including blood replacement if required.

Idiopathic thrombocytopenic purpura during pregnancy

Idiopathic thrombocytopenic purpura occurs in young women and frequently these young women will become pregnant. The majority of these patients can successfully carry a child without excessive morbidity or mortality. Typically, the platelet count falls across the pregnancy and the mother may require treatment. We use high-dose intravenous immunoglobulins since corticosteroids may be associated with an increased risk of hypertensive disorders in pregnancy. About 10 per cent of the infants born to these mothers will be thrombocytopenic with the platelet nadir occurring several days after delivery. Very severe thrombocytopenia is uncommon (< 1 per cent) and should suggest an alternative diagnosis such as alloimmune neonatal thrombocytopenia. Infant thrombocytopenia cannot be predicted by any maternal factor or serological test with the possible exception of a history of a previously affected infant. We manage these mothers with routine vaginal delivery unless there is an obstetrical indication for caesarean section.

Secondary immune thrombocytopenias

A variety of medical disorders cause secondary immune thrombocytopenia (Table 2). The treatment for secondary immune thrombocytopenia is similar to that of idiopathic thrombocytopenic purpura.

Thrombocytopenia complicating systemic lupus erythematosus

Thrombocytopenia can occur in up to 25 per cent of patients with systemic lupus erythematosus. The thrombocytopenia is usually caused by autoantibodies. Some patients will have concomitant platelet dysfunction characterized by increased bleeding and bruising. The treatment is similar to that for idiopathic thrombocytopenic purpura.

A subset of patients with systemic lupus erythematosus or lupus-like disorders have antibodies which interfere with phospholipid-dependent coagulation reactions, commonly detected by an unexplained prolongation of the patient's partial thromboplastin time. These antibodies are immunoglobulins with specificity for negatively charged phospholipids and are also called lupus anticoagulant antibodies. They tend to be heterogenous in their epitope specificity with most binding protein complexes including b_2-glycoprotein I. Another class of antibodies, the anticardiolipin antibodies, is detected by an enzyme-linked immunosorbent assay using cardiolipin as the antigen. Cardiolipin is the same antigen that is detected in the venereal disease research laboratory (VDRL) test for syphilis, which explains the false positive VDRL test in these patients. The two classes of antibodies are distinct, but have overlapping specificities. Most anticardiolipin antibodies recognize an epitope on b_2-glycoprotein I. The term 'antiphospholipid antibodies' applies to both sets of antibodies.

Antiphospholipid antibodies are associated with venous and arterial thrombosis. The antiphospholipid antibody syndrome includes any combination of arterial and venous thrombosis, recurrent fetal losses and thrombocytopenia. Many of these patients will also have a vascular rash termed livedo reticularis. Patients can have haematological abnormalities including mild thrombocytopenia, platelet dysfunction, autoimmune haemolytic anaemia and leucopenia. As the thrombocytopenia is usually mild, treatment is rarely necessary. Many patients require long-term anticoagulation therapy to prevent recurrent thrombotic events.

Thrombocytopenia secondary to lymphoproliferative disorders

Immune thrombocytopenia commonly complicates chronic lymphocytic leukaemia. This should be differentiated from thrombocytopenia of underproduction, which is seen in the spent stage of chronic lymphocytic leukaemia. Immune thrombocytopenia is often seen in patients with Hodgkin's disease and can predate or postdate the illness and is not a marker of disease activity.

Alloimmune thrombocytopenia

Alloimmune thrombocytopenia is caused by alloantibodies against platelet glycoproteins. There are two typical alloimmune thrombocytopenic disorders, alloimmune neonatal thrombocytopenia and post-transfusional purpura.

Alloimmune neonatal thrombocytopenia

Alloimmune neonatal thrombocytopenia is mediated by alloantibodies in maternal plasma directed against fetal platelet glycoproteins inherited from the father. This disorder causes severe and often life-threatening fetal thrombocytopenia that can occur *in utero*. The most common alloantibody to cause this disorder is targeted against a platelet glycoprotein called PL ^{A1} (HPA-1a) located on platelet glycoprotein IIIa.

Post-transfusion purpura

In cases of post-transfusion purpura the patient, usually a woman, develops severe thrombocytopenia 5 to 12 days after receiving a transfusion of a blood product containing platelets. The thrombocytopenia is often very severe (platelet count < 10×10^{9}/litre). Post-transfusion purpura occurs when a patient produces an alloantibody to a specific platelet antigen that she lacks, usually PL ^{A1}. The syndrome most commonly occurs in multiparous women because previous pregnancies lead to their sensitization. Patients, including men, who have previously been transfused are also at risk.

The diagnosis of post-transfusion purpura is made by the identification of a platelet-specific antibody in a patient with acute onset of thrombocytopenia 5 to 12 days after receiving a transfusion of a blood product. Although post-transfusion purpura is most commonly seen after transfusion of packed red blood cells, all blood products, including plasma, can cause the reaction. Post-transfusion purpura is self-limited with recovery occurring within 1 to 3 weeks. However, because the condition can be lethal, treatment with plasmapheresis or intravenous immunoglobulins should be considered. Platelet transfusions should be avoided except in cases of life-threatening haemorrhage.

Drug-induced thrombocytopenia

Many drugs can cause thrombocytopenia. These medications most commonly implicated include heparin, quinidine, sulfonamides, and gold. However, virtually every medication has been associated with thrombocytopenia.

Patients with drug-induced thrombocytopenia typically have moderate to severe thrombocytopenia. Thrombocytopenia is usually seen 1 to 2 weeks after beginning a medication, but it may occur in patients who have been taking the medication for several years. The platelet destruction is usually IgG-mediated. The thrombocytopenia usually resolves within days of stopping the causative drug. In cases of severe thrombocytopenia, the drug should be discontinued and the patient treated with reticuloendothelial blockade using either intravenous immunoglobulins or intravenous anti-D immune globulin. Treatment with corticosteroids is less effective. In cases of life-threatening haemorrhage, platelet transfusions may be required. Patients should not take the drug causing the thrombocytopenia again as it will cause thrombocytopenia with subsequent exposure.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia develops between 5 and 8 days after the initiation of heparin therapy but if the patient has been exposed to heparin within the last 3 months, it can occur earlier. Patients develop moderate thrombocytopenia (platelet counts (40–80) × 10^{9}/litre). Patients with heparin-induced thrombocytopenia frequently develop thrombotic complications, especially deep venous thrombosis and pulmonary embolism. Other clinical associations include arterial thrombosis, skin lesions, and uncommon thrombotic events such as adrenal gland thrombosis and haemorrhage.

Heparin-induced thrombocytopenia is caused by an IgG antibody, which recognizes a complex of heparin and platelet factor 4. The platelet factor 4/heparin/IgG immune complexes bind to platelet crystallizable fragment receptors causing platelet activation and microparticle formation resulting in activation of coagulation.

The frequency of heparin-induced thrombocytopenia varies among clinical settings. The risk of thrombocytopenia appears to be related to the type, dose, and duration of heparin administration. For example, unfractionated heparin is more immunogenic than low-molecular-weight heparin. Also, different patient populations have different risks of forming heparin-induced thrombocytopenia IgG. For example, the risk of heparin-induced thrombocytopenia IgG is higher in orthopaedic patients than in medical patients.

The diagnosis of heparin-induced thrombocytopenia should be considered in all patients receiving heparin therapy who develop thrombocytopenia or thrombotic complications. Serological tests can be used to confirm the diagnosis of heparin-induced thrombocytopenia. Enzyme assays measure the binding of platelet antibodies to a complex of heparin and platelet factor 4. The gold standard tests are biological assays, such as the serotonin release assay.

Treatment of heparin-induced thrombocytopenia involves discontinuation of heparin. The patient should be treated with an agent that inhibits thrombin generation, such as hirudin or argatroban. Warfarin should not be used to treat acute heparin-induced thrombocytopenia because it can trigger warfarin-induced limb gangrene.

Gold-induced thrombocytopenia

Gold-induced thrombocytopenia occurs in as many as 3 per cent of patients treated. There appears to be a genetic predisposition to the syndrome with HLA DR3 occurring in up to 80 per cent of affected patients. The thrombocytopenia usually occurs within the first several months of therapy and can range from mild to severe. Treatment involves stopping the drug and providing supportive treatment. The thrombocytopenia can persist for many months after the discontinuation of gold. This is probably due to persistence of an autoantibody, but may be due to the prolonged release of gold from tissue stores. Rapid correction of the thrombocytopenia may be achieved with intravenous immunoglobulins; however, a relapse of the thrombocytopenia may occur in 2 to 4 weeks. Patients also respond to corticosteroids. Some patients with persistent thrombocytopenia may respond to splenectomy. There is less experience using gold-chelating agents such as deferoxamine or dimercaprol.

Non-immune platelet disorders

Destructive thrombocytopenia and schistocytic haemolysis

Certain disorders are associated with both thrombocytopenia and schistocytic or fragmentation haemolysis. These disorders include thrombotic thrombocytopenic purpura, haemolytic uraemic syndrome, and disseminated intravascular coagulation.

Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura is a syndrome consisting of thrombocytopenia, microangiopathic haemolytic anaemia, renal impairment, fever, and neurological findings secondary to ischaemia. Thrombotic thrombocytopenic purpura is an uncommon disorder, but its recognition is important because it is usually fatal if not treated.

Most patients who develop thrombotic thrombocytopenic purpura are young to middle-aged with slightly more females affected than males. The presentation of illness may be insidious or acute. Typically, the patient has a several day history of generalized malaise, fatigue, or focal ischaemic problems. The focal ischaemic events usually involve the central nervous system and can include sudden weakness, paraesthesiae, and confusion. Approximately 50 per cent of patients will have a neurological event.

Most adult patients with thrombotic thrombocytopenic purpura do not have an associated underlying condition. Nonetheless, the initial evaluation of a patient with thrombotic thrombocytopenic purpura should exclude diseases associated with thrombotic thrombocytopenic purpura (Table 3). Thrombotic thrombocytopenic purpura can develop spontaneously, but is often triggered by an infection, pregnancy, or vaccination.

All patients with thrombotic thrombocytopenic purpura have destructive thrombocytopenia. The thrombocytopenia is the best indicator of disease activity. Additional laboratory investigations demonstrate abnormalities of microangiopathic haemolytic anaemia, such as anaemia, fragmented red blood cells, and increased reticulocyte count. Serum lactate dehydrogenase and bilirubin levels are elevated. Other abnormalities include elevated serum creatinine, proteinuria, and abnormal liver function tests. Investigators have identified the presence of abnormal von Willebrand factor multimers in patients with thrombotic thrombocytopenic purpura.

Thrombotic thrombocytopenic purpura is treated with plasmapheresis. This treatment has reduced the mortality from 80 per cent to 20 per cent. Plasma exchange of at least one to two volumes of plasma should be performed daily. Plasma should be replaced with cryosupernatant plasma or fresh frozen plasma. Cryosupernatant plasma may be more beneficial because it is depleted of von Willebrand factor. Plasmapheresis should be continued until the platelet count and serum lactate dehydrogenase have normalized. This generally occurs after three to ten exchanges. Plasma exchange is better than plasma infusion alone. However, when plasmapheresis is not immediately available, patients should be treated initially with plasma infusion. If the initial response to plasma exchange is poor, other therapies such as glucocorticoids may be added. Additionally, the volume of plasma exchange may be increased. Other treatments, such as antiplatelet agents, are of uncertain benefit. With discontinuation of plasma exchange, exacerbation of disease occurs in about a third of patients. This risk of relapse can be reduced by splenectomy.

Haemolytic uraemic syndrome

Haemolytic uraemic syndrome includes renal failure, microangiopathic haemolytic anaemia, and thrombocytopenia. Different types of haemolytic uraemic syndrome have been identified including classic epidemic, sporadic, hereditary and sporadic in association with non-infectious conditions. Epidemic haemolytic uraemic syndrome is seen primarily in children and occurs after a diarrhoeal illness caused by enterohaemorrhagic or verotoxigenic *Escherichia coli* serotype O157:H7 or *Shigella dysenteriae* serotype I. Haemolytic uraemic syndrome may be also associated with other bacterial, viral, and rickettsial infections. Patients have been reported to develop haemolytic uraemic syndrome after receiving immunizations.

Laboratory investigations demonstrate severe anaemia and thrombocytopenia. Examination of the peripheral smear shows fragmented red blood cells, burr cells, and spherocytes. Haemoglobinaemia and haemoglobinuria may be severe. Serum lactate dehydrogenase levels and other markers of red blood cell destruction are elevated. The serum creatinine is usually increased.

In children, the treatment of haemolytic uraemic syndrome focuses on providing supportive care with careful attention paid to fluid status and electrolyte levels. Plasma exchange should be considered in children with severe haemolytic uraemic syndrome. In adults, treatment of haemolytic uraemic syndrome generally includes plasmapheresis. Other therapies including antiplatelet agents, fibrinolytic therapy, and heparin therapy have not been shown to be beneficial, and are not recommended.

Disseminated intravascular coagulation

Disseminated intravascular coagulation is a disorder in which clotting occurs within the circulation. Disseminated intravascular coagulation is characterized by large amounts of thrombin that overwhelm the physiological inhibitors of coagulation. The thrombin causes platelet aggregation resulting in thrombocytopenia and fibrinogen cleavage into fibrin, which forms the microthrombi. The most common cause of disseminated intravascular coagulation is sepsis, but disseminated intravascular coagulation is associated with a large number of disorders including trauma and obstetric conditions (Table 4). The clinical presentation is variable, but patients with disseminated intravascular coagulation are usually very unwell presenting with fulminant bleeding and organ dysfunction. Some patients have thrombotic events. Occasionally, disseminated intravascular coagulation can be subclinical and detected only with laboratory tests. The diagnosis of disseminated intravascular coagulation is supported by the laboratory finding of thrombocytopenia in association with fragmented red blood cells, decreased fibrinogen level, and elevated fibrinogen and fibrin degradation products such as D-dimers. Coagulation studies often show a prolonged international normalized ratio, partial thromboplastin time, and thrombin time. Disseminated intravascular coagulation is best managed by identifying and treating its cause. If the patient is bleeding, replacement therapy with fresh frozen plasma, cryoprecipitate, and platelets is indicated. Heparin therapy may be of benefit in patients with clinical evidence of ongoing microvascular thrombosis.

Sepsis and infection

Transient thrombocytopenia occurs with systemic infections. Thrombocytopenia occurs in 50 to 75 per cent of patients with bacteraemia or fungal infections. It also occurs in association with viral infections, including HIV. The thrombocytopenia is generally mild to moderate and is not usually associated with symptoms of bleeding. The mechanism leading to the lowered platelet count is multifactorial including activation of platelets by bacterial products or mediators of inflammation; destruction due to immune mechanisms; or destruction due to chemokine-induced macrophage ingestion of platelets. Additionally, severe viral infections may lead to suppression of platelet production. Resolution of the platelet count occurs with eradication of the infection.

Thrombocytopenia associated with HIV is common, occurring in at least 20 per cent of patients with symptomatic disease. Various mechanisms contribute to the thrombocytopenia. Some patients have immune mediated destruction of platelets. Patients also have a defect in platelet production due to direct infection of megakaryocytes and the suppressive effects of medications. The platelet count can improve with antiretroviral therapy. Patients with severe thrombocytopenia should be treated similarly to patients with idiopathic thrombocytopenic purpura including the performance of a splenectomy.

Haemophagocytic syndrome

This rare syndrome is caused by phagocytosis of haematological cells by macrophages. Adult patients can present with an acute illness consisting of fever, weight loss, hepatosplenomegaly, pancytopenia, and increased liver enzymes. Bone marrow aspiration is diagnostic and shows morphological evidence of phagocytosis of platelets, red blood cells, and granulocytes by macrophages. The haemophagocytic syndrome may be associated with infections, particularly with the Epstein–Barr virus, T-cell lymphoma, histiocytosis, or immune disorders such as systemic lupus erythematosus and Still's disease. Treatment is directed at the underlying disorder.

Decreased platelet production

Platelet production is impaired by conditions affecting megakaryocyte progenitor cells, megakaryocytes, or the bone marrow stroma. It is rare to see a deficit in platelet production without abnormalities in the production of other cell lines as well. Decreased platelet production can occur when the bone marrow is aplastic, dysplastic, or infiltrated with other cells. Diagnosis of a defect in platelet production is usually made by evaluation of the bone marrow. Disorders causing decreased platelet production may be classified as congenital or acquired.

Congenital disorders causing decreased platelet production

Thrombocytopenia in infancy is usually due to increased platelet destruction and is only rarely due to decreased production. However, various congenital disorders may result in decreased platelet production. These disorders include congenital amegakaryocytic thrombocytopenia, thrombocytopenia with absent radii syndrome, Wiskott–Aldrich syndrome, May–Hegglin anomaly, Epstein's syndrome, Fechtner's syndrome, and Sebastian platelet syndrome. Bernard–Soulier syndrome is also associated with moderate thrombocytopenia.

Acquired disorders causing decreased platelet production

Toxins

A variety of drugs and toxins may cause bone marrow suppression and subsequent thrombocytopenia. Chemotherapy and irradiation cause direct destruction of megakaryocytes and other cells of the marrow. Other medications causing marrow aplasia are numerous and include chloramphenicol, non-steroidal anti-inflammatory drugs, antiepileptic medications, and gold.

Alcohol

Thrombocytopenia is the most common haematological abnormality associated with alcohol abuse. The thrombocytopenia can be due to hypersplenism (described subsequently) or alcohol suppression of the marrow. Alcohol induced marrow suppression can cause very severe thrombocytopenia requiring treatment by platelet transfusions. Elimination of alcohol intake will result in an increase of the platelet count within days to weeks. Associated haematological abnormalities include megaloblastic anaemia and ringed sideroblasts.

Nutritional deficiencies

Thrombocytopenia may occur with folate or vitamin B_{12} deficiency. The degree of thrombocytopenia is variable and may be severe. Associated haematological abnormalities include megaloblastic anaemia and hypersegmented neutrophils. Replacement of the deficient vitamin will result in recovery of the platelet count. Iron deficiency has also been associated with thrombocytopenia, although more frequently with thrombocytosis. Replacement of iron generally corrects the platelet count.

Infiltration of the bone marrow

The bone marrow may become infiltrated with non-haematopoietic or non-stromal cells. Conditions that may lead to marrow infiltration include metastatic cancer, haematological malignancies (leukaemia, lymphoma, myeloma), myelofibrosis, storage disorders, and granulomatous disorders (sarcoidosis, tuberculosis).

Acquired amegakaryocytic thrombocytopenic purpura

Bone marrow aplasia is characterized by hypocellularity of the marrow. Aplasia involving more than one lineage of haematopoietic cells is called aplastic anaemia. When isolated decreased platelet production occurs, it is called amegakaryocytic thrombocytopenic purpura. This rare condition frequently progresses to aplastic anaemia. Bone marrow examination reveals absent or severely decreased numbers of megakaryocytes. The disorder may be secondary to various aetiologies including drugs, toxins, and infections, but most frequently it is idiopathic. Treatment varies with the suspected aetiology and typically is supportive, but can include intravenous IgG, corticosteroids, and immunosuppressive therapies.

Myelodysplastic syndromes

Myelodysplastic syndrome can present with isolated thrombocytopenia. Examination of the bone marrow usually demonstrates abnormal megakaryocyte morphology and cytogenetic analysis reveals chromosomal abnormalities.

Disorders of platelet distribution and platelet sequestration

Splenomegaly and hypersplenism

Decreased numbers of circulating platelets may be seen in patients with splenomegaly. Normally, one-third of the circulating platelets are pooled in the spleen. With splenomegaly the size of the pool of platelets sequestered in the spleen increases, decreasing the number of circulating platelets. Increased destruction of the platelets may also occur. The thrombocytopenia is usually moderate (platelets > 40 × 10^9/litre). Bone marrow examination reveals normal numbers of megakaryocytes. Other laboratory abnormalities include leucocytosis with a normal differential and mild anaemia. Splenomegaly may be demonstrated by ultrasound or a liver–spleen scan. The diagnosis of hypersplenism can be confirmed by performing an autologous platelet survival test. This test will show a reduced recovery of transfused platelets (usually < 30 per cent) with a normal platelet survival. The thrombocytopenia is rarely severe enough to require treatment; however, splenectomy is curative.

Haemodilutional disorders

A low number of circulating platelets may also be seen in patients who have received large volumes of crystalloid solutions or blood products. This type of thrombocytopenia is commonly seen immediately after surgery and is transient. If treatment is required, the patient should receive platelet transfusions.

Extracorporeal circulation

Patients undergoing cardiopulmonary bypass commonly develop mild thrombocytopenia. The cause of the decreased platelet count is multifactorial; adherence of platelets to synthetic surfaces causes activation and damage to the platelets, haemodilution, and blood loss. The thrombocytopenia is usually mild. Generally, the platelet count recovers within 3 to 4 days to levels greater than the count preoperatively.

Hypothermia

Hypothermia is associated with transient thrombocytopenia. Decreased body temperature results in pooling of platelets in the peripheral circulation. Hypothermia may be seen in cases of environmental exposure, after prolonged surgery, and after transfusions of massive amounts of inadequately warmed blood products.

Thrombocytosis

Thrombocytosis is defined as a platelet count greater than 600 × 10^9/litre. An elevated platelet count may be primary (essential) or secondary to other disorders.

Thrombocythaemia

Primary thrombocytosis also known as thrombocythaemia is a chronic myeloproliferative disorder. Other chronic myeloproliferative disorders such as polycythaemia vera, myeloid metaplasia, and chronic myelogenous leukaemia can also cause an increase in platelet count.

Incidence and epidemiology

The true incidence of thrombocythaemia has been estimated as approximately two patients per 100 000 population per year. The average age at diagnosis is 60 to 80 years with males and females equally affected. Young women in their thirties may present with thrombocythaemia.

Aetiology and pathogenesis

Thrombocythaemia is probably a clonal process originating at the stem cell level leading to sustained proliferation of megakaryocytes with increased umbers of circulating platelets. Thrombopoietin may also play a role in the pathogenesis of the disorder. Studies have shown reduction of c-Mpl protein and messenger RNA expression. This may reflect an intrinsic defect of c-Mpl transcription or decreased receptor expression that results in ineffective clearance of thrombopoietin.

Clinical findings

Two-thirds of patients have symptoms at the time of diagnosis, typically thrombotic or bleeding. Thrombotic events are common, occurring in 20 to 30 per cent of patients. The thrombosis involves the microvasculature and patients present with headache, transient ischaemic attacks or strokes, paraesthesiae of extremities, distal extremity gangrene, and erythromelagia (burning pain and redness of the toes or fingertips). Patients with essential thrombocythaemia have an increased risk of angina pectoris and myocardial infarction. Patients at greatest risk for thrombotic events are older and have a history of thrombosis. Major bleeding complications are rare, but bruising is common.

Laboratory findings

Patients have an unexplained elevation of their platelet count, typically above 800 × 10^9/litre. Examination of the peripheral smear can reveal megathrombocytes and leucocytosis with immature myeloid precursor cells. Mild eosinophilia and basophilia can occur. Bone marrow evaluation shows increased cellularity, marked megakaryocytic hyperplasia, and clustering of megakaryocytes. In addition the megakaryocytes often are morphologically bizarre with nuclear pleomorphism. Bone marrow karyotypes are usually normal. The Polycythaemia Vera Study Group has suggested criteria for the diagnosis of essential thrombocythaemia (Table 5).

Management

Untreated, asymptomatic patients with thrombocythaemia can have a near normal life expectancy. Furthermore, the thrombotic risk in asymptomatic patients younger than 60 years of age with no history of thrombosis is not increased. Therefore, young, asymptomatic patients do not require treatment. Possible indications for treatment to lower platelet count include patients with a history of thrombotic events, patients with cardiovascular risk factors, elderly patients, and patients in whom platelet counts remain very high (> 1000 × 10^9/litre).

Low-dose aspirin can be used to prevent thrombosis and it may relieve symptoms such as headache and erythromelagia. However, aspirin may unmask bleeding tendencies so it should be avoided in patients with a history of bleeding. Hydroxyurea will lower the platelet count and usually reduces thrombohaemorrhagic complications. Adverse affects include myelosuppression and possibly an increased risk of leukaemic transformation. Anagrelide can effectively lower the platelet count, but its efficacy at reducing complications has not been definitively established. Interferon-a may also be used to lower platelet counts. Unfortunately, side-effects including flu-like symptoms, anorexia, and neuropsychiatric symptoms are severe enough to cause discontinuation of therapy in up to 25 per cent of patients.

Prognosis

The life expectancy of patients with thrombocythaemia is near normal. However, patients do have a high rate of morbidity secondary to thrombotic events. Three to four per cent of patients develop leukaemia. This occurs predominantly in patients who have been treated with alkylating agents.

Secondary thrombocytosis

Essential thrombocythaemia must be differentiated from reactive or secondary thrombocytosis. Causes of secondary thrombocytosis include infections, malignancy, chronic inflammatory bowel disease, rheumatoid arthritis, iron deficiency, and hyposplenism. Reactive thrombocytosis is not associated with symptoms related to the

elevated platelet count. Reactive thrombocytosis is not harmful and does not require treatment, although the underlying cause should be determined.

Disorders of platelet function

Congenital disorders of platelet function

Patients with congenital disorders of platelet function often present with a history of easy bruising, epistaxis, menorrhagia, and prolonged bleeding after surgery or dental procedures. Some of these patients may have family members with similar problems. The various platelet abnormalities may be classified functionally into disorders of platelet adhesion, aggregation, secretion, and procoagulant activity.

Disorders of platelet adhesion and aggregation

Platelet function disorders include Bernard–Soulier syndrome which is caused by a deficiency or abnormality of platelet glycoprotein Ib/IX and Glanzmann's thrombasthenia, caused by a deficiency of glycoprotein IIb/IIIa. Both are inherited in an autosomal recessive fashion and are very rare.

Disorders of platelet secretion

Disorders of platelet secretion occur when there are abnormalities of the platelet secretory pathways or if there is a deficiency of platelet granules. Grey platelet syndrome occurs when the alpha granules are decreased or absent. Dense granule deficiency or platelet storage pool deficiency is due to a deficiency of dense granules. In alpha delta storage pool deficiency, both the alpha and dense granules are deficient.

Disorders of platelet procoagulant activity

Platelets play an important role in haemostasis by providing a phospholipid membrane on which various coagulation reactions occur. In disorders such as Scott syndrome, abnormalities of the platelet membrane impair its procoagulant activity.

Treatment

There are no definitive therapies for any of the congenital disorders of platelet function. Administration of 1-desamino-8- D-arginine vasopressin induces the release of von Willebrand factor from endothelial cells and will improve bleeding time and haemostasis. An effect is seen within 1 to 2 h and lasts for up to 12 h. Antifibrinolytic agents, such as aminocaproic acid, may improve haemostasis. Menorrhagia may be controlled by oral contraceptive medications and perhaps by antifibrinolytic medications. In cases of life-threatening bleeding, platelet transfusions may be necessary. However, platelet transfusions can cause immunization against the platelet receptors and should be avoided.

Acquired disorders of platelet function

The most common acquired causes of platelet dysfunction are medications and toxins, systemic disorders, and haematological diseases.

Drugs

There are numerous drugs that have been shown to affect platelet function (Table 6). Aspirin has been demonstrated to cause a significant increase in bleeding. Aspirin acts by irreversibly inhibiting platelet cyclo-oxygenase resulting in decreased formation of thromboxane $A_{2,}$ an agonist for platelet aggregation. Non-steroidal anti-inflammatory agents affect platelet function by inhibiting cyclo-oxygenase. Ticlopidine and clopidrogel inhibit platelet function by inhibiting the action of platelet adenosine diphosphate. Glycoprotein IIb/IIIa inhibitors block platelet aggregation by directly inhibiting the platelet receptor for fibrinogen, glycoprotein IIb/IIIa. b-lactam antibiotics may bind to and modify the platelet membrane resulting in abnormal platelet aggregation with adenosine diphosphate, epinephrine, and collagen. Nitrates inhibit platelet aggregation. Calcium channel blockers and b-blockers affect platelet aggregation by unknown mechanisms. Other drugs that may adversely affect platelet function include antiepileptic medications, tricyclic antidepressants, and phenothiazines.

Chronic renal failure

Patients with chronic renal failure or uraemia have platelet dysfunction including defects in adhesion, aggregation, secretion, and procoagulant activity. The bleeding time may be prolonged. The pathogenesis of the platelet dysfunction is unknown, but is probably secondary to toxins present in the uraemic plasma. Treatment of a bleeding uraemic patient includes prompt dialysis. 1-desamino-8- D-arginine vasopressin will improve haemostasis. Maintenance of a normal haematocrit may decrease the bleeding tendency.

Cardiopulmonary bypass surgery

Excessive bleeding occurs in approximately 5 to 20 per cent of patients undergoing cardiopulmonary bypass surgery. Studies have demonstrated decreased platelet aggregation, altered platelet surface membrane proteins, selective depletion of platelet alpha granules, and evidence of *in vivo* platelet activation. An extrinsic platelet defect may occur resulting from thrombin inhibition by high doses of heparin. The aetiology of these abnormalities could be related to the hypothermia of the procedure and damage to the platelets as they pass through the pump system. The haemostatic abnormalities improve within hours after surgery.

Chronic myeloproliferative disorders and myelodysplastic syndromes

Disorders such as chronic myelogenous leukaemia, essential thrombocythaemia, polycythaemia vera, and myeloid metaplasia may be associated with abnormalities of platelet number and function. Abnormalities of platelet function include impaired aggregation with epinephrine, abnormal arachidonic acid metabolism, and storage pool defects. The bleeding tendency responds to treatment of the underlying disorder and correction of the associated thrombocytosis.

Dysproteinaemias

Patients with a paraproteinaemia, such as multiple myeloma or Waldenström's macroglobulinaemia, can have abnormalities in both platelet number and function. Non-specific binding of the paraproteins to the platelet membrane may interfere with membrane surface receptors. Treatment of the disorder causing the paraproteinaemia will usually correct the bleeding problem. Acutely, measures such as plasma exchange may be necessary.

22.6.4 Genetic disorders of coagulation

Eleanor S. Pollak and Katherine A. High

Haemostasis, the physiological process of blood clot formation, involves a co-ordinated interaction between the wall of the blood vessel, platelets, and blood coagulation proteins. The haemostatic mechanism maintains a state of readiness to respond to a multitude of haemostatic stressors to prevent haemorrhage while also preventing inappropriate clot formation. Although acquired diseases of the coagulation system frequently occur with liver disease and other pathological disease states, this chapter will specifically focus on genetic disorders resulting from abnormalities and/or deficiencies of the blood coagulation proteins. More specifically, this chapter will cover haemophilia, von Willebrand disease, and deficiencies/abnormalities of fibrinogen and factors II, V, VII, X, XI, XII, and XIII. The role of an inherited increased risk for excess clotting will also be addressed. These conditions may result from either the loss of function of anticoagulant proteins (antithrombin III, protein C, and protein S) or a gain of function of procoagulant proteins (factor V Leiden and prothrombin 20210 G to A).

The coagulation cascade as a haemostatic mechanism

The human blood coagulation system involves a co-ordinated array of reactions which generate a stable fibrin clot when needed and prevent unnecessary clot formation. The system involves numerous proteins which interact, principally on phospholipid surfaces, to create a meshwork of fibrin fragments entrapping haematopoietic cells (Fig. 1). The majority of coagulation enzymatic complexes involve protease enzymes. Many of these enzymes are serine proteases, and a subset of these have the distinguishing feature that their functional synthesis requires vitamin K to enable post-translational modification of glutamic acid residues in the NH_2 terminal region; this property provides the basis of the therapeutic mechanism by which the drug warfarin prevents proper synthesis of functional factors. The principal enzyme balancing the pro- and anticoagulant forces is prothrombin, thought to be the evolutionary forerunner of the mammalian coagulation proteins. In addition to its procoagulant functions, prothrombin, once activated, provides anticoagulant and cellular mobility functions as well.

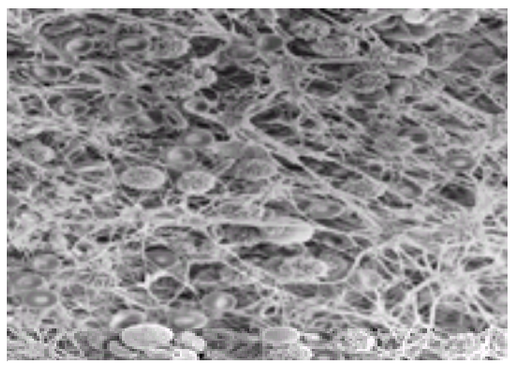

Fig. 1 Scanning electron micrograph of a whole blood clot. There is a meshwork of fibrin fibres emanating from platelet aggregates in which erythrocytes, lymphocytes, and other cells are trapped. (By courtesy of John W. Weisel and Chandrasekaran Nagaswami, Department of Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA, United States.)

In 1905, Morawitz first described the importance of thrombin, thromboplastin, and calcium in cleaving fibrinogen to create a fibrin clot. In the early 1930s and 1940s laboratory tests were developed that relied on *in vitro* fibrin clot formation to analyse the adequacy of a patient's clotting system. The waterfall cascade of sequential activation steps resulting in a fibrin clot was elegantly described in the early 1960s delineating separate pathways to account for the prothrombin time and the partial thromboplastin time which the earlier laboratory tests measure. However, the set of activation steps is now better described as an interwoven, reinforcing set of reactions (Fig. 2). The unique specificities of the coagulation enzymes summarized in the classical coagulation cascade have been found to be more versatile in activating diverse proteins under varied conditions. However, the separate pathways, now termed the tissue factor (extrinsic) and the intrinsic pathways, help define the steps involved in the principal tests used in clinical medicine for evaluation of haemostatic proteins. For the series of reactions and specific factors involved, the time to clot formation defines the principal parameter used in clinical evaluation of the health of a patient's coagulation system. The assays (the prothrombin time, the activated partial thromboplastin time, and activity levels of specific individual clotting factors) compare the time needed for clot formation in a patient's plasma with that in a control pool of plasma from normal donors.

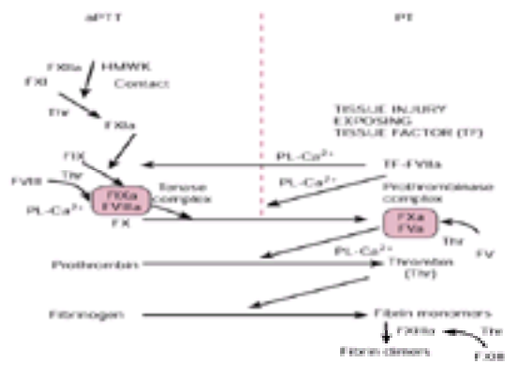

Fig. 2 Schematic representation of the enzymatic reactions involved in blood clot formation. Thr, thrombin; PL-Ca^{2+}, phospholipids/calcium; PT, prothrombin time; aPTT, activated partial thromboplastin time.

Endothelial injury and tissue damage first trigger clot formation. The response of the platelets forms the primary phase of healing by temporarily patching the site of vascular injury. Subsequent to this initial platelet phospholipid patch, a fibrin clot provides a more solid framework for the necessary but slower cellular repair. Secondary haemostasis begins with injury-induced exposure of the integral membrane protein tissue factor to plasma proteins enabling formation of the active enzymatic complex tissue factor–factor VIIa. The generation of tissue factor–factor VIIa then catalyses clotting by activating both factor X to factor Xa and factor IX to factor IXa. This activation primarily involves the cleavage of an arginine–isoleucine bond in a secreted plasma protein zymogen to form a two-chain active protein.

Thus, once tissue injury has signalled the need for fibrin clot formation and tissue factor–factor VIIa has initiated coagulation, the haemostatic process amplifies through the generation of factor IXa, which is ten times more abundant than factor VII and consequently leads precipitously to thrombin generation. Among thrombin's numerous roles is the activation of the essential procoagulant cofactors factors V and VIII. This process then further amplifies clotting by generating more thrombin through the active cofactors Va and VIIIa which then form the tenase (factor IXa/factor VIIIa) and prothrombinase (factor Xa/factor Va) complexes (see Fig. 1). Thrombin also activates the crosslinking enzyme, factor XIII, the fibrinolytic inhibitor, TAFI, and triggers platelet recruitment. Importantly, thrombin generation simultaneously counterbalances its procoagulation activities by inciting lysis of the clot via the release by endothelial cells of tissue plasminogen activator converting plasminogen to plasmin, the enzyme responsible for lysis of fibrin clots. Thrombin also dampens the clotting process by activating protein C that actively breaks down the critical procoagulant cofactors factors Va and VIIIa.

The basis for initiating clot formation in the prothrombin time and activated partial thromboplastin time test is titration of calcium into an anticoagulated plasma specimen along with a source of phospholipid. In addition, in the prothrombin time test, the source of phospholipid is a thromboplastin reagent which provides tissue factor to enable the tissue factor–factorVIIa complex to catalyse clot formation. In the activated partial thromboplastin time test the phospholipid reagent lacks tissue factor and thus prevents formation of the tissue factor–factor VIIa complex. An activator, such as silica particles, also greatly decreases the time required for clot formation through activation of factor XII via the contact activation system.

Deficiencies of specific clotting proteins

Haemophilia

Deficiency of either factor VIII (haemophilia A) or factor IX (haemophilia B), which together make up the factor VIIIa/factor IXa intrinsic tenase enzymatic complex, results in the clinical phenotype commonly known as haemophilia. A sex-linked bleeding diathesis, now thought to be haemophilia, was described in Talmudic writings as a cause of fatal haemorrhage at circumcision. In the modern era, the disease may cause bleeding at circumcision, but haemophilia principally presents with haematoma formation, easy bruising, and bleeding at the site of venepuncture during the toddler period. The disease exists in severe, moderate, and mild forms classified as such on the basis of a clinical laboratory blood coagulation test performed to assess the level of functional coagulant protein (per cent activity of factor VIII or factor IX). The pathological problem in both haemophilia A, factor VIII deficiency, and haemophilia B, factor IX deficiency (also called Christmas disease), is the inability to form a functional tenase complex to activate factor X to factor Xa. Although factor X can still be activated to factor Xa by tissue factor–factor VIIa, the available quantities of factor VII (400 ng/ml) do not allow sufficient activation of factor X to enable clotting to occur in a physiologically timely fashion. Although patients with haemophilia may have some difficulties with immediate haemorrhage subsequent to a cutaneous or superficial injury, they characteristically have joint and deep tissue bleeding problems as discussed below. The severity of disease is very well predicted by an *in vitro* assay for evaluation of the deficient protein level such that patients with severe disease have levels of factor activity of less than 1 per cent, patients with moderate disease have activity levels of 1 to 5 per cent, and patients with mild disease have activity levels of 6 to 30 per cent. Normal factor VIII and IX levels are 50 to 200 per cent and 75 to 125 per cent respectively.

Numerous genetic mutations have been described accounting for the factor deficiencies causing haemophilia. In part because of the considerable difference in size between the factor VIII gene (186 kbp), and the factor IX gene (34 kbp), the ratio of the frequency of factor VIII to factor IX deficiency is between four and five to one (approximately 186/34 kbp). Thus, the frequency of haemophilia A is approximately one in 5000 to 6000 and that of haemophilia B is approximately one-fifth of that. Among affected cases, approximately one in three to one in four patients presents spontaneously without a familial inheritance pattern. One of the only differences between factor VIII and IX deficiencies is the frequency of severe disease, which occurs more commonly in factor VIII deficiency (60 per cent of cases as compared with 45 per cent in haemophilia B). This difference is largely attributed to the frequency of mutation due to a factor VIII gene inversion in intron 22 of the 26 exon long factor VIII gene. At this locus of the factor VIII gene, a region of homology to sequences telomeric to the factor VIII gene, a recombination event results in the inability to synthesize any functional factor VIII, thus leading to severe disease (less than 1 per cent functional protein activity). In both factor VIII and factor IX deficiency, milder disease is commonly due to missense mutations.

The clinical features of haemophilia predominantly include bleeding into joints and soft tissues. The incidence of central nervous system bleeding has dramatically decreased with concentrate therapy. The life expectancy of people with severe haemophilia had increased from 11 years at the beginning of the twentieth century to approximately 60 years in the early 1980s, before the devastating effects of bloodborne viral disease again shortened average life expectancy.

In the untreated patient with severe disease, haemophilic arthropathy and joint deformity are inevitable complications. In decreasing order of involvement, the most commonly affected joints include the knee, elbow, ankle, shoulder, wrist, and hip. Recurrent bleeding episodes create a hypertrophic synovial lining with chronic inflammation; however, the pathophysiology responsible for recurrent joint bleeding remains unknown. Arthropathies commonly necessitate replacement of affected joints for pain control and improvement of mobility. Soft tissue haemorrhages frequently complicate haemophilia; further complications due to these haemorrhages include compartment syndrome, neurological damage, and extensive blood loss from retroperitoneal bleeds. Haematoma formation, a frequent complication of haemophilia, may arise spontaneously or with trauma and require extensive factor replacement and fasciotomy, the necessity for which can be assessed by mean arterial pressure in a compartment. Intracranial haemorrhage, occurring in approximately 5 per cent of patients, warrants immediate evaluation and treatment within the first 6 to 8 h of presentation; however, the majority of children presenting to an emergency room with central nervous system symptoms have not suffered from intracranial haemorrhage.

A pseudotumour, an encapsulated collection of blood most commonly originating in bone or soft tissues, is a very rare but extremely serious consequence of haemophilia occurring in approximately 2 per cent of patients. This complication is difficult to manage but may sometimes be treated with surgery at specialized haemophilia centres.

Frequently, patients with haemophilia have haematuria, the severity of which may range from self-limited episodes to gross haematuria with significant blood loss. Protease inhibitors for HIV therapy may lead to haematuria with flank pain or renal stones. Physicians should be aware of the possibility of nephrotic syndrome in patients placed on immune tolerance regimens.

Dental procedures warrant involvement of a haemophilia specialist. Factor replacement levels of 25 to 100 per cent are suggested depending on the complexity of the dental procedure. Antifibrinolytics such as e-aminocaproic acid or tranexemic acid and fibrin sealants may be a helpful adjuvant to replacement therapy.

Due to the sex-linked inheritance pattern, haemophilia is rarely found in women unless extensive lyonization takes place in the normal gene. Normal vaginal delivery is considered to be relatively safe in the case of a haemophilic infant; however, vacuum extraction and midcavity forceps deliveries and invasive fetal monitoring should be avoided due to the increased risk of formation of subgaleal and cephalic haematomas.

The laboratory diagnosis of haemophilia is based on a modification of the classic activated partial thromboplastin time assay used as a standard test for the haemostatic system. Normally patients are evaluated due to bleeding symptomatology or because of a prolonged activated partial thromboplastin time result. The activated partial thromboplastin time is a very sensitive but poorly specific screening test for haemophilia. All patients, even those with mild disease, will normally have a prolonged activated partial thromboplastin time unless there is a problem with specimen acquisition or the insensitivity of the activated partial thromboplastin time reagent. Once suspected, haemophilia can be evaluated by an inhibitor screen which involves performing a 50:50 mix of patient and normal plasma to evaluate whether the prolongation is due to a deficiency of a clotting protein or alternatively to the presence of an inhibitor. There are many causes of a prolonged activated partial thromboplastin time other than haemophilia (see Table 1). Classically, a phospholipid inhibitory antibody, called a lupus anticoagulant, will cause a prolongation of the activated partial thromboplastin time of the 50:50 mix due to the effect of the phospholipid inhibitory antibody on the normal pooled plasma. A lupus anticoagulant which causes a prolonged activated partial thromboplastin time may also result in a low factor VIII or factor IX level. In such cases, further testing for a lupus anticoagulant is necessary to rule out a low factor VIII due to a lupus anticoagulant as opposed to a deficiency.

Management of haemophilia predominantly involves administering the missing protein (factor VIII or factor IX) to a patient. Factor replacement therapy is most commonly administered in a so-called 'on-demand' regimen, when a patient's symptomatology necessitates treatment. However, prophylaxis is indicated during surgery or at times of expected injury. Prophylactic therapies during early childhood are now recommended when feasible after the first major bleeding episode as a means of preventing arthropathies in patients with severe disease. Prophylactic administration during the first few years of life requires special consideration due to the need for repeated intravenous access generally requiring an indwelling line. These have been associated with high rates of sepsis, particularly in children under the age of 3. Before the development of stringent purification and virucidal procedures, the transmission of viral disease was almost inevitable as each vial of plasma-derived concentrate was pooled from approximately 60 000 to as many as 400 000 donors, although the number has recently been reduced to 15 000. Tragically, the majority of patients with severe disease treated before 1985 developed HIV. Rates of development of hepatitis B and C are also extremely high. Although drastically reduced; the potential for transmission of infectious disease has not been totally eliminated. Many recombinant preparations are prepared with

human serum albumin thus leaving a possible source of transfusion of a bloodborne disease.

Treatment

Acute bleeding episodes

Safe and effective treatment options continue to improve for the management of acute bleeding episodes for patients with haemophilia A and B. Blood products available include fresh frozen plasma which contains both factors VIII and IX, prothrombin complex concentrates containing factors II, VII, IX, and X, activated prothrombin complex concentrates (factors IIa, VIIa, IXa, Xa), monoclonal-antibody purified factor VIII and factor IX, and recombinant factor VIII and factor IX. Recombinant factor VIIa is now approved for use in patients with inhibitors during acute bleeds. Currently trials using gene therapy approaches are under way and may provide a method for continuous prophylaxis against bleeding. Recombinant or highly purified products are the optimal therapy because of the great benefit to risk ratio. Availability, ease of administration, cost, viral safety, and thrombotic risk, particularly in patients undergoing high-dose therapy or procedures with a high risk of thrombotic complications, dictate the choice of product. Cryoprecipitate, made from the precipitate of thawed frozen plasma, contains factor VIII but does not contain factor IX. Cryoprecipitate and fresh frozen plasma should only be used in the haemophilia patient in an emergency setting where concentrates are not available. Inhibitor formation, the development of antibodies to the deficient protein, arises subsequent to transfusion of a blood product or factor replacement and is the major complication of treatment. An inhibitor presents an extremely difficult situation for patient management (see Complications of therapy below).

Several immunoaffinity purified plasma-derived factor VIII and factor IX products are available in the United States and Europe and currently have excellent records of viral safety, efficacy, and lack of thrombogenicity. When concentrate is unavailable, fresh frozen plasma is readily available in most emergency settings. Virucidal methods using solvent detergent treatment may now be applied in production of fresh frozen plasma; furthermore, each unit is from a single screened donor, thus the risk of transfusion-transmitted disease is low.

Recombinant factor VIII and factor IX have been licensed for nearly a decade. These proteins are produced in cultured mammalian cells and purified from conditioned medium. Recombinant factor IX is devoid of human plasma whereas the recombinant factor VIII concentrates utilize human plasma-derived albumin for stabilization. Because *in vivo* coagulant activity of recombinant factor IX is only 80 per cent of *in vitro* estimates used for labelling of product in IU/mg, it is recommended that the calculated factor IX dosage be multiplied by a factor of 1.2 for dose calculation when using recombinant factor IX. A plausible explanation for this discrepancy is a difference in post-translational modifications compared with plasma-derived factor IX.

During severe and critical bleeds it is optimal to achieve 50 to 100 per cent factor activity levels for 7 to 10 days (for example for pharyngeal, retropharyngeal, retroperitoneal, and central nervous system bleeds). More modest levels of 20 to 50 per cent for 2 to 7 days are generally adequate for dental extractions, haematuria, intramuscular or soft tissue bleeds with dissection, or bleeds of the mucous membranes. Levels of 20 to 30 per cent for 1 to 2 days are recommended for uncomplicated haemarthroses, superficial muscle, or soft tissue bleeds. The frequency of dosing is every 12 to 24 h for factor IX concentrates and every 8 to 12 h for factor VIII concentrates. At 24 h for factor IX and 12 h for factor VIII, the calculated amount to infuse would be one-half the initial amount of factor IX, as the half-life of factor IX is approximately 18 to 24 h.

The timing of factor level determination should be 15 to 30 min after the loading dose and immediately prior to subsequent doses for appropriate dose adjustments. When factor concentrates are used for patients with inhibitors, higher doses will most likely be required. Additionally, some authors have also reported good success and reduced cost with constant infusion regimens.

Calculation of the optimal factor concentration for administration

The number of IU (International Units) of factor required is equal to:

$$\text{body weight (kg)} \times \text{desired \% increase in factor VIII or IX level} \times C.$$

C is a constant depending on the product and the source of the product: *C* is equal to 0.5 for administration of plasma-purified and recombinant factor VIII, *C* is equal to 1 for administration of plasma-purified factor IX,* and *C* is equal to 1.2 for administration of recombinant factor IX.†

Surgery in patients with haemophilia

When possible, treatment should be instituted by caregivers aware of major and minor adverse reactions and complications occurring in the haemophiliac population. Care should also be given in association with an experienced reference laboratory able to provide timely evaluation of a patient's response to treatment. Therapeutic factor levels should be obtained prior to surgery. Depending on the type of surgery, the factor level should reach levels of 50 to 100 per cent of normal and should be maintained 2 to 7 days postprocedure. In addition to factor concentrates, fibrin glue has been recommended with circumcision, antifibrinolytics with dental procedures, aprotinin with cardiac procedures, and recombinant factor VIIa and/or apheresis in patients with high-titre inhibitors. The use of aprotinin, however, has been proposed to increase the risk of thrombogenicity. A factor level approaching 100 per cent is recommended for brain or prostate surgery, because of a higher risk of bleeding. In patients with milder haemophilia A administration of the synthetic octapeptide desmopressin (**DDAVP**) may be helpful in increasing factor levels. However, this is not the case for haemophilia B.

Complications of therapy

The main adverse outcomes related to treatment with concentrates include transmission of viruses when using plasma-derived products and development of inhibitory antibodies seen with both recombinant and plasma-derived products. Thrombosis has also been a complication of early complex concentrates used for patients with inhibitors.

The development of purification schemes which inactivate viruses, and the development of recombinant products, has dramatically decreased the incidence of transmission of viral disease. Early preparations of prothrombin complex concentrates presented a significant risk of thrombotic complications, but this risk has now been markedly reduced.

Inhibitor formation—the development of antibodies that inhibit clotting activity—occurs subsequent to transfusion of a blood product or factor replacement. An inhibitor presents a difficult situation for patient management. Therapeutic strategies largely rely on the ability to bypass the factor VIIIa–factor IXa tenase complex. Inhibitor formation almost exclusively arises in severely affected patients and occurs in approximately 7 to 52 per cent of patients with haemophilia A but in only about 1 to 3 per cent of patients with haemophilia B. This difference in inhibitor formation is not completely understood, but possible explanations include the higher incidence of severe disease in haemophilia A, prenatal exposure to maternal factor IX but not factor VIII antigens due to the former's ability to pass the placenta, the structural similarity between factor IX and other vitamin K-dependent proteins, the higher plasma levels of factor IX, and the greater inherent immunogenicity of factor VIII due to its larger size. One very rare but severe complication that may occur with the development of a factor IX inhibitor is the development of a potentially life-threatening anaphylactic complication following first treatment.

Therapeutic strategies for treatment of an inhibitor include acute management of the bleeding episode as well as a longer-term treatment directed toward suppression of antibody production. Quantification of the titre of factor inhibitor involves mixing the patient's plasma with test plasma containing a known amount of factor, normally from a pool of healthy donors. After incubation, factor activity levels present in the patient's incubation mixture are compared with that in a control mixture so that the amount of inhibitory antibody can be calculated. The Bethesda unit (**BU**), the standard unit used to report a titre of factor inhibitor, represents the amount of inhibitor that inactivates 50 per cent of factor activity. Acute management of bleeding in a patient with an inhibitor relies first on quantifying the BU of the inhibitor. With low-titre inhibitors (less than 5 BU), it may be possible to overwhelm the inhibitor with aggressive concentrate therapy. With high-titre inhibitors, it is usually necessary to bypass the inhibitor using either prothrombin complex concentrates, activated prothrombin complex concentrates, porcine factor VIII, or, more recently, recombinant factor VIIa. These bypassing agents, with the exception of porcine factor VIII, largely work by directly activating factor X to factor Xa, thus bypassing the need for the intrinsic tenase complex. With porcine factor VIII, it is wise to first perform testing to ensure that the patient's inhibitor does not crossreact with the porcine factor VIII. Because of the life-threatening bleeding complications in patients with inhibitor, immune tolerance regimens have been designed with the aim of eradicating the inhibitor in the long term. Therapeutic regimens such as the Malmö protocol involve infusion of high-dose factor concentrates along with immunosuppressive agents enabling a tolerance to the deficient factor. This protocol is highly effective in approximately 80 per cent of patients.

Viral diseases

Severely affected patients treated with plasma-derived concentrates before 1985 had an extremely high rate of viral disease. Over the course of a 70-year lifespan, a patient with severe haemophilia may be exposed to donations from 70 million individuals due to the pooling of thousands of donor units for concentrate production. Specific laboratory tests to screen for HIV, hepatitis C, and hepatitis B, in addition to much improved donor screening procedures, have dramatically limited the number of contaminations from individuals carrying viral diseases. Solvent detergent treatment procedures, which inactivate enveloped viruses (HIV and hepatitis viruses B, C, D, and G), and heat treatment procedures used to eliminate non-enveloped viruses (hepatitis A and E viruses and parvovirus B19) have radically decreased the risk of viral infection from plasma-derived products. The viral inactivation procedures in current use include pasteurization, vapour heating, high-dry heating, and nanofiltration. Recently, b-propiolactone ultraviolet inactivation has been discontinued due to ineffective virucidal technique.

HIV

In the late 1970s and early 1980s, HIV, the human immunodeficiency virus, appeared in the blood supply before routine laboratory testing was developed to detect its presence. The leading cause of death in American haemophilia patients in 1982 was haemorrhage; however, contaminated blood products during the period between 1979 to 1983 led to a sharp rise in viral disease shortly thereafter. A large proportion of patients with haemophilia became infected with HIV and have subsequently died from AIDS. Risk factors for infection included the severity of the disease (severely affected patients were much more commonly affected than those with moderate or mild disease), the type of concentrate used (factor VIII versus factor IX concentrate), the viral inactivation procedures used in product preparation, and the geographical location of the patient with regard to percentage of blood products contaminated.

The incidence of HIV infection in American patients who received plasma-derived concentrates between 1979 and 1984 was lower in patients receiving factor IX complex concentrates (55 per cent) than in those receiving factor VIII concentrates (approximately 90 per cent). Despite the devastating consequences of HIV for affected individuals and families, the projected impact on births of patients with haemophilia over the next two centuries is small (1.79 per cent reduction).

Hepatitides

Contaminated plasma-derived products also led to significant morbidity and mortality due to hepatitis viruses. Effective virucidal techniques have greatly reduced the incidence of hepatitic viral disease in this population. In the United States in the late 1980s 87 per cent of the 345 HIV negative, and more than 99 per cent of the HIV-positive patients showed evidence of prior infection with hepatitis B, hepatitis C, or hepatitis D viruses. Infection due to hepatitis A virus has rarely been reported in patients with haemophilia in the United States. Solvent/detergent inactivation of concentrates has been associated with a high prevalence of antibodies to hepatitis A virus.

Hepatitis B was commonly seen in patients with haemophilia until routine screening of liver enzymes and the subsequent availability of hepatitis-specific antibody and antigen tests in the 1980s. Most patients are now vaccinated against hepatitis B so that it is difficult to estimate hepatitis B infection from concentrate administration. The hepatitis delta virus, dependent on coinfection with hepatitis B virus, has also been a significant cause of morbidity in patients with haemophilia; its prevalence is largely attributed to the administration of prothrombin complex concentrates.

Routine testing for hepatitis C, instituted in the early 1990s, has reduced but not eliminated hepatitis C contamination in the donor pool. A variable susceptibility and morbidity is seen in response to hepatitis infection; cirrhosis was estimated at approximately 20 per cent and liver failure at 10 to 20 per cent 20 years after infection. Concurrent infection with HIV can accelerate complications of hepatitis C virus. There is also an increased likelihood of hepatocellular carcinoma with long-term infection with viral hepatitis.

Other infectious agents

The vast majority of patients with haemophilia have antibodies to parvovirus B19. Parvovirus B19 is a small, non-lipid enveloped, highly heat-resistant virus found to contaminate plasma-derived products. Methods that inactivate other non-lipid enveloped viruses in products have not proven to be routinely effective against this virus. Although parvovirus B19 infection is often mild and self-limited, infection with parvovirus B19 has the potential to severely compromise the health of an infected immunodeficient patient.

There is experimental evidence in animal models that cellular blood components, plasma, and plasma components have a potential, though minimal, risk of transmitting the prion disease Creutzfeldt–Jacob disease. To date, no definitive direct infection of a recipient of a blood product or blood product concentrate has been documented, although transmission has been reported from corneal and dura mater grafts and cadaveric pituitary hormones. The American Red Cross currently administers a questionnaire to screen donors for risk of prion disease. There is now concern that transmission of new variant Creutzfeldt–Jacob disease may differ from classical CJD and could potentially be transmitted through plasma-derived concentrates. This new variant has been associated with outbreaks of bovine spongiform encephalopathy, potentially from dietary exposure. Experimental evidence shows that bovine spongiform encephalopathy and new variant Creutzfeldt–Jacob disease are caused by the same infectious agent, and prion-related protein has been found in lymphoid tissue of patients with new variant Creutzfeldt–Jacob disease. In Europe, particular lots of concentrate have been removed from the market due to the development of new variant Creutzfeldt–Jacob disease in product donors.

Treatment of patients infected with hepatitis virus and/or HIV

Vaccination against hepatitis A and B is highly recommended for patients who receive concentrates and lack viral antibodies indicative of past infection. Treatment of hepatitis C with interferon-g is associated with significant improvement in approximately half of patients in many but not all studies. Liver transplantation has been successful in many cases for patients with liver failure who are unresponsive to treatment. The liver transplant fortuitously corrects the deficiency of clotting protein due to synthesis of clotting factors by the orthotopic liver. However, the possibility of reinfection with viral disease is significant and must be included in management decisions.

Drug-related hepatitis in haemophilia patients has been reported subsequent to treatment of HIV, particularly in response to indinavir. Additionally, complications in HIV-positive haemophilia patients taking protease inhibitors include haematuria, intracranial bleeds, and excessive bleeding often requiring hospitalization and administration of higher than expected doses of factor concentrate to correct the bleeding. Protease inhibitor therapy should not be withheld from HIV-positive individuals with haemophilia. A 6-month, prospective study of 20 haemophilia patients receiving protease inhibitors revealed only one unusual bleed which was corrected by factor infusion.

Gene transfer as a method of treating haemophilia

The development of clotting factor concentrates resulted in a dramatic improvement in life expectancy for individuals with haemophilia. None the less this treatment strategy has a number of disadvantages. The protein must be infused intravenously, and has a relatively short half-life in the circulation. This makes chronic prophylaxis difficult, especially in small children where venous access may present a problem. In addition, the product is expensive so that only about one-third to one-half of the world's haemophiliacs (those in the developed world) have access to the product. Although current viral inactivation techniques have largely eliminated the risk of HIV and hepatitis, there are ongoing concerns about the risk of other bloodborne diseases (Creutzfeld–Jacob disease, transfusion-transmitted viruses) that are not easily eradicated using current techniques. These factors have fuelled interest in the development of a gene transfer approach to the treatment of haemophilia. Such an approach, if successful, would result in continuous production of a level of clotting factor adequate to prevent bleeds rather than treating bleeds after they have occurred. The level of clotting factor required for this goal can be predicted based on a generation of experience with clotting factor concentrates. Thus in Swedish prophylaxis studies, it has been shown that maintenance of trough factor levels in the range of 1 to 3 per cent are adequate to prevent all the life-threatening bleeds and most of the joint bleeds in boys with severe haemophilia. The validity of a target of 1 to 3 per cent is further confirmed by the natural history of the disease; individuals with factor levels of less than 1 per cent are severely affected, whereas those with levels of 1 to 5 per cent have a moderately severe phenotype with a considerably lower incidence of spontaneous bleeding episodes.

Successful gene transfer approaches require three elements: a therapeutic transgene, a means of delivering it, i.e. a vector, and an appropriate target cell type in which gene transfer and expression will exert a therapeutic effect. Of the inherited diseases for which gene transfer approaches have been attempted, haemophilia has a number of advantages. First, tissue-specific expression is not required. Although clotting factors are normally synthesized in hepatocytes, biologically active

material can be synthesized in a variety of tissues, including fibroblasts, muscle cells, and endothelial cells. This allows latitude in the choice of target cell. Second, the therapeutic window is wide, since even small increases in circulating levels of factor are likely to result in some improvement in symptoms, and increases to 100 per cent would still leave the patient within normal limits. Excellent small and large animal models of the diseases exist (murine and canine), and determination of therapeutic efficacy is in the case of haemophilia relatively straightforward, since levels of circulating factor correlate well with symptoms of the disease.

A number of different strategies for gene therapy for haemophilia are under active investigation in preclinical studies, and three clinical trials are currently under way, with two more in late planning stages. The plethora of approaches suggests that there will be more than one successful combination of vector and target tissue that is safe and effective for haemophilia. The ongoing trials include an *ex vivo* approach in which fibroblasts from a patient are isolated from a skin biopsy, cells are expanded in culture, transduced with a retroviral vector expressing factor VIII, and then reimplanted onto the patient's omentum. Early data from this trial show safety in the first six patients treated, with evidence of gene transfer and expression in three out of six. In a second trial, a retroviral vector expressing B-domain deleted factor VIII is infused intravenously. This trial has enrolled 13 subjects with severe haemophilia A. There has been no evidence of safety concerns to date. Finally a third trial involves intramuscular injection of an adenoassociated viral vector expressing factor IX. This approach has been demonstrated to be safe and effective in animal models of haemophilia and is currently being tested in patients with severe haemophilia B. Two other planned trials both use liver as the target cell; one uses a gutted adenoviral vector to express factor VIII, and the other uses an adenoassociated viral vector to express factor IX in liver. The trials will determine whether any of these approaches will be safe and effective in patients with haemophilia.

Von Willebrand disease

In 1926 Erik von Willebrand first described what we now know as von Willebrand disease upon finding an autosomally inherited bleeding diathesis in a large kindred on the Aland Islands in the Gulf of Bothnia between Sweden and Finland. Although the bleeding disorder in this family resulted in haemorrhagic death in multiple family members, the bleeding diathesis in patients with von Willebrand disease is usually much milder. Most commonly, patients with von Willebrand disease manifest mucosal platelet-type bleeding tendencies of varying severity. Nose bleeds, menorrhagia, and easy bruising are the most common manifestations.

The pathophysiology of von Willebrand disease involves a functional deficiency of von Willebrand factor, a 270 kDa monomer that forms a large multimeric plasma glycoprotein of several subunits up to 100 subunits. von Willebrand factor, synthesized in the megakaryocyte and endothelial cell and stored in subcellular granules, enables proper two-chain factor VIII formation and serves as a carrier, thus preventing degradation of factor VIII and lengthening the half-life of the labile factor VIII protein to around 8 h. von Willebrand factor secreted by endothelial cells also binds to heparin glycosaminoglycan and to the platelet glycoprotein complex Ib–IX enhancing platelet activation and further platelet recruitment at sites of tissue damage. The interaction between platelets and von Willebrand factor is thought to provide the explanation for the mucosal bleeding phenotype occurring in patients with von Willebrand disease. Patients with von Willebrand disease frequently have reduced levels of factor VIII. However, the remaining factor VIII is normally sufficient to prevent the haemophilia-type symptomatology of arthropathy and deep tissue bleeding.

The gene for von Willebrand factor is located on chromosome 12, is 180 kbp in length, and consists of 52 exons. There are three types of von Willebrand disease: types 1, 2, and 3. Types 1 and 3 are quantitative deficiencies of the von Willebrand factor while type 2 is a qualitative deficiency due to binding defects of the von Willebrand factor. The inheritance of types 1 and 3 are autosomal dominant and autosomal recessive, respectively. However, rare reports of an autosomal dominant inheritance pattern for type 3 have been published. There are four principal subtypes of type 2 classified as follows: 2A, absence of high molecular weight von Willebrand factor species causing decreased platelet-dependent function; 2B, increased affinity of von Willebrand factor for platelet glycoprotein Ib–IX; 2M, platelet functional defect not caused by the absence of high molecular weight multimers; and 2N, a factor VIII binding abnormality.

Laboratory diagnosis of von Willebrand disease involves assaying the plasma for von Willebrand factor. The two principal tests are an antigenic test (von Willebrand factor anitigen) and an activity test (von Willebrand factor RCo) in which formalin-fixed platelet aggregation is induced due to the ristocetin-enhanced von Willebrand factor binding to glycoprotein complex Ib–IX. Comparison of the tests helps identify the enhanced ristocetin-induced aggregation seen in type 2B von Willebrand disease where von Willebrand factor ristocetin cofactor is typically much lower than von Willebrand factor antigen. Other tests performed in the evaluation of von Willebrand disease include the level of factor VIII, which is often decreased, and the activated partial thromboplastin time, which is elevated in approximately half of cases of von Willebrand disease due to the low activity of factor VIII. Non-reducing gel immunoelectrophoresis is employed to assay the distribution of multimeric subunits of von Willebrand factor with a gel containing antibody to von Willebrand factor antigen. This assay is particularly relevant for visualization of the presence of low, intermediate, and high molecular weight von Willebrand factor subunits. The intermediate and high molecular weight species are markedly decreased in subtypes of type 2 disease. A decreased normal pattern is seen in type 1 disease, although the decreased visual intensity may be difficult to quantitate. Type 3 disease shows near absence of all subunit molecular weights. The lower limit of the normal range of von Willebrand factor varies with blood type (A, B, O, AB). Thus, symptomatology must be evaluated based on normal ranges for each blood type. The bleeding time in a patient with von Willebrand disease is most often prolonged; however, the test is no longer routinely necessary because of the non-specific nature of a positive result and the higher specificity of other testing.

The specific treatment for von Willebrand disease varies with a patient's symptomatology, the circumstances of the need for treatment, the subtype of von Willebrand disease, laboratory results indicating the potential success of increased von Willebrand factor with non-protein based treatment, and the clinical experience with a particular patient and his or her biological family members. When possible, treatment based on non-blood products is preferred The mainstay of treatment for mild disease is treatment with the synthetic octapeptide DDAVP, desmopressin. DDAVP causes release of factor VIII and von Willebrand factor from endothelial cells raising the plasma von Willebrand factor by approximately two- to tenfold. Thus treatment with DDAVP relies on a partial quantitative deficiency of von Willebrand factor. Intravenous and nasal preparations are available. The nasal preparation allows a patient to self-administer medication at either regular intervals or on an as-needed basis. The phenomenon of tachyphylaxis, the decreased effectiveness of repeated doses of the compound, does occur, and there is usually little response after three consecutive doses. In the past, DDAVP was considered contraindicated in type 2B von Willebrand disease because of the thrombocytopenia sometimes observed with DDAVP infusion. However, this recommendation is controversial and should be assessed on a case-by-case basis. Patients with type 3 von Willebrand disease may lack sufficient intracellular reserves for effective therapy; thus alternative measures for such patients are usually necessary.

A trial of effectiveness of DDAVP is often indicated, particularly prior to prophylactic surgical use of the compound. The trial is normally performed after subtyping the von Willebrand factor disease to ensure that DDAVP is not contraindicated, as in type 2B. Optimally, the test should not be given within 24 h of the last DDAVP infusion nor at a time of environmental stress in order to minimize problems associated with tachyphylaxis or depletion of intracellular reserves. A therapeutic trial entails measurement of von Willebrand factor antigen before and 1 h after DDAVP infusion of 0.3 µg/kg. The patient should be watched carefully during this period because of possible flushing, mild anaphylactoid reactions, and possible hyponatraemia.

e-aminocaproic acid is frequently administered in the setting of dental surgery to inhibit fibrinolysis. However, care must be taken in administration to patients with a predisposition to thrombosis because of the potential deleterious effects of e-aminocaproic acid in this setting. Other compounds which may be administered include oestrogens in women because of the natural positive regulation of synthesis of von Willebrand factor with oestrogen compounds. This may ameliorate menorrhagia in such patients. Components in cryoprecipitate include factor VIII, fibrinogen, and factor XIII, in addition to von Willebrand factor. Cryoprecipitate had been the mainstay of plasma-based therapy until the recent availability of factor VIII concentrates with preserved von Willebrand factor protein such as Alphanate and Humate P. The use of cryoprecipitate, which does not undergo viral inactivation, has thus fallen out of favour.

Treatment of von Willebrand disease with DDAVP is the method of choice in patients who respond to this therapy. DDAVP for intravenous or subcutaneous use is supplied as either a 4 µg/ml 10 ml vial or a 15 µg/ml 1 or 2 ml vial preparation. The recommended dose is 0.3 µg/kg, mixed in 30 ml normal saline, infused slowly over 30 min or 0.4 µg/kg subcutaneously. This dose may be repeated after 12 to 24 h. A DDAVP nasal spray is available in a metered dose pump which delivers 0.1 ml (150 µg) per actuation. The bottle is at a concentration of 1.5 mg/ml and contains 2.5 ml with a nasal spray pump which can deliver 25 150 µg or 12 300 µg doses. For administration, patients who weigh less than 50 kg should deliver one 150 µg spray in one nostril. For those weighing over 50 kg, one spray should be delivered in each nostril for a total dose of 300 µg. Administration may be repeated after 24 h. Precautions to take with the medication include administration no more than every 24 h or for three consecutive days unless under the supervision of personnel from a haemophilia treatment centre. The medication should not be used in pregnant women or in children under 2 years of age. The medication should be used with caution in the elderly and in individuals with a history of cardiovascular disease.

Factor XI deficiency

Factor XI deficiency is an autosomal recessive bleeding diathesis of variable severity. It was first described in 1953 as a third type of haemophilia and is thus sometimes referred to as haemophilia C or alternatively Rosenthal syndrome. The deficiency predominantly occurs in Eastern European Ashkenazi Jews, accounting for more than 50 per cent the cases. In Ashkenazi Jews the disorder is reported to occur in 5 to 11 per cent of individuals in the heterozygous state and 0.1 to 0.3 per cent in the homozygous state. Genetically, the mutations are grouped into three types: type I, abnormalities in the intron–exon splice boundaries; type II, mutations

that result in a premature stop in translation; and type III, mutations resulting from a missense mutation.

The protein itself is an 80 000 kDa protein that circulates in the plasma as a zymogen in a non-covalent association with high molecular weight kininogen. It contains four apple domains in its protein structure, and although factor XIa is a cleaving protease, its structure differs from the serine protease coagulation proteins. Factor XI is principally activated by factor XIIa in the presence of a negatively charged surface (contact activation). The lack of any bleeding diathesis related to a severe deficiency of factor XII suggests the importance of thrombin as an alternative mechanism of *in vivo* factor XI activation.

The *in vitro* factor XI activity level does not correlate well with clinical phenotype. Family history of the bleeding complications and the specific mutated sites are more predictive. Bleeding manifestations are rare in heterozygotes and occur in approximately 50 per cent of homozygous patients.

Factor XI activity levels are assayed in an activated partial thromboplastin time based test. Bleeding problems include easy bruising, epistaxis, haematuria, postpartum haemorrhage, haematomas, and menorrhagia. Haemophilia symptoms, including haemarthroses and intramuscular bleeding, are rare. Bleeding most frequently occurs after trauma or surgery. Damage to tissues rich in fibrinolytic activity, such as oral mucosa and the prostate, are more commonly associated with bleeding problems.

Therapy for patients with factor XI deficiency is indicated for symptomatic bleeding and prophylactically for surgery in patients with markedly reduced levels (i.e. below 20 per cent), unless there is no personal or family history of any bleeding complication. Fresh frozen plasma should be readily available at surgery for infusion in case of a bleeding emergency. Factor XI has a half-life of 60 to 80 h; 10 ml plasma/kg/day is usually adequate for maintaining haemostasis. Prophylactic therapy for most surgery includes replacement of factor XI with plasma at a loading dose of 15 ml/kg followed by 3 to 6 ml/kg every 24 h. The protective level for surgical prophylaxis is suggested as 45 per cent for major surgery and 30 per cent for minor surgery.

Antifibrinolytic therapy with e-aminocaproic may be a helpful adjunct to plasma therapy; however, antifibrinolytics should be avoided in patients with haematuria or bleeding in the bladder because of possible obstruction by clots.

Deficiencies of proteins in the tissue factor and common pathways

The autosomally inherited deficiencies of factors II, V, VII, and X result in bleeding diatheses of varying severity. Such deficiencies of coagulation factor correlate poorly with tests of *in vitro* factor activity; these are thus quite different disorders from haemophilia, in which *in vitro* assessment predicts the clinical phenotype very well. These factor deficiencies can best be assessed by an initial screen using the prothrombin time as a measurement of the tissue factor pathway. Although the activated partial thromboplastin time may be prolonged with deficiencies of factors II, V, and X, but not VII, the prothrombin time is most often much more sensitive.

Factors II, VII, and X, are structurally homologous containing a signal peptide, a propeptide region necessary for recognition by the post-translationally modifying enzyme g-glutamyl carboxylase, an intermolecular binding region (two epidermal growth factor (EGF) domains in factors VII, IX, and X and two kringle domains in the prothrombin molecule), and a catalytic domain in the carboxy terminal of the molecule.

Deficiency of prothrombin (factor II) results from a lack of prothrombin or a malfunctional prothrombin protein. Deficiencies result in haemorrhagic manifestations. All reported patients with a prothrombin deficiency retain some prothrombin, thus suggesting that complete prothrombin deficiency is incompatible with life. This is consistent with the knockout mouse model which results in embryonic lethality at 9.5 to 11.5 days postcoitum in over 50 per cent of fetuses; however, for some unknown reason, some murine fetuses are able to survive to birth but promptly die within 2 days due to haemorrhage. Patients with heterozygous prothrombin deficiency most commonly are either asymptomatic or have minimal bleeding. Bleeding symptomatology includes easy bruising, soft tissue haemorrhage, excessive postoperative bleeding, epistaxis, and menorrhagia in women. Haemarthroses are uncommon.

Congenital disease is characterized by a lifelong and a family bleeding history. Levels of 20 to 30 per cent prothrombin normally prevent bleeding symptomatology. When necessary, administration of plasma is recommended at doses of 15 to 20 ml/kg followed by 3 ml/kg every 12 to 24 h. Prothrombin complex concentrates can be administered for serious bleeds and as a prophylactic before surgery. Transmission of viral disease and thromboembolic phenomena are risks of the administration of prothrombin complex concentrates.

Factor V deficiency occurs in fewer than one in a million individuals. Approximately 20 per cent of the body's factor V reserve resides in the platelets. Thus, it is not surprising that patients with factor V deficiency tend to have mucosal bleeding manifestations including epistaxis, gastrointestinal bleeds, and menorrhagia in women. Haemarthroses, although a possible complaint, are much less common than in haemophilia. Mild to moderate bleeding may be treated by raising the factor V activity to about 20 per cent of normal with a plasma dose of approximately 15 to 20 ml/kg followed by 3 to 6 ml/kg every 24 h. Because of the large amount of factor V stored in platelet alpha granules, platelet transfusions may be an appropriate therapy. However, patients should be monitored for the possibility of generation of antiplatelet antibodies.

Factor VII deficiency presents as a variable bleeding disorder ranging from mild to severe, with a possibility of fatal intracranial haemorrhage. Patients with homozygous or compound heterozygous mutations manifest symptoms similar to those of a patient with haemophilia. However, unlike the correlation between activity levels and severity of disease in haemophilia, the *in vitro* factor VII activity clotting test provides only a relative indication of possible disease manifestations. Manifestations include haemarthrosis, arthropathies, haematoma formation, and retroperitoneal bleeding. Fatal intracranial haemorrhage is estimated to occur in approximately 16 per cent of patients with severe disease. Levels below 10 per cent activity most often result in bleeding manifestations. Therapy includes replacement of factor VII levels to 10 to 25 per cent for patients undergoing most types of surgery. Therapy includes plasma at 5 to 10 ml/kg for 6 to 12 h for 1 to 2 days for minor episodes. For surgery, the recommended dose is administration of 15 to 20 ml/kg followed by maintenance doses of 3 to 6 ml/kg every 12 h.

Prothrombin complex concentrates may frequently be used to supply the factor VII along with the other vitamin K-dependent proteins. Although thrombogenicity has not been a recent problem, this does remain a potential complication. Recombinant factor VIIa has been used in Europe for several years and was approved for use in the United States in 1999 for treatment of haemophilia with inhibitors. Although the product has not yet been officially approved for use in factor VII-deficient patients in the United States, recombinant factor VIIa is therapeutically effective in this setting at a dose of 25 µg/kg for acute bleeds, a significantly lower dose than that used for treatment of haemophiliac patients with inhibitors. However, the possible development of a factor VII inhibitor must be considered, as this has been reported. The product is administered every 2 h for prophylaxis during surgery for the first 24 h, then reduced to every 3 h 24 to 48 h postoperatively, and then further reduced ccording to patient symptomatology and necessity, depending on the risk of bleeding into the surgical site.

Factor X deficiency may present with symptomatology similar to that of a patient with severe haemophilia. Haemarthroses, soft tissue haemorrhages, retroperitoneal bleed, central nervous system haemorrhages, pseudotumours, and menorrhagia may occur. Therapy with fresh frozen plasma includes a loading dose of 10 to 15 ml/kg followed by approximately 50 per cent of that at 24 h.

Deficiency of the contact activating factors, factor XIII, and fibrinogen

Although the activated partial thromboplastin time is grossly prolonged (often more than150 s) with deficiencies of the contact activating factors—factor XII, high molecular weight kininogen, and prekallikrein—these deficiencies are not associated with bleeding manifestations and will not be covered further here.

Factor XIII deficiency often presents shortly after birth with bleeding of the umbilical cord. Patients with clinical manifestations typically have factor levels of less than 1 per cent. Factor XIII is a transglutaminase that crosslinks fibrin monomers, thus stabilizing a forming fibrin clot. Patients with deficiency of factor XIII therefore have delayed wound healing and often suffer from soft tissue haemorrhages, haemarthroses, haematomas, and excessive bleeding from poorly healed wounds. Up to 25 per cent of individuals deficient in factor XIII may experience intracranial bleeding. For unknown reasons, affected males may have oligospermia and affected women may suffer from repeated spontaneous abortions. Since routine clotting tests are normal in factor XIII deficiency, a physician must specifically request a test for factor XIII deficiency which entails a clot solubility test using 2 per cent chloroacetic acid on a formed clot. Treatment of factor XIII deficiency involves administration of small amounts of factor XIII required to minimize bleeding complications. Prophylaxis includes using 2 to 3 ml/kg of fresh frozen plasma every 4 to 6 weeks or one bag of cryoprecipitate per 10 to 20 kg every 3 to 4 weeks. To prevent spontaneous abortions, products containing factor XIII can be administered every 14 to 21 days.

Afibrinogenaemia may cause dangerous haemorrhagic episodes. However, it is somewhat surprising that the mutation does not lead to embryonic death in light of the fact that the blood is incoagulable *in vitro*. The lack of necessity for fibrinogen during fetal development is supported by the viable fibrinogen knockout mouse model. Prolonged bleeding from the umbilical cord often permits early recognition of an affected child. The leading cause of death in afbrinogaemia is intracranial

haemorrhage. Haemorrhages from mucous membranes occur frequently, and haemarthroses occur in approximately 20 per cent of patients. Pregnancy related problems include first trimester abortion, placental abruption, and postpartum bleeding complications and may be markedly reduced by administration of fibrinogen. However, fibrinogen replacement may cause thromboembolic phenomena. The target fibrinogen level for replacement therapy is approximately 50 to 100 mg/dl. One bag of cryoprecipitate contains approximately 250 mg of fibrinogen; thus dosing of cryoprecipitate usually necessitates 5 to 10 bags per 70 kg person. Therapeutic complications include allergic reactions and the development of antifibrinogen antibodies. Thromboembolic phenomena may occur in conjunction with fibrinolytic inhibitors or oral contraceptives.

Dysfibrinogaemia results from a functional deficiency of fibrinogen associated with a malfunctional molecule, although some degree of antigen remains present. Approximately 55 per cent of patients with dysfibrinogaemia remain asymptomatic, 25 per cent have a bleeding tendency, and 20 per cent may experience thrombotic episodes ranging from mild to fatal events.

Numerous combined deficiencies have been described; the underlying mutation for several of these combined deficiencies has been determined. Combined deficiency of the two structurally similar proteins factor V and factor VIII is an autosomal recessively inherited disorder of variable bleeding severity. The mechanism responsible for the disorder results from a mutation in ERGIC-53, a 53 kDa transmembrane component of the endoplasmic reticulum–Golgi intermediate compartment. Mutations at this site are associated with factor levels of 4 to 30 per cent of normal factor V and factor VIII activity and generally show mucocutaneous and postsurgical bleeding of a severity similar to that seen in individuals with a single protein deficiency at the same level. Other combined deficiencies for which a genetic mechanism has been described include deficiency of factors II, VII, IX, and X caused by a mutation in the g-glutamyl carboxylase gene, required for a critical post-translational modification in vitamin K-dependent factors.

Hypercoagulable disease due to deficiencies of anticoagulant

Pathological diseases resulting from inappropriate clot formation in either the arterial or venous circulation are a major cause of morbidity in the Western world. The genetic contribution to this pathophysiology, particularly to thrombosis in the arterial circulation, is not well understood. Clearly cardiovascular disease represents a complex multifactorial process. The contribution of genetic causes to venous thrombotic disease is better understood; it may be associated with either an isolated deficiency of an anticoagulant protein, a malfunctional procoagulant protein, or a combination of these processes. The functional deficiencies become particularly relevant during times of increased environmental stress such as in the puerperium or in postsurgical, traumatic, or immobilized states. In addition to deficiency states, several common mutations involving a gain of function have also been described which can disrupt the delicate balance of coagulation by shifting the balance toward greater procoagulant function.

Procoagulant and anticoagulant plasma proteins interact with platelets and cellular phospholipids to promote physiological coagulation. Regulation of the formation of thrombin is the key step in the proper balance between pro- and anticoagulant functions. Anticoagulant proteins are particularly important in areas where there may be prolonged exposure of procoagulant factors and platelet phospholipids to the vessel wall, predisposing an individual to thrombotic disease. Deficiencies of anticoagulant proteins thus place a patient at an increased risk for thrombosis in the slowly flowing venous circulation. In the rapidly flowing arterial circulation, laminar flow largely prevents prolonged interaction between platelets and vessel walls.

The principal anticoagulant proteins that keep the procoagulant proteins in check include thrombomodulin, tissue factor pathway inhibitor, antithrombin III, protein C, and protein S. Thrombomodulin, an integral membrane protein expressed by endothelial cells, plays a key role in tempering the action of thrombin. Despite attempts to discover mutations in the thrombomodulin gene, only rare reports have implicated thrombomodulin in the pathophysiology of disease, although some recent studies suggest the existence of polymorphic regulation variants in the promoter region. Recently, a mutation in the small but critical protein known as tissue factor pathway inhibitor, which inhibits procoagulant function by binding to factor Xa either alone or in association with tissue factor–factor VIIa, has been suggested to be associated with a ninefold increased risk of venous thrombosis.

Deficiencies leading to a hypercoagulable state are most frequently caused by deficiencies of antithrombin III, protein C, and protein S. These anticoagulant deficiencies result from either a quantitative deficiency (type I) or a qualitative deficiency (type II). Deficiencies of any of these factors may cause life-threatening deep venous thromboses and pulmonary emboli, or may be asymptomatic. Clinical presentation relates to physical sequelae in the affected organ. In addition to deep venous thromboses and pulmonary emboli, symptomatology may include superficial thrombophlebitis, mesenteric vein thrombosis, and cerebral vein thrombosis.

Antithrombin III deficiency

A deficiency of antithrombin III was the first anticoagulant protein deficiency described which was associated with an increased risk of thrombosis. Antithrombin III is a 60 kDa glycoprotein found at high concentrations in the plasma—150 µg/ml: approximately 15- to 30-fold higher than that of many other pro- and anticoagulant proteins. Antithrombin III primarily inhibits thrombin but also inhibits factors IXa, Xa, XIa, XIIa, kallikrein, and plasmin. The ability to inhibit thrombin requires interaction with heparin, which increases the inhibitory activity several thousandfold. Historically, the risk of thrombosis in individuals deficient in antithrombin III has been thought to be higher than that seen with deficiencies of protein S or protein C, or than that seen with increased functionality of the procoagulant proteins factor V and prothrombin. Clearly the influences of gene–gene and gene–environment interactions contribute to this risk. A normal activity range for most procoagulant/anticoagulant proteins may be as low as 50 per cent. However, the critical requirement for antithrombin III can be surmised from the 80 per cent lower limit of a normal antithrombin III level, significantly higher than that for other coagulation proteins. This makes the diagnosis of antithrombin III deficiency particularly difficult in the post-thrombotic period when patients frequently have lower levels of antithrombin III due either to consumption of antithrombin III during clot formation or to the decreased function seen with heparin administration. Additionally, the presence of homozygous disease of antithrombin III deficiency has only been reported with rare type II deficiencies resulting from impaired heparin binding mutations. No homozygous type I deficiencies have been reported, probably due to their incompatibility with life.

The frequency of antithrombin III deficiency in patients with thrombophilia varies widely between studies. The cause of these widely differing frequencies has recently been carefully addressed by van Boven and colleagues. Their study clearly shows the strong influence of acquired and genetic factors which modulate the baseline risk due to one specific genetic mutation, highlighting the role of additional factors when combined with genetics. In thrombophilic family studies, the risk of thrombosis is 20 times greater than in control populations. The most frequent presentation is deep venous thrombosis with a pulmonary embolism, particularly after an inciting environmental influence such as surgery or immobilization in men or the start of oral contraceptives or pregnancy/postpartum in women. The average age of first onset is 33 years. In patients deficient in antithrombin III without a known acquired risk, the rate of incidence of thrombosis was less than 1 per cent per year.

Therapy for antithrombin III deficiency includes prophylactic treatment with warfarin, low molecular weight heparin, and treatment of an acute event with heparin or another anticoagulant therapy, for example administration of a fibrinolytic agent in the patient presenting early enough during an acute episode. Antithrombin III concentrate may be administered for therapy of deficiency during an acute event or as a prophylactic treatment to prevent further disease.

Deficiencies of proteins C and S

Deficiencies of proteins C and S present with thrombotic manifestations similar to those seen with antithrombin III deficiency. However, in protein C deficiency an additional condition includes warfarin-induced skin necrosis and dangerously life-threatening purpura fulminans in the homozygous or compound heterozygous protein C deficient neonate. A diagnosis of protein C deficiency is found in approximately 33 per cent of individuals with warfarin-induced skin necrosis, a condition which leads to skin necrosis several days after initiation of warfarin therapy. The proposed mechanism for this condition is due to the earlier decrease in protein C compared with decreases in procoagulant proteins following initiation of warfarin therapy (due to the short half-life of protein C, approximately 6 h). It is thus 'normal' clinical practice to begin warfarin only after a patient has first been anticoagulated with heparin or another immediately acting anticoagulant therapy.

Protein C acts in concert with its cofactor protein S to inactivate the active forms of the procoagulant cofactors, factors Va and VIIIa. Protein C is a vitamin K-dependent serine protease structurally similar to factors VII, IX, and X. Protein S is also vitamin K-dependent because of conserved NH2 terminus but lacks enzymatic function because of the existence of a sex-hormone binding globulin domain instead of a catalytic domain at the COOH terminus. Thrombin activates protein C to activated protein C when bound to thrombomodulin, a protein which acts like an endothelial cell receptor for thrombin. Symptomatic manifestations of protein C or protein S deficiencies are similar to that of antithrombin III deficiency. Deep venous thombosis with or without pulmonary embolism occurs in 50 per cent of patients by the age of 30 to 45, depending on the study population. Environmental and gene–gene interactions are particularly important. As with antithrombin III deficiency, superficial thrombophlebitis, cerebral vein thrombosis, and mesenteric vein thrombosis are all possible complications. Postphlebitic syndrome presents as a complication after deep venous thombosis in up to 50 per cent of patients.

Factor V Leiden and the prothromibn 20210 mutation

Since 1994, two additional common mutations have been described leading to an increased risk of thrombosis. These mutations, unlike the anticoagulant protein deficiencies, are due to gain of function mutations causing either an increased resistance to inactivation in factor V (factor V Leiden) or increased levels of a procoagulant protein (prothrombin) which results in higher levels of thrombin formation.

Activated protein C (APC) resistance was first described by Dahlback in a 42-year-old man with a history of recurrent thromboses. Dahlback noted an absence of prolongation of the activated partial thromboplastin time, found after addition of APC, which is normally prolonged due to inactivation of factors Va and VIIIa. Soon thereafter, Poort and colleagues identified a single mutation as the principal cause of APC resistance in the vast majority (over 90 per cent) of patients. The mutation leads to a decreased ability of APC to inactivate the cofactor Va due to an amino acid substitution (arginine for glutamine) at a critical hydrolysis point in the factor Va protein normally enabling inactivation. Other non-factor V Leiden causes of APC resistance include a haplotype in the factor V molecule, the H2 haplotype.

Factor V Leiden leads to thrombotic disease as described for hypercoagulable states due to deficiencies of anticoagulant protein. Because of the extremely high incidence of factor V Leiden in the Caucasian population (approximately 5 per cent), gene–gene interactions play a particularly important role in manifestation of disease. It should be noted that the frequency of factor V Leiden in most non-Caucasian populations is low.

The prothrombin 20210 mutation reported in 1996 results in an increased concentration of prothrombin, also tipping the balance towards excess thrombin formation. The cause of this increase is associated with a guanine to adenine mutation at the last base of the 3' untranslated region in the factor V gene. The mechanism by which this influences prothrombin levels is not understood.

---

*Because factor IX is not confined to the intravascular space, it is customary to double the desired intravascular dosage compared with factor VIII administration to account for this larger volume of distribution in part due to binding of factor IX to endothelial cells.
†When using the only available recombinant protein (BeneFix), it has empirically been shown that it is necessary to multiply this dosage by a factor of 1.2 IU/kg to achieve the projected desired level.

22.6.5 Acquired coagulation disorders

T. E. Warkentin

A 'coagulopathy' is a disorder associated with an abnormal coagulation assay result, such as a prolonged prothrombin time (**PT**) (often expressed as the international normalized ratio, or **INR**), activated partial thromboplastin time (**aPTT**), or thrombin clotting time (**TCT**). Coagulopathies can be associated with either bleeding or thrombosis, and have many causes (Table 1). The importance of the clinical context is illustrated by two patient scenarios that have in common a prolonged INR (6.0; usual therapeutic range, 2.0–3.0) during oral anticoagulant therapy: patient A has a life-threatening intracranial haemorrhage complicating warfarin therapy given for a prosthetic heart valve; in contrast, patient B, who was treated for deep-vein thrombosis (**DVT**) complicating heparin-induced thrombocytopenia (**HIT**), has the limb-threatening complication of warfarin-induced venous limb gangrene, caused by microvascular thrombosis.

Table 2 lists common screening tests for coagulopathy. Only a few bleeding disorders give normal results in all these tests (for example, a $_2$-antiplasmin deficiency, factor XIII deficiency, type 2a von Willebrand syndrome associated with aortic stenosis). A drawback of these assays is that only procoagulant *haemo*static pathways are assessed. Thus, deficiency of a natural anticoagulant such as antithrombin or protein C must be determined by specific testing.

Treatment approaches

Blood products are usually indicated for the treatment of patients with coagulopathies who are bleeding or who require a major invasive procedure. *Fresh-frozen plasma* (**FFP**), which contains all the *haemo*static factors at concentrations between 0.7 and 1.0 U/ml, is appropriate for liver disease, *haemo*dilution from massive transfusion, disseminated intravascular coagulation (**DIC**), reversal of coumarin anticoagulation, and replacement of isolated factor deficiency when specific-factor replacement is unavailable. For a 70-kg adult with a 3-litre plasma volume, 1 litre of FFP will increase the coagulation factors by about 0.25 U/ml. In most patients, this should lead to levels greater than the minimum required for adequate *haemo*stasis (>0.30 U/ml for most factors). Repeat FFP transfusion (for example, 500 ml every 6 h) is necessary if the *haemo*stasis defect is ongoing. FFP is being supplanted by cryosupernatant as a replacement fluid for thrombotic thrombocytopenic purpura (**TTP**). Solvent-detergent-treated plasma (**SD**-plasma), in which most blood-borne pathogens are inactivated (but not hepatitis A, parvovirus B19, or the agent that causes Creutzfeldt–Jakob disease, a theoretical bloodborne pathogen), has become available recently, but is limited by its high cost.

Cryoprecipitate contains fibrinogen (0.10–0.25 g per unit), factors VIII and XIII, von Willebrand factor (**vWF**), and fibronectin. Its major indication is the treatment of hypofibrinogenaemia, where it increases fibrinogen levels using just one-quarter of the volume of blood product compared with FFP. Cryoprecipitate is appropriate for patients with significant hypofibrinogenaemia, for example DIC, primary fibrinolysis, congenital hypofibrinogenaemia. For a bleeding patient whose fibrinogen level is about 0.5 g/l, 10 to 20 U of cryoprecipitate would probably increase the fibrinogen to above 1.0 g/l, although a lower than expected increment could occur if the patient had a higher volume of distribution (for example, a cirrhotic patient with ascites).

Specific-factor concentrates are available for use in patients with an isolated deficiency in certain factors, such as VIII or IX. Additionally, some factor IX concentrates, known as prothrombin complex concentrates (**PCC**), contain all four vitamin K-dependent procoagulant factors, and are appropriate for the rapid reversal of severe coagulopathy related to coumarin use. Activated PCC (for example, **FEIBA** (factor VIII inhibitor bypassing activity)) and factor VIIa are other specialized blood products with specific uses, for instance to manage a bleeding patient with an acquired factor VIII inhibitor.

Pharmacological therapies include the antifibrinolytic agents e-amino-caproic acid (**EACA**), tranexamic acid (**TA**), and aprotinin. EACA and TA bind to the lysine-binding sites of plasminogen; paradoxically, although increasing the susceptibility of plasminogen to proteolysis by plasminogen activator, these lysine analogues also prevent plasminogen from binding to fibrin, thus impeding fibrinolysis. Oral dosing for EACA is about 7 g (100 mg/kg) initially, followed by 3.5 g (50 mg/kg) every 4 h; similar doses are used for intravenous administration. For tranexamic acid, 1.0 to 1.5 g is given every 8 h by mouth; the dose is reduced to between 0.5 and 1.0 g every 8 h if given intravenously. Both drugs are available in 500-mg capsules. These drugs are appropriate for the treatment of hyperfibrinolysis, for instance bleeding following thrombolytic therapy or cardiac surgery. These drugs are generally contraindicated in patients with DIC, however, as blocking secondary fibrinolysis could lead to microvascular thrombosis. Aprotinin is discussed below in the section on cardiopulmonary bypass surgery.

Desmopressin, or 1-desamino-8-D-arginine vasopressin (**DDAVP**), a synthetic vasopressin analogue, leads to an increase in factor VIII and vWf levels that peak between 45 and 90 min after intravenous infusion (0.3 µg/kg in 50 ml normal saline over 20–30 min; maximum dose, 20 µg). Although repeat DDAVP can be given at 12- to 24-h intervals, the drug becomes less effective over time (tachyphylaxis) as endothelial stores of vWf are depleted. Blood pressure elevation, free-water retention leading to hyponatraemia, flushing, and angina are occasional side-effects.

Prohaemorrhagic acquired coagulation disorders

Vitamin K deficiency disorders

Vitamin K-dependent coagulation factors

Vitamin K is required for the post-translational modification of six *haemo*static factors, four with procoagulant activity (factors II, VII, IX, and X), and two with anticoagulant activity (protein C, protein S). The physiological relevance of a seventh factor, Factor Z, remains unclear. The enzyme, vitamin K-dependent g-glutamylcarboxylase, adds a carboxyl group to each member of a cluster of glutamyl residues, thereby forming the g-carboxyglutamyl residues crucial for enabling these six haemostatic factors to interact with phospholipid membranes in a calcium-dependent fashion. During this g-carboxylation reaction, the reduced form of vitamin K (vitamin KH_2) is oxidized to vitamin K epoxide; oral anticoagulants inhibit the two enzymes (vitamin K epoxide reductase and vitamin K reductase, respectively) that act in sequence to regenerate the reduced form of vitamin K.

Diet and absorption of vitamin K

Vitamin K_1 (phylloquinone) is exclusively derived from plants; vitamin K_2 (menaquinone) is synthesized by bacteria. Green, leafy vegetables, such as broccoli, lettuce, cabbage, and spinach, are very good dietary sources of vitamin K (100–500 µg/100 mg). Vitamin K is fat-soluble, and absorption occurs primarily in the small bowel. Serum vitamin K levels are only between 150 and 800 pg/ml and, as hepatic storage is limited (*t*½, just a few days), a regular daily intake of about 0.1 to 0.5 µg/kg is

required. Although bacterial synthesis is not a major source of vitamin K to humans, antibiotic treatment nevertheless predisposes to vitamin K deficiency.

Vitamin K deficiency

Malabsorption of fat-soluble vitamins caused by biliary tract disease, or primary bowel disorders such as coeliac or inflammatory bowel disease, can cause vitamin K deficiency. An inadequate diet, particularly when combined with antibiotic therapy, is another cause. Indeed, coagulopathy can arise during a brief period of decreased intake, for example 1-week postoperatively.

A disproportionately prolonged PT/INR in the appropriate clinical setting suggests vitamin K deficiency (Table 3). The diagnosis is usually confirmed by assessing the response to vitamin K administration. Compared with the treatment of a coumarin overdose, small amounts of vitamin K are effective: for example, 1 mg vitamin K_1 given subcutaneously or by slow intravenous infusion (over at least 30 min to minimize risk of an anaphylactoid reaction). For serious bleeding, FFP or especially PCC provides a more rapid correction of the coagulopathy.

Coumarin overanticoagulation

Oral anticoagulants (for example, coumarins such as warfarin and phenprocoumon) are widely used to prevent and treat thrombosis via their vitamin K antagonism. An INR target range between 2.0 and 3.0 is appropriate for most clinical indications, although a higher therapeutic range (INR, 2.5–3.5) is appropriate for patients at very high risk for thrombosis (for instance, mechanical prosthetic heart valves; thrombosis complicating the antiphospholipid antibody syndrome).

Bleeding is the major complication of coumarin, with minor and major bleeding episodes occurring in about 6 to 10 per cent and 1 to 3 per cent of patients/year respectively; the intracranial haemorrhage rate is between 0.25 and 1 per cent/year. Changes in diet or alcohol consumption, poor patient compliance, and the introduction of new drugs (Table 4) can cause bleeding by producing coumarin overanticoagulation. In contrast, recurrent gastrointestinal or urinary tract bleeding at therapeutic levels of anticoagulation often indicates an occult gastrointestinal or renal lesion, respectively.

The treatment of non-therapeutic (elevated) INRs depends on the clinical situation (Table 5). Oral vitamin K_1 use is appropriate in many non-urgent situations as it avoids the risk of anaphylactoid reactions to intravenous use, and has more predictable effects than subcutaneous injection. Much larger and prolonged vitamin K dosing (100–150 mg/day) is required to treat accidental or deliberate overdoses of long-acting, second-generation rodenticides ('superwarfarins'), such as brodifacoum.

Liver disease

Most haemostatic factors are produced exclusively by the liver. Exceptions include factor VIII (hepatic and extrahepatic synthesis), vWf (endothelium, megakaryocytes), and several factors produced by endothelium (for example, plasminogen activator, plasminogen activator inhibitor type I (**PAI-1**)). Table 6 lists the multiple effects on haemostasis caused by liver disease. Often, bleeding is primarily related to anatomical factors, such as oesophageal varices or gastric/duodenal ulcers, though reduced hepatic coagulation-*factor* synthesis can be a contributing factor. Increased susceptibility to DIC via superadded illness (for example, bacterial peritonitis), impaired clearance of activated coagulation factors, and hyperfibrinolysis are other factors.

A prolonged PT/INR is the most frequent laboratory abnormality (Table 3). The fibrinogen level is usually normal or increased; when hypofibrinogenaemia occurs, it generally indicates severe liver disease or hyperfibrinolysis. Fibrin(ogen)-degradation product (**FDP**) and D-dimer levels are often increased; thus, the laboratory picture can resemble that of disseminated intravascular coagulation even in a patient who is otherwise clinically stable.

Management of hepatic coagulopathy should include a trial of vitamin K_1 (for instance, 10 mg subcutaneously for 3 days), although this will not benefit most patients. Fresh-frozen plasma should be given to bleeding patients with a prolonged INR, or who require major invasive procedures. Retrospective studies suggest that minor invasive procedures (for example, paracentesis, pleurocentesis) can usually be performed safely with an INR as high as 1.8. For patients suspected to have significant fibrinolysis, antifibrinolytic therapy can be tried. PCCs should only be used in emergency situations, given their prothrombotic potential in this patient population. Platelet transfusions usually provide minimal increase in the platelet count in patients with platelet sequestration caused by hypersplenism. DDAVP improves haemostasis in patients with prolonged bleeding time secondary to hepatic platelet dysfunction.

Haemodilution and massive transfusion

Coagulopathies occur in most patients who receive crystalloids, colloids, or red cell concentrates (**RCCs**) following trauma, surgery, or fluid resuscitation for other major illnesses. In many patients, no bleeding results despite moderate abnormalities in the INR, aPTT, TCT, and platelet count. The reason is that all the individual coagulation factors remain at haemostatically effective levels, even though the laboratory assays are abnormal when all the factor levels are uniformly reduced.

Massive transfusion is defined as the transfusion of blood products equivalent to the patient's total blood volume within 24 h. RCCs do not provide significant amounts of platelets or coagulation factors. Thus, platelet, FFP, and, sometimes, cryoprecipitate infusions are often needed as well. Although 'formulas' to guide transfusion therapy have been devised, individualized assessment that takes into account clinically evident bleeding, risk factors for haemorrhage, supervening DIC or fibrinolysis, acute liver insult, and laboratory test results, is preferable.

Disseminated intravascular coagulation

Disseminated intravascular coagulation, or DIC, is a group of clinicopathological syndromes characterized by widespread activation of coagulation; there results intravascular generation of thrombin, formation of fibrin, and reactive fibrinolysis. Clinical consequences range from coagulation factor and platelet depletion, resulting in generalized haemorrhage, to widespread microvascular thrombosis, predisposing to multisystem organ dysfunction or limb necrosis. 'Acute' DIC, caused by septicaemia, trauma, and obstetrical complications, is most frequent; 'chronic' DIC, typically caused by malignancy, is often associated with a dramatic hypercoagulable state (Table 7). Although DIC is usually a systemic process, sometimes a localized abnormality (such as a vascular malformation or aortic aneurysm) leads to the regional activation of coagulation and resulting in the depletion of haemostatic factors.

DIC is usually triggered by the extrinsic coagulation pathway: tissue factor and factor VIIa (Fig. 1). The proinflammatory cytokine, interleukin-6 (**IL-6**), is a principal mediator of DIC in septicaemia and other systemic inflammatory responses, and impairs natural anticoagulant and fibrinolytic pathways. For example, a sustained increase in PAI-1 impairs plasmin formation despite intravascular fibrin generation.

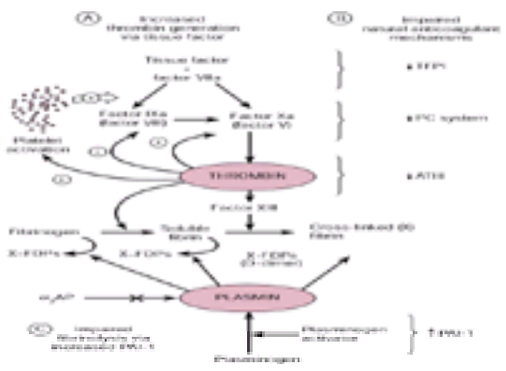

Fig. 1 Pathogenesis of thrombosis in DIC. (A) DIC is usually triggered by tissue factor, which activates coagulation by complexing with factor VIIa, ultimately resulting in the generation of thrombin. (B) Impaired natural anticoagulant mechanisms (e.g. excessive consumption of natural anticoagulants, or cytokine-mediated downregulation of natural anticoagulant pathways) predispose to microvascular thrombosis. (C) Impaired fibrinolysis via increased PAI-1 leads to greater microvascular thrombosis. Sometimes, hyperfibrinolysis is caused by increased plasminogen activator release, or low levels of b $_2$-antiplasmin. Abbreviations: a$_2$AP, a$_2$-antiplasmin; ATIII, antithrombin III; fDPs, fibrinogen degradation products; FDPs, fibrin degradation products; PAI-1, plasminogen activator inhibitor type 1; PC,

protein C; TFPI, tissue-*factor* pathway inhibitor.

Diagnostic and treatment approach to DIC

One or more prolonged clotting times and thrombocytopenia in a patient with one of the disorders listed in Table 7 suggests DIC. However, similar test results are seen in patients following major surgery, emphasizing the need to interpret the laboratory data in the appropriate clinical context. Typically, crosslinked fibrin-degradation products (D-dimers) are significantly increased in DIC. The protamine sulphate 'paracoagulation' test, based on visual detection of gelling of patient plasma after the addition of protamine sulphate, is a rapid test for fibrin monomers; the lower sensitivity of the test is helpful, as a positive result usually indicates clinically significant DIC associated with bleeding or thrombosis. Sometimes, specialized haemostasis assays are useful, for example protein C activity levels in purpura fulminans.

The cornerstone of DIC management is treating its underlying cause and providing supportive measures. For bleeding patients, replacement of depleted haemostatic factors with FFP, cryoprecipitate, and platelet transfusions may be needed. Recently, drotrecogin alfa (recombinant activated protein C) became available in some jurisdictions to treat severe septicaemia. Heparin can benefit patients with large-vessel thrombosis or acral ischaemia. The routine use of vitamin K and folate will avoid coagulation and platelet count disturbances in some patients.

Trauma and shock

Tissue injury due to trauma, burns, or hypoperfusion can cause DIC, especially when organs rich in tissue thromboplastin (for example, the brain) are injured.

Infection

Gram-negative and Gram-positive bacteria can cause DIC, either from procoagulant bacterial components (for instance, endotoxin, *Staphylococcus aureus*-toxin) or via the host response to infection (for example, IL-6). The clinical spectrum ranges from prominent thrombocytopenia with minimal activation of coagulation, to marked coagulation factor and natural anticoagulant depletion. Certain infections, such as meningococcaemia, *Capnocytophaga canimorsus* (from dog bites), sometimes produce severe acquired consumptive protein C deficiency, which leads to widespread ischaemic necrosis of the extremities (purpura fulminans). However, postvaricella purpura fulminans can be caused by acquired antiphospholipid antibodies that interfere with protein S.

Obstetrical complications

Acute DIC can be caused by thromboplastin-like materials released during placental abruption or amniotic fluid embolism. Pre-eclampsia too can be accompanied by DIC, although there can be clinical and laboratory overlap with other life-threatening complications of pregnancy (for example, fatty liver of pregnancy; HELLP syndrome (haemolysis, elevated liver enzymes, low platelets). Bleeding due to hypofibrinogenaemia is often prominent in pregnancy-associated DIC. Chronic DIC can be caused by fetal death.

Acute haemolysis

Haemolysis caused by incompatible blood transfusions, certain infections (for example, *Clostridium perfringens* septicaemia), or microangiopathic disorders such as TTP and HELLP, can sometimes be associated with DIC.

Immunological disorders

Severe allergic reactions (such as anaphylaxis), transplant rejection, glomerulonephritis, and other vasculitic disorders are sometimes associated with DIC.

Vascular anomalies

Giant haemangiomas cause overt DIC in about 25 per cent of affected patients (Kasabach–Merritt syndrome). Although activation of coagulation and fibrinolysis is localized to the vascular anomaly, depletion of haemostatic factors produces a clinical and laboratory profile indistinguishable from DIC. Eradication of haemangioma by radiation, embolization, or surgery is curative. Medical therapies have included heparin, antifibrinolytic drugs (combined with cryoprecipitate to thrombose the vascular tumour), glucocorticoids, and interferon.

DIC also occurs in about 0.5 to 1 per cent of patients with abdominal aortic aneurysms, which usually contain adherent thrombi.

Immunoglobulin-mediated factor deficiency

Coagulation-*factor* inhibitors are usually IgG antibodies that bind to specific coagulation factors, and either neutralize their activity (most coagulation-factor inhibitors) or result in accelerated clearance (for example, antiprothrombin antibodies associated with the antiphospholipid antibody syndrome). Acquired inhibitors against coagulation factors are rare in otherwise normal (non-haemophilic) individuals. Even the most common autoimmune coagulation-factor deficiency (factor VIII) has an estimated incidence of only 1 per 1 000 000 per year.

Acquired factor VIII inhibitor

Acquired factor VIII deficiency should be suspected in a patient with spontaneous bleeding, or bleeding following minor trauma, that occurs in association with a prolonged aPTT and a normal PT/INR (Table 3). Most commonly, muscle or cutaneous haematomas occur, but life-threatening retroperitoneal or intracranial haemorrhages are described; haemarthrosis is uncommon (cf. congenital haemophilia). The disorder occurs most commonly in the elderly (median age, 60 years), affects men and women equally, and is idiopathic in 50 per cent of cases. Other autoimmune disorders (for instance, systemic lupus erythematosus, **SLE**), lymphoid and other malignancies, penicillin treatment, or the postpartum state, have been observed in some patients. About 20 per cent of patients die of bleeding, often from their initial bleeding episode.

A rapid screening test for a coagulation-factor inhibitor is performed by repeating the aPTT after mixing patient plasma 50:50 with normal pooled plasma. An inhibitor is suggested by more than a 4-s prolongation time over the control, although some inhibitors require a 2-h incubation at 37 °C to show inhibition. Confirmation is obtained by a specific-factor assay showing reduced levels of factor VIII; inhibitor quantitation is most often performed by Bethesda assay, in which various dilutions of patient plasma are mixed with normal plasma and incubated for 2 h at 37 °C: a Bethesda unit (**BU**) is defined as the reciprocal of the plasma dilution that yields a 50 per cent reduction in residual factor VIII activity in the test system. Unfortunately, the Bethesda assay tends to underestimate the amount of inhibitor in non-haemophilic patients with acquired factor VIII inhibitors.

Therapy of bleeding depends upon its severity and the amount of inhibitor present, if known. For patients with minor bleeding, and low inhibitor levels (<5 BU), desmopressin (DDAVP) can be tried. Peak factor VIII levels occur between 45 and 90 min post-DDAVP, and repeat levels should be measured to assess efficacy. In other patients with low inhibitor levels but with more severe bleeding, purified human factor VIII concentrates are usually effective. One approach is to give an initial intravenous bolus of 100 U/kg, followed by a continuous infusion of factor VIII at 10 U/kg per h, with factor VIII levels measured again 4 to 6 h later. Careful clinical and laboratory assessment for response is needed, since inhibitor levels may have been underestimated, or higher inhibitor levels stimulated by factor VIII use.

Porcine factor VIII should be considered for bleeding patients in whom the inhibitor titres are not yet known, or to those with high inhibitor levels. This is because crossreactivity of the autoantibodies against porcine VIII is usually substantially less than with human factor VIII. After a loading dose of between 50 and 100 U/kg, repeat doses are given every 8 to 12 h, or further porcine VIII is given by constant intravenous infusion (4 U/kg per h).

Either PCCs or recombinant factor VIIa can be given for patients refractory to human or porcine factor VIII. Activated PCCs (for example, FEIBA or Autoplex) may be

somewhat more effective than non-activated PCCs, but their risk for causing thrombosis is greater. Factor VIIa is preferable for perioperative management, given its low risk for inducing thrombosis. In desperate situations, extracorporeal immunoadsorption using Staphylococcal protein A may be helpful in removing the antibodies.

Spontaneous disappearance of the inhibitor occurs in about 10 to 30 per cent of patients. Nevertheless, the unpredictable clinical course, and the potential for life-threatening bleeding, means that immunosuppressive therapy should be given to most patients, either with high-dose intravenous IgG (1 g/kg for 2 days, or 0.4 g/kg for 5 days) or corticosteroids (for instance, 1 mg/kg per day). For refractory patients, the substitution or addition of cyclophosphamide can be effective. Other options include combination chemotherapy (prednisone, cyclophosphamide, vincristine) or ciclosporin. Even partial remission can help reduce bleeding. Women with postpartum factor VIII inhibitors usually develop remission within 30 months, and usually do not develop recurrent factor VIII inhibitors with later pregnancies. They also may be less likely to respond to corticosteroids or other immunosuppressive therapy.

Other acquired coagulation-factor deficiencies

Hypoprothrombinaemia should be suspected in patients with the antiphospholipid antibody syndrome, particularly if bleeding occurs or the PT/INR is prolonged. Typically, these pathogenic anti-factor II antibodies are non-neutralizing, and therefore mixing patient plasma 50:50 with normal pooled plasma can produce correction of the aPTT, in contrast to other coagulation-factor inhibitors.

Thrombin inhibitors are rare, but may cause severe bleeding. More often, patients have antibodies that react preferentially against bovine thrombin: these are formed following the use of 'fibrin glue', which contains various bovine clotting factors. Patients have prolonged PT/INR, aPTT, and TCT (especially using bovine thrombin). However, it is more likely that any bleeding is the result of clinically significant anti-bovine factor V antibodies.

Factor V inhibitors

Rarely, IgG antibodies against factor V arise spontaneously or following treatment with topical bovine thrombin used at surgery. FFP usually does not provide enough factor V to treat bleeding; however, platelet transfusions are usually effective, as platelet activation causes factor V to be released into haemostatic plugs.

Factor XIII inhibitors

These inhibitors, which sometimes occur in association with isoniazid therapy, cause bleeding via impaired factor XIII-mediated crosslinking of fibrin. Factor XIII should be measured in a patient with unexplained bleeding and normal results of screening coagulation assays.

Factor X inhibitors

Factor X inhibitors are a rare cause of bleeding in patients with prolonged PT/INR and aPTT. The differential diagnosis also includes amyloidosis of the **AL** (amyloid light chain) variety, caused by adsorption of factor X to amyloid fibrils.

Factor IX inhibitors

In non-haemophilic patients, factor IX inhibitors are rare and usually associated with autoimmune disease. Treatment includes PCCs or purified factor IX, and immunosuppression. The differential diagnosis of acquired, isolated, factor IX deficiency includes the nephrotic syndrome (urinary loss of factor IX).

Factor XI inhibitors

These rare inhibitors are most often observed in association with systemic lupus erythematosus, and usually do not cause bleeding or require specific treatment.

Factor VII inhibitors

Factor VII inhibitors are extremely rare, and usually do not cause bleeding or require treatment. The diagnosis is suggested by an isolated prolonged PT/INR in the absence of coumarin or vitamin K deficiency.

Acquired von Willebrand syndrome

Rarely, bleeding is caused by a severe acquired deficiency of vWF, most often in the setting of a monoclonal gammopathy, benign or malignant. Typically, there is disproportional deficiency of the largest vWF multimers due to antibody-mediated clearance (acquired type 2a von Willebrand syndrome (vWD)). Aortic stenosis and obstructive cardiomyopathies are other causes of type 2a von Willebrand syndrome: this probably explains why aortic valve replacement has been reported to cure recurrent gastrointestinal haemorrhage in patients with colonic angiodysplasia.

Heparin and acquired heparin-like anticoagulants

Bleeding is a complication of heparin treatment, particularly when the aPTT is above the therapeutic range. In patients with massive accidental or deliberate heparin overdose, intravenous protamine should be given to treat bleeding complications.

Rarely, patients with spontaneous bleeding and prolonged aPTT and TCT measurements have circulating heparin-like anticoagulants. Usually associated with multiple myeloma and other plasma-cell dyscrasias, the coagulopathy does not necessarily respond even to large-dose protamine infusion, and fatal haemorrhage can ensue. Circulating dermatan sulphate glycosaminoglycan appeared to explain the bleeding in a patient with renal failure.

Coagulopathies secondary to plasma-cell dyscrasias

Multiple myeloma, macroglobulin*aemi*a, and other plasma-cell dyscrasias such as primary amyloidosis can cause various coagulopathies (Table 8). Usually, the TCT is prolonged, most often because of paraprotein-induced interference with fibrin polymerization. A long bleeding time suggests inhibition of platelet function by paraprotein; rarely, acquired von Willebrand syndrome is the cause. Apheresis can improve haemostasis by quickly reducing paraprotein levels, as antineoplastic chemotherapy is initiated.

Hyperfibrinolysis

Activation of fibrinolysis occurs normally when fibrin clots are formed during physiological or pathological haemostasis. However, primary fibrinolysis (Table 3) is sometimes the major cause for bleeding, and requires specific treatment.

Thrombolytic therapy

About 0.5 to 0.7 per cent of patients with myocardial infarction who receive thrombolysis with either streptokinase or tissue plasminogen activator (**t-PA**) develop an intracranial haemorrhage. The thrombolytic agent should be stopped immediately in any such patient, and they should receive cryoprecipitate and an antifibrinolytic drug (for instance, EACA); platelets and FFP can help to increase factor V and VIII levels that may have been reduced by plasmin generated by thrombolysis. It can take between 24 and 36 h for fibrinogen levels to recover after stopping thrombolytic therapy.

Malignancy

Cancer-associated DIC usually causes a hypercoagulable state. However, promyelocytic leuk *aemi*a (**PML**) and prostatic adenocarcinoma are two malignancies commonly associated with prominent hyperfibrinolysis. Laboratory abnormalities include prolonged PT/INR, aPTT, and TCT, and a hypofibrinogen *aemi*a. The use of all-*trans*- retinoic acid (**ATRA**) during induction chemotherapy of PML has reduced the frequency of life-threatening bleeding. Antifibrinolytic therapy can control

bleeding in cancer-associated fibrinolysis, but there is a risk of thrombosis if tissue factor-induced DIC, rather than the release of plasminogen activator by the tumour, is primarily responsible for the coagulopathy.

Cardiopulmonary bypass surgery

Excess bleeding, defined as more than 1 litre per procedure, is a common problem following heart surgery utilizing cardiopulmonary bypass (extracorporeal circulation). About 20 per cent of all red cell concentrates in the United States are given for cardiac surgical bleeding. About 5 per cent of patients require urgent resternotomy for critical rates of blood loss (defined as: >500 ml in the first h; >400 ml/h in the first 2 h; >300 ml/h in the first 3 h; or >1 litre in 4 h). Re-exploration reveals bleeding vessels in two-thirds of patients; the remainder have diffuse oozing.

Thrombocytopenia, transient platelet dysfunction, and hyperfibrinolysis are the major haemostatic defects. Typically, the platelet count falls by between 30 and 60 per cent mainly from haemodilution, although platelet losses from bleeding and within the extracorporeal perfusion device also occur. The thrombocytopenia persists for 3 to 4 days, followed by recovery of the platelet count to values exceeding the preoperative baseline. Marked prolongation of the bleeding time (>30 min) quickly improves to under 15 min shortly after surgery, and to normal several hours later. Some platelet function defects are 'extrinsic' and reversible (for example, hypothermia, heparin), whereas others indicate longer-lasting 'intrinsic' changes (surface glycoprotein deficiency, acquired-granule depletion). Preoperative treatment with aspirin or abciximab also increases bleeding.

The importance of hyperfibrinolysis in postcardiac surgical bleeding is suggested by meta-analysis of studies of high-dose aprotinin, a plasmin inhibitor derived from bovine lung: a two-thirds reduction in blood transfusion, and 50 per cent reduction in resternotomy. Other antifibrinolytic drugs that reduce bleeding include the lysine analogues, tranexamic acid (for example, 10 mg/kg bolus pre-cardiopulmonary bypass (**CPB**); then 1 mg/kg per h, although dosing regimens vary widely) and EACA (total dose, up to 20 g). Although these therapies are usually given before CPB, they may also provide benefit when used postoperatively for bleeding patients.

Management of postcardiac surgical bleeding also includes blood transfusions, especially platelets and fresh-frozen plasma, although their benefit is unproven. Residual heparin, including heparin 'rebound', can respond to additional protamine. Desmopressin probably is ineffective. No universally accepted algorithm for management exists.

Liver disease

Hyperfibrinolysis complicating liver disease is discussed elsewhere.

Venom-induced coagulopathies (snake bites) (see also Chapter 8.2)

Envenomations can harm or kill humans generally through systemic effects, for instance profound hypotension. Sometimes, however, life-threatening coagulopathies result.

Snake bites

In the United States, about 8000 bites from venomous snakes occur each year, resulting in 10 to 20 deaths. This relatively low mortality reflects the less lethal character of New World snakes, as well as the victim's usual close proximity to medical facilities and antivenin therapy. Pit vipers (rattlesnakes, copperheads, cottonmouths, massasaugas) account for 99 per cent of snakebite poisonings in the United States. Worldwide, about 30 000 to 40 000 people die from snakebite, about half in India. Although death usually results from multiple mechanisms (such as circulatory shock, rhabdomyolysis, renal failure, pulmonary failure, neurotoxicity), bleeding is sometimes the major factor.

Venoms contain multiple digestive enzymes with a broad spectrum of activity that can include effects on human haemostasis (Table 9). Within a species, haemostatic effects of envenomation vary with snake age, diet, and other factors. North American rattlesnakes typically cause the 'defibrination syndrome'; despite even profound hypofibrinogen*aemia*, bleeding is uncommon. In contrast, venom from Old World vipers frequently cause generalized activation of the coagulation system (DIC), with a greater chance for bleeding or microvascular thrombosis. Bleeding can also result from platelet inhibitors present within venom; for example, the platelet fibrinogen receptor antagonist, echistatin (*Echis carinatus*), or 'haemorrhagins' such as jararhagin (*Bothrops jararacussu*) that damage endothelium.

Immediate treatment of a snake bite includes efforts to limit the venom spread (immobilizing and placing a constriction band proximal to the bite site). Rapid transport to medical facilities is crucial since antivenin therapy is the mainstay of treatment. Antivenin treatment is indicated for patients with significant pain or swelling, as well as suspected or proven haemostasis abnormalities, as these indicate envenomation rather than a 'dry bite'. Hypersensitivity testing to the antivenin should be performed to rule out pre-existing hypersensitivity to horse serum. The treatment of snake bite is discussed in Chapter 8.2.

Coagulation studies should include: complete blood count (including platelets), PT/INR, aPTT, TCT, fibrinogen, and FDPs. Abnormal results indicate envenomation, and are an indication for antivenin therapy. The bedside assessment of defibrination involves placing a few millilitres of blood in a clean, dry test tube at room temperature for 20 min; incoagulable blood indicates defibrination. Usually, blood products should only be given to patients with bleeding. A small clinical trial found that heparin was ineffective in patients with DIC caused by a Russell's viper bite.

Laboratory and therapeutic uses of snake venoms

Snake-venom fractions are useful for certain laboratory assays. For example, the thrombin-like enzyme, batroxobin (Reptilase®, *Bothrops atrox moojeni*), cleaves fibrinopeptide A from fibrinogen even in the presence of heparin. Thus, a prolonged Reptilase time indicates hypofibrinogen *aemia* even in heparin-containing plasma.

Ecarin activates prothrombin irrespective of its g-carboxylation status; thus, it can be used to detect **PIVKA** (proteins induced by vitamin K antagonists) to document vitamin K deficiency or dysprothrombin*aemia*. An ecarin clotting time (**ECT**) is superior to the aPTT for monitoring therapy with hirudin, particularly the high doses used for heart surgery. Differences in phospholipid dependency of venom prothrombin activators has led to the use of a Textarin®/ecarin ratio to detect lupus anticoagulants; a ratio over 1.3 is a sensitive and relatively specific test for lupus anticoagulants.

Russell's viper venom contains a potent activator of factor X (**RVV-X**); the dilute Russell's viper venom time (**dRVVT**), performed by adding RVV-X and diluted rabbit brain phospholipid to test plasma prior to recalcification, measures the rate of formation and activity of the phospholipid-dependent prothrombinase complex in producing thrombin. The dRVVT is thereby prolonged in the presence of a lupus anticoagulant.

A commercially available protein C activator (Protac®) from *Agkistrodon contortrix contortrix* (the southern copperhead) has greatly simplified assays for protein C activity, as well as in screening for defects in the protein C anticoagulant pathway.

The defibrinogenating snake venom, ancrod (Arvin®, derived from the Malayan pit viper, *Calloselasma [Agkistrodon] rhodostoma*), which proteolyses fibrinopeptide A, has been used for antithrombotic therapy, including the management of heparin-induced thrombocytopenia (**HIT**), acute stroke, thrombotic nephropathy, and priapism. The inability to control thrombin generation is a potential drawback of this therapy. Batroxobin (Defibrase®) is another defibrinogenating venom that has seen limited clinical applications.

Prothrombotic acquired coagulation disorders

Some acquired coagulation disorders are characterized by an increased risk for thrombosis, rather than bleeding. Accordingly, the appropriate treatment usually involves anticoagulant therapy, even if there are abnormal coagulation or platelet count values.

Macrovascular thrombosis

Some acquired coagulation disorders typically cause thrombosis in large veins and arteries, although small-vessel thrombi can also result.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (**HIT**) is caused by IgG antibodies that recognize multimolecular complexes of platelet factor 4 (**PF4**) and heparin. Thrombosis results from IgG-induced platelet activation (via platelet Fc receptors), resulting in the generation of procoagulant, platelet-derived microparticles, tissue-factor expression by endothelium, and inactivation of heparin by PF4 released from platelets. Increased thrombin–antithrombin complex levels indicate DIC in almost all patients with HIT, although a prolonged INR or low fibrinogen level occur in less than 10 per cent of cases.

Typically, the fall in platelet count begins 5 to 10 days after starting heparin; however, in patients who received heparin within the past 100 days, the platelet count can fall abruptly upon resuming heparin therapy, probably because of residual circulating HIT antibodies. HIT occurs in as many as 5 per cent of certain high-risk populations: for example, postoperative orthopaedic patients receiving unfractionated heparin. HIT is less frequent in patients initially treated with low-molecular-weight heparin (**LMWH**).

Most patients with HIT develop venous or arterial thrombosis (Fig. 2), most commonly a deep-vein thrombosis (**DVT**), pulmonary embolism, major limb artery thrombosis, stroke, or myocardial infarction. Acute or chronic adrenal failure from bilateral adrenal haemorrhagic necrosis has been described. The thrombocytopenia is typically moderate in severity (median platelet count nadir, 60 × 10^9/l), but in only 10 per cent of patients does the platelet count fall to less than 20 × 10^9/l. In at least 10 per cent of patients, the platelet count never drops below 150 × 10^9/l (Fig. 2).

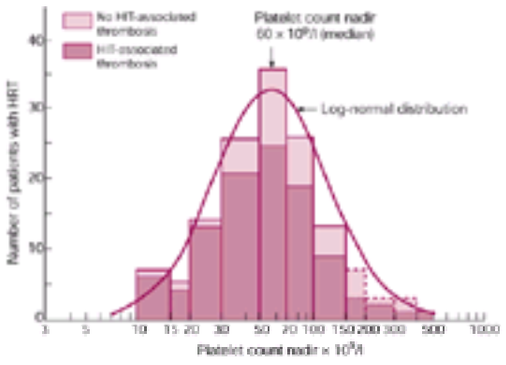

Fig. 2 Thrombosis in relation to the severity of thrombocytopenia in patients with HIT. The magnitude of thrombocytopenia in HIT shows a log-normal distribution. Thrombocytopenia is typically mild-to-moderate (between 20 and 150 × 10^9/l in about 80 per cent of patients; median platelet count nadir, about 60 × 10^9/l). Thrombosis occurs in 50 per cent or more of patients with HIT, irrespective of the platelet count nadir, including patients whose platelet count never falls below 150 × 10^9/l. (Reprinted with permission from Warkentin, 1998.)

Laboratory testing for HIT antibodies includes activation and antigen assays. The former assays detect antibodies via their heparin-dependent, platelet-activating properties. Commercially available antigen assays detect antibodies that bind to surface-immobilized PF4 complexed to heparin or polyvinylsulphonate.

Treatment includes stopping heparin and instituting alternative anticoagulation. Coumarin alone should not be given to patients with acute HIT, particularly to those with associated DVT, as there is a risk for inducing progression to venous limb gangrene. The dramatic natural history of HIT, with a risk for subsequent thrombosis of about 50 per cent even after stopping heparin, means that an alternative anticoagulant, together with DVT surveillance, should be considered for all patients with suspected HIT. Suitable anticoagulants with a rapid-onset of action include danaparoid (a low-molecular-weight heparinoid with predominant anti-factor Xa activity), lepirudin (a recombinant hirudin with potent antithrombin activity derived from leech salivary glands), and argatroban (a synthetic, small-molecule, direct thrombin inhibitor). Among patients with HIT, LMWH treatment has a high risk for clinical crossreactivity, and should be considered a contraindicated treatment for acute HIT. Many patients will benefit from selected adjunctive treatments, for instance surgical thromboembolectomy for acute arterial thrombosis of a limb.

Adenocarcinoma-associated chronic DIC

Metastatic adenocarcinoma sometimes presents as venous or arterial thrombosis accompanied by DIC. The diagnosis is suggested by an unexpected rise in the platelet count during heparin treatment, followed by an abrupt platelet count fall, together with new or progressive thrombosis, when heparin is stopped, despite therapeutic anticoagulation with warfarin. The clinical situation can mimic HIT ('pseudo-HIT'), but HIT antibodies are absent, and the platelet count recovers during resumption of heparin (Fig. 3). Oral anticoagulants are ineffective, and may even cause venous limb gangrene (discussed subsequently). Heparin, especially LMWH, is the preferred treatment. Tissue factor-containing tumour ves-icles, and factor Xa-activating enzymes found in tumour extracts, are two possible explanations for these procoagulant effects of adenocarcinoma.

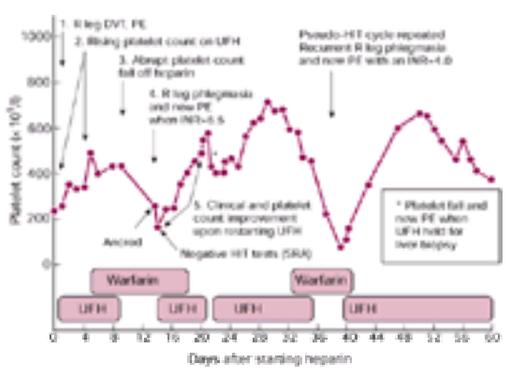

Fig. 3 Pseudo-HIT. Adenocarcinoma with thrombocytopenia and phlegmasia cerulea dolens after stopping unfractionated heparin (UFH). The timing of thrombocytopenia onset suggested HIT, prompting the use of an alternative anticoagulant (ancrod). Heparin was restarted when HIT antibodies were not detected by activation assay (serotonin-release assay, SRA). Subsequently, heparin discontinuation led to the recurrence of thrombocytopenia and warfarin-associated phlegmasia cerulea dolens (repeat of pseudo-HIT cycle). Abbreviations: DVT, deep venous thrombosis; INR, international normalized ratio; PE, pulmonary embolism.

Antiphospholipid antibody syndrome ('lupus anticoagulant')

This clinicopathological syndrome is characterized by large-vessel venous and/or arterial thrombosis, recurrent miscarriages, and thrombocytopenia. An associated 'lupus anticoagulant' (or 'non-specific inhibitor') is a prolonged aPTT that results from the interference by antibodies against phospholipid-dependent coagulation reactions; these antiphospholipid antibodies are usually directed against protein cofactors such as b $_2$-glycoprotein I (**b2GPI**) and prothrombin. Sometimes, a prolonged PT/INR is caused by non-neutralizing antiprothrombin antibodies that cause hypoprothrombinaemia by increased prothrombin clearance.

Despite these laboratory abnormalities, bleeding is unusual, since severe thrombocytopenia or hypoprothrombinaemia is uncommon. More often, antiphospholipid antibodies are associated with intermittent thrombosis; rarely, the abrupt onset of life-threatening multiple vascular occlusions occurs ('catastrophic antiphospholipid antibody syndrome'). The explanation for the paradoxical association with thrombosis remains elusive, but it could be caused by antibody interactions with other protein cofactors described (for example, activated protein C, protein S, thrombomodulin). Many patients have a thrombocytopenia that is typically mild and intermittent. Other less common complications include cardiac valvulitis and microvascular thrombosis, which can manifest as acrocyanosis, digital

ulceration/gangrene, and livedo reticularis.

Antiphospholipid antibodies are detected by enzyme-linked immunosorbent assays (**ELISA**) using purified phospholipids as the target antigen, for example the anticardiolipin antibody assay. Lupus anticoagulant activity is shown by demonstrating inhibition of phospholipid-dependent coagulation assays. Several assays should be performed, as anti-b$_2$GPI antibodies especially interfere with the conversion of prothrombin to thrombin (that is, best detectable by dRVVT), whereas antiprothrombin antibodies interfere most with global coagulation assays (for instance, kaolin clotting time). The coagulation times remain prolonged following mixing with normal plasma; confirmation involves adding excess phospholipid to neutralize the effects of the antiphospholipid antibodies. Not all aPTT reagents are sensitive to antiphospholipid antibodies, and so these phospholipid-dependent coagulation assays should be performed in the appropriate clinical situation, even if the aPTT is normal.

The term 'lupus anticoagulant' refers to the frequent occurrence of these antibodies in patients with systemic lupus erythematosus; nevertheless, most patients with the antiphospholipid antibody syndrome do not have SLE. Some patients have other autoimmune disorders, malignancy, infections, or procainamide treatment, but usually no associated condition is identified (primary antiphospholipid antibody syndrome). Many patients require long-term anticoagulation, although the optimal agents and therapeutic level of anticoagulation remain to be defined. Corticosteroids can benefit patients with bleeding caused by hypoprothrombinaemia.

Microvascular thrombosis

Some disorders of haemostasis are characterized by small-vessel thrombi, affecting either arterioles (for example, TTP) or small venules (for example, coumarin-induced necrosis).

Thrombotic microangiopathy

Thrombotic microangiopathy is a clinicopathological syndrome of microangiopathic haemolysis and thrombocytopenia carrying a risk for arteriolar occlusion by microaggregates of platelets and vWF, particularly affecting the kidneys and central nervous system. Microangiopathic red cell changes are characteristic, for example 'helmet cells' (schistocytes) and small, triangle-shaped, red cell fragments. The prototypic illness is thrombotic thrombocytopenic purpura (**TTP**), which typically affects adults and is idiopathic. However, familial and secondary forms of TTP also exist. The haemolytic-uraemic syndrome is a nephrotropic variant of TTP with a distinct pathogenesis, including its association with verocytotoxin-producing *Escherichia coli* acquired from eating undercooked meat (hamburger disease).

The pathogenesis of TTP involves the formation of platelet–vWF microaggregates in high shear situations (arterioles). Platelet-bound vWF levels are increased during TTP. Patients with familial TTP have ultra-large multimers of vWF during remission; these very large multimers disappear during active disease. Recently, a constitutional deficiency of a vWF-cleaving metalloproteinase has been identified in patients with familial TTP. In patients with non-familial TTP, an IgG autoantibody, which inhibits the vWF-cleaving metalloproteinase, has been identified that disappears in remission.

The mainstays of treatment for acute TTP are corticosteroids and fresh-frozen plasma given by infusion or apheresis. Corticosteroids, often given as prednisone 200 mg/day, may treat the autoimmune component of TTP. Provision of either fresh-frozen plasma, or the cryoprecipitate-depleted fraction of plasma (cryosupernatant), has greatly reduced mortality in TTP, possibly by providing limited disulphide-bond reductase activity that facilitates vWF cleavage. Furthermore, apheresis may help cleave the pathogenic autoantibody and large vWF multimers.

Coumarin-induced skin necrosis

Coumarin-induced skin necrosis (**CISN**) is characterized by necrosis of the skin and underlying subcutaneous tissues that typically begins 3 to 6 days after commencing warfarin or coumarin anticoagulants. CISN results from failure of the protein C natural anticoagulant system to downregulate thrombin generation in the microvasculature. The relatively short half-life of protein C, compared with prothrombin, explains the temporal profile of CISN—that is to say, a transient period of disproportionately reduced protein C activity soon after starting coumarin (Table 10). Furthermore, a relatively high proportion of affected patients have a hereditary abnormality of the protein C anticoagulant pathway, especially protein C deficiency. Other disorders associated with CISN include congenital deficiency in protein S or antithrombin, factor V Leiden, and HIT. The pathology is a predominantly non-inflammatory, small-vessel thrombosis affecting the subcutaneous postcapillary venules and small veins.

CISN characteristically affects central (non-acral) sites with substantial underlying fatty tissues, such as the breast, buttocks, hips, and thighs (Fig. 4). Less common areas include the anterior abdomen, flank, back, penis, legs, arms, and face. About 75 per cent of patients are women; one-third have multiple lesions that can be symmetrical. The earliest features are localized pain, induration, and erythema; over the next few hours, the skin lesions progress to central purplish or black discoloration, with blistering, subsequently demarcating to full-thickness skin necrosis. CISN is rare (1/10 000 patients treated with warfarin).

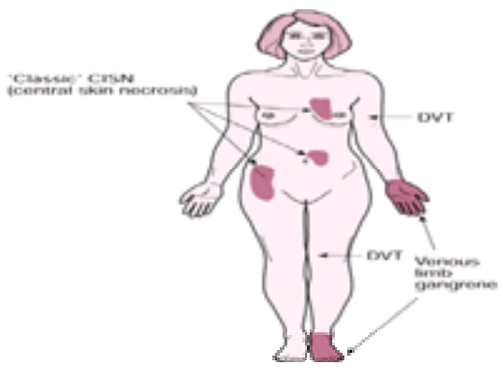

Fig. 4 Coumarin-induced skin necrosis: 'classic' syndrome (usually affecting central tissue sites) and coumarin-induced venous limb gangrene. Typically, an active deep-vein thrombosis (DVT) subtends the distal extremity affected by venous limb gangrene. (Reprinted with permission from Warkentin, 1996.)

Prompt reversal of anticoagulation with vitamin K may prevent incipient CISN if recognized early. However, the diagnosis is usually not made until necrosis is established; at this point, it is unknown whether vitamin K, fresh-frozen plasma, or protein C concentrates alter its natural history. In patients without HIT, warfarin is usually replaced by heparin. Many patients require surgical treatment, such as skin grafting or tissue amputation. Following recovery, it is usually safe to reintroduce warfarin provided certain precautions are taken, for example the gradual initiation of oral anticoagulation.

Coumarin-induced venous limb gangrene

Venous limb gangrene involves the acral (peripheral) regions of the body—most often the toes, feet, and legs, but sometimes also the fingers, hands, and arms—usually in association with DVT. The severity ranges from an initial stage of phlegmasia caerulea dolens ('swollen, blue, painful' limb) to extensive venous limb gangrene requiring limb amputation. Two disorders predispose to coumarin-induced venous limb gangrene: HIT and cancer-associated DIC. Recent data suggest that the supratherapeutic INR (typically, >3.5) that characterizes venous limb gangrene is caused by a severe reduction in factor VII, which parallels a severe reduction in protein C activity that explains the microvascular thrombosis underlying this syndrome. Essentially, coumarin interferes with the protein C anticoagulant pathway, while at the same time it is unable to control the increased thrombin generation characteristic of HIT or cancer-associated DIC.

Purpura fulminans

Purpura fulminans is a rare syndrome of DIC and microvascular thrombosis that results in multicentric ischaemic necrosis of the skin and subcutaneous tissues, predominantly affecting the extremities. The most common cause is overwhelming septicaemia, especially with meningococcus. A severe, acquired reduction in protein C activity complicating DIC is the most likely cause for the microvascular thrombosis, and some experts recommend treatment with protein C concentrates, if available. Autoantibodies against protein S have been implicated in patients with postvaricella purpura fulminans. In other patients with apparent 'idiopathic' purpura

fulminans, autoantibodies that interfere with the protein C anticoagulant system have been described.

P>**Septicaemia and other systemic inflammatory response syndromes**

Multiple organ failure often complicates septicaemia and other systemic inflammatory disease syndromes, including adult respiratory distress syndrome, fat embolism, and acute pancreatitis. Thrombocytopenia and coagulopathy are common, and some patients have DIC that could contribute to organ dysfunction via microvascular thrombosis. However, a prothrombotic basis for organ failure is usually speculative, as microthrombosis is rarely documented pathologically, and non-thrombotic microvascular disturbances that impair tissue oxygen delivery also occur.

Haemostasis in the newborn

Neonatal vitamin K deficiency

Haemorrhagic disease of the newborn caused by vitamin K deficiency was once a relatively common cause of bleeding during the first week of life, particularly in breast-fed infants. Low vitamin K levels in mother's milk, and insufficient colonization of the newborn bowel by vitamin K-produc-ing bacteria, predispose to the inability to meet the infant's vitamin K requirements (1 µg/kg per day). The routine administration of vitamin K, either 1 mg given intramuscularly immediately after birth, or three oral doses of vitamin K, has led to the near-disappearance of this problem. Bleeding within 24 h of birth can occur in certain high-risk settings, for example mothers receiving anticonvulsants or warfarin; in these cases, the mother should receive vitamin K, 10 mg by mouth, each day for 2 weeks prior to delivery. Vitamin K deficiency occurring later in infancy despite appropriate neonatal vitamin K prophylaxis can indicate hepatobiliary or bowel disease.

Neonatal disseminated intravascular coagulation

DIC commonly complicates neonatal infection, asphyxia, respiratory distress syndrome, aspiration of meconium or amniotic fluid, maternal hypertensive syndrome, hypothermia, and brain injury. This condition poses a significant risk of bleeding or thrombosis, as the immature liver has an impaired capacity to synthesize coagulation factors, and the reticuloendothelial system has a limited ability to clear activated coagulation factors. Treatment is aimed at the underlying cause of the DIC, with blood product given for the bleeding.

Neonatal purpura fulminans

Purpura fulminans can begin within hours or days following birth, often first affecting the heels or venepuncture sites. The underlying cause is usually a congenital abnormality affecting the protein C anticoagulant system (homozygous deficiency of protein C or protein S; homozygous factor V Leiden), although infection with group B b-haemolytic streptococcus is described. Fresh-frozen plasma given every few days prevents a recurrence in some patients.

22.7 The blood in systemic disease

D. J. Weatherall

There are few diseases that do not produce some alteration in the blood. Here, some of the haematological changes associated with general systemic diseases will be summarized. Many of these topics are discussed elsewhere in this book but they are brought together in order to emphasize how blood changes may give the first indication of the presence of non-haematological disorders. It should be remembered that the haematological consequences of systemic disease vary considerably depending on the age of the patient. Recent reviews which deal specifically with this topic in children and the elderly are cited at the end of this chapter.

Malignant disease

The most common haematological finding in malignant disease (Table 1) is the anaemia of chronic disorders, which was described in Chapter 22.5.3. It may occur together with localized or widespread malignancy and is sometimes associated with an elevated erythrocyte sedimentation rate (ESR). It is found in patients with practically every type of carcinoma or reticulosis, is refractory to haematinics, but may respond to successful removal of a primary tumour.

The anaemia of patients with carcinoma, particularly of the gastrointestinal tract, may be complicated by chronic blood loss and superimposed iron deficiency. Chronic bleeding of this type is often associated with a mild thrombocytosis.

Disseminated malignancy

The most common haematological change with disseminated malignancy is a leucoerythroblastic picture characterized by the presence in the blood of immature myeloid cells together with some nucleated red cells, and, sometimes, a mild reticulocytosis. The red cells often show a moderate degree of anisocytosis and poikilocytosis. This finding is very commonly accompanied by the presence of tumour cells in the bone marrow. Clinically, it can cause confusion with the diagnosis of primary myelosclerosis; but splenomegaly is unusual in patients with disseminated carcinoma.

Occasionally, widespread carcinoma leads to a leukaemoid reaction with white-cell counts in the range seen in chronic myeloid leukaemia. The differentiation between these two conditions was described earlier.

The microangiopathic haemolytic anaemia of disseminated malignancy is most frequently found in association with a mucin-secreting adenocarcinoma, particularly of the stomach, breast, and lung.

Less common forms of anaemia associated with cancer

Autoimmune haemolytic anaemia is sometimes found in patients with an underlying lymphoma. It is much less common in other forms of malignancy except for the association with tumours of the ovary. However, there have been reports of autoimmune haemolysis occurring with a wide variety of tumours, including lung, stomach, breast, kidney, colon, and testis.

Pure red-cell aplasia may occasionally be the presenting feature in a patient with a tumour of the thymus. There have been occasional reports of this type of anaemia occurring in patients with carcinoma of the bronchus or lymphomas.

Finally, it should be remembered that there is an association between pernicious anaemia and carcinoma of the stomach. A patient may present with a megaloblastic anaemia associated with a malignancy of this type. In the early literature on sideroblastic anaemia, an association with carcinoma was well documented. Since acquired sideroblastic anaemia has been classified as part of the myelodysplastic syndrome there seem to have been no further reports of this association and its significance remains uncertain.

Polycythaemia

The relation between secondary polycythaemia and an underlying neoplasm is discussed in Chapter 22.4.14. It has been found in patients with renal tumours, hepatomas, hamartomas of the liver, uterine fibroids, vascular tumours and cystic adenomas of the cerebellum, and carcinoma of the lung.

Changes in the platelets and blood coagulation

An otherwise unexplained thrombocytosis may be the first indication of an underlying malignancy. It is important to remember that this is not always associated with chronic blood loss; bronchial carcinoma may present in this way. Thrombocytopenia may sometimes occur with bone marrow infiltration by tumour cells, but is seen most frequently as a side-effect of chemotherapy. Autoimmune thrombocytopenia has been observed most commonly in association with lymphoid malignancies, but it can also occur in association with tumours of the lung, breast, and testes.

Generalized haemostatic failure associated with disseminated carcinoma is considered in detail elsewhere (Fig. 1 and Fig. 2).

Fig. 1 Disseminated intravascular coagulation in association with carcinoma of the prostate. The patient started to bleed extensively from the iliac-crest marrow biopsy site and from venesection sites. Marrow biopsy showed widespread tumour metastases. (Reproduced from Hardisty RM, Weatherall DJ (ed.) (1982). *Blood and its disorders*, 2nd edn. Blackwell Scientific, Oxford, with permission.)

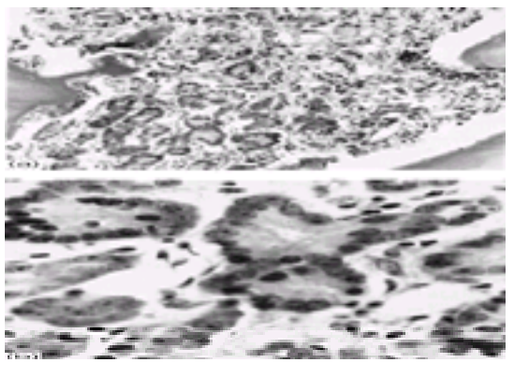

Fig. 2 Section prepared from Gardner-needle biopsies from bone marrow infiltrated with neoplastic cells; the primary tumour was in the prostate. (Reproduced from Hardisty RM, Weatherall DJ (ed.) (1982). *Blood and its disorders*, 2nd edn. Blackwell Scientific, Oxford, with permission.) (a) H and E stain ×230; (b) H and E stain ×920.

Some bleeding disorders associated with cancer seem to be due to selective impairment of coagulation. This may result from pathological inhibitors of different parts of the coagulation system or from isolated factor deficiencies. The mechanism is unknown. If the bleeding disorder is not characterized by consumption of clotting factors or fibrinolysis, a detailed analysis of the activities of the intrinsic and extrinsic pathways must be made in case a correctable lesion is present (Table 2).

Patients with cancer have an increased tendency to thrombosis. Apart from debilitation and periods of prolonged bed rest there is undoubtedly a hypercoaculable state associated with many tumours. This seems to involve a variety of procoagulants including fibrinogen and factors V, VII, VIII, IX, and XI. Low-grade, disseminated, intravascular coagulation can consume anticogulants such as anti-thombin III, protein C, and protein S. Cancer cells can initiate clotting by releasing a tissue factor, a phenomenon which is described in patients with lung, kidney, colon, and breast cancers. The syndrome of non-bacterial thrombotic endocarditis, characterized by cerebral embolic strokes and extensive fibrin/platelet vegetations on the mitral and aortic valves, is most commonly associated with cancers of the lung, prostate, and pancreas.

White-cell abnormalities

In addition to the leukaemoid reaction, there are several white-cell changes that should make the clinician think about an underlying malignancy. For example a persistent monocytosis or eosinophilia may be associated with Hodgkin's disease or with bronchial carcinoma. Persistent lymphopenia may occur in patients with Hodgkin's disease.

Haematological changes due to cancer chemotherapy

Many agents used in cancer chemotherapy depress the bone marrow causing varying periods of neutropenia and thrombocytopenia associated with a variable anaemia. The bone marrow may also show marked myelodysplastic features. Haemolytic reactions have been associated with a number of drugs, including mitomycin C, and bleomycin–cisplatin. In some cases these drugs are associated with a syndrome of microangiopathic haemolytic anaemia resembling the haemolytic uraemic syndrome. Circulating immune complexes have been observed in some cases and there have been reports of response to plasma exchange and immunosuppression. Some chemotherapeutic agents appear to cause a warm antibody type of haemolytic anaemia. In patients who are glucose-6-phosphate dehydrogenase deficient, the administration of doxorubicin can produce a haemolytic reaction.

Haemophagocytic syndrome

This disorder, which is described in a later section in its association with viral illness, has now been reported in patients with cancer, lymphoma, and acute leukaemia. It is characterized by pancytopenia, fever, and splenomegaly; the bone marrow resembles histiocytosis with intense haemophagocytosis by macrophages.

Infection

Most of the important haematological changes in association with infection are considered in Section 7. Just a few points of particular haematological relevance are summarized below.

Acute bacterial infection

Most acute bacterial infections are associated with a neutrophil leucocytosis. This may be so marked, and associated with a 'shift to the left' with production of myelocytes in the blood, that the condition may present a leukaemoid type of reaction. Occasionally, in patients who are severely ill with acute bacterial infection, the neutrophil response seems inadequate. Some may be frankly neutropenic. A number of these individuals will prove to have an underlying haematological disorder or a debilitating condition such as alcoholism, but many who recover from their infection show no such underlying abnormality. A marrow examination usually reveals a paucity of mature granulocytes. This clinical picture is particularly common in newborn infants, especially those born prematurely. Some infections seem to be particularly prone to association with a reduced white-cell count. They include salmonellosis, brucellosis, pertussis, rickettsial infections, disseminated tuberculosis (in some cases), and disseminated histoplasmosis.

Other leucocyte changes are less common in acute infection. Monocytosis has been reported in patients with typhoid fever and sometimes in brucellosis or subacute bacterial endocarditis. In endocarditis a monocytosis may be associated with the presence of undifferentiated reticuloendothelial cells in the blood that show erythrophagocytosis.

Some degree of anaemia is found almost invariably in patients with bacterial infection. It usually presents a picture of the anaemia of chronic disorders. Haemolytic anaemia may occur in severe septicaemias and is usually associated with disseminated intravascular coagulation. Some organisms, *Clostridium welchii* for example, produce an a-toxin that acts as a lecithinase and causes fulminating intravascular haemolysis.

Disseminated intravascular coagulation is a common accompaniment of severe bacterial infection. Many mechanisms have been suggested, including vascular injury with activation of factor XII or the generation of procoagulants from white cells by the action of endotoxin. Thrombocytopenia is also common in patients with septicaemia. Although this may sometimes reflect disseminated intravascular coagulation, the mechanism is probably more complicated. There may be quite dramatic thrombocytopenia without any other evidence of a consumption coagulopathy. Several mechanisms are involved, including suppression of platelet production by the bone marrow, damage to circulating platelets by immune complexes, endothelial damage, and direct interaction of the platelets with bacteria; phagocytosis of bacteria by platelets may provoke the rapid disappearance of platelets from the circulation.

Chronic bacterial infection

Chronic bacterial infection is usually associated with the anaemia of chronic disorders. Some particularly interesting haematological changes are sometimes ascribed to tuberculosis (Table 3). While the most common change is a mild, normochromic, normocytic anaemia with a raised ESR; more spectacular blood changes have been reported, particularly in association with disseminated tuberculosis. These clinical pictures include leukaemoid reactions, pancytopenia, myelofibrosis, and even polycythaemia. The main problem in assessing these associations is whether the reported patients had infections due to atypical mycobacteria superimposed on an underlying blood disease, or whether disseminated tuberculosis can occasionally produce a clinical picture similar to leukaemia or a myeloproliferative disease. In practice, any patient who presents with an atypical myeloproliferative disorder, and who is going downhill for no apparent cause, should be investigated for tuberculosis. Attempts should be made to grow the organism from bone marrow cultures.

Virus infections

Haematological changes occur quite commonly in association with many virus illnesses. Changes associated with specific viral infections such as infectious mononucleosis are considered in Section 7.

Many virus infections are associated with a modest neutropenia and often with a relative or absolute lymphocytosis. Atypical lymphocytes are characteristic of patients with infectious mononucleosis but they may also be found in association with many other virus infections.

Rubella, acquired in childhood or adult life, is often associated with a leucocytosis and an atypical lymphocytosis. A small proportion of patients develop an acute fulminating thrombocytopenic purpura approximately 4 days after the appearance of the rash. It is usually self-limiting but fatalities have been reported. Thrombocytopenia is also common in infants with congenital rubella. This condition is also characterized by a non-immune haemolytic episode shortly after birth. Thrombocytopenia has also been reported in association with measles. In particularly severe forms of rubella and morbilli, severe haemorrhagic states due to disseminated intravascular coagulation have been seen. Similar changes occur occasionally in patients with varicella infections.

Haematological changes very similar to those seen in infectious mononucleosis can occur in patients with cytomegalovirus (CMV) infection. Infants may exhibit hepatosplenomegaly with purpura and anaemia. The anaemia is characterized by a haemolytic picture with many normoblasts in the peripheral blood. This form of anaemia may last for several weeks and may be associated with severe thrombocytopenia. There are well-documented cases of an infectious mononucleosis-like disorder occurring after transfusion with fresh blood or after perfusion for open heart surgery. This self-limiting syndrome usually occurs 1 to 3 months after blood transfusion and resolves within a few weeks. It is characterized by a moderate rise in temperature, with hepatosplenomegaly, lymphadenopathy, and transient maculopapular rashes, and a lymphocytosis indistinguishable from that of infectious mononucleosis.

Haematological problems are common in patients with AIDS. Lymphopenia is particularly common; neutropenia occurs in 0 to 30 per cent of HIV antibody-positive asymptomatic individuals, and in 20 to 65 per cent of patients with AIDS. Thrombocytopenia occurs in 5 to 20 per cent of asymptomatic HIV-1 infected persons and rises to 25 to 50 per cent in patients with AIDS. There is also a strong association of thrombotic thrombocytopenic purpura with HIV infection. Anaemia is also common. Bone marrow examination often reveals dyserythropoiesis with a variable degree of erythrophagocytosis. There have been a number of reports of the presence of lupus anticoagulant in the blood of patients with AIDS. In addition to these haematological complications, there is the added risk of drug-induced marrow hypoplasia, associated particularly with treatment with zidovudine (AZT).

Haematological complications of infectious hepatitis are rare but can be extremely severe. Coombs' positive haemolytic anaemia has been reported. There is also considerable literature on the occurrence of aplastic anaemia. This disorder seems predominantly to affect young males; the onset of aplasia is usually about 9 weeks after the onset of hepatitis. The condition is associated with a mortality in excess of 90 per cent. In those patients who recover, the period to complete haematological normality ranges between 3 and 20 months.

Many viruses are capable of provoking severe bleeding due to intravascular coagulation. Why viruses can fire off the coagulation cascade is far from clear. Activation of factor XII due to vascular injury or damage to platelets with the release of coagulants have been suggested as possible mechanisms.

The human parvovirus has a particular affinity for red-cell progenitors. It probably causes transient red-cell aplasia quite commonly but this only gives rise to a symptomatic anaemia in patients who have a markedly shortened red-cell survival. Thus parvovirus infection appears to be responsible for the aplastic crises in patients with sickle-cell anaemia, pyruvate kinase deficiency, or other congenital haemolytic anaemias. Viruses can cause acute damage to the bone marrow in immunesuppressed patients as part of the virus haemophagocytic syndrome.

The haematological changes associated with the virus haemorrhagic fevers are described in detail in Section 7.

Parasitic disease

The major haematological accompaniments of the parasitic diseases are described in Section 7. Those which produce important haematological changes will be briefly summarized here.

Toxoplasmosis

Congenital toxoplasmosis can produce a condition identical to erythroblastosis fetalis. The clinical picture is of a pale, hydropic infant with a large spleen and liver

associated with severe anaemia, thrombocytopenia, and a leucocytosis, often with a marked eosinophilia. In adult life the acquired forms of toxoplasmosis produce a clinical disorder resembling infectious mononucleosis.

Malaria (Plate 1)

Malarial infection produces a variety of haematological abnormalities. The most severe changes occur during *Plasmodium falciparum* infection. In acute infections in non-immune individuals, there is usually minimal anaemia at the onset of the illness. During the 2 to 3 weeks after treatment there may be a steady decline in haemoglobin level. On the other hand, individuals with chronic malaria, some degree of immunity, and low-level parasitaemias, may be severely anaemic at presentation with an inappropriately low reticulocyte count. The bone marrow is often hyperplastic and shows a marked degree of dyshaemopoiesis (Fig. 3).

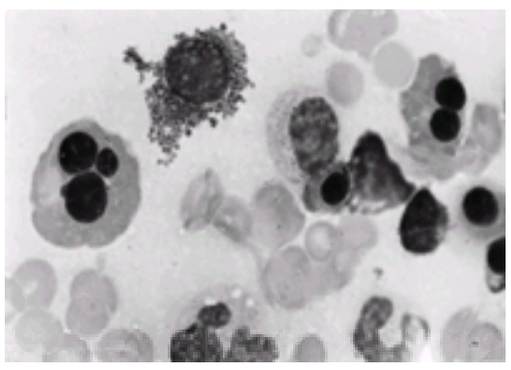

Fig. 3 Bone marrow appearances in *P. falciparum* malaria. There is marked dyserythropoiesis with several multinucleate red-cell precursors (Giemsa stain ×800).

The precise details of the pathophysiology of the anaemia of malaria are still unclear. There is no doubt that in acute attacks there may be massive destruction of parasitized red cells but, curiously, there is strong evidence that the survival of non-parasitized cells is also shortened. Although there is some indirect evidence for an immune basis for red cell destruction, particularly in children, little solid evidence exists for immune destruction in non-immune adults. There is growing evidence that the lack of marrow response may be, at least in part, due to the high levels of tumour necrosis factor (TNF) that are produced during malarial infection. TNF suppresses proliferation of erythroid progenitor cells *in vitro*. Chronic malaria has several features that augment this effect. Large numbers of pigment particles are ingested by the resident macrophages of the spleen and marrow, providing the possibility of a sustained stimulus for TNF production at the site of erythropoiesis.

In some patients with severe *P. falciparum* infections, there may be marked intravascular haemolysis and haemoglobinuria. The mechanism is not certain. Some of these patients may be glucose 6-phosphate dehydrogenase deficient but this is by no means the whole story. It has been suggested that some patients with fulminating malaria have disseminated intravascular coagulation. This is probably uncommon and plays very little part in the pathophysiology of either the anaemia or haemorrhagic phenomena that occur. Thrombocytopenia is extremely common but is only rarely associated with evidence of consumption of blood-clotting factors. In most forms of malarial infection there is a neutropenia. Monocytosis has also been described.

Several interesting haematological manifestations are associated with unusual forms of malaria. In the tropical splenomegaly syndrome, there may be anaemia, thrombocytopenia, and neutropenia, all secondary to hypersplenism. Congenital malaria infection is contracted in intrauterine life from the mother; newborn babies have a febrile illness associated with profound anaemia that appears to result from the combination of haemolysis and bone marrow suppression.

Leishmaniasis

Visceral leishmaniasis, or kala azar, is associated with hepatosplenomegaly, lymphadenopathy, and a pancytopenia, particularly in young children. Early in the course of the disease there is often marked neutropenia. The marrow may be grossly infiltrated with parasitized macrophages. The anaemia is due mainly to a short red-cell survival; there is also an inappropriate marrow response and a variable degree of hypersplenism.

Hookworm

The haematological changes of hookworm infestation are described in Chapter 22.5.3. It is one of the most common causes of iron-deficiency anaemia in the world population. During the systemic phase of the illness, when the larvae invade the lungs, there may be a marked eosinophilia. During this phase the bone marrow shows a remarkable increase in the percentage of eosinophilic myelocytes, which may be out of proportion to the eosinophilia observed in the peripheral blood.

Visceral larva migrans

This condition is characterized by striking haematological changes including anaemia, a marked leucocytosis with eosinophilia, and changes in the titre of anti-A and anti-B blood-group antibodies.

Schistosomiasis

In the chronic phase of *S. mansoni* and *S. japonicum* infections there may be severe portal hypertension, splenomegaly, and the typical picture of hypersplenism.

Other trematode infestations, including clonorchiasis and paragonamiasis, are associated with eosinophilia and anaemia. Antibodies to the P_1 blood-group antigen may be found in grossly elevated titres in the blood of many patients with acute fascioliasis.

Rheumatoid arthritis and related disorders

In patients with rheumatoid arthritis, anaemia is extremely common. It usually follows the general pattern of anaemia of chronic disorders. It is occasionally complicated by genuine iron deficiency, which may result from a variety of causes including poor diet and chronic blood loss due to the effects of treatment, particularly ingestion of salicylates and non-steroidal anti-inflammatory agents or corticosteroids. Furthermore, significant bleeding into actively inflamed joints can occur. It has been estimated that if only two knee joints were affected, the annual blood loss through this mechanism could amount to as much as 2500 ml. It is not certain how much of the iron derived from this blood is available for reutilization for haemoglobin synthesis. The diagnosis of iron deficiency complicating rheumatoid arthritis may not be straightforward; levels of serum iron and iron-binding capacity may be difficult to interpret because of coexisting inflammation. Determination of marrow stores and estimation of serum ferritin may be more helpful. Although the last two are elevated in inflammatory conditions, a low level suggests genuine iron deficiency.

There are no particular changes in the neutrophil response in uncomplicated rheumatoid arthritis; a marked leucocytosis may reflect a response to corticosteroid therapy or a superadded infection such as a septic arthritis. The platelet count is elevated in between 20 and 50 per cent of patients with rheumatoid arthritis. The degree of thrombocytosis parallels the degree of activity of the illness and cannot be accounted for on the grounds of associated intestinal blood loss due to drug therapy.

The haematological changes of Felty's syndrome are summarized in Section 18. There is anaemia, thrombocytopenia, and marked neutropenia. Although many of these changes are features of hypersplenism, recent studies on the neutropenia in this disorder indicate that it has a complex basis. Immune destruction of neutrophils may play a major part.

A variety of haematological changes are due to drug therapy for rheumatoid arthritis and related disorders. Salicylates may produce chronic blood loss, while drugs containing phenacetin produce methaemoglobinaemia and Heinz-body haemolytic anaemia that may sometimes be preceded by a marked eosinophilia.

Phenylbutazone produces pancytopenia, which may be severe and irreversible; this drug has now been discontinued in the United Kingdom. Oxyphenylbutazone and penicillamine may also cause severe marrow depression. The administration of gold occasionally causes marked thrombocytopenia or pancytopenia.

The management of the haematological manifestations of rheumatoid arthritis and Felty's syndrome is unsatisfactory. The anaemia generally reflects the activity of the disease. If there is genuine iron deficiency, iron replacement therapy is indicated. The vexed question of whether intramuscular iron administration has some non-specific effect on the anaemia of rheumatoid arthritis, even in the absence of reduced body iron stores, remains unresolved. Similarly, there is controversy about the best way to manage Felty's syndrome. After splenectomy there is sometimes a dramatic rise in the neutrophil and total leucocyte counts, but this is not always associated with a decreased incidence of infection. Some patients show no change in the white-cell count after surgery. It is difficult to advise about the best approach to the management of this condition; only if there are recurrent, life-threatening infections should splenectomy be done. Patients require extremely careful surveillance after the operation. There may be some place for the use of prophylactic antibiotics in those whose neutrophil counts do not respond.

Recent studies have suggested that the anaemia of rheumatoid arthritis, and related inflammatory states, may respond to erythropoietin given in the higher therapeutic dose range. This treatment is extremely expensive and has only been evaluated in a few clinical trials. Its use should be reserved for those patients who have severe anaemia which is refractory to treatment of the underlying inflammatory disorder by any other means.

Systemic lupus erythematosus and other collagen disorders

It is quite common for systemic lupus erythematosus (SLE) to present with a haematological disorder. This is not the case in the other collagen–vascular disorders.

The most common blood change in SLE is anaemia, which occurs in nearly all patients at some stage of the illness. It is usually a mild anaemia of chronic disorders, which may be complicated by blood loss from analgesics or anti-inflammatory medication, renal impairment, or haemolysis. Acquired autoimmune haemolytic anaemia may be the sole presenting feature in SLE and may antedate the appearance of other typical features by many years. The incidence of this complication varies in reported series but occurs overall in approximately 5 per cent of cases. The Coombs' test is invariably positive with anticomplementary reagents and is positive with anti-IgG during episodes of acute haemolysis. Other forms of anaemia in SLE include those associated with hypersplenism due to splenomegaly, and the occasional occurrence of a hypocellular bone marrow, probably due to involvement of small vessels by the disease process.

The most consistent finding in the white-cell count in SLE is leukopenia, which occurs in up to half the patients at some time during the illness. This is often a combined neutropenia and lymphopenia. Mild eosinophilia occurs occasionally, particularly in association with skin involvement.

A mild thrombocytopenia occurs in 10 to 25 per cent of all cases of SLE. More severe thrombocytopenia, producing a picture almost indistinguishable from idiopathic thrombocytopenic purpura, occurs in a small proportion of patients and may be the sole presenting feature in some. Although early reports indicated that splenectomy might be associated with a flare-up of the systemic symptoms of SLE in patients with thrombocytopenia, this has now been shown to be incorrect.

Lupus anticoagulant

This is an antibody that prolongs phospholipid-dependent coagulation tests *in vitro*. Although it received its name because it was found in patients with SLE, it occurs more frequently in patients without this disease and is associated with thrombosis rather than with bleeding. It is particularly common in patients with lupus-like autoimmune disorders without the associated criteria for the diagnosis of SLE. Originally it was thought to occur in approximately 10 per cent of patients but using more sensitive assays it is now clear that it occurs in about 50 per cent.

Both lupus anticoagulants and associated anticardiolipin antibodies are immunoglobulins which react with phospholipid and other molecules (platelet factor IV). They may be associated with venous thromboembolism, arterial thromboembolism, an increased fate of fetal loss, or thrombocytopenia. They are discussed in detail in Section 18.11.

Other collagen disorders

The haematological changes in the other collagen–vascular diseases are much less impressive. They are all associated with the anaemia of chronic disorders. Polyarteritis nodosa may be characterized by an eosinophilia.

The interesting syndrome of polymyalgia rheumatica and temporal arteritis may present to the haematologist (Section 18.11). Haematological changes are characterized by a severe anaemia of chronic disorders with a marked elevation of the ESR. The leucocyte count is usually normal, although there may occasionally be a mild eosinophilia. There is a marked increase in the a_2- and g-globulins, although this is polyclonal in type. This blood picture can very closely resemble that of multiple myeloma or disseminated malignancy.

Renal disease

Almost all forms of renal disease are associated with haematological changes. However, by far the most important is the severe refractory anaemia that accompanies chronic renal failure.

Anaemia

Anaemia is an important and intractable complication of chronic renal failure. The correlation between the blood urea nitrogen and the haemoglobin level is inconsistent. Although erythropoietin deficiency is an important component, the anaemia has an extremely complex aetiology, which is only partly understood. The red cells of patients with chronic renal disease have a shortened survival, although they survive normally when injected into healthy recipients. Similarly, normal red cells have a shortened survival in uraemic recipients. The nature of the intracorpuscular defect has not been determined. Most red-cell enzymes are present at normal levels and the intracellular level of ATP is elevated. However, changes in membrane function have been demonstrated, in particular decreased activity of the Na^{+}–K^{+} pumps; the toxic substances that cause these changes have not been identified.

There is also impaired red-cell production in the anaemia of chronic renal failure. The fact that the anaemia of chronic renal failure can be corrected by the administration of recombinant erythropoietin suggests that the ineffective production of this hormone due to renal damage is the major aetiological factor in the anaemia of renal failure. However, it has been found that the serum from patients on haemodialysis also inhibits the proliferation of erythroid progenitors. The suppressive activity is found in serum fractions containing material of molecular weights ranging from 47 000 to above 150 000. Interestingly, patients on continuous ambulatory peritoneal dialysis (CAPD) have higher haemoglobin levels than those on haemodialysis. It is possible this reflects the more effective removal of middle molecular-weight molecules of this type by CAPD. Patients on haemodialysis with low haemoglobin concentrations are more likely to have fibrous replacement of their bone marrow. This has been correlated with secondary hyperparathyroidism, suggesting a role for parathyroid hormone in the bone marrow unresponsiveness and fibrosis (see Section 20).

The anaemia of chronic renal failure may be exacerbated by deficiency of iron resulting from blood loss due to excessive blood sampling, incorrect haemodialysis procedures, or bleeding due to defective platelet function (see below). A small proportion of patients with chronic renal failure develop splenomegaly and hypersplenism. Folate deficiency is found occasionally in patients on haemodialysis. There have been a few reports of nephrosis leading to severe urinary loss of transferrin and hence to a low plasma iron-binding capacity. Some patients with renal disease have chronic inflammatory lesions, which may lead to a superadded anaemia of chronic disorders.

The type of renal lesion is also an important factor in determining the severity of anaemia. For example the renal failure of polycystic disease of the kidneys is associated with a relatively higher haemoglobin level than other forms of renal failure. Interestingly, the shrunken kidneys of some patients on long-term dialysis programmes develop cysts and this phenomenon is also associated with a rise in haemoglobin level. It seems likely that both these conditions are associated with a relative increase in the output of erythropoietin.

The anaemia of chronic renal failure is normochromic and normocytic unless there is associated iron deficiency. The red cells show characteristic deformities with multiple tiny spicules and contracted poikilocytes. The capacity of the red cells for oxygen transport does not seem to be impaired. There is often an increased

intracellular concentration of 2,3-diphosphoglycerate (2,3-DPG) in response to anaemia and hyperphosphataemia, and the oxygen affinity of haemoglobin is decreased. This right shift in the oxygen dissociation curve may be augmented by uraemic acidosis. However, part of the advantage of the acidosis is cancelled out by the direct effect of low pH on glycolysis and 2,3-DPG production. Intensive dialysis may cause a reduction in the concentration of intracellular phosphate, which has the effect of increasing the oxygen affinity of haemoglobin. This effect may play a part in the so-called dialysis disequilibrium syndrome.

In patients with chronic renal failure who have associated iron deficiency, the red-cell indices are typical of this condition; the reduced mean corpuscle haemoglobin and volume are corrected by iron therapy.

The bone marrow in chronic renal failure shows normoblastic erythropoiesis but the degree of erythroid hyperplasia is not compatible with the degree of anaemia, indicating suppression of erythropoiesis.

White cells

The total and differential white-cell count is usually normal in patients with chronic renal failure. However, the phagocytic activity of granulocytes may be reduced and complement activation by haemodialysis membranes may cause stasis of white cells in the pulmonary circulation with temporary granulocytopenia. Cell-mediated immunity is also depressed.

Platelets and coagulation

There is a variety of haemostatic defects in different forms of renal disease. Most forms are associated with a bleeding tendency, which is seen in its most florid form in acute renal failure. The main features are purpura, and mucosal and gastrointestinal bleeding associated with abnormal platelet function and a prolonged bleeding time; these changes are reversible by dialysis. Various mechanisms have been proposed. These include a direct action of metabolites on platelet function and a disturbance of prostaglandin balance because of a deficiency of a renal factor that modifies vascular production of prostacyclin and/or platelet endoperoxide and thromboxane synthesis. These changes result in an abnormality of the control of platelet cAMP causing the platelets to become refractory to aggregation agents. Many conditions that lead to renal failure are also associated with thrombocytopenia. For example the circulating immune complexes found in patients with acute glomerulonephritis, polyarteritis nodosa, or lupus nephritis may be responsible for platelet activation and the release of aggregating agents. Thrombocytopenia may also be aggravated by heparin therapy or the use of immunosuppressant drugs in patients who have received kidney grafts. Mild thrombocytopenia is well recognized in patients with functioning renal allografts. This has also been found to be associated with an inability to clear the immune complexes. Graft rejection is associated with enhanced platelet aggregation and thrombocytopenia.

The nephrotic syndrome is characterized by a marked tendency to thrombosis. This also has a complex pathogenesis. Both platelet aggregation and release reactions have been shown to be enhanced in this condition. Protein loss in the urine may also play a part. It has been found that an increased loss of antithrombin III is related to thrombotic episodes. Conversely, coagulation factors IX and XIII are also lost in the urine of patients with a nephrotic syndrome; the deficiency of factor IX may be sufficient to induce bleeding.

The haematological changes associated with the haemolytic uraemic syndrome and thrombotic thrombocytopenic purpura were considered earlier in this section.

Polycythaemia

The polycythaemias associated with renal lesions and following renal transplantation are discussed elsewhere.

Treatment of the haematological complications of renal disease

The management of the anaemia of chronic renal failure, which has been revolutionized by the availability of recombinant erythropoietin, is considered in Section 20. The management of bleeding in patients with acute renal failure is based on correction of uraemia by dialysis and appropriate replacement therapy. Peritoneal dialysis is probably more effective in reversing abnormalities of platelet function, although there is no definite evidence that one form of dialysis is superior to another. If there is severe thrombocytopenia, platelet transfusions should be given.

Gastrointestinal and liver disease

Many of the haematological changes that occur in gastrointestinal and liver disease are described in Section 14. Here we will simply summarize the haematological manifestations of those disorders that present frequently with anaemia or defective haemostasis.

Gastrointestinal blood loss

Blood loss in excess of 20 ml/day will always result in a negative iron balance and ultimately in iron-deficiency anaemia, the time taken depending on the body stores of iron when the bleeding started.

The haematological picture shows the typical changes of iron-deficiency anaemia, with hypochromic, microcytic red-cell morphology. Occasionally, there are some clues that this blood picture is associated with chronic blood loss. Quite frequently there is a mild to moderate thrombocytosis, and if iron is being taken there may be a dimorphic blood picture (Fig. 4), red-cell polychromasia, and a low-grade reticulocytosis. It is always worth examining the peripheral blood film very carefully as it may give some clue as to the site of the blood loss. For example the presence of target cells may indicate liver disease, whereas the presence of distorted cells and Howell–Jolly bodies suggests malabsorption due to adult coeliac disease complicated by hyposplenism.

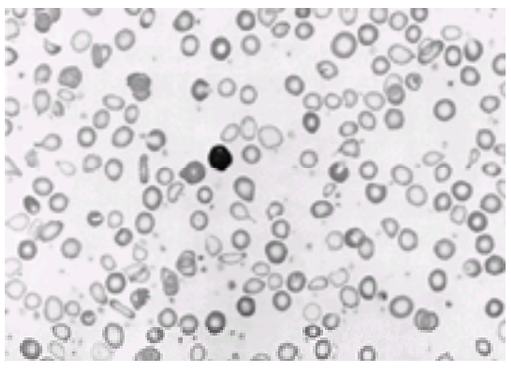

Fig. 4 Peripheral blood picture associated with gastrointestinal bleeding. The red cells show a dimorphic picture with hypochromic and normochromic forms. The platelet count is elevated, a typical finding in bleeding (Giemsa stain × 600).

The diagnosis of the site of acute upper intestinal bleeding is considered in Section 14. The investigation of chronic gastrointestinal blood loss may be difficult. First, it is essential to determine whether iron deficiency anaemia is due to a defective intake or due to excessive loss of iron. If gastrointestinal blood loss is suspected the first step is to confirm that this is occurring, by examination of several stool specimens for occult blood. Currently, the most commonly used method is the Haemoccult card which contains a filter paper impregnated with guaiac, or a similar commercial kit. The peroxidase activity of red blood cells releases a free oxygen radical from hydrogen peroxide (the developer) which then reacts with the guaiac to produce a blue colour. This test is simple, easy to perform following a rectal examination, and is quick. Nevertheless, it is relatively insensitive, since blood loss must exceed 20 ml daily for 80 to 90 per cent of tests to be positive (the normal loss in a healthy individual is 0.5–1.2 ml daily as measured by ^{51}Cr-labelled red cells). False positive results may result from peroxidase or non-specific oxidants in the diet. Thus in many screening programmes, subjects are requested to omit red meat, fresh fruit, cauliflower, swede, turnip, tomatoes, horseradish, and vitamin C supplements from

their diet during the 3 days prior to testing. Non-steroidal anti-inflammatory drugs and aspirin may also give positive results but, since the increased blood loss is in the upper gastrointestinal tract, the haemoglobin is metabolized in the small intestine and is therefore not detected in stools by Haemoccult unless blood loss is considerable. Iron therapy does not affect guaiac-based tests. Many newer tests, which are said to be even more sensitive, are being developed but their role in clinical practice is not yet established.

Once having established that there is gastrointestinal blood loss the next step is to determine the site. This requires a detailed history and clinical examination as outlined in the introduction to this section. The next step is a careful endoscopy, followed by sigmoidoscopy and colonoscopy. If these investigations do not provide a diagnosis, and there is persistent bleeding, the duodenum and small bowel should be studied radiologically. Occasionally it is necessary to resort to coeliac or superior mesenteric angiography, which may be useful for showing duodenal or ileal varices, bleeding from Meckel's diverticulum or non-specific ulcers of the ileum, small bowel tumours, and vascular lesions. However, small lesions can only be visualized if there is active bleeding at the time of the examination, probably at a rate of at least 0.5 ml/min.

Inflammatory diseases of the bowel

A mild anaemia of chronic disorders is a common accompaniment of inflammatory disease of the ileum, caecum, and colon. It is observed frequently in patients with Crohn's disease, ileocaecal tuberculosis, ulcerative colitis, and other forms of proctocolitis. In many of these conditions the anaemia of chronic disorders is complicated by intermittent blood loss or dietetic iron deficiency. In some cases of extensive Crohn's disease there may be an added factor of malabsorption. Anaemia occurs in about one-third of these patients and it may be complicated by reduced vitamin B_{12} or folic acid absorption. In one large survey of patients with Crohn's disease, anaemia was present in 79 per cent of the males and 54 per cent of females. Forty-six out of a total of 63 patients had bone marrow biopsies, and of these 39 per cent were megaloblastic. Of this group, 11 were folate deficient, six vitamin B_{12} deficient, and one had both deficiencies. On the other hand, macrocytic anaemia is unusual in patients with ulcerative colitis and the anaemia is usually hypochromic due to blood loss. Interestingly, there have been occasional reports of autoimmune haemolytic anaemia occurring in association with ulcerative colitis; in several cases the autoantibodies showed rhesus specificity.

The anaemia of intestinal inflammatory disease may be made worse by drugs used in its management. Patients who receive salazopyrine for colitis occasionally develop an acute haemolytic anaemia associated with Heinz-body formation. Bone marrow depression may occur in patients receiving immunosuppressive treatment for colitis or Crohn's disease. Ileocaecal tuberculosis may be associated with any of the bizarre haematological manifestations of tuberculosis described above, and it may be complicated by the side-effects of antituberculous drug therapy.

Whipple's disease may produce a clinical picture and blood changes that can mimic several primary haematological disorders. The typical clinical triad of diarrhoea, arthropathy, and enlarged lymph nodes is usually associated with a mild normochromic, normocytic anaemia, a raised ESR, and a polymorphonuclear leucocytosis. Quite often there is associated lymphopenia or eosinophilia. Some cases present less typically. When the spleen is enlarged the condition may closely mimic a primary reticulosis. Malabsorption of vitamin B_{12} or folic acid may occasionally be encountered in this disorder (see Chapter 14.9.6).

Structural disease of the stomach, and small and large bowel

The structural changes and resulting abnormalities of absorption associated with gastritis are described in detail in Section 14. Similarly, the various anatomical abnormalities of the small-gut and malabsorption syndromes that lead to vitamin B_{12} and folate deficiency are reviewed earlier in this section. The relation between gastric surgery and iron and vitamin B_{12} metabolism is discussed in Section 14.

Most anatomical lesions of the small bowel present to the haematologist as a macrocytic anaemia with a megaloblastic bone marrow due to vitamin B_{12} or folate deficiency or as a refractory iron-deficiency anaemia. Several abnormalities of the small gut are associated with the production of a relatively profuse bacterial flora that utilize vitamin B_{12}. These conditions include surgically produced blind loops, strictures, anastomoses between loops of small bowel, fistulae between various sections of the bowel, diverticula of the small bowel, malfunctioning gastroenterostomies, interference of gut motility in conditions such as scleroderma, Whipple's disease, postvagotomy, and after extensive gut resection, where the disorder may also produce malabsorption. All these conditions are associated with defective vitamin B_{12} absorption, which can be partly corrected by the administration of broad-spectrum antibiotics but not by intrinsic factor.

Megaloblastic anaemia due to intestinal malabsorption is fully reviewed in Section 14.9. It should be remembered, however, that the malabsorption syndromes may present to the haematologist in other ways. For example there is a very high incidence of iron-deficiency anaemia in this group and, particularly in childhood, this is the much the more common form of presentation than a megaloblastic anaemia. The peripheral blood changes of hyposplenism are quite frequently associated with an underlying malabsorption syndrome, which itself may also present with a bleeding disorder due to defective absorption of vitamin K. Patients with malabsorption syndrome frequently have biochemical evidence of vitamin E deficiency; although this may produce a slightly shortened red-cell survival, there is no evidence that vitamin E deficiency alone produces a significant degree of anaemia.

Liver disease

There is usually a moderate degree of anaemia in patients with chronic liver failure (Table 4). The red cells are normochromic or slightly macrocytic with mean corpuscle volume values ranging from 100 to 115 fl. Target cells and a variable degree of polychromasia with a slightly elevated reticulocyte count are often found. The degree of macrocytosis and target-cell formation corresponds reasonably well with the degree of liver failure. The bone marrow tends to be hypercellular with erythroid hyperplasia and macronormoblastic changes.

The actual mechanism of the anaemia of liver failure is uncertain. However, there may be many complicating factors that cause a worsening of the anaemia in this condition. Nutritional folate deficiency is very common in patients with liver disease, particularly the alcoholic form. Secondary iron deficiency is also common and usually results from chronic intestinal blood loss associated with a poor dietetic intake. Interestingly, in patients with severe portal hypertension and cirrhosis, or in those who have undergone portacaval shunt surgery, there may be some increase in iron absorption with marked haemosiderosis of the liver.

A variety of different forms of haemolytic anaemia occur in patients with liver disease. In Zieve's syndrome there is jaundice, hyperlipidaemia, and haemolytic anaemia that follows an excessive alcohol intake. Other forms of haemolytic anaemia may occur. Acute haemolysis has been well documented in patients with viral hepatitis, particularly those who are glucose 6-phosphate dehydrogenase deficient. An acquired haemolytic anaemia with a positive Coombs' test may occur occasionally in patients with chronic active hepatitis. Another form of haemolytic anaemia in liver disease, usually alcoholic cirrhosis, has been observed in which there are marked red-cell abnormalities with burr and spur-shaped forms predominating.

Bleeding and haemostatic failure are extremely common accompaniments of liver failure. They have a complex aetiology including diminished hepatic synthesis of coagulation factors V, VII, IX, X, and XI, prothrombin and fibrinogen. In some forms of liver disease there may be malabsorption of vitamin K with reduction in the K-deficient clotting factors, and reproduction of a dysfunctional form of fibrinogen has been reported in some patients with cirrhosis and hepatocellular carcinoma. In some forms of liver failure there is enhanced fibrinolysis, due to decrease synthesis of a $_2$-plasmin inhibitor. In severe liver failure disseminated intravascular configuration may occur. Thrombocytopenia is extremely common in liver disease, sometimes due to hypersplenism but in other cases its pathogenesis is not clear.

The management of bleeding in liver diseases is considered in Section 14.21.

The haematological effects of alcohol

Because excessive consumption of alcohol is so common, it is important for clinicians to appreciate the remarkably diverse haematological manifestations that it causes.

Anaemia is particularly common in chronic alcoholics. It has an extremely complex aetiology including a deficient diet, chronic blood loss, hepatic dysfunction, and the direct toxic effects of alcohol on the bone marrow.

Macrocytosis is particularly common in chronic alcoholics. An unexplained macrocytic blood picture should always raise the possibility of alcoholism, although its absence does not rule out the diagnosis. It may be associated with normoblastic or megaloblastic erythropoiesis. In moderately severe alcoholics who are maintaining

a reasonable diet, it probably reflects the direct toxic action of alcohol on the bone marrow. The normoblasts may show vacuolation or there may be no specific changes on light microscopy. Megaloblastic anaemia is usually seen in severe alcoholics who are poorly nourished, and is due to folate deficiency. While a folate-poor diet is the major factor, there is some evidence that alcohol plays a more direct part in interfering with folate metabolism by an unknown mechanism. It should be remembered that macrocytosis can also occur in alcoholics during a reticulocytosis in response to bleeding or alcohol withdrawal. It may also reflect coexistent liver disease. The occurrence of sideroblastic anaemia in severe alcoholics was mentioned in an earlier chapter. It is often associated with a macrocytosis or a dimorphic blood picture and occurs in severe alcoholics. The sideroblastic changes revert to normal after stopping alcohol.

Simple iron deficiency is also found commonly in alcoholics and probably reflects both a poor diet and chronic blood loss due to gastritis or bleeding varices. It may be associated with folate deficiency; the blood film is then dimorphic with macrocytes, microcytes, and hypersegmented neutrophils. Alcoholics with chronic pancreatitis may develop iron loading due to increased absorption. These changes, which are specific for alcohol, may be accompanied by any of the haematological manifestations of liver disease.

Alcohol has deleterious effects on the white cells. Severe alcoholics are prone to infection. The neutropenia of alcoholism may reflect both the toxic effect of alcohol on the marrow and folate deficiency. There is also some evidence that alcohol can interfere with neutrophil locomotion and with their ability to ingest foreign material including micro-organisms.

Thrombocytopenia is commonly seen in chronic alcoholics and may occur without accompanying folate deficiency or splenomegaly. Megakaryocytes may be normal or diminished in number. Following withdrawal of alcohol the platelet count usually returns to normal, although it may become markedly elevated for a few days.

Chest disease

(See also carcinoma and tuberculosis, above, and secondary polycythaemia, Chapter 22.3.8).

Pneumonia

Most bacterial pneumonias are associated with a neutrophil leucocytosis. Two relatively common forms of pneumonia are associated with more specific haematological changes. In mycoplasma pneumonia, cold agglutinins can usually be detected in increased amounts towards the end of the first week in up to 80 per cent of cases. The cold antibodies are polyclonal IgM to the red-cell I antigen. Although a positive Coombs' test and an increased reticulocyte count have been described in these cases, serious haemolysis is rare. Occasionally, the condition is complicated by disseminated intravascular coagulation.

There is increasing evidence that in patients with pneumonia caused by *Legionella pneumophila* (Legionnaires' disease) there may be severe thrombocytopenia and, sometimes, lymphopenia. Several cases have been reported to be complicated by disseminated intravascular coagulation.

Pulmonary eosinophilia (see also Section 17.11)

This term refers to a group of disorders that have in common a raised eosinophil count in the peripheral blood in association with pulmonary infiltrates on the chest radiograph. The exact nature of many of the disorders that constitute this syndrome is uncertain. In its simplest form there may be a brief period of respiratory distress in association with eosinophilia. This condition is sometimes called Löffler's syndrome. At the other end of the spectrum there is a severe illness associated with widespread pulmonary infiltrates and eosinophilia, which may culminate with the features of polyarteritis nodosa.

The transient disorder described by Löffler probably represents a heterogeneous group of conditions, which in many cases are associated with parasitic infection. Many parasitic disorders can cause this type of illness, including ascariasis, ankylostomiasis, trichiuriasis, taeniasis, and fascioliasis. A similar condition has been well documented as part of a hypersensitivity reaction to drugs. The most common is *p*-aminosalicylic acid but similar reactions have been observed in patients receiving penicillin, sulphonamides, and nitrofurantoin. A similar clinical picture is associated with the syndrome of allergic alveolitis, including farmer's lung, bird fancier's lung, and a variety of other occupational disorders. Another condition characterized by a marked eosinophilia with pulmonary infiltrates goes under the general term tropical eosinophilia. There is considerable evidence that this disorder is due to occult filarial infection. Pulmonary eosinophilia may also be due to hypersensitivity to fungi, particularly *Aspergillus fumigatus*.

Idiopathic pulmonary haemosiderosis and Goodpasture's syndrome

These disorders occasionally present as a refractory anaemia that has the characteristics of the anaemia of chronic disorders, although it may become markedly hypochromic and microcytic due to chronic blood loss.

Skin diseases

Megaloblastic anaemia and the skin

The whole relation between skin disease and megaloblastic anaemia is extremely complex and much of the work in this field is still controversial. The subject is discussed elsewhere (see Section 23).

A proportion of patients with various dermatoses show evidence of folate depletion, at least biochemically, and in some cases, haematologically. This has been reported in patients with erythroderma, psoriasis, or extensive eczema. There is a well-documented association between malabsorption and dermatitis herpetiformis. Although megaloblastic anaemia is not found frequently in association with disorders of the skin, some patients with these conditions do have mild megaloblastic changes. Earlier reports suggested that a significant proportion of them had abnormalities of small-intestinal function and structure, leading to the descriptive term 'dermatogenic enteropathy'. This concept has been questioned and it is now agreed that a completely flat small-bowel mucosa is rarely seen in these conditions. The relation between dermatitis herpetiformis and malabsorption of the coeliac type seems to be a special case. Several series have shown a high incidence of small-bowel changes of coeliac disease in patients with this condition. Furthermore, there appears to be a high incidence of splenic hypoplasia with typical haematological changes of defective function of the spleen (see Chapter 22.4.4).

Other dermatological disorders

Several dermatological diseases have a major haematological component. Of particular importance are the systemic mast-cell syndromes, Sezary syndrome and cutaneous T-cell lymphomas, hereditary telangiectasia, and some of the inherited disorders of collagen.

Endocrine disease

Pituitary deficiency

A mild, normochromic, normocytic anaemia is very common in patients with anterior pituitary deficiency. The mechanism is not absolutely clear, although the anaemia has many features in common with that of hypothyroidism and is fully responsive to appropriate replacement therapy.

Thyroid disease

Hypothyroidism is associated with a variety of haematological changes. Anaemia is common and may be normocytic, microcytic, or macrocytic.

Severe microcytic anaemia in hypothyroidism is most commonly seen in women who have menorrhagia, which is a frequent complication of this condition. Severe macrocytosis in hypothyroidism usually indicates an associated vitamin B_{12} deficiency; there seems to be a genuine association between pernicious anaemia and myxoedema. It has been suggested that mild macrocytosis may occur in hypothyroidism in the absence of vitamin B_{12} or folate deficiency, although published series of studies have shown a remarkable variability in the incidence of this phenomenon. Some patients with severe hypothyroidism have a small proportion of misshapen red

cells on their peripheral blood films.

The anaemia of uncomplicated myxoedema is normochromic and normocytic. The mechanism is still uncertain. Recent studies have shown that T_3, T_4, and reverse T_3 can all potentiate the effect of erythropoietin on the formation of erythroid colonies *in vitro*. This effect appears to be mediated by receptors with b_2-adrenergic properties. It appears that the thyroid hormones have a direct effect in altering the erythropoietin responsiveness of erythroid progenitors. It has also been suggested that part of the normochromic anaemia of hypothyroidism may be a physiological adaptation to reduced oxygen requirements by the tissues.

Curiously, patients with hyperthyroidism do not have elevated haemoglobin levels. There is some recent evidence that there may be a mild increase in the red-cell mass in hyperthyroidism, but that this is compensated for by an increase in plasma volume. In some patients with severe hyperthyroidism, there is a mild anaemia associated with abnormal iron utilization.

Adrenal disease

A mild, normochromic, normocytic anaemia together with neutropenia, eosinophilia, and lymphocytosis is observed in some patients with Addison's disease. There is a variety of haematological changes following the administration of corticosteroids or endogenous overproduction of these agents. These include granulocytosis, reduced lymphocyte count, involution of lymphatic tissues, and a decrease in the eosinophil and monocyte count.

Parathyroid disease

Primary hyperparathyroidism is occasionally associated with anaemia, which responds to removal of the parathyroid glands. The relation between parathyroid disease and marrow fibrosis is discussed in Section 12.

Diabetes mellitus

The structural changes that occur in the haemoglobin of diabetic patients are discussed in Chapter 12.11.1. There have been recent reports that there may be an increase in the red-cell volume of patients with severe diabetes. The mechanism and significance of this observation remains to be clarified. Severe diabetic acidosis is associated with a marked leucocytosis, even when there is no underlying infection. Hyperosmolarity impairs neutrophil function; reduced neutrophil migration has been observed in patients with diabetic ketoacidosis or poorly controlled hyperglycaemia. Because of the high incidence of atheroma in patients with diabetes, both platelet function and vessel-wall metabolism have been studied in considerable detail in this condition. Synthesis of prostaglandin I_2 in biopsy specimens of forearm veins is reduced. A variety of changes in platelet reactivity and survival have been observed. The relation of these changes to the vascular disease of diabetes requires further clarification.

Neuropsychiatric disease

Anorexia nervosa

About a third of patients with severe anorexia nervosa have a mild, normochromic, normocytic anaemia. In patients who are severely malnourished there may be mild neutropenia. There have been reports of the finding of irregularly shaped red blood cells in this condition. The platelet count is usually normal but there may be mild thrombocytopenia and in one study there was a marked increase in the rate of platelet aggregation.

Trauma

The brain is rich in thromboplastin activity. Acute disseminated intravascular coagulation occurs quite commonly after severe head or brain injury.

Myasthenia gravis

The association between myasthenia gravis and pure red-cell aplasia is described in Section 24.22. An immune neutropenia has also been described as part of the myasthenia–thymoma syndrome.

Lesch–Nyhan syndrome

This X-linked recessive disorder is described in detail in Chapter 11.4. There have been occasional reports of the development of severe megaloblastic anaemia, presumably resulting from defective nucleic acid synthesis; the condition has been reversed by the administration of large doses of adenine.

Abetalipoproteinaemia

This condition is characterized by an ataxic neurological disease, retinitis pigmentosa, fat malabsorption, and the absence of chylomicrons and low-density lipoproteins. It is caused by the failure to synthesize or secrete lipoprotein-containing products of the apolipoprotein B gene. It is characterized by the presence of from 50 to 90 per cent of acanthocytes in the peripheral blood. These are abnormal, spiky red cells, which have a moderately shortened survival. Despite these changes there is only a mild haemolytic anaemia.

Acanthocytosis with neurological disease and normal lipoproteins (amyotrophic chorea-acanthocytosis)

This syndrome is characterized by marked acanthocytosis associated with a progressive neurological disease, beginning in adolescence or adult life, which includes orofacial dyskinesia, lip and tongue biting, choreaiform movements, sensorimotor polyneuropathy, distal muscle wasting, and hypotonia. Because it has been found to follow both dominant and recessive forms of inheritance it is likely that this is a heterogeneous disorder. The cause is unknown.

Cardiac disease

There are several important haematological manifestations of cardiac disease, all of which are dealt with in more detail in Section 15. The severe haemolytic anaemia that occasionally follows the insertion of prosthetic valves, particularly the aorta, is described in Chapter 15.7.

A variety of abnormalities of coagulation are found in patients with cyanotic congenital heart disease. These include thrombocytopenia, low plasma fibrinogen levels, defective clot retraction, a deficiency of factors V and VII, and increased levels of fibrin degradation products. Overall, the severity of these abnormalities correlates with the degree of secondary polycythaemia. The exact mechanism is not known. In addition to the quantitative changes in blood platelets, there may also be qualitative abnormalities of platelet function. These include defects in both aggregation and release. They may be associated with a prolonged bleeding time. Again, the mechanism is not understood.

The striking haematological changes that may accompany bacterial endicarditis were mentioned earlier in this chapter. Dressler's syndrome may be associated with the anaemia of chronic disorders, atypical lymphocytes in the peripheral blood, and, certainly in the earlier descriptions of the disease, an eosinophilia of varying degree. Similar changes have been observed in the postpericardiotomy syndrome.

22.8.1 Blood transfusion

P. L. Perrotta and E. L. Snyder

Blood transfusion is important for the care of patients with severe anaemia, haemorrhage, thrombocytopenia, and coagulation disorders. Advances in the understanding of red cell, platelet, and leucocyte antigen structure, as well as the immune responses to these antigens, have vastly improved transfusion therapy. Routine blood bank procedures, including ABO typing, antibody screening, and compatibility testing, identify most patients at risk for serious immune-mediated red cell transfusion reactions. One of the most important technological improvements in transfusion therapy was the development of sterile, disposable, and flexible plastic containers that allow separation of whole blood into cellular and non-cellular components, including red blood cells, platelets, and plasma. Anticoagulants and additives currently used in blood collection containers allow storage of liquid red cells for up to 42 days. These advances have essentially eliminated the use of whole blood.

Individual components are stored under optimal conditions. Only that portion of blood required by the patient is transfused. Plasma separated from whole blood can be further fractionated into coagulation factor concentrates, albumin, or gamma globulin. Cell separators capable of collecting platelets, plasma, granulocytes, peripheral blood stem cells, and, more recently, red blood cells, are also in widespread use across the United States and Europe. Changes in recruiting and screening blood donors, as well as advances in the testing of donor blood have reduced the risk of viral transmission in Europe and the United States. All units of blood collected in the United States and Britain are tested for hepatitis B, hepatitis C, HIV-1, HIV-2, HTLV-1, and syphilis. Nucleotide testing for HIV and hepatitis C is now performed in most European countries and in the United States. Other risks of transfusion therapy include acute and delayed haemolytic, febrile non-haemolytic, allergic, and septic reactions. Premedication before transfusions, and leucoreduction of blood components have reduced these risks.

Although the hazards of blood transfusion are relatively small, the expected benefit of a transfusion must outweigh any risk to the patient. Therefore, a thorough understanding of the indications and complications of blood transfusion are required to minimize exposure to unnecessary allogeneic blood products and to prevent wastage of limited blood resources.

Blood group systems

ABO system

Over 250 distinct antigens have been identified on the surface of red blood cells. The most clinically important belong to the ABO system. The codominantly expressed A and B genes, located on chromosome 9, code for glycosyl transferases that add either *N*-acetyl-D-galactosamine (A gene) or D-galactose (B gene) to the common precursor H antigen (Table 1). The O gene is structurally similar to the A gene except for a single base deletion that eliminates production of a functional enzyme. The AB antigens are of critical importance because individuals who lack the A and/or B antigens form IgM and IgG antibodies directed against the missing antigen(s). Circulating A and B antibodies can fix complement and cause intravascular haemolysis. Anti-A and Anti-B antibodies are 'naturally occurring', that is, they are formed without prior clinical antigenic stimulation. Presumably, individuals become immunized following exposure to carbohydrate ABO antigenic determinants commonly found in the bacterial environment. Accordingly, group A persons produce anti-B, group B produce anti-A, and group O produce both anti-A and anti-B. Circulating A and B antibodies are of critical importance in blood therapy because they are of high titre, can fix complement to C9, and are responsible for the vast majority of major haemolytic transfusion reactions.

Rh system

The Rh blood group system is composed of at least 44 distinct antigens. The five major antigens in the Rh system (D, C, c, E, and e) are responsible for the vast majority of Rh-related transfusion problems. It is now known that the D polypeptide is encoded at the *RHD* locus, whereas the CcEe polypeptide is coded by alleles at the *RHCE* locus. Based on the D gene frequency in North America and Europe, approximately 15 per cent of individuals will not produce D antigen and are 'Rh negative'. The most common nomenclatures used to classify the Rh antigens include those developed by Weiner and Fisher–Race (Table 2 and Table 3). Each of these systems has its advantages and limitations. Very rare individuals who lack all Rh antigens are termed 'Rh-null'. Rh-null red cells are morphologically abnormal and typically have shortened survival, resulting in a mild haemolytic anaemia. The successful cloning of the RhD gene potentially allows application of molecular techniques to determine fetal RhD status.

The most clinically important Rh antigen is D because it is highly immunogenic—the likelihood of a D-negative person developing anti-D following exposure to as little as 0.1 ml of D-positive red cells is extremely high. Approximately 80 per cent of Rh-negative individuals transfused with a single unit of Rh positive red cells will develop anti-D. Anti-D is responsible for immune reactions including haemolytic disease of the newborn (HDN) and immune-mediated transfusion reactions. Despite widespread use of Rh immune globulin, anti-D remains the most common cause of serious HDN. Rh-negative women most commonly produce anti-D following exposure to D-positive red cells during pregnancy, a miscarriage, or abortion. The anti-D formed is of the IgG class and therefore can cross the placenta where it may cause a potentially fatal intrauterine HDN in an Rh-positive fetus.

Other blood groups

There are a large number of other well-characterized red cell blood group systems. Antibodies directed against some of these antigens may be naturally occurring

and of little clinical significance (e.g. Lewis, Ii). Other antibodies may form following exposure to the corresponding antigen (e.g. Kell, Duffy, Kidd). Some of these antibodies are clinically significant in that they are associated with immune-mediated red cell destruction of transfused cells and HDN (Table 4). In most cases, compatible blood can be found for patients with significant red cell alloantibodies. Based on the high incidence of some red cell antigens on the cells of specific donor populations, some patients may be difficult to transfuse if they have developed multiple antibodies. This is particularly true in patients with sickle cell disease and other red cell disorders who require frequent transfusions. There have been recent advances in the understanding of the molecular genetics of many blood group antigens. These advances will eventually be used to resolve blood group discrepancies, screen for red cells of specific antigen makeup, and to identify fetuses who are at risk for HDN.

The Kell (K) blood group system is clinically important because antibodies to Kell system antigens can cause haemolytic transfusion reactions and HDN. Only the D antigen is more immunogenic than the K antigen, the major antigen of the system. Kell is present in about 10 per cent of white individuals. Therefore, a K-negative blood recipient is unlikely to receive K-positive red cells during transfusion. The Kell blood group is linked to chronic granulomatous disease, a congenital disease resulting in decreased oxidative capacity of neutrophils, which leads to recurrent, severe bacterial infections. The genetic defect seen in chronic granulomatous disease is located on the X chromosome near the Kx Kell locus. The red cells of patients with chronic granulomatous disease are acanthocytic and are prone to mild haemolytic destruction. Systemic abnormalities described in chronic granulomatous disease include cardiomyopathy, areflexia, skeletal myopathies, and muscle wasting.

The Duffy (Fy) blood group is composed of six antigens, of which Fy^a and Fy^b are most important to transfusion practice. Fy^a antibodies have caused severe haemolytic transfusion reactions and severe HDN. Fy^b antibodies have more rarely been associated with these complications, and antibodies against the remaining Duffy antigens are rarely clinically important. Antibodies against Fy^a and Fy^b are reasonably common in diverse populations because the antigen frequency varies dramatically across racial groups. Fy^a and Fy^b antigens are present in 66 per cent and 83 per cent of white blood donors, respectively. These antigens have a much lower incidence in African populations. The Duffy system has an interesting association with malaria. Specifically, $Fy(^{a-b-})$ negative red cells are resistant to *Plasmodium vivax* and *Plasmodium knowlesi* infection. Red cells from most West African blacks are $Fy(^{a-b-})$ and therefore, resistant to these forms of malaria.

The Kidd (Jk) system is composed of three antigens (Jk^a, Jk^b, Jk^3). Jk^a and Jk^b antigens are found on approximately 75 per cent of white donor red cells. Anti-Kidd antibodies have caused severe haemolytic reactions and milder forms of HDN. Kidd antibodies are formed following exposure to Jk antigens during transfusion or pregnancy. They are unusual in that once formed, these antibodies often fall to non-detectable levels, and may not be detected in an already immunized patient. In this situation, transfusion of additional Kidd-positive red cells may cause a rapid immunological response, leading to formation of high-titre anti-Kidd, and subsequent haemolysis.

Detection of blood group antibodies

Antibody screening and antibody identification

Prior to receiving a blood transfusion, patients' red cells are typed for ABO and Rh status using commercially available reagents. During 'front typing', the donor's red cells are reacted with antibodies directed against the A, B, and D antigens. Blood grouping is confirmed during 'back typing' in which donor serum is tested for the presence of anti-A and anti-B antibodies. Following blood grouping, recipient serum or plasma is screened for red cell antibodies. Antibody screening is typically performed by incubating a patient's serum with two to four group O red cells sources that, in sum, contain all the common and clinically significant red cell antigens. If an antibody is present in the serum, it will react with the screening cell and cause red cell agglutination. Naturally occurring ABO antibodies do not interfere with antibody identification because screening cells are type O. Antibody screening is commonly performed at room temperature (immediate phase), after incubating patient serum and test red cells at 37°C, and after incubation with antihuman globulin serum (Coombs phase). Some blood banks screen samples after adding various antigen–antibody enhancing substances including polyethylene glycol, low-ionic strength saline, and albumin. Each has certain advantages and disadvantages in terms of sensitivity and specificity in detecting clinically significant antibodies. Most blood banks still perform 'tube testing' in which red cell agglutinates are identified in standard test tubes. There are a number of newer systems that are being used to detect antigen–antibody reactions. These include gel systems based on the differential mobility of red cell agglutinates through gel columns, and capture systems in which test red cells are immobilized on microtitre plates. Newer automated and semiautomated systems will probably replace tube testing for the majority of ABO grouping, Rh typing, antibody screening, and crossmatching.

If a patient's serum reacts with one or more screening cells, additional tests are performed to identify the antibody(ies). In most cases, the serum is tested against a larger commercial 'panel' of group O red cells of known antigen profile. Based on the reactivity pattern, the antibody can usually be identified. There are a large number of techniques used to identify red cell antibodies. Many are based on using materials that either enhance or suppress the reactivity of a specific antibody. In some cases, a patient's serum may react with all panel cells. These 'panagglutinins' can be caused by: (1) a single antibody directed against a high incidence antigen present on all panel test red cells; (2) multiple antibodies that in total react with all test cells; or (3) an autoantibody. Autoantibodies are often found in autoimmune haemolytic anaemias, in which case the patient's serum will also react with his or her own red cells (see section on autoantibodies, below).

Compatibility testing

Routine compatibility testing is typically performed on red cell units before being transfused to a patient. Specifically, donor red cells are reacted with patient serum and if no reaction is observed, the unit is considered 'compatible'. In emergency situations, there may be insufficient time to perform compatibility testing. Many hospitals will supply group O Rh-negative red cells until a patient sample is obtained and tested. If a patient's ABO Rh status is known with certainty, then type-specific non-crossmatched blood can be provided. In either case, compatibility testing is performed on these transfused units as soon as possible. It is important to realize that supplies of O negative blood are often limited. A 'computer crossmatch' has been instituted at hospitals in North America. Patients with known ABO and Rh typing, and who have a negative antibody screen are provided ABO compatible blood while omitting the crossmatch step described above. Although a true serological crossmatch is not performed, the computer crossmatch is safe in the vast majority of transfusions.

Autoantibodies

Autoantibodies consist of immunoglobulins that react with a wide range of self-antigens including membrane and intracellular components, adsorbed plasma proteins, and nuclear antigens. Patients with warm autoimmune haemolytic anaemia often require transfusion. In this case, the blood bank may have difficulty finding a 'compatible' unit of red cells because the patient's serum not only reacts with his or her own red cells, but also those of all donor red cells. Additional time may be required by the blood bank to exclude the presence of a significant underlying alloantibody that is obscured by the autoantibody. Upwards of 25 per cent of previously transfused autoimmune haemolytic anaemia patients may have an underlying alloantibody. An underlying alloantibody may result in accelerated red cell destruction. Therefore, transfusion therapy must be carefully planned in these patients. Autoimmune antibodies often appear to have specificity for Rh antigens (e.g. anti-e), but the transfusion of antigen negative red cells (e.g. e-negative) is not indicated as *in vivo* red cell survival of antigen negative cells is usually no better than antigen positive cells.

Clinical use of blood components

Red blood cells

Red blood cells account for approximately 75 per cent of the annual cost of transfusion therapy in the United Kingdom. Red blood cells, prepared from whole blood by removing most of the plasma, are indicated for patients with both acute haemorrhage and chronic anaemias (Table 5). Earlier solutions, composed of citrate, dextrose, and phosphate buffers allowed storage of red cells from 21 to 35 days. It was later observed that the addition of adenine to the preservative solution improved cell viability by increasing intracellular ATP levels. The haematocrit of red cell units varies from 70 per cent (citrate, phosphate, dextrose, adenine (CPDA-1)) to 55 to 60 per cent (additive solution, AS). Citrate contained in blood preservatives binds calcium to inhibit clotting and may cause hypocalcaemia and alkalosis in neonates and massively transfused patients. Red blood cells or AS units refrigerated at 1 to 6°C have a shelf-life of 35 (red blood cells) to 42 (AS units) days depending on the ingredients of the preservative. During storage, the following changes are observed in red cell units: (1) a fall in pH; (2) decreases in red cell ATP and 2,3-diphosphoglycerate; (3) increased supernatant potassium; and (4) decreased supernatant glucose. Leucocytes can be removed from the product at the blood centre collection site (prestorage leucodepletion), in the hospital blood bank prior to release, or at the patient's bedside using leucoreduction filters. Red blood cells with uncommon antigen profiles can be frozen within 6 days of collection and stored for up to 10 years. They are frozen with approximately 40 per cent glycerol to avoid cell dehydration and damage during the freezing process. Frozen red cells are no longer used as a leucoreduced product.

The patient's overall clinical status and laboratory parameters should both be considered when deciding to transfuse a patient. A decision should not be based on the

haematocrit alone. Younger patients will usually tolerate a given degree of hypoxaemia and hypotension better than older patients who may have underlying coronary or myocardial disease. Evidence of symptomatic anaemia include excessive fatigue, malaise, headache, tachycardia, hypotension, and end-organ damage. Hypovolaemic shock typically ensues with acute loss (<24 h) of over 30 per cent of total blood volume. Initially, the haematocrit will be falsely elevated in acute haemorrhage, but will then fall with fluid resuscitation. Slowly developing, chronic anaemias are usually better tolerated then rapid onset anaemias due to the ability of the body's fluid compensatory mechanisms. Transfusion is rarely indicated when the haemoglobin (Hb) is greater than 10 g/dl, and is often not considered until the Hb is less than 7 g/dl. A patient's cardiac and pulmonary status must be considered when determining transfusion thresholds. Patients with unstable angina or acute myocardial infarction may require transfusion when the Hb is less than 10 g/dl. In the absence of active red cell destruction, transfusing a single unit will typically increase the Hb by 1 g/dl (haematocrit by 3 per cent).

Platelets

The availability of plastic primary collection bags with attached satellite containers allows the harvesting of platelets as a by-product of red cell separation. In the United States, platelets are prepared by the platelet-rich plasma method, whereas the buffy coat method is used in Europe. Each unit of 'random donor' platelets prepared by differential centrifugation of a single whole blood collection typically contains at least 5.5×10^{10} platelets suspended in 50 ml of plasma. Platelets stored under agitation at 20 to 24°C in plastic containers that allow oxygen diffusion have a shelf-life of 5 days. The risk of bacterial growth and development of platelet function abnormalities (platelet storage defect) preclude storage longer than 5 days. 'Random donor' platelets are usually administered in pools of 4 to 6 units. In the absence of conditions associated with decreased platelet survival, each unit can be expected to raise the recipient's platelet count by 5000 to 10 000/µl. Single donor platelets prepared by apheresis contain more than 3×10^{11} platelets suspended in about 200 ml plasma, equivalent to 6 average random donor platelet units. Platelets are not normally crossmatched with the recipient's serum. ABO type-specific platelets should be provided whenever possible because transfusion of out-of-type platelets may result in a postplatelet increment 10 to 20 per cent less than that expected for ABO type-specific platelets. Rh antigens present on the small number of contaminating red cells found in platelet concentrates are capable of immunizing a Rh negative recipient. If Rh negative platelet concentrates are not available for an Rh negative patient, Rh positive platelets can be transfused followed by administration of Rh immune globulin within 72 h of transfusion.

Platelets are provided to thrombocytopenic patients who are bleeding or to severely thrombocytopenic patients as a prophylactic precautionary measure. Spontaneous bleeding is rare when a patient's platelet count is over 20 000/µl, and studies suggest that patients who receive chemotherapy can tolerate platelet counts as low as 5 to 10 000/µl. Postsurgical patients may require platelet transfusions to control or prevent postoperative bleeding when the platelet count is over 50 000/µl. Overall coagulation status should also be considered because patients with plasma coagulation factor disorders are more likely to bleed at marginal platelet counts. Actively bleeding patients on aspirin, an irreversible inhibitor of platelet function, may require transfusions at higher platelet counts, although transfused platelets will also be affected if the patient remains on aspirin.

Platelet refractoriness is a major problem for patients who are dependent on platelet transfusions. The corrected count increment (CCI) is used to identify patients who are refractory to platelet transfusions through either HLA or platelet (HPA) alloimmunization. The CCI is calculated as follows:

$$\text{CCI} = \frac{\text{Post (/ml)} - \text{Pre (/ml)} \times \text{BSA } (m^2)}{\text{plts} \times 10^{-11}}$$

where Pre = pretransfusion platelet count, Post = post-transfusion platelet count drawn 1 to 4 h after completion of the transfusion, plts = number of platelets transfused (1 U 'random donor' platelets ~ 0.7×10^{11} plt; 1 U single donor platelets ~ 3 to 4×10^{11} plt), and BSA = body surface area in m^2.

Causes of a platelet refractory state include disseminated intravascular coagulation (DIC), sepsis, and circulating immune complexes. After documenting a low CCI (<5000), crossmatch-compatible platelets or HLA-matched single donor platelets should be considered. These products are not readily available in most blood banks. Increasing the dose of standard platelet concentrates can be considered until compatible platelets are identified. Leucocyte reduction filters, as well as UV-B irradiation, decrease the rate of HLA alloimmunization to platelets. Leucocyte reduction filtered blood products should be provided to patients who will require many platelet transfusions.

Granulocytes

There is renewed interest in granulocyte transfusion kindled by improvements in apheresis collection techniques and the use of steroids and/or growth factors to improve granulocyte yields. Granulocytes are primarily transfused to neutropenic oncology patients who develop Gram positive or Gram negative bacterial sepsis unresponsive to antibiotic therapy for a minimum of 24 to 48 h. Granulocytes collected from non-stimulated healthy donors by apheresis contain at least 1×10^{10} neutrophils/unit and can be stored for only 24 h at 20 to 24°C. Higher numbers of granulocytes can be collected when donors are stimulated by steroids and/or growth factors. They contain large numbers of red cells (20–50 ml) and must be crossmatched with the recipient's serum. Granulocytes should be irradiated (2500 cGy) because of the large number of lymphocytes present in the product. They are considered for the above patients provided they also have an absolute neutrophil count less than 500/µl and a reasonable chance of marrow recovery. Because of their short half-life, granulocytes are usually provided daily until the patient can maintain an absolute neutrophil count greater than 500/µl without transfusion or until the infection resolves. Infusion of larger numbers of granulocytes does allow measurable increases in recipient neutrophil counts, but the optimal dose and frequency remain undefined. Febrile reactions to granulocytes are common, the reactions being more severe when amphotericin is infused near the time of granulocyte transfusions. Overall, the additional benefit of granulocyte transfusions for these neutropenic patients as compared to antibiotic treatment alone is unclear. The collection of granulocytes, or any blood component, by apheresis is not an entirely innocuous process. The donor is at risk for uncommon, but potentially serious, adverse reactions including hydroxyethyl starch-related hypertension and anaphylaxis, and citrate-induced hypocalcaemia. Minor, but typically tolerable, side-effects of pretreating granulocyte donors with dexamethasone (insomnia, flushing) and/or G-CSF (bone pain, headaches, insomnia) occur in a substantial number of donors.

Plasma, cryoprecipitate, and plasma derivatives

Plasma therapy began in the late 1940s with the development of fractionation techniques in which large pools of human plasma collected from many donors could be separated into specific plasma proteins. Plasma is separated from whole blood by centrifugation and frozen within 8 h of collection in order to maintain the activity of labile coagulation factors, factors V and VII. Fresh frozen plasma (FFP) contains all coagulation factors, plasma proteins, and complement. FFP should not be transfused for volume expansion because of the risk of transfusion-transmitted disease and the availability of other, safer non-plasma substitutes. The primary indications for FFP transfusion include deficiency of multiple coagulation factors as seen in liver disease and DIC. It is often used to reverse warfarin anticoagulation urgently. One unit of clotting factor activity is defined as the amount of activity in 1 ml of normal plasma. FFP is not particularly effective in replacing individual clotting factors because of the large volumes that would be required to obtain adequate factor levels. The patient's fluid and cardiovascular status may preclude the use of large amounts of plasma.

FFP is no longer the treatment of choice for coagulopathies where virally inactivated or recombinant products exist, such as for deficiencies of factor VIII (haemophilia A) or factor IX (haemophilia B). Fears of transmitting infectious disease with plasma transfusion remain of concern, particularly for pooled products. In addition to donor screening and testing, other strategies to decrease infectious risk include photoinactivation and solvent/detergent treatment technologies. Solvent and detergent treated plasma prepared from 500 l plasma pools (2500 donors) is available in the United States. This treatment effectively removes lipid enveloped viruses including HIV and HCV, but does not eliminate non-enveloped viruses such as parvovirus B-19 and, possibly, other unrecognized non-lipid-enveloped pathogens.

Cryoprecipitate is prepared by thawing FFP between 1 and 6°C. Each 10 to 20 ml unit contains 100 to 350 mg fibrinogen/unit, at least 80 IU/unit factor VIII, and some von Willebrand factor. Use of cryoprecipitate is generally reserved for patients with von Willebrand's disease or those with severe hypofibrinogenaemia (<100 mg/dl). Cryoprecipitate and thrombin are combined to make 'fibrin glue.' This biological sealant works well but exposes the recipient to the risks of transfusion-transmitted disease due to the use of cryoprecipitate.

Albumin is available as a 5 or 25 per cent solution and is used to treat hypovolaemia and hypoalbuminaemia, primarily in surgical settings. Albumin is virally inactivated by heat treatment plus other viral inactivation steps, and is tested for HCV RNA. Properly processed albumin is not considered to transmit viral disease. Readily available non-plasma colloidal solutions have replaced albumin in many situations requiring volume expansion. Intravenous immunoglobulin (IVIg) is used to treat patients with immune thrombocytopenia, Guillain–Barre syndrome, and autoimmune haemolytic anaemias. Prompt and adequate doses of Rho (D) immunoglobulin (RhIG) available in intramuscular and IV preparations are used to prevent alloimmunization in D-negative patients who are exposed to D-positive red cells through transfusion or pregnancy. Rapid advances in molecular techniques led to the cloning and purification of recombinant clotting factors. Recombinant factor

VIII, IX, and factor VIIa are available.

Complications and management of transfusion therapy Table 6)

Acute intravascular haemolytic reactions

Acute intravascular haemolytic transfusion reactions (AIHTR) are one of the most serious transfusion complications. These reactions occur in blood recipients who have developed antibodies directed against antigens present on the transfused red blood cells. ABO incompatibility remains the most common cause of immediate intravascular haemolytic reactions. Donor erythrocytes carrying either A and/or B red cell antigens bind to the recipient's naturally occurring anti-A and/or anti-B antibodies, resulting in complement fixation, formation of the C5b-9 membrane attack complex, and subsequent haemolysis. Biological response modifiers, such as proinflammatory cytokines (IL-1, TNF-a), chemokines (IL-8), and complement fragments (C3a, C5a), also play a role in the pathophysiology of AIHTRs. AIHTRs are typified by the sudden onset of back pain, hypotension, tachycardia, fever, chills, diaphoresis, and dyspnoea. The symptoms usually begin soon after the transfusion is started in immunocompetent recipients. Laboratory studies reveal an increase in unconjugated bilirubin (typically to 2–3 mg/dl) and marked elevation of lactate dehydrogenase. Other evidence of intravascular haemolysis include haemoglobinuria and haemoglobinaemia. The direct antiglobulin test (direct Coombs) becomes reactive due to the coating of donor red cells with the recipient's antibodies.

AIHTRs are usually caused by transfusions of ABO incompatible blood resulting from patient identification or clerical errors, but they can also be caused by incompatibility within other blood group systems (Duffy, Kidd). Proper labelling of clots used by the blood bank for compatibility testing and careful identification of patients are the best ways to prevent potentially fatal reactions. AIHTRs are medical emergencies and treatment consists of immediately stopping the transfusion, close monitoring of vital signs, cardiac and airway support, and maintenance of urine output with saline diuresis with or without a loop diuretic (Table 7). Dialysis must be considered in patients with renal failure.

Delayed extravascular haemolytic reactions

Delayed haemolytic transfusion reactions (DHTRs) generally occur in patients who have a negative antibody screen on pretransfusion testing, but who then experience accelerated destruction of transfused red cells 7 to 14 days post-transfusion. In most cases, red cell destruction is caused by an antibody that is initially of a titre below the limits of detection on routine screening. The antibody then rapidly forms on secondary exposure to the offending antigen. Only rare DHTRs are caused by primary allosensitization in which a patient synthesized a new antibody. The antibodies typically fix complement to C3 and stop, thus, resulting in extravascular as opposed to intravascular haemolysis. Antibodies most commonly implicated in DHTRs include those directed against Rh (E, c), Kell, Duffy, and Kidd blood group antigens. DHTRs can be diagnosed by an unexpected post-transfusional fall in haematocrit, development of unconjugated hyperbilirubinaemia, and appearance of a positive direct antiglobulin test. There is usually a delay of 3 days to 2 weeks between transfusion and onset of extravascular haemolysis. Only rarely do delayed reactions cause intravascular haemolysis with associated haemoglobinaemia and haemoglobinuria.

Febrile non-haemolytic reactions

Febrile non-haemolytic transfusion reactions (FNTRs) to red blood cell and platelet transfusion are very common. They are caused by the development of antibodies in the recipient directed against HLA and/or leucocyte-specific antigens on donor white blood cells and platelets. Reactions between leucoagglutinins present in the transfused product and recipient leucocyte antigens can also occur. Subsequent formation of leucocyte antigen–antibody complexes results in complement binding and release of endogenous pyrogens such as IL-1, IL-6, and TNF-a. Cytokines generated by leucocytes during platelet and red cell storage may also contribute to FNTRs. Symptoms occur during or several hours after the transfusion, and typically include low-grade (> 1°C rise) and high grade fevers, accompanied by shaking chills. Rarely, vomiting, dyspnoea, hypotension, and decreased oxygen saturation may develop. The severity of symptoms is often directly related to the number of leucocytes in the product or the rate or volume of transfusion. Leucoreduction of blood components decrease the frequency of febrile transfusion reactions. Premedication with an antipyretic such as acetaminophen can ameliorate mild febrile transfusion reactions. Antihistamines are not helpful in preventing or treating febrile transfusion reactions. Corticosteroids can also minimize febrile transfusion reactions if they are administered several hours before the transfusion. Intramuscular or subcutaneous meperidine will usually resolve severe rigors in a matter of minutes. If symptoms do not resolve in less than 4 h or are especially severe, other complications such as sepsis due to contaminated blood products or a haemolytic reaction should be considered.

Allergic reactions

Allergic reactions to plasma, platelets, and red blood cells are relatively common. They present as pruritis and/or urticaria in the absence of fever. Allergic reactions are usually IgE mediated and most symptoms are attributed to histamine release. It may be difficult to distinguish allergic and febrile transfusion reactions when urticarial symptoms are accompanied by low-grade fever. Common symptoms and signs include erythema, papular rashes, wheals, and pruritis. Severe anaphylaxis resulting in bronchospasm and hypotension are possible. As in other allergic responses, symptoms are not dose-related and severe manifestations can occur following small exposures. Treatment of mild allergic reactions consists of stopping the transfusion and administering diphenhydramine or other antihistamines. In a mild allergic reaction with only pruritis and hives, it is acceptable to continue transfusing the same unit providing the symptoms promptly resolve and there is no fever or vasomotor instability. If symptoms recur after the transfusion is restarted, a new unit should be obtained. Severe anaphylactic reactions with bronchospasm and cardiovascular collapse are rare and should be treated like any other anaphylactic reaction with steroids, vasopressors, and airway support. Washed red blood cells in which the residual donor plasma has been removed and replaced by saline may benefit patients with repeated or severe allergic reactions. Leucocyte reduction filters are not helpful because they do not remove the implicated soluble mediators.

Septic reactions

Blood products can become contaminated by bacteria if a donor is bacteraemic at the time of collection or if improper arm preparation occurs during venipuncture. Transfusion of blood products contaminated by bacteria is particularly dangerous and can result in profound hypotension and shock. There are no laboratory screening tests commonly used to detect bacterial contamination and contaminated units cannot be easily identified by inspection. The risk of septic transfusion reactions is higher for platelet transfusions than other blood components because platelets are stored at room temperature. Common organisms implicated in septic transfusion reactions include Gram-positive (*Staphylococcus* sp.) and Gram-negative (*Enterobacter*, *Yersinia*, *Pseudomonas* sp.) bacteria. Blood cultures should be obtained from patients who develop high fevers following or during transfusion, especially if they become hypotensive. A Gram stain of the suspected contaminated product may be helpful but is often negative, and the product should be cultured if possible. Other symptoms attributed to preformed endotoxin and cytokines include skin flushing, severe rigors, and rapid-onset cardiovascular collapse. The symptoms may occur during, or minutes to hours after the transfusion is completed. Treatment includes fluids, cardiorespiratory support, and broad-spectrum antibiotics. Febrile transfusion reactions can usually be distinguished from septic transfusion reactions by the former's self-limited nature and lack of profound hypotension.

Transfusion-related acute lung injury

Transfusion-related acute lung injury (TRALI) is a serious complication of blood transfusion therapy that presents as non-cardiogenic pulmonary oedema. It typically occurs within 6 h of transfusion. It is clinically identical to the adult respiratory distress syndrome (ARDS). The most common clinical findings are rapid-onset symptoms including dyspnoea, tachypnoea, cyanosis, fever, and hypotension. Lung auscultation reveals diffuse, crackly, and decreased breath sounds. Invasive cardiac monitoring demonstrates normal cardiac pressures and function with hypoxaemia and decreased pulmonary compliance. Radiographic findings include diffuse, fluffy infiltrates typical of pulmonary oedema. The aetiology is believed to involve immune-mediated reaction of HLA antibodies or other leucoagglutins with white cells resulting in leucocyte activation. Granulocytes are first activated by HLA or other Ag–Ab complexes and then migrate to the lungs. The activated leucocytes bind to the pulmonary capillary bed via integrins and other cell adhesion molecules where they release proteolytic enzymes that destroy tissue, resulting in a capillary leak syndrome and pulmonary oedema. More recently, reactive lipid products released from donor cell membranes have been associated with the development of TRALI. TRALI should be suspected in patients with severe and rapid-onset respiratory distress following transfusion therapy, or, more specifically, pulmonary oedema without hypervolaemia. Definitive diagnosis requires identification of HLA and/or granulocyte antibodies in either the donor's or recipient's serum, as well as the corresponding antigens on the recipient's or donor's leucocytes. This testing is performed in a few specialized laboratories. Approximately 80 to 90 per cent of patients with TRALI will survive with supportive care including aggressive respiratory support, supplemental oxygen, and mechanical ventilation. Based on the presumed pathogenesis of TRALI, leucoreduced blood products could theoretically decrease the incidence of TRALI. Drugs used to treat TRALI have included corticosteroids and diuretics.

Transfusion-associated graft-versus-host disease

Acute graft-versus-host disease (GVHD) is a rare complication of blood transfusion, but is fatal in approximately 90 per cent of patients. TA-GVHD occurs when donor immunocompetent T and NK cells attack immunoincompetent recipient cells because these recipient cells appear foreign due to differences in major or minor histocompatibility antigens. GVHD is commonly seen following allogeneic bone marrow transplant but may also rarely occur in immunodeficient or immunosuppressed patients following blood transfusion. Removal of T cells from a donor graft can prevent acute GVHD in oncology patients, but is associated with increased graft failure and a decrease in a 'graft-versus-leukaemia' effect. The risk of TA-GVHD is related to the number of viable T lymphocytes transfused, the recipient's immune status, and the HLA disparity between donor and host. Therefore, multiply transfused patients who receive cells from donors who share HLA haplotypes with the recipient are at greatest risk. Clinically, TA-GVHD is characterized by the acute onset of rash, abdominal pain, diarrhoea, liver abnormalities (elevated liver enzymes, hyperbilirubinaemia), and bone marrow suppression 2 to 30 days following transfusion. The maculopapular rash seen is similar to that observed in acute GVHD following bone marrow transplant, and biopsy of the skin may help to confirm the diagnosis. Pancytopenia may be severe and is attributed to destruction of recipient marrow stem cells by donor lymphocytes. Immunosuppressive therapy with prednisone and cyclosporine has had little effect in TA-GVHD. Fortunately, TA-GVHD can be prevented by irradiating products prior to transfusion. Specifically, irradiation of cellular blood products with 2500 cGy inactivates donor lymphocytes and is the most effective method for preventing TA-GVHD.

Transfusion-transmitted isease

Despite major improvements in blood safety during the past 20 years, there remains a relatively small risk of transfusion-transmitted disease. The use of volunteer donors and predonation screening questionnaires were the first steps taken to reduce the risk of transfusion-related hepatitis and HIV. These risks continue to drive mandated pretransfusion testing requirements in developed countries. The advent of enzyme immunoassays in the 1970s, and more recent nucleotide testing, have further decreased the risk of transfusion-transmitted disease (Table 8). Transfusion-transmitted disease is a persistent problem in parts of the world that do not have access to screening tests.

Pretransfusion testing typically includes screening for syphilis, hepatitis B (HBsAg, anti-HBc), hepatitis C (anti-HCV), human immunodeficiency virus (anti-HIV-1/2, HIV-1 p24 antigen), human T cell lymphotropic virus (anti-HTLV-1/2), and syphilis. Serum alanine aminotransferase is measured in most European countries as a non-specific surrogate marker of hepatitis. When positive, these tests are typically confirmed by supplemental or confirmatory testing. Current estimates of the risk of transfusion-related HIV range from 1:500 000 to 1:750 000 units transfused. Despite improvements in tests used to detect HIV antibodies in donors, the 'window period' in which HIV could be transmitted by an infected, but HIV seronegative, donor remained in 1996 at about 25 days. The introduction of screening for HIV-1 p24 antigen in 1997 decreased the window period to approximately 15 days.

Genomic testing for hepatitis C virus (HCV) RNA was implemented in the United States and Europe to detect seronegative, yet infectious units. Nucleotide testing (NAT) for hepatitis C and HIV is typically performed on small pools of samples. The importance of hepatitis C transmission in blood therapy has been confirmed in many countries by retrospective review. During these 'look backs', recipients of blood components from donors later found to be positive (since anti-HCV screening was only instituted in 1991) are examined. A large percentage of these recipients, up to 75 per cent, are found to be anti-HCV positive. The majority of those who seroconvert will develop chronic liver disease. NAT testing will decrease the transfusion-related hepatitis C by decreasing the window period, from approximately 60 to 80, to 10 to 20 days. Hepatitis G virus has been transferred by blood transfusion, but its significance is unclear in that transfusion-acquired HGB infection has not been associated with acute or chronic hepatitis.

Several techniques have been developed to inactivate viruses in plasma including solvent and detergent treatment, and photochemical inactivation using psoralens and long wavelength UV light. Methods to inactivate infectious pathogens in cellular blood components, including platelets and red cells, are not currently available but are under development. Due to the low risk of viral infection by transfusion and the fact that most patients who receive plasma also receive cellular blood components, the cost-effectiveness of virally-inactivated plasma is very low. Albumin, immune globulin, factor concentrates, and other plasma derivatives are also virally attenuated, following standard treatment protocols.

Other pathogens, such as CMV and parvovirus B19, are common in the general donor population, and may pose a serious threat in immunocompromised patients. Approximately 40 to 60 per cent of blood donors have been exposed to CMV during their lifetime and subsequently are CMV seropositive. Only about 2 per cent of CMV seropositive donors, however, are actively infected and transfusion of their blood to an immunocompromised recipient could cause potentially serious disease. The actual risk of post-transfusion seroconversion to a CMV negative recipient who receives CMV-untested blood depends on the prevalence of CMV seropositivity in the donor population.

A number of parasitic diseases are known, or are suspected to be transmitted by blood transfusion. These include malaria, Chagas' disease, babesiosis, leishmaniasis, and toxoplasmosis. Transmission of Lyme disease (*Borrelia borgdorferi*) by transfusion has not been documented. The risk of new-variant Creutzfeldt–Jakob disease (nvCJD), first described in the UK in 1996, is unknown. It is unclear whether nvCJD is transmissible by blood transfusion and this form of transmission has not been reported. Fears of transmitting nvCJD, however, have resulted in implementation of a universal white blood cell reduction policy in the United Kingdom. There is a risk of acquiring babesiosis by blood transfusion, and infections with this organism can be dangerous in at risk populations (e.g. splenectomized patients) if untreated.

Use of special blood products

Leucoreduction

Leucocytes contained in blood components can provoke febrile non-haemolytic reactions, induce HLA alloimmunization, and transmit cytomegalovirus (CMV) to at-risk recipients. Leucocytes are most effectively removed from red cell and platelet concentrates by leucocyte reduction filters. Third-generation leucocyte reduction filters remove 3 to 4 $\log_{10}$ of the total intact leucocytes found in red cell and platelet concentrates. American Association of Blood Bank standards require that units labelled leucoreduced in the United States contain less than 5×10^6 white blood cells. Red cells are either leucoreduced shortly after blood collection (prestorage leucodepletion), following refrigerated storage (poststorage leucodepletion), or at the bedside during transfusion. Filters are similarly used to leucoreduce platelet concentrates—apheresis devices have been designed to collect leucoreduced platelets directly (process leucoreduction). Quality control measures must be in place in order to verify adequate leucoreduction of transfused products.

Leucoreduction has been shown to reduce the prevalence and severity of febrile transfusion reactions and to decrease the risk of HLA alloimmunization. Leucoreduced products are less likely to stimulate the HLA alloantibodies implicated in both febrile transfusion reactions and antibody-induced platelet refractoriness. Other generally accepted benefits of white blood cell reduction include reducing platelet refractoriness, and decreasing the risk of transmitting white blood cell-related infectious agents including CMV and HTLV-I/II. Prestorage leucoreduced products are preferable because they are also devoid of cytokines and other biological response modifiers which play a role in transfusion complications. Many of these proteins are not efficiently removed by leucocyte reduction filters. With the dramatic decrease in the risk of viral transmission, investigators are focusing on the immunomodulatory effects of blood transfusion. These effects specifically deal with associations between allogeneic transfusion and bacterial infection, tumour progression, and tumour recurrence. Universal white blood cell reduction of both red blood cells and platelets has been required and/or is being implemented in a number of countries including the United Kingdom, Canada, France, Ireland, Portugal, and the United States.

Irradiation

Blood components are irradiated to prevent potentially lethal transfusion-associated graft-versus-host disease by interfering with the ability of lymphocytes to proliferate. Irradiation of supportive blood components is indicated in bone marrow or peripheral blood stem cell transplant recipeints, patients with congenital immunodeficiency states, neonates, premature infants, and during intrauterine exchange transfusion. Patients with AIDS commonly receive irradiated components, although there is no clear increased risk of transfusion-associated graft-versus-host disease in this population. Standard guidelines recommend irradiating red blood cells, platelets, and granulocytes with a minimum dose of 2500 cGy. Platelets and red cells are not adversely affected by this exposure. It is not necessary to irradiate FFP or cryoprecipitate because they do not contain viable leucocytes. Bone marrow or peripheral blood stem cells must never be irradiated prior to transplant.

Cytomegalovirus-safe

Cytomegalovirus (CMV) infection is a leading cause of morbidity and mortality in marrow and solid organ transplant patients. Most serious CMV infections that develop in these populations are a result of latent reactivation of recipient CMV, but CMV can also be transmitted by blood transfusion. Therefore, blood banks supply products that have a low potential of transmitting CMV. The available products include CMV seronegative units prepared from donors who are CMV antibody negative, and leucodepleted components. The latter refers to blood components leucoreduced in a blood centre or laboratory using cGMP techniques. Depending on the donor population, however, as many as 80 to 90 per cent of blood donors may be CMV seropositive. Thus, the demand for CMV seronegative products may exceed supply. In addition, CMV seronegative products can transmit CMV disease. Studies suggest that CMV seronegative and leucodepleted filtered products are equivalent in preventing CMV transmission. Many transfusion specialists consider cGMP leucodepleted units as CMV 'safe' in that they are unlikely to transmit CMV disease. In addition to CMV seronegative marrow and solid organ transplant recipients, CMV seronegative or safe components are generally indicated for premature infants, during intrauterine transfusions, for patients with congenital immunodeficiencies, CMV seronegative pregnant females, and seronegative patients with HIV. The British Committee for Standards in Haematology has concluded that leucoreduced components are an 'effective alternative' to seronegative products for preventing CMV transmission by transfusion.

Alternatives to blood component therapy

Autologous transfusion

Commonly used forms of autologous transfusion include preoperative blood donation, acute normovolaemic haemodilution, and autologous blood salvage. Many blood centres provide autologous preoperative blood donation services in which a patient's blood is drawn and stored for later use, usually during a surgical procedure. The criteria for autologous donations are less stringent than those for allogeneic donors. Preoperative blood donation can be utilized in elderly patients, although there is a higher risk of anaemia and more serious cardiovascular complications associated with the donation. Although the use of autologous blood decreases the risk of viral infection, the risk of bacterial contamination remains. Acute normovolaemic haemodilution is performed by removing blood from a patient immediately before surgery and replacing the blood volume with crystalloid or colloid solutions to maintain haemodynamic stability. The withdrawn blood is then later reinfused. Autologous blood salvage is performed by collecting and then returning blood lost during or shortly following operative procedures using intraoperative salvage devices. This technique is primarily employed in cardiac and orthopaedic surgery.

Growth factors

Haematopoietic growth factors used in transfusion therapy are designed to limit the exposure of patients to allogeneic blood. The isolation, characterization, and subsequent synthesis of erythropoietin by recombinant technology (rHuEPO) was one of the most important advances in decreasing red cell transfusions. Use of rHuEPO has dramatically reduced the transfusion needs of patients with renal failure and various anaemias. rHuEPO has also been employed to increase the yield of autologous donations and to stimulate erythropoiesis following surgery. Granulocyte colony stimulating factor (G-CSF) has been shown to decrease infection rates in neutropenic patients undergoing chemotherapy, replacing marginally effective granulocyte transfusions. There is rapid growth in the use of other growth factors including FLT-3 ligand, c-MPL ligand (thrombopoietin, TPO) and various combinations of growth factors. These growth factors have been shown to reduce thrombocytopenia following non-myeloablative chemotherapy. Thrombopoietic growth factors also have the potential to stimulate platelet apheresis donors, increase stem cell harvest yields, and to expand progenitor cells *ex vivo*. Development of neutralizing antibodies against endogenous thrombopoietin has plagued clinical testing of thrombopoietic growth factors.

Blood substitutes

Red cell substitutes currently in development include haemoglobin-based oxygen carriers (HBOCs), perfluorocarbon emulsions (PFCs), and liposome-encapsulated haemoglobin. The two major types of blood substitutes, HBOCs and PFCs, are in phase II and III clinical trials. HBOCs are artificially derived products with oxygen carrying properties. They are structurally similar to haemoglobin but do not contain red cell stroma which is toxic and leads to renal damage. Development of HBOCs has been hampered by the relatively short half-life of these oxygen carriers in the circulation. PFCs are synthetic hydrocarbons that have the ability to carry dissolved oxygen. The particles circulate for only a few hours until they are removed by the reticuloendothelial system. Research efforts to modify or remove red blood cell antigens from donor units is proceeding slowly, but a truly universal compatible red cell unit may one day be within reach.

22.8.2 Haemopoietic stem cell transplantation

E. C. Gordon-Smith

Introduction

The idea that haemopoietic stem cells from the bone marrow could be transferred from a normal individual to a patient to replace defective bone marrow has a long history. With the exception of rare instances where marrow was obtained from an identical twin, such attempts in humans universally failed until a clear understanding of the immune processes involved in tolerance and rejection became available. Much of the pioneering work in making possible human bone marrow transplantation was carried out by E. Donald Thomas and colleagues in the United States, work for which Thomas received the Nobel Prize jointly in 1990. In the post-Second World War era, experiments on inbred mice showed that lethally irradiated animals could be rescued by transfusion of bone marrow from unirradiated mice and that this protection was the result of engraftment of the normal marrow in the recipient. Successful engraftment depended upon the donor marrow being genetically acceptable by the recipient mouse or the recipient mouse being sufficiently immunosuppressed. Successful engraftment when there was immunological disparity between the donor and recipient was followed after a period of 2 weeks or so by a 'secondary' disease in which the recipient failed to thrive and developed gastrointestinal disorders and skin abnormalities manifest by poor further development and eventual death from infection. This so-called 'runt disease' is the murine equivalent of graft-versus-host disease (**GVHD**) in humans in which immunocompetent cells from the immunologically disparate donor mount an attack against recipient tissues. From these and other experiments in outbred animals it was recognized that transplantation of bone marrow would carry the special risk of GVHD and that histocompatibility would be a critical requirement for successful transplantation.

Further work in animals demonstrated that certain treatments, in particular total body irradiation and cyclophosphamide, were sufficiently immunosuppressive to permit engraftment, and that GVHD could be controlled to some extent, where there was not great disparity between the histocompatibility antigens of donor and recipient, with methotrexate. The elucidation of the major histocompatibility locus on chromosome 6 in humans, with the identification of the histocompatibility antigens at the A, B, or C (class I) and DR (class II) loci of the HLA system, finally allowed the identification of appropriate donors for human transplantation. The paramount importance of histocompatibility in haemopoietic stem cell transplantation has been confirmed subsequently by extensive clinical practice. The first successful transplant from a non-identical, but HLA compatible, sibling was carried out in 1968 for a patient with severe combined immune deficiency where the underlying disease prevented rejection. Successful allogeneic transplantation from sibling donors in patients who required conditioning with total body irradiation and cyclophosphamide to permit engraftment was carried out in 1969 in Seattle by the group led by Thomas. Many thousands of such transplants have been carried out subsequently, though it would be fair to say that the indications for transplantation, particularly in malignant disease, are not always as clear as they might be and the problems of GVHD, graft failure, and infection remain hazards which contribute to transplant-related mortality. On the other hand, better support with blood products and antibiotics, improved tissue typing techniques, and the introduction of less toxic ways of controlling rejection and GVHD, as well as better selection of recipients, have improved outcomes steadily over the last 30 years.

Histocompatibility complex and haemopoietic stem cell transplantation

The organization of the major histocompatibility complex (**MHC**) on chromosome 6, and its importance in transplantation, is described in detail in Chapter 5.7. The closeness of the relevant genes in the complex means that within families there is little crossing-over in germ line cells and inheritance more or less follows the autosomal pattern, so that the chances of a sibling having the same HLA type as a patient is about 1:4. This is genotypic identity, in which many unidentified sequences are identical by descent between siblings. At each HLA locus there are large numbers of possible alleles in humans leading to a potential of many millions of different histocompatibility profiles. However, within populations, certain HLA alleles tend to be associated and segregate together, 'genetic disequilibrium', so that it is theoretically and practically possible to find phenotypically identical pairs within an unrelated population.

The identification of phenotypes was originally based upon serological testing for A, B, and DR antigens. The introduction of molecular techniques for identifying DNA sequences directly has shown that there may be a large number of HLA gene products whose cognate protein molecules are assigned to the same phenotype by serological methods. Some of these differences are moreover of considerable importance in terms of immunological incompatibility. These observations on the MHC within the population have made possible the establishment of large volunteer donor pools of individuals prepared to supply haemopoietic stem cells, but also highlight the difficulties of unrelated transplants from an immunological point of view. Indeed, even where there appears to be close identity in an unrelated pool, there are likely to be many fine genetic variations. Selection of donors by improved typing techniques has reduced the risks associated with unrelated transplants, but selection has also restricted the range of appropriate donors. It has also become clear that there are very wide variations in the linkage disequilibria at MHC loci between different populations of the world so that a donor pool of one ethnic type may have a much reduced chance of providing donors for another.

Where there is a histocompatibility disparity between donor and recipient, haemopoietic stem cell transplants may be possible, but the incidence of complications rises steadily as the degree of disparity increases. It is also apparent that the antigens of the MHC are not the only antigens which are important in determining the presence or absence of GVHD. GVHD is mediated by CD4+ and CD8+ cytotoxic T lymphocytes, but the role of specific HLA antigens and minor antigens in determining the attack, and the part played by recipient antigens in susceptibility to the disease, have not been worked out in detail. As discussed later, the immunological attack on normal tissues which produces GVHD seems to be linked to an ability to attack abnormal tissues, particularly malignant, producing a graft-versus-leukaemia (**GVL**) effect. Much effort has gone into trying to identify the cells which mediate GVL and to see if they can be separated from those that produce GVHD. So far the results are inconclusive. The problems and benefits of immunological disparity obviously only apply in the allogeneic transplantation procedures and are absent when autologous stem cells are used to restore haemopoiesis after intensive chemotherapy.

Haemopoietic stem cells

The idea that there was a cell in the haemopoietic system which was capable of giving rise to all lineages of the haemopoietic system for life through a process of self-renewal, proliferation, and differentiation of progeny became current in the early part of the twentieth century. Experiments by Till and McCulloch in mice demonstrated that there were individual cells which could give rise to colonies of different haemopoietic lineages in the spleen of irradiated and transplanted mice. Subsequently it was shown that the passage of small numbers of early precursor cells could repopulate the haemopoietic system serially in lethally irradiated mice. It seems probable that a single stem cell can repopulate an entire animal in terms of haemopoiesis and the immune system. In animals, stem cells can be identified by immunophenotyping, purifying this population of cells, and showing that they are capable of haemopoietic reconstitution in a series of lethally irradiated animals. Such experiments in humans are impossible, but the best *in vitro* techniques have suggested that the human haemopoietic stem cell is closely related to precursors that carry an antigen designated CD34, lack other haemopoietic markers including CD33, and have no lineage-specific markers. Whether such cells are truly the most primitive cells that are capable of giving rise to both haemopoetic and immunological precursors is not of practical importance since successful haemopoietic reconstitution, both in allogeneic and autologous transplants, is closely related to the number of such cells present in the donation. The CD34+, CD33- cells represent some 1×10^{-3} to 10^{-4} of the cells of normal human haemopoietic marrow.

Sources of haemopoietic stem cells

In the first 20 years or so of haemopoietic stem cell transplantation virtually all donations were collected from the bone marrow. Animal experiments had demonstrated that marrow infused intravenously into a recipient was capable of repopulating the marrow and this method of delivery was practised from the beginning in human transplantation. Within normal marrow, haemopoietic stem cells are located in specific areas, usually close to the bony trabeculas in the haemopoietic spaces. The observation that marrow infused into the circulation could find its way to the marrow cavity indicated that haemopoietic stem cells were capable of trafficking through the circulation and homing to the appropriate part of the marrow microenvironment. It was also recognized that there were small numbers of stem cells in normal circulating blood, and that this number was increased during the marrow recovery following cytotoxic chemotherapy. The discovery of haemopoietic growth factors and their subsequent production by recombinant technology led to their use in clinical practice. Administration of many of these cytokines, particularly granulocyte colony-stimulating factor (**G-CSF**), granulocyte–macrophage colony-stimulating factor (**GM-CSF**), and stem cell factor increases the number of circulating colony-forming cells and CD34+ cells enormously, such that for a period of a few days following treatment there would be more than adequate numbers in the circulation to use as a source of transplant cells. Homing and mobilization of haemopoietic stem cells seems to be a continuous, dynamic process—even under normal conditions.

In the early development of the fetus, haemopoiesis takes place in the liver, and fetal liver cells have been used as a source of haemopoietic stem cells, mainly for the treatment of inherited disorders characterized by severe combined immune deficiency. The logistics of such transplants, which require 11-week-old fetal livers, make this an impractical approach. However, research on embryonic stem cells suggests that there may be other important sources of stem cells, not only for haemopoiesis but for other types of tissue replacement. Of more immediate practical importance was the finding that cord blood contained large numbers of haemopoietic cells with high proliferative potential and characteristics of stem cells. Cord blood has become a third practical source of donor cells. Each of these sources—bone marrow, peripheral blood, and cord blood—have advantages and disadvantages that impinge on clinical management. A critical requirement for successful transplantation is that there should be a sufficient number of stem cells—the ability to expand stem cells *ex vivo* would solve this and other requirements, but so far this has not proved to be practical for clinical use.

Haemopoietic stem cells from bone marrow

Until about 1993 most transplants were conducted using bone marrow stem cells. Much of the data concerning the success and problems of stem cell transplantation are derived from the use of bone marrow and this remains the principal source of stem cells in allogeneic transplants. Bone marrow is harvested with the patient under general anaesthetic by aspiration from the posterior, superior iliac crests, and if necessary the sternum. Experience showed that some 3×10^{8} nucleated cells/kg from the bone marrow were required for successful engraftment and this usually involved collecting 1 to 1.5 litres of bone marrow mixed, of course, with blood. Donors usually have a unit of blood collected before harvesting, which is returned at the end of the procedure to ameliorate the anaemia. The procedure takes 1 to 2 h and the donor usually requires brief admission to hospital to recover. Serious complications are very rare and are those associated with the general anaesthetic or local complications such as osteomyelitis or abscess formation. The advantage of this source of stem cells from the donor's viewpoint is that collection is rapid with a maximum of 48 h involvement. The disadvantage is the need to have an anaesthetic and the pain or discomfort that follows the procedure.

Haemopoietic stem cells from peripheral blood

Haemopoietic stem cells may be mobilized into the peripheral blood following exposure to granulocyte colony-stimulating factor. For allogeneic transplantation, donors receive G-CSF (filgrastim or lenograstim) at a dose of 10 µg/kg subcutaneously daily for 5 days. The peripheral granulocyte count rises to 30×10^{9}/l or higher and CD34+ cells appear in the peripheral blood reaching a maximum 5 to 6 days after the start of treatment. Leucocytes are collected by cytopheresis with the objective of reaching more than 2×10^{6} CD34+ cells/kg body weight of the recipient. Sufficient cells can usually be collected in one procedure. Attempts to increase the circulating stem cell concentration still further using additional cytokines, such as stem cell factor, have not proved to be sufficiently safe for general use. The main disadvantages for donors of this type of stem cell collection is that of bone pain or ache following the injections of G-CSF and the procedure of cytopheresis. The advantage is the avoidance of admission to hospital and an anaesthetic. When autologous collection of stem cells is required, the concentration of CD34+ cells may be increased further by giving cyclophosphamide (or some other chemotherapeutic agents, such as etoposide) before starting the G-CSF. The recovery from the marrow suppression so produced leads to mobilization of stem cells even without G-CSF. This procedure is used mainly for patients with malignant disease for whom the stem cells can be used to rescue them from the effects of further chemotherapy.

The use of peripheral blood for harvesting stem cells for allogeneic transplants provides high numbers of CD34+ cells and more rapid engraftment than that seen with bone marrow-derived stem cells. On the other hand, peripheral blood contains more T cells than bone marrow and, whilst original concerns that acute GVHD would be unacceptably severe unless T cells were removed has not proved to be the case, chronic GVHD does seem to be more prevalent. Nevertheless, the ease of collection and advantages of rapid engraftment have meant that most autologous transplants, and an increasing proportion of allogeneic, are sourced from the peripheral blood.

Haemopoietic cells from umbilical cord blood

Sourcing haemopoietic stem cells from umbilical cord blood has several theoretical and practical advantages.

Umbilical cord blood is widely available with no risk to mother or infant, there is low viral contamination, the immaturity of the immune cells reduces the risk of GVHD, and the cells may readily be stored frozen. Furthermore, a balance of umbilical cord blood stem cells from different ethnic groups to take advantage of genetic disequilibrium can be achieved and specific HLA types can be targeted. A disadvantage is the relatively small numbers of haemopoietic stem cells that are present, so that cells derived from umbilical cord blood are mainly suitable for child recipients rather than adults; a further difficulty is the lack of any back-up source of cells should the transplant fail or relapse occur. There is also the theoretical risk that the umbilical cord blood stem cells carry some latent genetic defect which might appear years after the transplant.

Plasticity of stem cells

It has become apparent that there are present in the bone marrow, and in other tissues, cells which are totipotent in their capacity to develop into differentiated cells depending upon the molecular and cellular microenvironment to which they are exposed. Thus bone marrow-derived cells may differentiate to cardiac muscle cells, nerve cells, striated muscle fibres, and many other tissues, whether they be ectodermal, mesodermal, or endodermal in origin. This potential is also present in embryonic stem cells. The reconstitution of a whole animal from a single somatic nucleus reinserted into an enucleated oocyte (cloning) is the ultimate indication of plasticity. In the future, haemopoietic stem cells may be used to repair neurological or muscle defects and other sources of stem cells used to prepare haemopoietic deficiencies.

Donors for allogeneic stem cell transplantation

Problems of transplant-related morbidity and mortality, graft rejection, GVDH, and infection increase with increasing donor disparity. HLA-matched sibling donors are not only phenotypically matched for the MHC, but have genotypic identity throughout most of the MHC. This does not eliminate transplant-related morbidity and mortality, but reduces the incidence and severity of the problems compared with unrelated volunteer donors matched phenotypically for the MHC. Sibling donors are therefore preferred. Same sex donors are more successful than mismatched, and transplantation from male donors is more successful than female. HLA-matched sibling donors are only available for about 1 in 3 recipients in populations with an average of two or three children per family. To overcome this shortfall, volunteer donor banks have been established, now including some 3 million typed donors worldwide. This pool can provide HLA-suitable matches for about 80 per cent of recipients with the same genetic disequilibrium as the donor pool, though finding the right match may take several weeks. Even with fully matched donors, either sibling or volunteer, extensive immunosuppression of the recipient is required pretransplant to prevent graft rejection and post-transplant to control GVHD. New methods of immunosuppression which allow the stepwise development of donor marrow may produce a greater degree of tolerance and permit successful engraftment of haemopoietic stem cells with some degree of HLA disparity. Volunteer donor stem cells were the source of about a quarter of all allogeneic transplants in 1999 and this proportion is increasing.

Stem cells from umbilical cord blood banks have been used successfully in transplants for genetic abnormalities, particularly Fanconi anaemia, and also for children with malignant disease. However, this source has proved difficult for adults mainly because of the low numbers of stem cells in the cord blood.

Management of recipients for haemopoietic stem cell transplantation

The treatment of recipients pretransplant includes measures to induce immunosuppression and irradication of diseased bone marrow. This was the theory behind the so-called conditioning regimens used during the first 30 years of stem cell transplantation. For haemopoietic stem cell transplantation for malignant disease, most protocols contained cyclophosphamide combined either with total body irradiation (single dose or fractionated) or with busulphan. For non-malignant conditions, particularly acquired aplastic anaemia, cyclophosphamide in higher dosage, either alone or combined with antilymphocyte globulin (ALG), was the major immunosuppressive agent. Some of the more widely used regimens are indicated in Table 1. The incidence and severity of GVHD was reduced by giving methotrexate intermittently post-transplant. The introduction of cyclosporin to reduce graft failure and ameliorate GVHD greatly improved the results of transplantation. Such conditioning regimens, particularly for malignant and genetic disorders, carry considerable delayed as well as acute toxicity, particularly for children. Where radiation is used and to a lesser extent busulphan, infertility is usual, growth is retarded, and other endocrine functions may be impaired. Late onset of solid tumours also occurs. Where transplantation was used for patients who had already received irradiation or chemotherapy to the central nervous system, for example patients with a relapsed acute lymphoblastic leukaemia, intellectual impairment as well as the above problems are common.

Subsequently it has been recognized that much of the success of stem cell transplantation in certain malignant conditions, most notably chronic myeloid leukaemia but also acute myeloid leukaemia, is related to the immunosuppressive attack (GVL), provided by donor lymphocytes. Likewise the repopulation of marrow by donor haemopoietic stem cells does not require the immediate abolition of recipient marrow. Conditioning regimens have been introduced which do not rely on cytotoxic measures to obliterate recipient marrow and immune system, but which have increasing immunosuppressive effects to allow the gradual reintroduction of donor marrow. Such regimens include fludarabine, a highly immunosuppressive drug that is not very cytotoxic, together with antilymphocyte globulin or monoclonal antibodies that have a specific immunosuppressive effect. Depletion of T cells in the donor preparation, with subsequent later add-back of donor lymphocytes, is also employed. Some examples of these so-called non-myeloablative regimens are included in Table 1. Results using this approach have been encouraging, but long-term follow-up will be necessary to confirm these advantages.

Removal of T cells from donor preparations has long been used as a way of preventing GVHD. Unfortunately, survival rates are not generally improved by T-cell depletion. The benefit of reducing GVHD is balanced by an increasing graft failure and, in malignant disease, by an increase in cancer relapse.

Graft-versus-host disease (GVHD)

Acute GVHD may develop at any time within the first 6 weeks post-transplant. The typical features and classification of severity are shown in Table 2. Grades III and IV of GVHD are an important cause of transplant-related morbidity and mortality. The immunosuppressive effect of GVHD may lead to reactivation of latent viruses, particularly cytomegalovirus, as well as death from fungal or bacterial infections. Liver failure, catastrophic diarrhoea, and gastrointestinal haemorrhage are other direct causes of death from GVHD. Chronic GVHD mainly affects the skin. It may follow acute GVHD or arise *de novo* 6 weeks or so post-transplant. The rash may vary from a mild dryness of the skin in localized areas to a major extensive scleroderma-like illness with progressive ulceration and scarring. Extensive and chronic GVHD is associated with a poor outcome. Examples of acute and chronic GVHD are shown in Fig. 1.

Fig. 1 Skin manifestations of acute and chronic graft-versus-host disease. Acute GVHD: (a) Grade I, skin +, showing typical palmer maculopapular rash (recovered); (b) Grade IV, skin 4+, generalized erythroderma with early exfoliation; liver 3+, bilirubin > 250 µmol/l (fatal); (c) Grade III, skin 4+, bullous desquamation (recovered). Chronic GVHD: (a) Scleroderma-like plaques on hands; (b) Sclerotic scarring on back; (c) Severe ulceration and contracting scleroderma-like skin involvement.

Amelioration of GVHD with cyclosporin plus or minus methotrexate has already been discussed and the role of T-cell depletion mentioned. The optimal regime for prevention has yet to be elucidated. Treatment depends on the use of corticosteroids together with specific anti-T-cell monoclonal antibodies. Management of chronic GVHD with thalidomide has also been tried.

Graft versus leukaemia (GVL)

The observation that patients with leukaemia, particularly chronic myeloid leukaemia, who had allogeneic transplants and developed acute and/or chronic GVHD had considerably less relapse, though not better survival, than patients without GVHD led to the idea that there was a specific GVL effect (Fig. 2). This was confirmed when it was found that patients with chronic myeloid leukaemia who relapsed post-transplant could be put back into cytogenetic and molecular remission by giving them donor lymphocytes in increasing dosage. Sometimes this was associated with an increase of GVHD, but by no means in every case. There seems to be a hierarchy of susceptibility to GVL effect: chronic myeloid leukaemia being the most clear-cut, some effect in acute myeloid leukaemia, less in acute lymphoblastic leukaemia, and uncertain in lymphoma and myeloma. It is not yet clear whether the cells responsible for GVL are identical to those which produce GVHD or whether it is a separate population. Donor lymphocyte infusions now form part of the management plan post-transplant both for the management of relapse and for some of the non-myeloablative regimes.

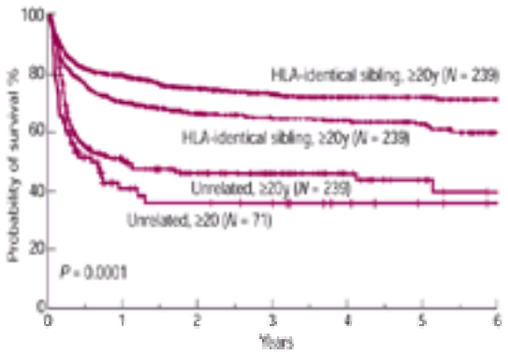

Fig. 2 Probability of survival after allogeneic bone marrow transplantation for severe aplastic anaemia by donor type and recipient age (1991 to 1997). Data from 2064 transplants from the International Bone Marrow Transplant Registry, reproduced with permission.

Indications for haemopoietic stem cell transplantation

The indications for haemopoietic stem cell transplantation fall broadly into two groups. In the first, donor stem cells are used for replacement therapy—a rather crude form of gene therapy for inherited disorders and the re-establishment of marrow function in non-malignant bone marrow failure syndromes. The main indications in

this group are shown in Table 3. In the second group, donor stem cells are used as an adjunct to chemotherapy, both through additional cytotoxicity and biological modification through the GVL effect, in malignant disease. It is in this group that uncertainties remain as to the most appropriate timing as well as effectiveness of allogeneic transplantation. Randomized controlled trials have proved difficult to mount and much of the evidence is placed upon registry data or historical controls. At the same time that the results of haemopoietic stem cell transplantations have improved, the results of chemotherapy have also become better. Nevertheless, particularly in children and younger adults, allogeneic transplantation is widely used with some success, particularly for relapsed conditions. There is a very marked inverse relationship between success of transplantation and age, children having much less transplant-related morbidity and mortality due to reduction in infection and GVHD. Children also tolerate a higher degree of HLA mismatching than adults. The upper age limit for allogeneic transplant has continued to rise as results improve and in some conditions where transplantation is the only hope of cure, for example chronic myeloid leukaemia, patients aged more than 60 years have been successfully transplanted. However, the transplant-related morbidity and mortality at this age is very marked. As would be expected, results of allogeneic transplantation are best in low-risk groups, in first complete remission or with chemosensitive disease, and are worst in relapsed and resistant disease. However, it was in this last group that the potential benefits of allogeneic transplantation were first clearly demonstrated by Thomas and his group in Seattle. In most protocols for the management of leukaemias the inclusion of allogeneic transplantation, where a suitable sibling donor is available, is considered either up-front or as a form of rescue in younger patients. The results of unrelated donor transplants consistently lag behind those of matched sibling donors and whilst HLA antigen-mismatched stem cells are used in desperate situations, success rates decline as transplant-related morbidity and mortality increases.

Indications for autologous transplantation

The use of autologous haemopoietic stem cells for treatment of malignant disease can only be considered a form of rescue from increased chemotherapy since the allogeneic effects which produce GVL do not exist. Where there may be tumour antigens that are amenable to immune suppression, attempts have been made to induce specific immunotoxicity, so far without clear-cut benefit. On the other hand, autologous stem cell rescue does allow greatly increased chemotherapy regimens for lymphoma, myeloma, and a variety of solid tumours with shortening of hospital stay—indeed in some cases treatment can be managed in an outpatient setting—and a prolonged course of therapy with repeated rescue from stored cells. Autologous stem cells will also provide the vehicle for gene therapy once techniques for gene insertion and long-term expression become practical.

Future directions for haemopoietic stem cell transplantation

Transplant-related morbidity and mortality should continue to decline as management of infections, particularly viral and fungal infections, improve. Undoubtedly the plasticity of totipotent stem cells will be explored to treat non-haemological or oncological conditions and both autologous and allogeneic stem cells will be used for specific gene therapy for both acquired and inherited disorders.

23.1 Diseases of the skin

T. J. Ryan and R. Sinclair

Introduction

Dermatology is concerned not only with skin diseases but with the Greek ideal of beauty, being confident of 'looking good'. Dermatologists observe the attitudes of parents, schoolteachers, spouses, employers, beauticians, nurses, and others to stigma. Whether it be incipient baldness, the wrinkles of ageing, or tattoos, there are cultural factors to be understood, and a cost of not treating. When is ugliness illness; how much is disfigurement worth in a court of law, and on what does wellbeing depend?

Throughout this section, the impairment, disability, and handicap of skin failure will be emphasized. Dermatology is made difficult by its great variety of physical signs. It is an encyclopaedic subject with more than 3000 named entities. Fortunately, fewer than 10 diseases represent 70 per cent of dermatological practice—acne; bacteriological, viral, and fungal infections; tumours; dermatitis; psoriasis; leg ulcers; and warts.

Good physicians look at the skin while listening to the patient or eliciting physical signs. Recognizing minor details depends not merely on seeing but of knowing their significance. Unfortunately, so much of recognition is the naming of physical signs, and dermatologists have accumulated an enormous amount of jargon. Physicians should know enough to recognize a life-threatening physical sign, such as a melanoma, the malignant pustule of anthrax, or the eroded blisters in the mouth in pemphigus vulgaris. Furthermore, they should recognize signs that are significant indications of systemic disease, such as erythema nodosum, splinter haemorrhages, arsenical keratoses, and the white macules of tuberous sclerosis.

There is no branch of medicine more dependent on observation and less dependent on the laboratory than that of dermatology. However, in few other branches of medicine is there a requirement for the specialist to be so experienced in histopathology. One advantage is that a biopsy can be sent away to experts together with a photograph of the clinical lesion. It is also ideal for telemedicine, easily transmissible to specialist opinion.

In spite of the advances in antimicrobial and corticosteroid therapy, which have completely altered the nature of skin clinics in technically advanced countries, there is no diminution in the number of patients attending for help with skin problems. There is an increase in skin cancer, in the demand for cosmetic treatment, and in the number of environmental agents that damage the skin and cause dermatitis. In developing countries the overwhelming demand is for better management of bacterial and parasitic skin infections, but this is complicated by poverty, malnutrition, poor housing, and water shortage..

The structure of the skin

The skin consists of the epidermis and its supporting dermis lying on a layer of fat (Fig. 1). It is similar to mucosal surfaces where the surface epithelium is separated from its underlying lamina propria by a basement membrane zone which, in turn, is separated from the submucosal fat by the muscularis mucosa.

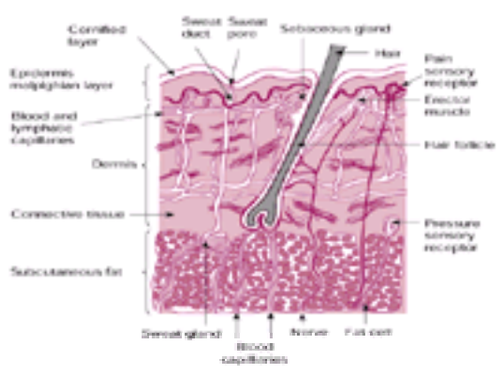

Fig. 1 The structure of human skin.

Unlike in the mucosa or skin of most animals, a subdermal muscle layer only exists in human skin in the areola and scrotum. The epithelium gives rise to all the cutaneous appendages, including: the eccrine sweat glands found over the entire cutaneous surface, but which are more numerous in the palms and soles; the apocrine sweat glands found in the axilla, groin, and beneath the breasts; the hair; and oil-producing sebaceous glands on the upper chest and back.

The epidermis is a stratified squamous epithelium (Fig. 2) comprising a germinative basal layer that is adherent to the basement membrane zone. Through cell division, the basal layer gives rise to successive layers of differentiating cells whose principal function is to synthesize the insoluble protein, keratin. In the process, these cells ultimately die and are shed from the skin surface. Keratins are the intermediate filaments of the epithelial-cell cytoskeleton, which serve as a scaffold in these cells and contribute to cell integrity.

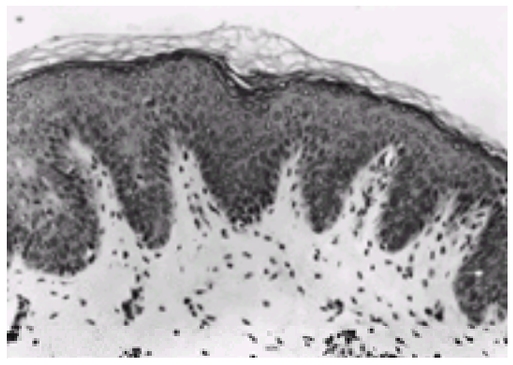

Fig. 2 A section of skin showing the epidermis and upper dermis. Note that the epidermis and the dermal projections interdigitate. The epidermal cells lose their nuclei as they approach the surface.

The epidermis is infiltrated by a number of dendritic cells, including melanocytes, Langerhans, and indeterminate cells. The function of the indeterminate cells is unknown. Skin pigmentation is due to melanin fed into the basal keratinocyte rather than to that stored within the melanocyte. Skin colour is partly due to melanocyte numbers and activity, and partly a reflection of how melanin is stored and processed in the keratinocyte. Melanin is produced from tyrosine and dopamine and acts as a free-radical scavenger.

The rich vasculature has a generous reserve to meet the requirements of wounding and repair, so common at the skin surface. Vasodilatation can increase blood flow by a factor of 200, essential for thermoregulation. Macromolecules and cells leave the dermis through the lymphatic system, which is initiated in an elastic network at the junction of the upper and middle dermis (Fig. 3). The lymphatic system is responsive to hydrostatic forces and to movement of the solid elements of the dermis by massage or compression. The dermis also supports the extremely complex neural network necessary for touch and for sensing danger. All the main constituents of the dermis, collagen, and elastic fibrous proteins embedded in the mucopolysaccharide ground substance, are secreted by fibroblasts.

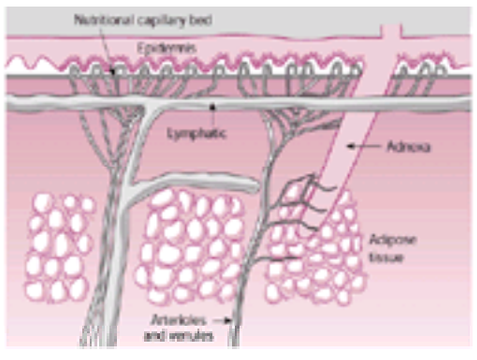

Fig. 3 The lymphatics are the exits from the skin for cells and macromolecules. They control hydrostatic and oncotic pressure and they are one pathway for antigen presentation.

The two functions of basal cells, repair or reduplication and the production of keratin, require that the epidermis should turn over in a controlled way and die in an orderly fashion. Turnover takes about 30 days from the time of reduplication at the basal layer to its loss from the surface. Whereas the lower layers of the epidermis depend on oxygen for mitosis and migration, cells in the upper differentiating layers are anaerobic with no mitochondria. The optimal temperature for epidermal metabolism is probably lower than that for most body cells. Both lipids and carbohydrates provide the energy for epidermal cell metabolism.

Functions of the skin and 'skin failure'

Like the heart, lungs, and liver, the skin can also fail with disastrous consequences. It is the largest organ of the body and, being on the surface, is continuously exposed to injury.

Skin has to be both supple and strong because it is fondled, bent, stretched, trodden upon, and compressed, as well as scratched and prodded. Not only must skin have the capacity to rapidly repair itself to form a physical barrier impervious to excess water loss and to the absorption of damaging environmental agents, it must resist wear and tear. These functions are impaired in people with skin diseases, making them more vulnerable and less able to repair damage, and causing them social embarrass-ment.

Langerhans cells take up antigens and load protein-derived peptides on the major histocompatibility complex (**MHC**), travel to the lymph nodes, and present the antigens to lymphocytes that are preprogrammed to return to the skin. Depletion of these cells, by ultraviolet radiation, prevents contact dermatitis mediated by delayed cellular immunity. This network of cells is the primary immunological defence system of the skin and is termed the 'skin-associated lymphoid tissue' (**SALT**), analogous to the **MALT** (mucosa-associated lymphoid tissue) found in the bowel. The sensation of pain, so finely mediated by the precise innervation of the epidermis, has a similar warning function, helping us to recognize the environment and to itch in the presence of smaller invaders and to follow this with an accurate scratch response. The skin is capable of the presystemic metabolism of drugs and other substances applied topically. It is also capable of forming toxic metabolites. Skin can synthesize vitamin D from calciferol in the presence of sunlight, and contains the enzyme to metabolize it to 1,25-dihydroxycholecalciferol. There is an interaction between the cells in the dermis and those in the overlying epidermis. This interaction is mediated by cytokines, those important in the skin include: interleukins 1, 2, 3, 6, 8, and 10; interferons a, b, and g; and multiple growth factors including epidermal growth factor (**EGF**), fibroblast growth factors (**FGF**) 1 and 2, insulin growth factors (**IGF**) 1 and 2, vascular endothelial growth factors (**VEGF**) 1 to 5, transforming growth factors (**TGF**) a and b, and neurotrophins. Furthermore, a range of peptides, complement factors, eicosanoids, and platelet-activating factors in the epidermis are involved in intracellular communication.

The epidermis contains very high levels of interleukin-1 (**IL-1**), 100 000 times greater than the content of most other tissues. Most IL-1 is produced by keratinocytes and, although this is a continuous process, levels are increased in the presence of ultraviolet light and endotoxins. There is a large intrakeratinocyte preformed pool of IL-1 and a predominantly intracellular inhibitor as a controlling factor by competing for receptors, which are normally scarce in the epidermis but can be induced by ultraviolet rays, trauma, or g-interferon.

The dermis supports the epidermis and its adnexa. Like bone, the skin resists distortion. It is subjected to compression and shearing strains and many mechanical stresses are transduced into biochemical signals. Skin is more supple than bone, and hydrostatic forces or swelling pressure are more finely sensed and distributed.

The dermis, in addition to being a supporting structure, determines many of the characteristics of the epidermis. It is an essential inducer and controller of hair, sweat, and sebum, and provides a selective environment whereby hormones such as oestrogen and testosterone can influence some, but not all epithelial functions; for example, in the pathogenesis of acne hirsutism and androgenic alopecia.

Sexual attraction, being subject to whim and advertising, is an important function on which the fortunes of the cosmetic industry are founded. The social anthropologist has done much to draw attention to what denotes sex appeal; for instance, colouring or decolouring, tattooing, distorting, stretching, and, of course, adorning with jewellery and clothing are all involved. Sex appeal depends on the skin not being too greasy, too matt, or too wrinkled. The White adolescent wants a preparation to reduce a greasy forehead; the Black person wants grease to rid him of any degree of powdery exfoliation. One person must have a beauty spot, and another must not. Some scents attract, while the stink of sweaty feet and rotting shoes repels.

The influence of the psyche

Blushing, cold sweats, and pallor are skin reflections of the mind. Any group of students shown a mite under the microscope will laugh at the sudden awareness of itching it induces in one of their number. The acute inflammatory process mediating a weal or any exudation can be enhanced by anxiety or diminished by relaxation. While a 'neurotic' basis for urticaria, prurigo nodularis, or lichen simplex is no longer overemphasized by terms such as 'angioneurotic oedema' or 'neurodermatitis', modern Western scientific medicine has made such terms unpopular. This is because the influence of the psyche cannot be measured, is mainly subjective, and therefore, by some, is not to be believed. Practitioners of alternative medicine, as well as almost every lay person, recognize a link between anxiety and skin disease.

The principal anxieties resulting from skin disease are the fear of being infectious, unclean, and, ultimately, unwelcome. As with sexually transmitted diseases, a person's upbringing and religious and social mores will often determine their reaction to skin disease.

Few patients will accept that our largest organ can simply wear out or be worn down like the heels of a leather shoe, which after all is only skin. They will, however, believe that their skin disease is due to a malfunction of the liver, an impurity in the blood, to worry, or to a dietary indiscretion. Such beliefs must be countered with tactful explanation.

Occasionally, problems with the psyche will manifest on the skin; for example, Picker's nodules, neurotic excoriations, acne excorieé, trichotillomania, and even onychomania. The relationship of the problem to the psyche is usually acknowledged by the patient; however, patients who refuse to admit to their artefactual dermatitis can be challenging both diagnostically and therapeutically.

A common frustration of patients seeking advice or help is being told their skin problem is trivial. However, when the effect of all chronic or trivial diseases on well being is measured, it is found that the degree of handicap has been belittled. Not all skin disease is psychosomatic.

The handicap of skin disease

Common skin diseases, such as dermatitis and psoriasis, affect the following 'functional specificities' on which personal autonomy depends:

- to move around in and manipulate the environment (Fig. 4 and Fig. 5);

Fig. 4 Psoriasis of the hands interferes with dexterity and makes patients unwelcome in many occupations, such as food handling or public relations.

Fig. 5 A callus or corn is common in ageing skin and pain can make walking very difficult. The patient can be more handicapped than an amputee with a comfortable prosthesis.

- to service oneself;
- to resist normal stresses and traumas;
- to groom oneself;
- to be intimate; and
- to organize oneself emotionally.

Some diseases, for instance leprosy, affect other faculties such as sight. To have personal and economic independence it is necessary to perform effectively in any situation. Skin diseases affecting the hands and feet prevent the patient from getting out and about or from moving around the home (Fig. 4 and Fig. 5). Skin disease, for a variety of reasons, may prevent or threaten the expected care of the home, self, or family, and it often interferes with education and employment.

The threat to life

Absence of skin, as in burns and ulcers, is a common cause of disability and death. Isolation due to rejection by a community is associated not only with poverty, but with infanticide, suicide, and a greater loss of life especially during childbirth. Skin disease does sometimes constitute an emergency and may cause death. Fatal melanoma is not rare, and only human immunodeficiency virus (**HIV**) infection and accidents worldwide are more common causes of death in males aged between 20 and 30 years. There is a 10 per cent incidence of metastasis from squamous epithelioma of the lip, a problem which may increase as actinic damage supersedes pipe-smoking as the major aetiological factor.

Angio-oedema of the upper respiratory tract is the most frightening of dermatological emergencies, accounting for the deaths of most cases of the very rare hereditary angio-oedema due to C1-esterase inhibitor deficiency and other much more common causes of urticaria.

Respiratory obstruction is recorded in other diseases such as epidermolysis bullosa (due to inhalation of 'casts') and Behçet's disease (due to ulceration of the larynx).

Many chronic skin diseases cause death by impairing the skin's ability to protect against adverse climatic conditions, environmental irritants, and infective agents, which all result in fluid loss or increased demands being placed on internal organs such as the heart. Blistering disorders, such as toxic epidermal necrolysis (**TEN**), pemphigus vulgaris, widespread impetigo, or epidermolysis bullosa, are especially threatening.

Erythroderma due to eczema (Fig. 6), psoriasis, or lymphoma commonly results in failure of body temperature control, in a high cardiac output, and, more rarely, in uncontrollable protein-losing enteropathy. Fluid loss and prerenal failure are important and particularly relevant factors in hot countries. In the tropics many die from uncontrolled dermatitis and commonly associated superinfections.

Fig. 6 Some diseases are a threat to life. Exfoliative dermatitis is life-threatening because of fluid loss, heart failure, and loss of temperature control. This patient died following perforation of the small intestine while being treated with steroids.

Restricting employment

Not to be able to resist normal stresses and traumas is a common inconvenience. It accounts for the need for sufferers from atopic eczema, even when in remission, to avoid occupations such as hairdressing, nursing, food handling, and mechanical engineering. Unemployment may be the consequence. Wear and tear of the skin is the most common consequence of work and those who have lowered resistance are unable to work. Some skin diseases present as blisters or as psoriasis in response to even minimal trauma—known as the Koebner phenomenon.

To communicate and to be welcome

The skin is involved in display. Through it we make contact with others. It is observed and touched. If there are defects in a person's skin, observers may not like what they see and will not touch it. Many children with such defects experience insults from other children who refuse to hold hands or play with them. Adults experience more subtle signals, which may prevent a normal sex life and interfere with employment (Fig. 7). Isolation causes premature death.

Fig. 7 Acne vulgaris is a cosmetic disability that makes a teenager feel very self-conscious and unwelcome.

The greatest handicap of all is to be unwelcome. Whether real or merely perceived, it is the commonest social effect of skin disease. The whiteness of the skin of vitiligo, the blood on the sheets, and scale on clothing and furniture left by the person with psoriasis are huge disadvantages. Albinos are outcasts in Africa, while those with severe psoriasis are rejected in the United Kingdom.

Prevalence

An examination of more than 20 000 Americans aged between 1 and 74 years revealed that 60 per cent had significant skin disease (least frequent among children and most common in the old), which often persisted for more than 5 years. In about 10 per cent of cases the condition was a physical handicap: diseases of the hand being the greatest and most frequent handicap. It has been estimated that 6.8 million Americans are handicapped in their social relationships because of a skin condition. Diseases of the skin account for almost half of all reported cases of industrial illness in the United States.

The interview, examination, and investigations

The interview

The following questions form a suitable basis for conducting a dermatological interview:

1. How long have you had it; exactly when did it start; have you had it before?
2. Which part of your skin was first affected; where were you when it started; what were you doing?
3. How did it progress, to what sites, and what was there before?
4. Does it come and go; how long does each individual lesion last?
5. Does it itch; is it painful, tender, numb?
6. Does it develop blisters or clear fluid?
7. Does anything make it better?
8. Does anything make it worse?
9. Have you consulted any one about this? What was their diagnosis?
10. What ointments, creams, lotions, or bath oils have you used? Have you had any medicine or injections?
11. Has anyone else you know got it; does it run in your family; do any other diseases like asthma, eczema, or hay fever run in your family?
12. Have you had any previous illnesses?

The examination

Clinical examination

Undressing, removal of bandages, and, in some countries, even the removal of a hat may be difficult to achieve. In such cases more will be learnt by generally looking at the patient than trying to force compliance. However, the patient must undress when the diagnosis is in doubt.

One should keep looking until something is recognized. Often much of a rash is atypical, but somewhere there should be a classical physical sign. Good lighting is essential; sunlight is best. A magnifying glass is essential for detecting nail-fold telangiectasia, scabies, or crab lice.

Touch assures the patient there is no abhorrence and that contagiousness and uncleanliness are insignificant. Papules are palpable, macules are not. Compression distinguishes purpura from telangiectasia and reveals much about the depth of the lesion and its hardness.

Skin scrapings for fungal mycelia

Skin scrapings are best taken from moist areas since mycelia in dried scales or in the nails may be too desiccated. Scrapings should be placed on a slide and covered with 10 per cent potassium hydroxide, this helps to clear the keratin of extraneous material which obscures the fungus. Gentle heating is helpful, but not essential. In hot climates the rate of evaporation from potassium hydroxide is such that crystals form and it is best to renew the solution regularly.

Finding parasites

A microscope is essential for the diagnosis of mycelia, lice, and other parasites. Vaseline placed over the aperture of a 'boil' raised by bot or tumbu fly larvae may force their emergence since they cannot survive without oxygen. If onchocerciasis is suspected, a new itchy papule can be picked up on the end of a needle, quickly snipped, placed in saline, and examined under the microscope to see whether microfilariae swim out. Scabies mites can be picked out of the end of the burrow on the fronts of the wrists and between the fingers.

Wood's light

Ultraviolet-A rays (UVA, 360 nm) (Wood's lamp) highlight white areas in white skin, as in tuberous sclerosis, and are helpful for identifying *Microsporum audouini* and *M. canis*, which fluoresce green. Erythrasma due to *Corynebacterium minutissimum* fluoresces coral red. Porphyrins in teeth or urine fluoresce pink, and anaerobes such as *Bacteroides melanogenicus* in wounds and ulcers fluoresce red.

Biopsy investigations

The lesion chosen for biopsy should not be modified by excoriation, therapy, or secondary infection. For interpretation, the histopathologist will need some history, such as the site, duration, and appearance of the rash (macular, papular, vasculitic, vesicular), whether it is itchy, and whether the lesion is recent, established, or resolving. A drug history is of particular importance. If possible, a provisional diagnosis and one or two differential diagnoses should be provided. Multiple biopsies from different sites taken from lesions in different stages of development are helpful.

Collection and transport of biopsy samples

Samples for direct immunofluorescence

Direct immunofluorescence is useful for the diagnosis of cutaneous lupus erythematosus (biopsy preferably taken from the centre of the lesion) and vesiculobullous disorders (preferably perilesional skin for suspected bullous pemphigoid, or non-lesional skin for pemphigus or dermatitis herpetiformis).

It is best to provide the biopsy material as a separate specimen rather than dividing it for use in other investigations, this prevents the histological appearance of a crush artefact. The specimen must be received fresh (not in formalin), either in saline-soaked gauze or in an empty container placed inside a larger container containing ice. Ideally, the specimen should be received by the laboratory within 4 h of its removal. A biopsy can remain preserved in saline-soaked gauze for up to 24 h; however, the longer the time, the greater is the risk of a false-negative result. As a last resort, honey is a good preservative.

Samples for microbiology

If infection is suspected, a separate biopsy from the lesion should be submitted fresh in a sterile container. Ideally, it should be placed in sterile, saline-soaked gauze and received by the laboratory within 4 h.

Histological terminology and definitions

The histological report may include the following terms:

- *Hyperkeratosis*: thickening of the horny layer usually resulting from the retention and increased adhesion of epidermal cells.
- *Parakeratosis*: cell nuclei in the horny layer usually resulting from a high rate of cell turnover as in psoriasis.
- *Spongiosis*: separation of cells within the spinous layer by oedema fluid, i.e. the epidermis looks like a sponge—a feature of eczema. Severe spongiosis produces vesicles that may coalesce into blisters.
- *Acantholysis*: loss of cohesion between prickle cells and isolation, and balloon-like appearance of individual epidermal cells, a feature of the blistering disorder pemphigus.
- *Liquefaction*: degeneration and rupture of basal cells—characteristic of lupus erythematosus, lichen planus, and erythema multiforme.
- *Pigmentary incontinence*: the shedding of melanin from the epidermis into the dermis following injury to the basal layer.
- *Elastotic degeneration*: changes in dermal collagen that occur in light-exposed and ageing skin; whorled masses of disorganized elastin-staining fibres replace normal collagen.
- *Fibrinoid degeneration*: deposition of eosinophilic material resembling fibrin.
- *Necrobiosis*: a type of focal necrosis of collagen that leads to the formation of a palisading granuloma, i.e. macrophages lining up like a fence around the necrotic material.
- *Lichenoid*: a heavy infiltrate of white cells hugs the epidermal interface with the dermis and fills the upper dermis.

The basis of rashes

The skin is not homogeneous. It varies in its thickness, rate of epidermal turnover, amount and quality of hair, sebaceous glands, sweat, etc. Some rashes follow the distribution of a particular skin component; for example, of hair follicles in folliculitis (Fig. 8), sweat glands in prickly heat, sebaceous glands in acne vulgaris, dermatomes in herpes zoster, or annular and reticulate patterns as in some rashes determined by the vascular anatomy.

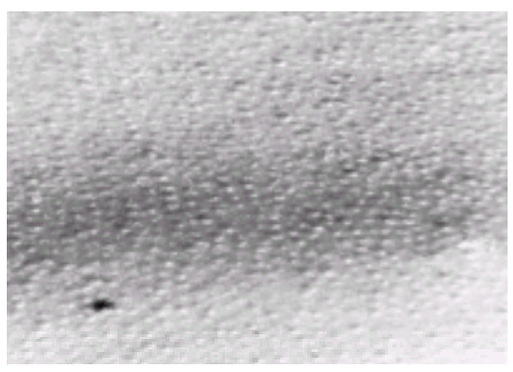

Fig. 8 Perifollicular hyperkeratosis having the distribution of the hair follicle.

Inflammation near the surface of the skin usually damages the epidermis so that vesiculation scaling or erosion become a feature of the response. In contrast, deep dermal or subcutaneous inflammation merely produces 'lumps' known as nodules, and swelling or redness with intact skin markings and no distortion of the epidermis may be the only feature. Rashes may be fundamentally classified into epidermal conditions and dermal conditions: those causing epidermal rashes are included in Table 1, and conditions causing deep dermal rashes are shown in Table 2.

Pityriasis lichenoides, pityriasis rubra pilaris, mycosis fungoides, lichen planus, discoid lupus erythematosus, and Darier's disease are examples of epidermal rashes with specific histology. A biopsy to confirm the diagnosis is recommended if these disorders are suspected. The management of some of these disorders is complex, and a pretreatment biopsy is helpful to document the diagnosis histologically before the morphology of the rash is altered by treatment.

Almost all dermal rashes will require a biopsy to confirm the diagnosis. Occasionally, rashes will be polymorphous with various sites showing epidermal and others dermal change. This is common in epidermal rashes, particularly when they are partly treated. By definition, dermal rashes show no epidermal change whatsoever, even if only 5 per cent of the rash shows epidermal involvement it is still considered an epidermal rash.

The rate of development of the rash is often determined by the type of inflammatory response—oedematous weals or blisters are more acute than white-cell infiltration, purpura, or pustules, and ischaemic necrosis and exfoliation are late responses.

The clinician is a detective and in assessing physical signs must know the sequence of events leading up to what can be seen. The distribution of the rash and its minutest morphology are important. Some classical distributions are shown in Fig. 9 and Fig. 10, while Table 3 illustrates some well-known morphological terms and Fig. 11 and Fig. 12 show some other shapes.

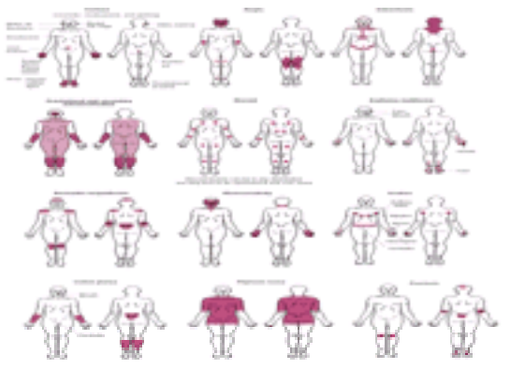

Fig. 9 Distribution of rashes.

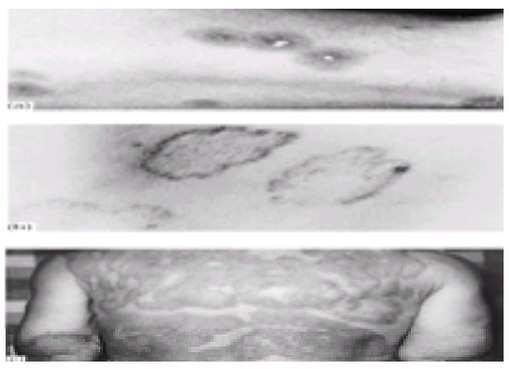

Fig. 10 (a) An example of the 'target' lesion of erythema multiforme. (b) Healing of the centre of the lesion is a feature of many skin diseases, including fungus infections and, in this case, psoriasis. (c) Annular erythema in lupus erythematosus with Ro antibody. This pattern of widespread erythema is also observed in association with underlying malignancy.

Fig. 11 Example of a linear distribution, in this case lichen planus. The distribution does not conform to a dermatome and the exact cause of the linear lesions remains largely unexplained.

Fig. 12 A primary chancre of the lower left eyelid illustrating how skin diseases due to exogenous causes are often asymmetrical.

The management of skin disease requires the elimination of possible agents causing injury and the recognition and treatment of altered host responses. Endogenous

rashes tend to be symmetrical, whereas biting insects and fleas, for example, will produce groups of bites quite indiscriminately. Unlike the rashes of secondary syphilis, the site of the primary chancre is not influenced by host symmetry (Fig. 12). Fungus infections such as cattle ringworm or even *Trichophyton rubrum* in humans are frequently more obvious on one side of the body than another, whereas psoriasis is usually exactly symmetrical.

Injury to the skin from contact dermatitis usually has the distribution of contact; in cases due, for example, to mascara, gloves, or shoes, there will be symmetry (Fig. 13), but casually brushing against a noxious plant will produce bizarre asymmetrical patterns. Scratching spares the centre of the back, and a completely clear area between the shoulder blades when the rest of the body is covered with scratch marks (Fig. 14(a)) suggests that the cause of the rash is the injury done by such scratching. Scabies mites do not seem to like climbing about in hairy areas, so usually spare the head but favour between the fingers, the front of the wrists, or the glans penis.

Fig. 13 Occasionally, symmetry in the distribution of contact may be due to a symmetrical application as in the case of this glove dermatitis.

Fig. 14 (a) The central area of the back is spared from this dermatosis induced by scratching, simple because the patient is unable to reach the site. (b) External irradiation from the sun spares the area beneath the lobes of the ear and under the chin in this case of solar dermatitis. (c) Small islands of unaffected skin scattered throughout a generalized redness and keratoderma are characteristic of pityriasis rubra pilaris.

External irradiation from the sun spares skin beneath the lobes of the ear and under the chin (Fig. 14(b)), whereas an airborne pollen dermatitis will not spare such areas but may have a similar cut-off point below the collar. Small islands of normal skin in a generalized erythroderma are characteristic of pityriasis rubra pilaris (Fig. 14(c)).

Recognizing the signs of exogenous injury make it easier to eliminate the cause. Unfortunately, much skin disease is due to altered host responses, known as 'vulnerability'.

Vulnerability

This is a common characteristic in skin disease, and is seen in dermatitis due to the irritants affecting vulnerable atopic skin. It is seen in the haematogenous localization of immune complexes or other agents at sites altered by previous injury. It is also seen in the Koebner phenomenon, a term used to describe the development of psoriasis, warts, or lichen planus when the skin is injured to a degree that, in most people, would produce no more than a temporary wound but in predisposed individuals results in a recognizable skin disease.

Vulnerability is well worth recognizing because it may be possible to treat the predisposition when it may not be possible to eliminate the trigger. Thus, those whose skin breaks down too easily from unavoidable exposure to solvents may be helped to retain their job by liberally applying emollients.

Recurrent episodes of vasculitis in the legs due to immune complexes may be reduced by more frequent elevation of the legs, the use of supportive bandages, and the avoidance of cold environments. Vulnerability in the legs is due to the chronic stress of blood stasis and venous hypertension, which can be shown to cause inhomogeneity of capillary vessel patterns, adhesiveness of endothelium to leucocytes, and reduced fibrinolysis.

The ecology of the skin, with its integrated, well-balanced interaction between bacteria and surface secretions, also determines the skin's response at its interface with the environment. Erythrasma, pitted keratolysis, pityriasis versicolor, and seborrhoeic eczema are partly constitutional and partly due to exogenous organisms. The seborrhoeic diathesis is poorly understood but such persons seem especially vulnerable to colonization by immunogenic organisms.

Factors determining or modifying skin disease

Changes of skin with age, gender, and race

Newborn–childhood

Birthmarks are usually first noticed in the newborn but some, like cavernous haemangiomas, may not be present on the first day of life. Certain epidermal or so-called 'congenital-type' pigmented naevi do not appear until puberty. In type 1 neurofibromatosis, café-au-lait macules and Lisch nodules may not appear until the child is 5 years of age, axillary freckling is uncommon before the age of 3 years, and neurofibromas tend not to appear until puberty. Only the plexiform neurofibromas present at birth. Some birthmarks have important diagnostic significance indicating serious systemic disease. Examples are the hypopigmented lesions of tuberous sclerosis (see Fig. 65) and the telangiectatic lesion of the Sturge–Weber syndrome.

Fig. 65 Typical oval or 'leaf-like' hypopigmented lesions of tuberous sclerosis. They are present at birth.

Puberty

Secondary sexual characteristics develop at puberty, and at the same time an increase in susceptibility to apocrine diseases, sweating, and blushing is characteristic. Acne vulgaris is mainly a problem for the teenager. Certain diseases such as ichthyosis and eczema tend to improve, while others such as herpes simplex infection and psoriasis are more common. Naevi, particularly pigmented ones, tend to become more prominent.

Pregnancy

See Chapter 13.13.

Old age

Skin diseases in old age are common and reduce the quality of life. Most elderly people have multiple skin problems, including seborrhoeic eczema, intertrigo, and dermatophytosis. Probably the principal characteristic of elderly skin is its inhomogeneity or the increased diversity that develops with age. Some changes are endocrine-related, such as hirsutism and baldness. Others are more specifically age-related, like dryness, decreased sweating, or poor healing of superficial wounds. Dry, scaly, rough skin occurs in about 80 per cent of people over the age of 75, as well as disparities in the size and thickness of the epidermis and in its pigmentation. Seborrhoeic warts are universal and actinic injury, Campbell di Morgan spots, and dilatation and derangement of superficial venules are common. For reasons that are still obscure, some diseases are age-related: for example, pruritus, pemphigoid, and lichen sclerosus et atrophicus.

Degenerative disease and the cumulative exposure to solar radiation explains neoplasia of the skin. Degenerative disease of the vascular system explains venous ulcers and arterial ischaemic diseases. In one study, after controlling for age, sex, and sun exposure, premature wrinkling increased with years of smoking. Heavy smokers were 4.7 times more likely to be wrinkled than non-smokers.

Race

Differences in populations are partly explained by genetic factors, but so much adaptation to the environment occurs that customs and diet may determine some attributes. Although it is frequently reported that certain diseases are absent in tropical climates, this is probably because they have never been looked for or recognized. Erythema is violaceous so that purpura may be difficult to detect in people with dark skins; minor skin problems may not be complained of in the tropics, where many neoplastic and inflammatory diseases are so florid and attendance for advice is so often delayed. A move to a more temperate climate is often associated with urbanization, which can equally influence the skin. The most easily recognized difference between one person and another is their skin colour, and the consequences of sun exposure are much reduced in those with dark skins. Vitiligo is probably more common in the Caucasian races of the Middle East, North Africa, and India. The Japanese rather readily seem to develop a slate-blue or ashy discoloration of the trunk following inflammatory disease. On the other hand, acne vulgaris is uncommon in Japanese people, while both acne and rosacea seem to be uncommon in those with black skins. However, comedone formation due to cosmetics without full-blown acne is common in black skin. Blackness is due to more evenly dispersed, larger and less degradable pigment granules. The stratum corneum of black skin is more compact with a higher lipid content and is subject to less penetration by irritants. Another easily recognized factor is hair size and shape. Facial hirsutism is rare in Japanese women and relative sparseness of hair is a feature of mongoloid races. On the other hand, Mediterranean and some Indian races seem to be particularly hirsute (Fig. 15). The shininess of black skin is partly due to sebum and partly to thermal stress which encourages increased eccrine sweating. Such skins tend to become rather dry in a temperate climate. Scales show up on dark skins. Keloids are a considerable problem for Afro-Caribbeans and can sometimes be massive. Susceptibility to infection depends on immunological factors and on previous exposure. As with malaria or syphilis, some populations seem to acquire a genetic resistance to tuberculosis and leprosy.

Fig. 15 Hair growth on the forehead of an Indian child. This is entirely within normal limits and is of racial origin.

Is it contagious (Table 1, Table 2, Table 3, Table 4, Table 5, Table 6 and Table 7)?

Physicians are often asked whether a skin disease is 'infectious'. The questioner really means, 'Did I catch it?' 'Can I give it to someone else?' 'Is the treatment of choice a simple antiseptic or antibiotic regimen?' The physician may ask, 'Am I missing something which is a danger to other patients in the the ward or to my nursing staff?' Infections are often present in several members of the family at the same time (Fig. 16).

Fig. 16 Infections such as impetigo are highly contagious and tend to be found in more than one member of the family, as in these triplets.

There are many infections, dealt with elsewhere in this textbook, in which a highly virulent organism has broken the defences of a normally resistant host, but there are also organisms that are usually harmless but occasionally, because of immunosuppression or other changes in the host, produce a rash. Pityriasis versicolor, candidiasis, erythrasma, and trichomycosis axillaris, all discussed in Section 7, are examples. More difficult is the relationship with staphylococcal or streptococcal bacteria—although these generally sit in silence on the skin, they are unwelcome in a ward full of more susceptible and vulnerable patients. Psoriasis is not infectious, but the massive exfoliation from such a patient is a great source of cross-infection. Bacterial spread by skin scales is generally considerable and the basis of surgical gowning. Few would feel bound to treat every patient with psoriasis for bacterial infection, but the same degree of infection in atopic eczema is thought to be contributory to the disease, perhaps through a bacterial superantigen effect.

Pathology from skin infection is more common in hot humid climates, and erosions from scratching, prickly heat, and other infections (such as lice or scabies) predispose to boils and other patterns of pyoderma, especially in the groins and axillas.

The primary pathology of infection is often asymmetrical, but an immune response attempting to get rid of it is usually exactly symmetrical and takes 5 to 10 days to develop.

The most difficult diagnostic problem is that of viral disease. The hospital doctor is not well placed to recognize its variety. Rather, it is the general practitioner called to the patient's home who sees virus disease in its early stages or in its transient phase. It is essential to know what rashes are currently endemic.

People with rashes due to infection commonly have an associated fever, lymphadenopathy, coryza, diarrhoea, vomiting, hepatomegaly, or headache. However, the abrupt sterile pustulation of generalized pustular psoriasis (Fig. 17) or the painful deep swelling of delayed-pressure urticaria or vasculitis will also be accompanied by high fever and a neutrophil leucocytosis, but usually there is no lymphadenopathy in these non-infectious processes. Erythema multiforme, Sweet's disease, and toxic epidermal necrolysis similarly show great systemic effects. Since people with widespread skin disease may be unable to control their body temperature, high fever in such persons is not necessarily a sign of infection.

Fig. 17 Pustules are not necessarily due to infection. These pustules are from pustular psoriasis and are sterile.

When the diagnosis is in doubt, good practice is to take adequate swabs and specimens for culture and histological examination, and to treat and touch the patient as his or her comfort requires. Washing the hands suffices to avoid the transmission of scabies, fungus, and most bacterial diseases as well as warts and syphilis. However, practitioners should take the utmost care to avoid inoculating their skin when taking scrapings or biopsies. Patients with much exfoliation should not be nursed on a general ward, but in a single cubicle.

Pustules need not be caused by infection; for instance, the primary lesions are always sterile in psoriasis or an irritant folliculitis from oils. Vesicles need not be due to viruses since they are a feature of papular urticaria, dermatitis hepetiformis, and vasculitis (see Fig. 83). Dark skins exposed to much oil and cosmetics often have a chronic pustular dermatosis of the lower legs that may be sterile.

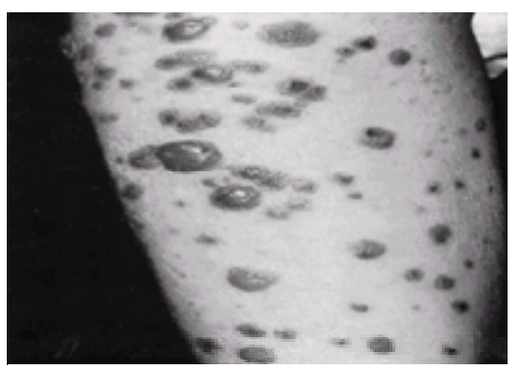

Fig. 83 The presence of blisters in vasculitis is due to the intensity of the oedema in the upper dermis; sometimes it is due to necrosis.

Humidity is a principal cause of profuse skin infection, and treatment by cooling and drying has always been a standard therapy for infected eczema. The fact is that drying is promoted by the use of wet dressings and the consequent evaporation. Wet dressings that are occlusive and changed infrequently encourage infection: ideally, they should be changed every 2 to 4 h. Occlusive surfaces, for instance between the toes, the groins, and the breasts, need to be treated with drying agents (such as those commonly present in deodorants (aluminium chloride)) or with powders. Dry mopping of the ear in otitis externa is similarly helpful.

In some parts of the world, skin clinics are overwhelmed by massive numbers of patients suffering from scabies (Fig. 18), staphylococcal and streptococcal infection, and dermatophytosis. Control is impossible because reinfection is inevitable. Soap and water do much to reduce the incidence of common dermatoses, but water is too valuable to use for washing when there is a drought.

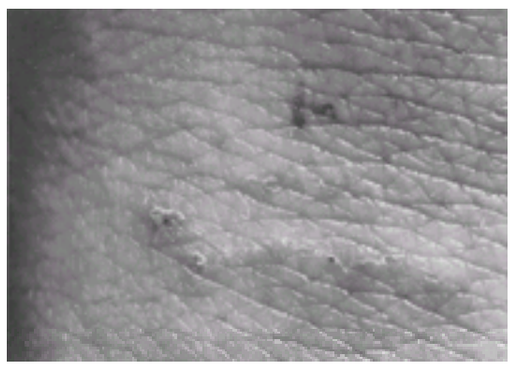

Fig. 18 The diagnostic feature of scabies. The burrow of the mite in the horny layer of the epidermis. The dark spots are haemoglobin in the belly of the mite.

In Mediterranean countries, ringworm of the scalp would be easy to manage (Fig. 19) were it not that the population explosion provides more children for infection than it is possible to treat, and that subclinical infections are difficult to recognize.

Fig. 19 Multiple exudative lesions due to tinea capitis.

Is it hereditary?

See Chapter 23.2 for a complete discussion.

Is it due to malnutrition?

Skin diseases resulting from malnutrition have been termed the 'dermatoses of the poor'. Although they are common in starving communities, they are also seen in those living only on drugs or alcohol, those suffering from malabsorption syndromes, and those debilitated by neoplasia or severe chronic infections. Increasingly, elderly patients suffering from dementia are responsible for more cases in Western urban communities. Poor personal hygiene and lack of, or failure to use, water supplies contribute to some aspects of skin diseases in malnutrition, as well as to the infections of both skin and mouth which often accompany them.

The skin makes up 8 per cent of body weight and uses up about one-eighth of the body's protein; hence it is affected early in malnutrition.

In experimental malnutrition and in studies of people during the Second World War, early signs were dryness of the skin and hyperpigmentation. At birth, malnutrition is seen as loss of vernix and maceration. At all ages the skin is wrinkled and peeling with deficient subcutaneous fat. Older persons proceed to a mild ichthyosis and the associated hyperkeratosis is often a sign of slow turnover. The dry scale is well knit and retains pigment, and histologically may be dense and homogenized. The stratum corneum is unsupple and cracks appear in the horny surface, particularly on the front of the legs (Fig. 20). It is known as eczema craquelée and such eczema that develops is often well marginated, unlike other forms of endogenous eczema.

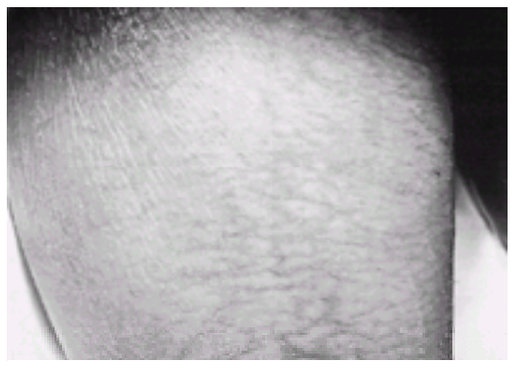

Fig. 20 An early and common sign of malnutrition of the skin, especially in the elderly, is cracking of a well-made stratum corneum giving a pattern of eczema craquelée.

Most malnutrition is a consequence of mixed deficiencies including protein loss. There is weight loss, weakness, and emaciation. Anaemia, oedema, sore tongue, and dry, thin hair are often features.

Vitamin A deficiency should be thought of when there is significant dryness of the eyes and perifollicular hyperkeratosis. It is the commonest preventable cause of blindness.

Vitamin B deficiency causes a dermatitis that has a seborrhoeic distribution, particularly of the nasolabial folds, scrotum, and vulva. The lips are dry, cracked, crusted, or ulcerated; the tongue is sore and smooth.

Nicotinic acid deficiency or pellagra causes the well-known triad of dementia, diarrhoea, and dermatitis. Early signs are prominent sebaceous follicles of the nose. The light-sensitivity dermatosis is also exacerbated by heat, friction, and pressure. The erythema is a characteristic dusky brown and the dermatitis is well marginated. In dark skins the lesions are relatively depigmented but equally well marginated.

Vitamin C deficiency causes perifollicular haemorrhages, painful bruising, or woody oedema of the legs. This means that they look oedematous but are hard to the touch. In a dark skin it may appear that the skin is stretched and shiny. Although coiled hairs are an early sign, they are common in the normal population, especially in the elderly. Swollen and bleeding gums are an important sign but occur only in those with teeth. Vitamin C deficiency should be considered in any non-healing

wound.

Protein deficiency is common in all forms of malnutrition. However, a characteristic disease is recognizable when the protein deficiency is supplemented by carbohydrate and there is no active starvation. In children this is typified by kwashiorkor. Features of protein deficiency include:

1. erythema as in a second-degree burn;
2. dry hyperkeratotic hyperpigmented scales;
3. peeling like enamel paint, cracking like crazy paving;
4. skin signs are maximal over pressure areas; and
5. there is straightening and reddening of the hair.

In some dark skins, raised annular patches of pigmented scales on the trunk are an early sign of malnutrition. This is known as pityriasis rotunda.

Management includes avoiding secondary deficiencies, since the sudden provision of some but not all the necessary foods may precipitate conditions like blindness from vitamin A deficiency. In malnutrition, zinc may be lacking or poorly absorbed, leading to alopecia, diarrhoea, glossitis, and an eroded perioroficial rash called acrodermatitis enteropathica. Some improvement in the rash of kwashiorkor has been described using local zinc ointments, and with the prescription of other trace elements such as selenium.

Is there an association with a systemic disease?

There is a number of associations of skin disease with diseases of the gastrointestinal tract and haematological, cardiovascular, respiratory, renal, and central nervous systems. However, no completely satisfactory system for listing these has been devised. Many of the skin diseases are discussed more fully in other sections.

Gastrointestinal system

Oral mucosa

Leucoplakia may be associated with Darier's disease, pachyonychia congenita, or simple white sponge naevus. It is premalignant in dyskeratosis congenita. In mucocutaneous candidiasis oral candida is associated with nail dystrophy, alopecia areata, and endocrinopathy. Oral hairy leucoplakia is a sign of the acquired immunodeficiency syndrome (**AIDS**). Major aphthous ulcers are a feature of Beçhet's syndrome, while minor aphthae are found in systemic lupus erythematosus, Crohn's disease, as well as iron and folate deficiency states.

Oesophagus

Bullae are common in epidermolysis bullosa, and occasionally the entire epithelial lining of the oesophagus may be coughed up as a cast. Bullae also occur in pemphigus and mucocutaneous pemphigoid. The superficial erosions that follow rupture of the bullae in pemphigus heal without scarring, while scarring and stricture formation complicate healing in mucocutaneous pemphigoid and epidermolysis bullosa. Stiffness and loss of peristalsis frequently occur as an early sign in scleroderma, best demonstrated by a prone barium swallow. Carcinoma of the oesophagus has been associated with plantopalmar hyperkeratosis (tylosis). Webbing of the postcricoid region with anaemia is associated with dyskeratosis congenita—an atrophy of the skin and nails.

Stomach

Pernicious anaemia is an organ-specific autoimmune disease leading to atrophy of parietal cells that clusters with vitiligo and alopecia areata. Carcinoma may present with acanthosis nigricans (Fig. 105) and tripe palms. Gastric polyposis is associated with perioral and finger lentiginoses in the Peutz–Jeghers syndrome, as well as with nail dystrophy and alopecia in the Canada–Cronkite syndrome.

Fig. 105 Acanthosis nigricans: a darkening and thickening of the skin with a tendency to papilloma formation. The angles of the mouth are often involved, as in this patient with carcinoma of the lung.

Gastrointestinal bleeding is a consequence of telangiectasia in hereditary haemorrhagic telangiectasia as well as in acrosclerosis with telangiectasia. It may also occur in disorders of elastic tissues such as Ehlers–Danlos syndrome or pseudoxanthoma elasticum. Henoch–Schönlein purpura usually causes lower gastrointestinal bleeding.

Malignant atrophic papulosis (Degos' disease) is a rare vasculitis of the skin, gastrointestinal tract, and brain. The skin lesion is a porcelain-white punctate scar and the viscera suffer from infarction.

Small bowel

Regional ileitis may present with granulomatous swelling of the buccal mucosa or lips as well as with perianal granulomas and fistulas (Fig. 21). Erythema nodosum, oral aphthous ulcers, and pyoderma gangrenosum are also associated with Crohn's disease, along with any secondary skin changes due to malabsorption.

Fig. 21 Perianal granuloma in Crohn's disease.

Dermatitis herpetiformis is associated with subclinical coeliac disease and may be complicated by small bowel lymphoma. Pigmentation and malnutrition of the skin is particularly recorded in Whipple's disease. Bowel bypass syndrome due to anatomical blind loops may present with widespread pustules and vasculitis ulcers. Metastatic carcinoid syndrome produces characteristic flushing.

Colon

Ulcerative colitis is responsible for many disorders of the skin and mouth, but aphthous ulcers are more common here. Rashes include erythema multiforme, erythema nodosum, and pyoderma gangrenosum. Perianal abscesses and fistulas are also common associations.

Dermatomyositis is most commonly associated with carcinoma of the large bowel.

Pancreas

Paraneoplastic migratory thrombophlebitis (Trousseau's sign) is most likely to be associated with carcinoma of the pancreas. Acute fat necrosis of the trunk or limbs is a consequence of acute pancreatitis. There is an increased electrolyte concentration in the sweat of patients with cystic fibrosis.

Glucagonoma produces the characteristic eruption of necrolytic migratory erythema. The skin lesions are dusky red, annular, and scaly with a vesicopustular element due to epidermal-cell necrosis in the most superficial layers of the epidermis. In addition to the skin changes seen as a complication of diabetes, diabetes mellitis is directly associated with a number of skin disorders. Diabetic dermopathy produces hyperpigmented dull-red papules with superficial scale on the shins of 30 to 60 per cent of patients with diabetes. It heals with atrophic brown scars. Diabetic thick skin is also common, and may manifest as a generalized process in 20 per cent of cases or be localized to the neck and upper back (scleroedema of Bushcke), the fingers (Huntley's papules), or the back of the hands (cheirarthropathy). Acanthosis nigricans and anogenital pruritis are common in obese insulin-resistant diabetic patients, while generalized granuloma annulare, diabetic bullae, lipoatrophy, diabetic yellow skin, and perforating disorders are all uncommon.

Necrobiosis lipoidica diabeticorum (**NLD**) (see Fig. 114) is a characteristic eruption consisting of yellowish to red-brown plaques on the shin, which eventually become atrophic in the centre and may ulcerate. Potent topical steroids or intralesional injection of triamcinolone may be required to control NLD, but care is required as they have a tendency to aggravate the atrophy. NLD occurs in 0.3 per cent of diabetic patients and pre-dates diabetes in 30 per cent.

Fig. 114 Necrobiosis lipoidica usually affects the skin of the shins. The yellowish atrophic plaques are associated with diabetes mellitus.

Although diabetes may be complicated by skin infections such candida or bacterial furuncles, a dermatophytic infection is no more common than in non-diabetic patients. Hyperlipidaemia may be associated with xanthoma, neuropathy with foot deformity and ulceration, and angiopathy with cold, pale hairless legs. NLD, diabetic dermopathy, the erysipelas-like erythema seen on the legs and feet of elderly people with diabetes, and the diabetic rubeosis of the face are all thought to be due to microangiopathy.

Liver

The skin consequences of liver disease include spider naevi, palmar erythema, purpura and bruising, white nails, and clubbing of the fingers. There is loss of hair in the beard, axillas, and pubic region. Gynaecomastia, acne, Dupuytren's contracture, xanthoma, jaundice, pruritus, and pigmentation are other features.

A number of patients presenting with porphyria cutanea tarda or lichen planus will be found to be infected with the hepatitis C virus. Hepatitis B infection is associated with polyarteritis nodosa and the childhood exanthem of pink palpable lesions named the Giannoti Crosti syndrome. A proportion of patients with non-infectious or autoimmune hepatitis will have cutaneous features of lupus or sarcoidosis. Haemochromatosis produces diffuse skin pigmentation and patients may develop hepatocellular carcinoma.

Other systemic manifestations in the skin

These include renal disease in cutaneous vasculitis and lupus erythematosus. Cardiovascular disease and skin disease occur with carcinoid, or secondary to amyloid, scleroderma, as well as subacute bacterial endocarditis, which may produce nodules in the skin—Osler's nodes. Myxoma is recorded with pigment anomalies of the skin in the **LAMB** (lentigenes, atrial myxoma, mucocutaneous myxomas, blue naevi) and **NAME** (naevi, atrial myxoma, myxoid neurofibroma, ephelides) syndromes. Disease occurring in the CNS is observed in Beçhet's syndrome, sarcoid, lupus erythematosus, and with vascular stenosis and livedo reticularis (Sneddon's syndrome). There is also respiratory failure in sarcoid, Churg–Strauss vasculitis, and asthma is common in atopy. Haematological associations include Sweet's acute febrile neutrophilic dermatoses, pyoderma gangrenosum, leukaemia-associated genodermatoses, leukaemia cutis, B-cell lymphoma, and Hodgkin's disease.

Is climate responsible?

Heat, cold, food, and water are all dependent on the climate. The management of skin disease requires washing, soaking, and adequate nutrition as well as control of body temperature. Children and the newborn are particularly susceptible.

Humidity explained why, 70 per cent of lost combat man-days in Vietnam during the rainy season were through skin disease. The distribution of water determines the ecology of many human parasites, such as biting insects that thrive in the rainy season. Wet clothing can cause severe discomfort (particularly inside a boot, around the waist, or between the legs) while marching. Even in the Arctic, occlusive clothing can accumulate much sweat and make walking impossible. 'Immersion foot' and 'paddy foot' can bring a military campaign to an end. In Kuwait, outbreaks of industrial dermatitis were blamed on the absorption of allergens by the skin that become moisturized in certain seasons, while in Scandinavia a low humidity in some factories accounted for drying of the epidermis and consequent irritant dermatitis.

Seasonal variations not only account for increased bacterial injury and epidemics of viral exanthems, but also for eczema; for example, in the atopic patient sensitive to sunlight, or the allergic contact dermatitis due to handling plants seen so often in market gardeners and florists. Sweaty feet in hot weather increase the dermatitis from footwear, and sweat-pore occlusion encourages widespread bacterial infections in extreme heat. The incidence of some disease is influenced by height above sea-level and by the thickness of the atmosphere. People are less likely to be sun-burned at the low level of the Dead Sea where UVA greatly predominates over

UVB, but actinic dermatitis is common in Mexico and in the Andes. Many infections are most exuberant at sea-level. At the slightly higher level of 600 to 1500 m, transmission of leishmaniasis and onchocerciasis by flies is more common. Many of the skin diseases caused by infections with a unique geographical distribution are discussed in Section 7, including pinta, buruli ulcer, or deep mycoses. In this chapter they are only mentioned if they are important in the differential diagnosis of some physical sign, such as depigmentation, wartiness, and blisters.

Both cold weather and low humidity predispose to irritant dermatitis; for instance, the high incidence of dry skin in hospital is explained by the central heating and the very light clothing worn. Pediculosis is encouraged when people huddle together to keep warm.

While much is said about changes in the world's climate, less is said about changes in the skin's microclimate. These are brought about by changes in home heating and bed linen, as well as by clothing, including footwear. Duvets encourage perspiration and can exacerbate nocturnal itch and scratch. Plastic-soled shoes also increase foot temperature and perspiration and lead to tinea, pitted keratolysis, or juvenile plantar dermatosis. The skin, like antique wooden furniture, suffers from contemporary Western overheating and the resultant drying out. Dermatitis is one consequence. The second commonest environmental cause of neonatal mortality is hypo- or hyperthermia.

Cold

Every polar explorer who is inadequately protected will suffer frostbite, snow blindness, and even death. Although the majority of people in more temperate climates do not die of cold, individual susceptibility to its effects varies. A high incidence of skin disease can be attributed to inadequate protection against minor degrees of cold injury. Vasoconstriction and increased blood viscosity mediate internal disease.

It is often noted that residents of the United Kingdom have pink cheeks and blue hands to a degree not seen in, for instance, Australia or the United States. This is because of chronic exposure to cooling. In Canada or Scandinavia where the winters are a danger to the unprotected, there would be no such exposure of the schoolchild or teenager as seen during the winter in the United Kingdom, where 10 per cent of the population are affected by chilblains, acrocyanosis, Raynaud's phenomenon, and the various manifestations of perniosis, an incidence never approached in most other parts of the world.

Chronic cold causes thickening of the subcutaneous and dermal tissues, as in pigs. During the miniskirt era, girls' thighs regularly became fatter in temperate climates. Fat insulates the surface of the skin from the inside, so cooling of the surface is obvious. Chronic cooling causes telangiectasia, which is often perifollicular, and sometimes even angiokeratoma. Pink cheeks are one consequence, but similar changes may be seen over the fat of the calf or upper arm. Cooling causes stasis in the venules so that circulating noxious agents, such as immune complexes and bacteria, usually localize and deposit at such sites.

The anatomy of the skin vasculature is such that cooled skin often shows a pink and blue mottling known as cutis marmorata. If the changes are fixed and do not reverse with warmth, for example in a hot bath, it is then known as livedo reticularis (Fig. 22(a)). This is commonly seen in collagen vascular diseases such as lupus erythematosus. Much disease is localized in the venules of such damaged vasculature. Chilblains or perniosis is essentially a cold-induced ischaemia. Pressure from tight clothing often encourages the damage done by cooling (Fig. 22(b)).

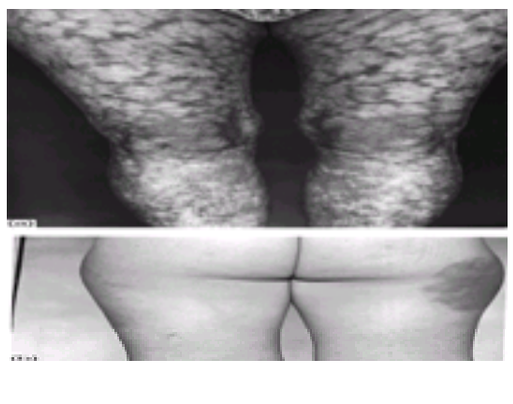

Fig. 22 (a) Chronic vascular disease, especially if inflammatory, summates with the physical effects of cooling to produce livedo reticularis. A non-inflammatory variety associated with cerebrovascular disease is known as Sneddon's syndrome. (b) An equestrian chilblain is due to the combination of the insulating effect of fat and pressure from tight jeans in a young girl riding on a damp and frosty morning.

Ultraviolet radiation and the sun

The sun emits electromagnetic rays comprising a continuous spectrum of short to long waves. Only a narrow range of wavelengths between 400 nm and 770 nm react with photocells in the retina and observed as the various colours of the rainbow. Beyond red (770 nm) is infrared. Heat is due to infrared radiation, which can be felt. Below violet (400 nm) are the ultraviolet (200–400 nm) and X-rays. Most short wavelengths, that can neither be seen nor felt, are filtered out by the Earth's thick atmosphere which includes ozone and water vapour. Therefore, as there is less atmosphere above mountain tops, the danger of radiation exposure is greater. The content of water vapour in the atmosphere varies, which accounts for protection from sunburn in winter, cloudy days, the early morning, or late evening sun. The thick atmosphere of the low-lying Dead Sea in Israel and Jordan is also protective against UVB radiation. Glass filters out wavelengths below 320 nm, so that the closed windows of a car will protect even in a tropical desert unless one is sensitive to the longer wavelengths of ultraviolet radiation. Porphyria is, for example, a disease triggered by UVA radiation and is thus difficult to protect against by shade, cloud, or glass.

Ultraviolet radiation (**UVR**) is arbitrarily divided into UVC (200–280 nm), UVB (280–320), and UVA (320–400 nm). The principal effects of ultraviolet light on the skin are elastic fibre damage and cutaneous ageing, apoptosis, immunosuppression, suntan, sunburn, and carcinogenesis. While each subclass of UVR can produce all of these effects, UVC is relatively more likely to cause cancer, UVB relatively more likely to produce burning, and UVA relatively more likely to produce ageing. UVA is estimated to be 10 times less effective than UVB at producing a suntan and 100 times less effective than UVB at producing non-melanoma skin cancer. This is the basis of so-called 'safe tanning' using UVA light in solariums. However, high-dose UVA does cause non-melanoma skin cancer. In addition, the spectrum responsible for producing melanoma has not been established and may include UVA.

UVR immunosuppression may lead to the reactivation of herpes simplex. It may also suppress tumour surveillance and thereby enhance carcinogenesis. The immunosuppressive, and hence anti-inflammatory, action spectrum has been defined for psoriasis at 312 nm. UVA is only effective for the treatment of psoriasis when the phototoxicity is augmented by a photosensitizer such as psoralen. The action spectrum for the suppression of atopic dermatitis has not been defined, but the skin of patients may improve when exposed to both UVA and UVB. However, a number of related factors influence the response of atopic dermatitis to sunlight and artificial UVR, including ambient humidity (which tends to moisten skin) and heat (which lowers the threshold to itch and scratch).

The diagnosis of UVR damage is determined by recognizing the distribution of the rash as being typical of exposure. Thus the head, nose, and cheeks are principally affected, but there is often sparing below the eyebrows, under a forelock, beneath and behind the ears, and below the chin (see Fig. 14(b)). The sides and back of the neck are picked out, but there is a sharp border to the sun damage where the collar shields the skin from sunlight. Much, of course, depends on the style of clothing as well as on the direction of irradiation. The backs of the hands and dorsum of the feet are often caught by the sun; however, there may be some tolerance of such skin previously exposed and tanned so that skin not so tolerant is clearly more prone to burning. Mediation of sunburn erythema is partly due to the generation of prostaglandins. Plant dermatitis often produces a rash having the distribution of sun exposure. Phytophotodermatitis is a rash in the distribution of actual contact with plant juices on which the sun then acts and produces a burn. The pattern of such casual contact is often streaky and bizarre. Some perfumes containing berloque or musk ambrette are also responsible (see Fig. 53).

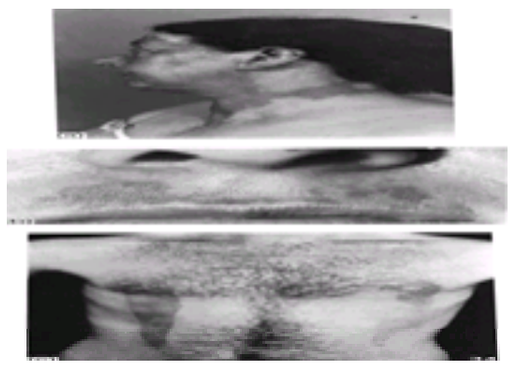

Fig. 53 Pigmentation due to cosmetic agents. Often initially a dermatitis, it is especially induced by exposure to ultraviolet rays. It tends to have the streaky distribution of application. (a) Neck pigmentation from eau de cologne. (b) Lip pigmentation from lanolin. (c) From eau de cologne and sunbathing, the bizarre pattern is characteristic of an exogenous cause.

White skin and the sun

Over the past 50 years, hats, parasols, long skirts, and shawls as well as shady verandas have been replaced by bikinis, solariums, and reckless sun-worshipping. Even redheads and blondes attempt to get a suntan. Only recently through public education has this trend been slowed.

Exposure to sunlight is a major cause of skin ageing and of the epidermal and dermal degenerative diseases that accompany ageing (Fig. 23). In Australia, South Africa, and the south-western United States solar keratosis, basal-cell carcinoma (**BCC**), chronic solar cheilitis, and squamous-cell carcinoma (**SCC**) (Fig. 24) are the commonest reasons for referral to a dermatologist (Table 8). Some two out of every three Australians will develop one or more non-melanoma skin cancers during their lifetime; in Queensland, the lifetime risk of developing a melanoma is 10 per cent. Even children are not completely immune, and persons who burn easily and still persist in exposing themselves regularly to the sun will inevitably suffer gross skin changes, even at an early age. Fortunately, the most common skin cancers have a low potential for metastases.

Fig. 23 Prominent sebaceous glands and comedo formation in solar elastosis.

Fig. 24 Squamous epithelioma of the lower lip as a consequence of sun exposure.

Disorders

Solar keratosis

Solar keratoses are erythematous scaling lesions between 2 and 10 mm in diameter, seen on areas of maximal sun exposure such as the face, dorsum of the hands, forearms, and lower legs. Histologically, these precancerous lesions show dysplasia of the basal keratinocytes. The estimated risk of transformation into either SCC or BCC is very low—1 per cent per annum. Many small lesions resolve spontaneously, particularly with photoprotection. Larger lesions respond to cryosurgery, while patients with multiple lesions may require treatment with topical fluorouracil cream.

Basal-cell carcinoma

Basal-cell carcinoma is a slow-growing invasive neoplasm arising from the basal cells of the epidermis or outer root sheath of hair follicles. Some 50 per cent occur on the head and neck, 30 per cent on the upper trunk, and the remainder elsewhere. BCC can be subdivided into nodular, ulcerated (rodent ulcer), morphoeic, pigmented, and superficial forms. They have a tendency to local invasion, but metastasis rarely, if ever, occurs. Local recurrence is most common with morphoeic BCC. Treatments are influenced both by tumour factors (for example, the size, site, margin definition, and subtype of the BCC) and host factors (for example, general infirmity, coexisting illnesses (such as a bleeding diathesis or susceptibility to bacterial endocarditis), access to local facilities, and patient preference). Options include surgical excision, curettage and electrocautery, radiotherapy, cryosurgery, and injection of interferon-a. Topical immunomodulatory creams, such as imiquimod, are also effective in selected cases.

A number of genetic syndromes of increased susceptibility to BCC have been described. These include the Gorlin syndrome, Bazex syndrome, and Rombo syndrome. Exposure to arsenic also increases BCC susceptibility.

Squamous-cell carcinoma

Squamous-cell carcinomas are faster growing areas of ulceration or tender nodules that occur on areas of maximal sun exposure, such as the dorsum of the hands, balding scalp, face and neck, upper trunk, and lower legs. While UVR is the principal aetiological factor, other predisposing factors include exposure to radiotherapy, chronic leg ulcers, burn scars or sinuses from osteomyelitis, erythema ab igne, and the porokeratosis of Mibelli. Systemic immunosuppression, as used to prevent organ transplant rejection, increases the susceptibility to SCC by 100-fold. In addition, people with xeroderma pigmentosa, dystrophic epidermolysis bullosa,

Rothmund Thomson syndrome, and arsenic exposure have a greater susceptibility to developing SCC. Up to 1 per cent of SCCs will metastasize, most commonly to regional lymph nodes; however, 20 per cent of any metastasis is bloodborne to the liver, lungs, brain, and bone. Survival rates following metastatic SCC are poor, with less than 30 per cent responding to current therapies. High-risk SCCs include rapidly growing tumours, large lesions (>2 cm in size), deeply invading tumours (>4 mm), poorly differentiated tumours or tumours with perineural invasion, recurrent tumours, tumours of the lips or ears or arising within scars, and tumours occurring in immunosuppressed patients.

Following surgery, 75 per cent of local recurrences occur within 2 years, and 95 per cent within 5 years. In addition, patients are at risk of developing a second primary skin cancer. Within 5 years, 12 per cent of patients will have developed a new SCC, 43 per cent a new BCC, and 2 per cent a melanoma.

Melanocytic naevi (moles)

Melanocytic naevi are benign neoplasms of melanocytes. Junctional naevi are localized collections of naeval melanocytes found in the epidermis and superficial dermis, they are flat and pigmented. Compound naevi are localized collections in the epidermis and superficial and deep dermis, these naevi are pigmented and raised. Intradermal naevi are localized collections in the deep dermis with no involvement of the epidermis or junctional dermis, such naevi are flat and flesh-coloured. Most naevi are absent at birth. They tend to first appear and increase in number during childhood, reaching their maximum in early adulthood. Naevi counts have been shown to increase at an earlier age in Caucasians who live closer to the equator, where sun exposure and intensity is greatest.

Large numbers of naevi, both common acquired naevi and atypical naevi, are markers of individuals who are susceptible to developing melanoma. Atypical naevi are large (>6 mm) compound naevi often with a surrounding macular erythematous component, irregular in colour or shape, but nevertheless benign. These lesions may or may not show histological evidence of dysplasia, therefore the old term 'dysplastic naevi', which leads to much confusion, is not recommended. Although the clinical differentiation of atypical naevi from melanoma is difficult, it may be facilitated by regular surveillance and clinical photography. The presence of more than five atypical moles on a person has been shown to be a powerful and independent marker of melanoma susceptibility.

'Congenital naevi' is a term applied both to compound naevi present at birth and to acquired naevi that are clinically and histologically similar to moles present at birth. One child in 100 is born with a congenital pigmented naevus, while 6 to 12 per cent of children and adults have a 'congenital type naevus'. The risk of evolution of a small congenital naevus (<2 cm) into invasive melanoma is unknown, but is thought to be much less than 1 per cent. Prophylactic excision is not universally advocated, but rather considered on a case-by-case basis. Large congenital naevi (20 cm) occur in 1 in 500 000 births and probably carry a 4 to 6 per cent risk of progression to melanoma over a lifetime. The melanoma usually develops after puberty and does not always occur in the naevus itself. Unfortunately, removal of large lesions is rarely easy and may involve numerous surgical procedures.

There may be a natural evolution of acquired naevi from junctional to compound to intradermal naevi. The malignant potential of individual lesions is low, therefore prophylactic excision of acquired melanocytic naevi to prevent transformation into melanoma is not advised. Most melanomas arise *de novo* in the absence of any clinical or histological evidence of a pre-existing naevus. Excision of naevi is advocated where it is not possible to clinically exclude a diagnosis of melanoma. The lesion should be totally excised and submitted for histological assessment. Destructive therapy of melanocytic naevi without histological assessment is a recipe for disaster, for clinical diagnosis is not completely accurate and an opportunity to re-excise an incompletely or inadequately removed tumour may be missed. Patients who subsequently present with metastatic melanoma without an identified primary will rightly or wrongly point the finger at the physician who removed the 'naevus', and claim compensation. Therefore, complete removal and histological examination is advocated even when moles are removed for purely cosmetic reasons.

Melanoma

Melanoma is a malignant neoplasm of melanocytes, which, although initially confined to the epidermis, later invades deeper layers of the skin. Melanoma is one of the most common cancers and cause of cancer-related deaths among adult Caucasians. It is caused by childhood exposure (in particular intermittent exposure) to sunlight resulting in sunburn. The incidence of melanoma increases with age, the lifetime risk for people in the United Kingdom being around 1 to 2 per cent. The greater exposure to sunlight experienced by Australians has increased their lifetime risk to between 3 and 10 per cent, depending on their proximity to the equator. Melanoma is rare during childhood and in Blacks and Asians.

Hutchinson's melanotic freckle occurs on the head and neck of older people who have been heavily exposed to sunlight. These are slow-growing *in situ* melanomas with the potential to progress to invasive melanoma and metastasize. Acral lentiginous melanoma, including subungual melanoma, is equally common in all races and therefore does not appear to be caused by exposure to the sun. A tendency to delayed diagnosis gives this variant a generally poor prognosis.

Superficial spreading and nodular melanomas predominately occur on the trunk in men and on the limbs in women, not necessarily at sites heavily exposed to sunlight. The clinical features of a superficial spreading melanoma include a history of a new mole or a change in the size, shape, or colour of an existing mole. Itching and bleeding are late signs. On examination, melanomas are asymmetrical, irregular in outline and colour, and often stand out as different from other moles on the patient's skin. They are frequently over 6 mm in diameter at the time of diagnosis; however, this feature is now less common than in the past due to improved awareness of the early warning signs by at-risk populations. These signs are illustrated in Plate 1, Plate 2, Plate 3, Plate 4, Plate 5, Plate 6 and Plate 7.

The risk of metastasis, and hence the 5-year survival rate, is related to the depth of invasion of the melanoma measured in millimetres from the granular layer of the epidermis, known as the Breslow thickness. Patients with lesions confined to the epidermis (melanoma *in situ*) have a 5-year survival rate of 100 per cent; those less than 0.76 mm, 98 per cent; between 0.76 and 1.5 mm, 95 per cent; between 1.5 and 3 mm, 80 per cent; and lesions of more than 3 mm in depth, 60 per cent.

At presentation, 10 per cent of cutaneous melanomas will have metastasized. In order to identify the primary lesion it is important to look at the entire cutaneous surface—in the eyes, inside the mouth, and the vulva, etc.—and to examine the skin with a Wood's light (see above), for the primary melanoma may have undergone spontaneous regression after giving rise to metastases and only be identified as a hypopigmented patch under such light.

Metastasis is usually to the regional lymph node basin. If a single lymph node is involved the 5-year survival is 45 per cent, if two lymph nodes are involved the survival rate is 28 per cent, but this rate drops to 9 per cent if more than four lymph nodes are involved. The median survival time following metastasis is between 5 and 16 months. Although systemic metastasis is predominately to the lung, liver, brain, and bone, lesions can arise anywhere including bowel, kidney, and muscle. Localized skin metastasis is also common.

In general, there is a low yield from routine investigations for melanoma; moreover, chest radiographs and CT and/or MRI scans are not routinely ordered in asymptomatic patients. However, the investigation of new symptoms results in a high percentage of positive findings, and this policy is the preferred approach. When metastasis does occur, 50 per cent will be within 1 year, 85 per cent within 2 years, and 95 per cent will be within 5 years. The survival rate of such patients increases with disease-free time following removal of a melanoma; the only caveat is that metastasis following thin lesions, albeit rare, may be delayed.

There is no adjuvant therapy that improves survival, and chemotherapy and radiotherapy are only used for palliation. Surgery, when possible, remains the treatment of choice for metastatic melanoma. Initial optimism regarding the use of adjuvant interferon or elective lymph node dissection has now waned. However, the use of lymphoscintography and sentinel-node biopsy to identify high-risk patients for such therapy now seems helpful in finding lymph node metastases, but its use as a tool to improve long-term survival is still uncertain. The only intervention that improves survival is early diagnosis and complete removal of the primary melanoma. Even re-excision of the scar does not improve survival; but it is still recommended with ever-decreasing margins with the sole intention of reducing the incidence of local recurrence/metastasis. Currently, the margins recommended are 0.5 cm for *in situ* melanoma and 1 cm for invasive melanomas with a Breslow thickness of less than 1.5 mm. A minimum margin of 1 cm and a maximum margin of 2 cm of normal skin is recommended for lesions between 1.5 mm and 4 mm deep. Although re-excision of the scar for lesions greater than 4 mm is unlikely to be worthwhile, a minimum margin of 2 cm is recommended.

Rashes due to sun or artificial light and associated ultraviolet rays

Sunburn

Initially this is an erythema occurring about 6 to 8 h after exposure, which may progress to blistering and later to skin-peeling. However, redness may begin as early as 2 h if the exposure is excessive. Sunburn tends to resolve, often with peeling, after 24 to 72 h, depending on its severity. Topical corticosteroids and oral non-steroidal anti-inflammatory agents may provide partial relief.

Solar urticaria

Here, erythema and wealing occur immediately on exposure to sun, often of sites not habitually exposed to the sun. It is a rare but very disabling condition due to a broad spectrum of wavelengths that rarely responds to sunscreens, although it often does well with plasmapheresis or, paradoxically, phototherapy.

Polymorphic light eruption

Polymorphic light eruption is an altered quality of sunburn. Thus instead of erythema there is an itchy papular or eczematous response about 6 to 8 h after exposure, which may persist for several days (Fig. 25). There are several variants including a lymphoma-like pattern with heavy lymphocytic infiltrates.

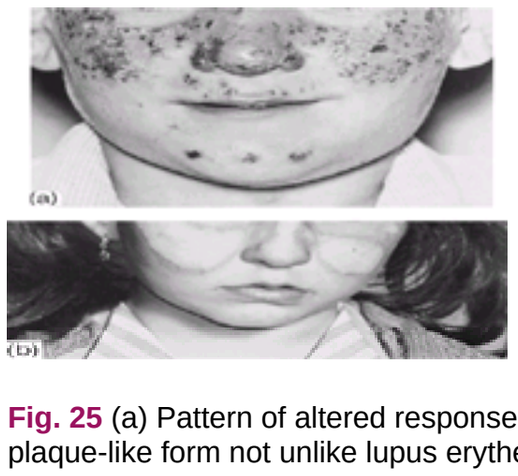

Fig. 25 (a) Pattern of altered response to sunburn wavelengths: an eczematous prurigo with excoriations. (b) Pattern of altered response to sunburn wavelengths: a plaque-like form not unlike lupus erythematosus.

Actinic prurigo

Sun-induced prurigo shares features with atopic eczema, polymorphic light eruption, and persistent light eruption due to photosensitivity agents in the environment. It is uncommon except in genetically susceptible individuals with HLA-A24 and CW4 and the rare subtype DR4 DRB1*0407, which is particularly common among some native Americans. It has a chronic course that is only initially seasonal. Urticarial plaques develop a few hours after ultraviolet exposure and are followed by a persistent eczematous rash, which is not always confined to exposed skin.

Exacerbation or localization of other dermatoses in sun-exposed sites

This is characteristic of pellagra, Hartnup's disease, lupus erythematosus, dermatomyositis, pemphigus erythematosus/foliaceous, Darier's disease, herpes simplex, rosacea, scleroderma, erythema multiforme, actinic lichen planus, and lymphocytoma. It sometimes occurs in psoriasis, seborrhoeic dermatitis, atopic eczema, acne, and bullous pemphigoid.

Ultraviolet rays may diminish antigen surveillance by reducing the population of Langerhans cells.

Porphyrias

See Chapter 11.5 for further discussion.

Drug eruptions and photosensitivity

Various drugs can cause acute eruptions of erythema that swell or blister like severe sunburn, which, since UVA is often responsible, are independent of bright sun. The reactions are often dose-dependent, as with psoralens in PUVA therapy. Ingestion of a spinach (Atriplex) also causes photosensitivity (see Table 9). Some eruptions present only as deep pigmentation.

Xeroderma pigmentosum

See Chapter 25.2 for further discussion.

Persistent light eruption

'Persistent light eruption' is the term given to a sensitivity to light induced by agents previously applied to the skin, often years before. Drugs eliciting light sensitivity are listed in Table 9.

Investigations

Patients should be asked about their family history, their occupation, drug or food ingestion, and exposure to perfumes, as well as how and when any exposure occurred. It is important to know whether glass is protective. Many patients confuse the effects of heat and sunlight, making it important to clarify whether exposure to an open fire, for example, also exacerbates their condition.

Light-testing has become a useful dermatological tool, with a number of centres having access to a monochromator that specifically evaluates each band of light.

Prophylaxis

Health education in schools should emphasize that burning in the sun is not related to heat or wind, rather it is maximal when the sun is directly overhead. Therefore protection is essential between the hours of 10 am and 2 pm, mainly achieved by covering the head and body and keeping in the shade. Sunscreens are effective only if they are properly used; that is to say, they must be applied evenly and thoroughly and well before exposure, and reapplied at appropriate intervals, but they are no substitute for avoidance. Frequent, uninhibited exposure leads to the accumulation of almost inevitable and irreversible injury, which may only become apparent some 20 years later.

Management

The ill-effects of a cool, sunny, and windy noon must be explained, as well as the relative safety of a hot sunny evening. Ensuring protection for those who are sensitive to UVB includes giving advice on the time of day and season likely to be harmful. Most patients can safely take a swim in the early morning or late afternoon. Those with severe sensitivities, such as xeroderma pigmentosum, can be saved from all ill-effects by diligent protection, including clothing. Indeed, clothing and shade are the best protections for children sensitive to the sun, but a wet T-shirt can transmit ultraviolet rays; tightly woven silks, Lycra, and cottons are more effective than loosely woven yarns or wool. Fluorescent lighting emits small amounts of UVR and is safe for all but the most sensitive. Glass windows are protective against UVB and shorter wavelengths, while Perspex and certain plastics also protect against UVA. Natural pigment and thickening of the epidermis accounts for normal tolerance.

Sunscreens are rated, according to UVB protection, by a solar protection factor (SPF). There is an inverse relationship between SPF and sun protection, such that

there is only a minimal difference between SPF 8 and SPF 16 and probably no real difference between SPF 16 and SPF 50. The limiting factor of any sunscreen is correct application and reapplication.

Sun-screening agents include thick reflective pastes or creams such as zinc oxide or titanium dioxide; these filter out both UVA and UVB and also prevent tanning. Sun-screening agents may absorb light, with invisible lotions or creams containing *p*-aminobenzoic acid in 70 per cent alcohol mainly filtering UVB. This allows some tanning due to the effects of UVA.

Is it what I have eaten? Food and drug eruptions

It is generally accepted that much of what we eat is antigenic and that absorption does occur. Usually allergens are complexed with antibodies in the gut wall and tolerance occurs. It is easy to demonstrate that antibodies are made to counteract food allergens and that complexes circulate in the blood as a result of eating. This is not necessarily allergy because resulting inflammation is rare.

Infrequent ingestion is more likely to cause an allergy than tolerance.

Both erythema and acute urticaria can be caused by food, but chronic urticaria is rarely so. In the atopic person, IgE-mediated food allergy is well recognized. Contact urticaria occurs when eggs or milk touch the lips and cause immediate swelling, whereas generalized urticaria and bowel upset result when agents such as fish, nuts, or strawberries are eaten. However, in many patients such eruptions are examples of non-allergic intolerance.

Anaphylactoid reactions are either idiosyncrasies, whereby an individual reacts abnormally to a substance tolerated by most of the population due to some defect in their physiology, or they result from a direct effect or action of a drug on a mast cell, or other cell, often on first exposure to the eliciting substance. Examples of non-allergic responses include C_1-esterase deficiency and angio-oedema, or lactose intolerance and lactase deficiency, causing diarrhoea.

A high iodine level in a diet induces blistering in dermatitis herpetiformis and exacerbates erythema nodosum leprosum. Sources include iodophors used in dairy cleansing, iodine-containing food supplements, and dough improvers in bread, as well as in cough mixtures.

Following the development of toxic erythema and purpura in an extensive epidemic amongst eaters of margarine in The Netherlands and Germany, the possibility that food additives could cause rashes is now well recognized. Urticaria, asthma, and migraine have also been studied in this respect. The total number of food additives exceeds 20 000 and an average person eats about 1.5 kg every year. Salicylates and benzoates as well as many colouring agents present in more than 1000 drugs marketed in the United States partly act through the control of prostaglandin metabolism. Some 10 per cent of people sensitive to aspirin are also sensitive to the colouring agent tartrazine. The mechanism, though suspected to be related to prostaglandin metabolism, has yet to be clarified. It is confusing that some other types of food allergy, perhaps less dependent on IgE and on the release of histamine from mast cells, are prevented by prostaglandin inhibitors: 'If one takes indometacin, one can eat anything'!

Careful studies of food additives have led the authors to the conclusion that food containing additives is very rarely a danger, but food without additives is commonly so. So far as intolerance is concerned, the potentiating effect of psychological tension and unaccustomed or overindulgent eating habits is a probable explanation.

Shellfish and strawberries are well known for not only releasing histamine from mast cells but for causing thrombocytopenic purpura. Usually such agents cause urticaria within hours of ingestion. However, the response is inconsistent, since there may be times or forms of presentation of the same food that avoid this effect. Eggs, nuts, chocolate, fish, shellfish, tomatoes, pork, strawberries, milk, cheese, and yeast are common causes of a sudden transient thrombocytopenia, and sensitivity to food in this way is the basis of the 'thrombo' test. A 20 per cent fall in the platelet count 1 h after ingestion occurs in 70 per cent of persons showing allergy to aspirin, barbiturates, and penicillin. In one series, 203 out of 215 patients with urticaria showed a prolonged bleeding time from the ear lobe 2 h after challenge with a drug, chemical, or food. Bitter lemon or tonic water containing quinine is especially well documented.

In patients with atopic eczema and asthma the problem of food allergy is more complex. These patients seem to be more susceptible to histamine release even from non-allergic sources.

The gut of the newborn with atopy is said to be more immature in its handling of foreign protein; or it may be that the complexing of IgA is less effective so that IgG is brought into play in the immature gut in a manner not usual for the mature immunological system of the adult gastrointestinal system. This is the basis for advocating breast feeding without cows' milk substitution for all babies of atopic parents. Hypoallergic foods are marketed which contain 'predigested' casein, and this is an industry with a strong following. However, minute amounts of antigens from the maternal diet are found in breast milk, so it cannot be assumed that the first experience of a dietary antigen occurs at the time of weaning. Even the fetus is normally supplied by minute samples of the mother's diet. What matters is how much and when.

Another form of food sensitivity is that occurring in nickel-sensitive subjects. Nickel sensitivity is one of the commonest aggravating factors of hand dermatitis, and there seems little doubt that contamination from metal pots and from some green vegetables can contribute to the contact allergic dermatitis in sensitive individuals.

Drug eruptions

The 1975 Boston Collaborative Program of Drug Surveillance observed that adverse reactions accounted for 3 per cent of hospital admissions and 14 per cent of medical resources, and that 30 per cent of hospital patients developed adverse reactions.

It is wise to assume that any drug can cause any rash, but until there are simple, reliable, and specific *in vitro* tests for testing human tissue for hypersensitivity, the diagnosis of drug eruptions will depend entirely on clinical judgement. The physician has to decide whether the rash has some other cause by recognizing certain physical signs, ranging from the mite burrows in scabies to the herald patch of pityriasis rosea. Then if a drug seems a likely cause, there must be an attempt to decide which of the medications currently prescribed, or taken secretly, may be responsible.

Drug rashes are essentially blood borne and therefore often have a symmetrical urticarial, erythematous, or purpuric and ischaemic pattern determined by the vascular anatomy. Less likely is a 'primary epithelial' reaction in the initial stages, and so scaling or even the vesiculation of eczema as a first manifestation of a generalized drug rash would be unusual. The exceptions are well known and include the intraepidermal immunologically induced 'pemphigus' rash of penicillamine, rifampicin, and captopril, especially when the first of these is used to treat rheumatoid arthritis; another is when cell-mediated hypersensitivity to epidermal protein and the drug occurs in a person previously having a contact dermatitis to a local antihistamine or sulphonamide. The psoriasis-like rash of practolol and various other b-blockers as well as the scaly eruption (particularly of the scalp) from methyldopa, are exceptions.

Nevertheless, if a rash looks like eczema, it is probably not caused by a drug. If it is an erythema and urticaria, it may well be. As later stages of the rash are frequently complicated by secondary desquamation and peeling, the diagnosis should be made on the initial manifestation.

Unlikely or likely drugs

It may be helpful to rule out unlikely offenders such as digoxin, paracetamol, steroids, other hormones, and vitamin and electrolyte supplements. In any drug group there are likely and less likely offenders. Thus of the antibiotics, oxytetracycline, nystatin, and erythromycin are not under suspicion, but dichlortetracycline is a common cause of a photosensitivity rash. Moreover, ampicillin is almost invariably responsible for a characteristic bright-pink maculopapular rash in patients with infectious mononucleosis

Sulpha-containing medications such as sulphonamides, thiazide diuretics, oral hypoglycaemic agents, dapsone, and even captopril are capable of causing most rashes. Non-steroidal anti-inflammatory drugs (**NSAIDs**), antibiotics, antiepileptics, gold, penicillamine, allopurinol, halides, and other antihypertensives are all possible candidates worthy of consideration.

Timing

While drug rashes usually relate to newly started medications, this is not always the case. For example, a person may have tolerated multiple courses of a particular antibiotic prior to becoming allergic to it. Maculopapular drug exanthems most commonly begin 7 to 10 days after the drug is commenced, by which time many antibiotic courses will have been completed. The rash often increases in severity with time until the patient stops taking the drug. Once the drug is stopped, the rash may last a further 7 to 14 days and often evolves from a typical maculopapular exanthem to a scaly rash that may resemble the peeling that follows sunburn or even be slightly eczematous. Repeat exposure to that drug, even years later, will usually lead to recurrence of the exanthem within hours to days. Interestingly, some patients do not react on re-exposure, suggesting a toxic rather than an allergic mechanism. This is particularly common in people who react to amoxicillin in the context of infectious mononucleosis.

Other exanthems frequently show a different time course. Anaphylaxis often begins within minutes, while fixed drug eruptions usually begin 30 min to 8 h after rechallenge. Lichenoid drug eruptions often do not begin for many months and sometimes even years. Urticarial reactions are variable: they may start within a few hours with an antibiotic allergy, but may take a week or two to develop following treatment with NSAIDs or angiotensin-converting enzyme inhibitors.

Erythema multiforme, or Stevens–Johnson syndrome, occasionally occurs surprisingly early after a drug's administration, leading to the suspicion that the disease for which the drug was given may have prepared the host in some way.

Many patients do not admit to taking a drug, perhaps because it was never prescribed but borrowed from a family member or neighbour or bought over the counter and therefore considered to be harmless. In general, drug rashes do not persist after withdrawal of the drug—exceptions include pemphigus from penicillamine.

Transient susceptibility

The best example of a susceptibility reaction is urticaria. Many people with chronic urticaria are susceptible to it for a period of many months, during which time the rash may be triggered by prostaglandin synthetase inhibitors, such as aspirin or indometacin. It is possible that certain drug exanthems require both a drug and an infection to provoke the rash, so the underlying disease of the patient should always be taken into account. Patients with infectious mononucleosis or chronic lymphocytic leukaemia are prone to toxic erythema with ampicillin, while people with AIDS are 1000 times more susceptible to developing the Stevens–Johnson syndrome following treatment with sulphonamides. Sometimes immune-complex diseases, such as cutaneous vasculitis from infective organisms, are provoked by interference with immunological mechanisms by certain drugs. The particular set of circumstances, which may not recur, would depend on the formation of antibodies, the nature of the infectious organism, and the taking of the drug at that time. Diseases such as psoriasis or dermatitis herpetiformis may go into spontaneous remission, during which time they are less likely to be provoked by drugs. Dermatitis herpetiformis is provoked by iodine so readily that it should be avoided if possible.

Drug allergy is rarely proven, but overdosage is a frequent well-established fact due to faulty prescribing, attempted suicide, or altered metabolism as in renal or hepatic failure. Interethnic differences in drug metabolism are due to human gene polymorphisms. Drugs may interfere with metabolism, with hormones, they may be deposited, they may react with sunlight, they may modify the ecology of the skin in respect to infective organisms; they may cause reactivity of certain cells such as the mast cell; they may be cytotoxic; and they can act as allergens in the formation of immune complexes, hapten–protein complexes, delayed cellular immunity, and a variety of other mechanisms. Some are not understood, such as the effect of halogens on the formation of granulomas (Fig. 26(a)) and in the causation of an acneiform eruption (Fig. 26(b)). This includes the use of fluoride gel preparations applied to the teeth to prevent dental caries.

Fig. 26 (a) Iodides and bromides are occasionally responsible for a granulomatous eruption with pseudoepitheliomatous hypertrophy. Potassium iodide in a cough mixture was responsible for the eruption in this patient. (b) Prolonged administration of iodides or bromides causes a particularly inflammatory form of acne which, although commonly in the distribution of acne vulgaris, may be more widespread. This eruption was due to an iodide-containing 'tonic' for the blood.

Specific drug eruptions

The most common diagnostic problem is a toxic urticated erythema. It begins like measles without the upper respiratory and conjunctival prodromal signs. It usually develops, over a number of hours, as a bright pink indurated papular eruption (Fig. 27) and, unlike urticaria, persists for days, ultimately involving the epidermis and producing scales (Fig. 28). After the first 2 to 3 days the rash tends to be fixed, with the principal changes due to mild bleeding of the skin with overlying slight peeling. Fever and arthropathy may be associated. Common causes are ampicillin, phenylbutazone, phenothiazine, co-trimoxazole, diazides, and sulphonylureas. Exfoliative dermatitis is the end result of this type of reaction (Fig. 29). Gold, phenylbutazone, indometacin, allopurinol, hydantoins, sulphonylureas, ampicillin and amoxicillin, co-trimoxazole, carbamazepine, phenytoin, cefaclor, gentamicin, and *p*-aminosalicylic acid are causative drugs.

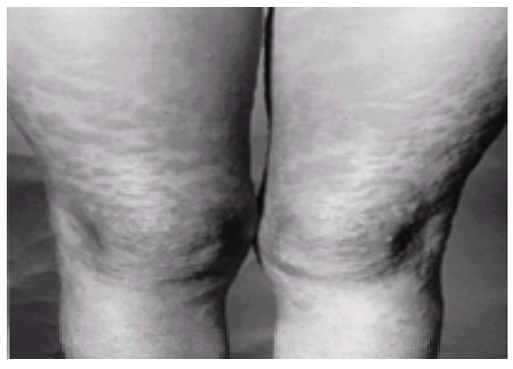

Fig. 27 One of the most common drug eruptions, initially a bright-pink papular eruption, symmetrical, and becoming confluent. This case is due to ampicillin.

Fig. 28 A later stage of acute drug eruption, in this case due to Myocrisin®. The epidermis is reacting to the dermal inflammation by hyperplasia spreading centrifugally to produce an annular scaly lesion, with the scale exfoliating in the centre of the lesion and attached to the spreading margin.

Fig. 29 Severe oedema, crusting, and exfoliation due to dermatitis from arsenicals.

Psoriasis

b-Blockers can cause a psoriaform scaly eruption that may be modified by basal-cell necrosis. The high turnover as in psoriasis, with the slowing down that results from such necrosis, gives rise to a hyperkeratotic scale that is more adherent than in psoriasis and often slightly yellowish. The palms and soles, elbows, and knees are particularly favoured (Fig. 30).

Fig. 30 Hyperkeratosis and slight scaling is a feature of the psoriasiform eruption caused by b-blockers.

Labetalol, propranolol, and oxprenolol cause a partly psoriaform and partly lichenoid rash, which is most marked over bony prominences. There is an itchy hyperkeratosis of the palms and soles. Most b-blockers merely exacerbate ordinary psoriasis. Other drugs capable of this include lithium, antimalarials, non-steroidal anti-inflammatories, potassium iodide, amiodarone, and calcitriol, it also occurs on the withdrawal of oral steroids.

Lupus erythematosus

Lupus erythematosus, like erythemas or necrotizing vasculitis, is most commonly caused by hydralazine, phenytoin, practolol, penicillamine, and isoniazid. Many other drugs have been incriminated. The drug-induced lupus erythematosus is reversed by withdrawal of the drug, but it recurs when it is readministered. The disease is characterized by antinuclear antibody in high titre with normal DNA binding. Inhibition of C4 underlies the immunological disease induced by hydralazine.

Scleroderma

An epidemic originating from denatured rape-seed oil in Spain caused facial oedema, exanthems, and ultimately a scleroderma-like syndrome.

Fixed drug eruption

Although the mechanism is unexplained, the eruption is easy to recognize as it is usually circular and erythematous (Fig. 31), and it frequently blisters. Postinflammatory hyperpigmentation due to pigment incontinence in the dermis is characteristic. It is fixed in site, and whenever the subject takes the causative drug the eruption begins within a few hours in exactly the same site. The tongue and the glans penis are common sites. The affected area can be transplanted without loss of responsiveness in some cases. In pigmented races, very dark pigmentation remains between attacks. In addition to the drugs listed in Table 10, purgatives, blood cleansers and tonics, and many other home remedies containing phenolphthalein, are common causes. Continued ingestion leads to the development of multiple new spots. Skin biopsy is diagnostic in the early stages, and it is safe to rechallenge patients in order to determine the causative agent.

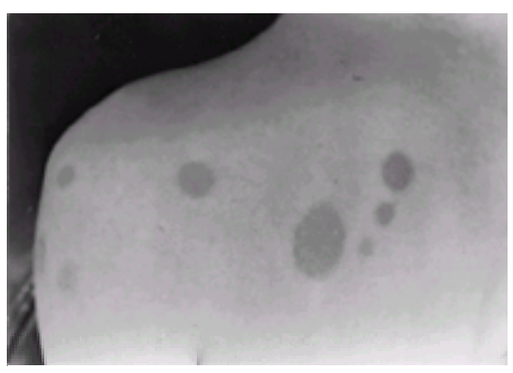

Fig. 31 Fixed drug eruption due to phenolphthalein present in a laxative. Such an eruption characteristically appears within half a day of taking the causative drug and the site affected is the same on every occasion. Violaceous annular lesions are common and may persist for several weeks.

Anticonvulsant hypersensitivity syndrome

This severe reaction is characterized by an extensive morbilliform skin rash that often evolves into an exfoliative erythroderma or toxic epidermal necrolysis (TEN), accompanied by fever, lymphadenopathy, hepatitis, nephritis, and leucocytosis with atypical lymphocytes on the blood film. There is a significant mortality and intensive nursing care is required. Other drugs such s allopurinol can produce a similar syndrome.

Management of drug eruptions

The best way is to stop the use of all drugs likely to cause the eruptions. Readministration of the drug is possible for most drug eruptions other than those that cause anaphylactic shock, but it is usually at a risk of considerable morbidity and therefore should be considered only if essential to the patient. Skin tests are unhelpful, as a risk of dangerous anaphylaxis, false-negatives, and lack of knowledge of the antigen, makes skin testing useless.

Blood tests are of no help in trying to find which drug is causing the problem. Various tests, such as the reaction of basophil cells or the release of lymphokines from lymphocytes, have not proved of routine value. Eosinophils may suggest that an eruption is due to a drug, and, as mentioned above, a fall in the platelet level within 1 h or a prolongation of bleeding time 2 h after injection is helpful for some urticarial rashes.

Dermatitis

Definition

Dermatitis is a non-specific inflammatory response of the skin to a combination of exogenous and endogenous factors. There is no clear distinction between dermatitis and eczema, and the two terms are interchangeable. Endogenous dermatitis comprises discoid, asteatotic, varicose (or stasis or gravitational), vesicular, hand/foot (pompholyx), atopic, and seborrhoeic dermatitis. Exogenous dermatitis includes irritant contact, allergic contact, phototoxic, and photoallergic dermatitis. However, sometimes there is no clear distinction between these two types.

Clinical features

Dermatitis has both dermal and epidermal components. Some signs are confined to the dermis such as swelling, heat, itchiness, tenderness, and redness, but at the same time the epidermis proliferates and therefore thickens and produces scale. The oedema in the dermis extends to the epidermis, swells the cells, and separates them to give the histological appearance of a sponge, known as spongiosis, and frequently this results in vesicles, which distinguish dermatitis from other proliferative states of the epidermis such as psoriasis. Acute weeping exudation occurs when the vesicles burst (Fig. 32). Itching is usually severe in dermatitis.

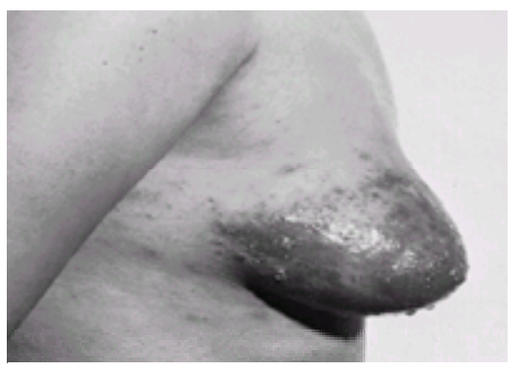

Fig. 32 Acute dermatitis is characterized by an oedematous epidermis in which vesiculation, oozing, and crusting are the principal features. The borders are often ill-defined, while the centre of the lesion is confluent.

The reaction pattern of dermatitis is not homogeneous. It is made up of papular elements of different ages and size, sometimes confluent in the centre (Fig. 33), with widely scattered satellite papules or vesicles. The scales are of varied size and broken by excoriation, exudate, and even pinpoint haemorrhages.

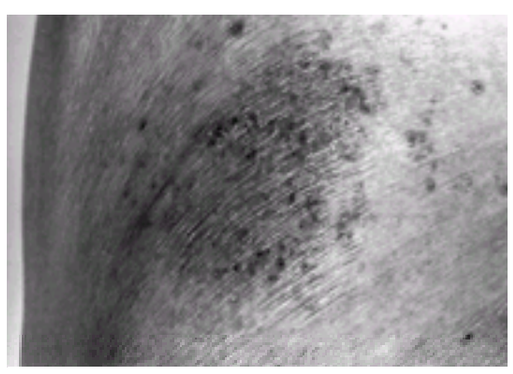

Fig. 33 Dermatitis comprises papules that are confluent in the centre and become vesicular or evidently excoriated. Oedema makes the line markings in the skin more prominent. There are satellite lesions beyond an ill-defined border.

A secondary factor prominent in pigmented skin is a loss of melanin, or at least a failure to retain it, in the acute lesion so that the skin is depigmented. In later or more chronic stages the dermis is darkened by pigment 'incontinence', so that thickened chronic epidermal plaques may contain increased pigment in the underlying dermis. Chronically scratched skin has a brownish violaceous colour due to the combination of pigment, vasodilatation, and epidermal thickening.

For unknown reasons, dermatitis of the foot frequently provokes an autosensitization or 'id' response in the hand. Thus, vesicular eczema of the hands often follows a fungus infection of the feet, varicose eczema of the lower legs often spreads to the forearms and face, and a severe allergic contact dermatitis may generalize to the trunk and limbs.

Contact dermatitis

Primary irritant contact dermatitis

An irritant can be defined as a chemical that in most people is capable of producing cell damage if applied for a sufficient time and in a sufficient concentration. Fibreglass spicules rubbed into the skin are a typical example (Fig. 34). Irritant contact dermatitis is caused by exposure to a single or a few contacts with a highly irritating substance such as a concentrated acid, or by chronic low-grade cumulative exposure to substances that are mildly irritating, such as a very dilute acid. A low-grade, cumulative, irritant contact dermatitis can occur after a few months or even several years, depending on the nature of the irritant and the sensitivity of the skin. This is exemplified by housewives' hand dermatitis, which usually recovers slowly or incompletely because of the inability to fully protect the hands against all irritants (Fig. 35). Many people at home or in industry are in daily contact with various chemicals over long periods. They work in wet or extremely dry conditions with skin cleansers, alkalis, acids, cutting fluids, solvents and oxidants, reducing agents, enzymes, and medicaments. The skin is also worn and irritated by cold and heat, sun, pressure, scratching, or friction of various kinds from tools or clothing. Many variables influence the skin's toughness or vulnerability. It can be immature in the newborn or worn out in the aged. The most important cause of lowered resistance is a constitutional disease, such as the ichthyotic skin of old age (Fig. 36), atopic eczema, or psoriasis.

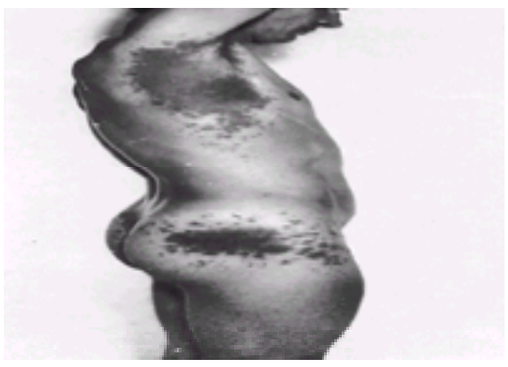

Fig. 34 Primary irritant dermatitis due to small spicules of fibreglass at sites of friction after this patient had insulated a roof.

Fig. 35 Chronic dermatitis causes irregular thickening of an inhomogeneous epidermis. The texture of the stratum corneum varies so that it is firmly attached at some points but exfoliates with small scales at others. Loss of moisture causes decreased suppleness, cracking over joints, and exposure of deeper epidermal cells. This causes irritation of the dermis at the bottom of the deep crevasses.

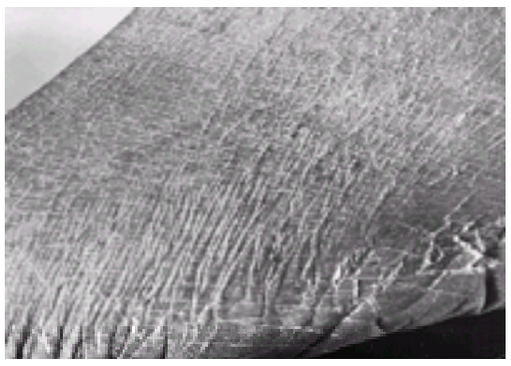

Fig. 36 Chronically thin and slowly turning-over epidermis results in a closely knit stratum corneum which is firmly adherent but cracks excessively. It is characteristic of elderly, malnourished, or ichthyotic skin. Such skin is less resistant to primary irritants.

Contact allergic dermatitis

Allergic contact dermatitis is caused by a type IV delayed hypersensitivity reaction to a chemical in contact with the skin. Initial sensitization can occur 7 to 10 days after the first contact with a potent allergen. However, it is more usually a consequence of many months or years of exposure to small amounts of the allergen. Once sensitized, contact with the allergen can produce dermatitis within 24 to 48 h and all areas of the body are equally susceptible. Sensitivity can vary due to the amount of exposure, the degree of penetration of the skin, and the tolerance of the immune system.

It is believed that certain allergens, such as nickel and chrome, have a greater affinity for the skin than others. This is partly due to the easier recognition and assimilation by the epidermal antigen-presenting cells known as Langerhans cells. The allergen binds to epidermal microsomal protein, or to some cell-surface marker, or to serum proteins that are plentiful in the epidermis. It is a complex of the allergen with such protein that is recognized as foreign. Although the T lymphocyte ultimately recognizes the complex, the macrophage is a necessary intermediary. Suppression of Langerhans cells by ultraviolet rays diminishes cell-mediated immunity. Genetic factors play a part in the recognition process. Once recognized, T-cell proliferation occurs in the paracortical area of the lymph node, and on re-exposure sensitized lymphocytes release lymphokines. The mechanisms of lymphocyte stimulation include some role for suppressor and effector cells. The role of antibodies, some of which are clearly specific for the same antigen, is also unknown. The inflammatory reaction resulting from recognition is variable and dependent on other pharmacological agents, including secretions from the mast cell, and on prostaglandins. Some of the variation in response, such that persons are consequently labelled as more or less allergic, depends on these secondary factors, and these can be modified by various conditional factors, including anxiety and the hormonal status of the monthly menstrual cycle.

Contact dermatitis sensitizers

In the following, we will concentrate on some specific groups of sensitizers and irritants.

Cosmetics

Cosmetics applied to the skin, although more rarely a cause of dermatitis in technically advanced countries where the industry has worked hard to eliminate allergens, are still a source of much disease in developing countries. Perfumes and preparations containing tars, formaldehyde, and Dowicil are increasingly incriminated, and

are as commonly irritant as they are allergic.

Vaseline dermatitis in the Bantu is an example. In technically advanced countries, deodorants are a common cause of dermatitis, while in the hair industry, glyceryl monothioglycollate (acid perms) is the most common allergen. Hair bleaches, such as ammonia persulphate, commonly cause immediate, non-immune wealing. When in doubt, because the constituents are so complex, cosmetics should be tested by direct application to the skin, but this can give rise to false-negative results. Hair dyes are now so common that their relative safety can be expected. However, again in developing countries, the dye paraphenylenediamine may produce an acute dermatitis, often first affecting the eyelids and other aspects of the face before showing much evidence of dermatitis on the scalp.

Clothing and textile dermatitis

On the whole this is rare, but clips containing metal are quite a common cause of dermatitis (Fig. 37); for example, jeans' buttons can cause dermatitis of the skin below the umbilicus. There is also evidence that the rubber in the elastic of many garments is sometimes the cause of dermatitis. Dyes are usually a problem at sites of friction where there is also moisturization by sweat: the majority of which are azodyes or paraphenylenediamine. In the textile industry, chrome and formaldehyde are important agents causing dermatitis.

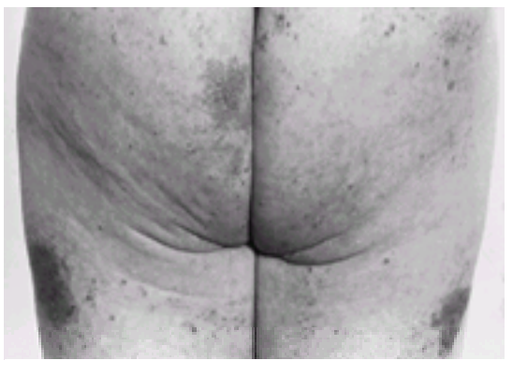

Fig. 37 Contact dermatitis due to garments containing nickel. The diagnosis is made by observing how the distribution of the rash corresponds to the distribution of the contact with the causative agent.

Shoe dermatitis is commonly due to chrome or to rubber additives such as mercaptobenzothiazole or butyl phenol formaldehyde. Adhesives and dyes may also be responsible. This form of dermatitis should be considered in every person with eczema of the feet. It often spares the area between the toes as this is the point where the shoe is not in contact with the skin. Much modern footwear has plasticized toecaps and fails to absorb sweat. Increased sweating encourages a shearing strain on the skin, particularly in the athletic child. Frictional dermatitis of the foot is common in such children and is known as juvenile plantar dermatosis.

Foods

In technically advanced countries, handling animal feeds containing antibiotics gives more trouble than handling food for human consumption. Elsewhere, plants and fruits such as garlic, cinnamon, onions, and lemons and oranges cause much trouble, as do shellfish and various species of fish that are sometimes contaminated by algae. This is an important hazard for fisherman, which, in the United Kingdom, is known as the 'Dogger Bank' itch.

Plastics

An increasingly frequent cause of dermatitis arises from the use of acrylic and epoxy polymers or resins. Acrylics account for dermatitis from adhesive tape, spectacle frames, bonding agents, dentures, hearing aids, bone cement, artificial fingernails, sealants, printing plates, and inks.

Epoxy resins are used as surface coatings for steel pipes and ships, powder paints, electrical insulation adhesives, construction of concrete and steel buildings, and for the surface of roads and bridges. Although they are amongst the most potent sensitizers, they are only active during their initial handling since complete polymerization makes the sensitizing monomer non-available. About 90 per cent of contact dermatitis from epoxy resins is from bisphenol A. Protection in industry depends on common-sense avoidance of handling them and general cleanliness in the workshop, but volatile epoxy resins affecting the face are difficult to avoid.

Rubber

Natural as well as synthetic rubbers require the addition of several agents that are strong sensitizers. They make the rubber more malleable and supple, prevent perishing by oxidization, and some speed up the manufacturing processes.

Accelerators include thiuram, mercaptobenzothiazole, and guanides; antioxidants include the monobenzyl ether of hydroquinone. Most cases of rubber sensitivity are due to clothing such as rubber gloves, or to tyres or rubber linings used in the transport industry. Others include the contraceptive sheath, shoes, fingerstalls, masks (particularly motorbike or scuba-diving masks), elastic bands, bicycle or golf-club handles, and rubber sheets or cushions. Anaphylaxis is not rare from a type I sensitivity to rubber latex surgical gloves.

Colophony

Rosin is made from pine trees and is used worldwide for paper size adhesives, inks, undersea cables, Elastoplast, violin rosin, and cosmetics. Some medicaments like Zam-Buk®, Secaderm® salve, and ilonium also contain colophony, therefore explaining the contact dermatitis arising from the use of these agents. It is responsible for about 3.5 per cent of positive patch tests in the London contact dermatitis clinics.

Plants and wood

Sensitivity to plants and woods accounts for enormous worldwide morbidity and occasional mortality. Some plants release their allergen only when bruised, others when lightly touched, and others by airborne pollen. Some produce a contact non-allergic urticaria (that is, immediate stinging) as with the nettle or cowage (*Mucuna pruritum*); others cause an allergic dermatitis, or even photosensitivity. Many are highly irritant.

In North America the commonest cause is poison ivy, in Europe it is *Primula obconica.* Both produce a severe, streaky blistering eruption from contact allergy mediated by cellular immunity.

Chrysanthemum or ragweed plants, members of the Compositae or daisy family, cause a more diffuse redness and oedema of the face from sesquiterpene lactones. This may look like a photosensitivity and be enhanced by sunlight (see above). Avoidance of the plant may be impossible for someone whose job depends on contact with it, and is a special problem where it is a common environmental weed. In the Poona region of India the weed *Partheneum hysterophorus* can lead to death. Dermatitis resulting from contact with this plant builds up into a severe erythroderma with secondary infection and even pseudolymphoma. In those who are suffering from other diseases it may summate and lead to a very severe illness.

Potentially allergenic plants are most numerous in the cashew family, such as poison ivy, poison oak, poison dogweed, elder or sumac, mango, wax, or lacquer trees, and hence in one form or another they are present worldwide. Attacks can be aborted by washing within an hour of contact. Severe oral dermatitis and acute gastrointestinal systems can be troublesome when sensitivity is due to the mango or cashew nut.

Contamination of other handled agents can also cause outbreaks of dermatitis, as has been recorded with articles of clothing, mail, and even from voodoo dolls.

Wood dermatitis is often due to its resins or its attendant lichens, liverworts, and mosses, and even its insect parasites are occasionally responsible. It is a severe cause of industrial dermatitis in workers in the furniture industry. Furthermore, it can even cause mouth dermatitis in children handling wooden toys, and, in music classrooms, has also been noticed in those playing recorders made of certain woods.

Medicaments

An enormous number of medicaments are now used, often containing unknown constituents. The problem particularly arises where these have been repeatedly applied to the skin over a number of years, and therefore a contact dermatitis is found in patients with leg ulcers, pruritus ani or vulvae, and in those suffering from otitis externa. Local anaesthetics, lanolin and cetylstearyl alcohols, antibiotics and antiseptics, antifungal compounds, and antihistamines are the most significant groups of causative agents. Topical corticosteroids are increasingly recognized as relatively common contact sensitizers (hydrocortisone, hydrocortisone-17-butyrate, budesonide).

An example of the importance of recognizing such sensitivity is illustrated by ethylene diamine; this is a common cause of dermatitis and is present in certain neomycin–nystatin ointment mixtures (for example, Tri-Adcortyl®) and in aminophylline suppositories. It is used as a solvent in many industries and is one cause of coolant-oil dermatitis. This combination of an industrial use and a medicament may mean that a person loses his employment as a result of the previous use of a medicament. Sensitivity to ethylene diamine has serious implications, since it is also sometimes used as a preservative of intravenous aminophylline, and deaths have been recorded.

Metal

Beryllium, used in the manufacture of fluorescent lights, causes skin ulcers, dermatitis, and granulomas. Chrome confers hardness to metals, and dermatitis from it is also common in the leather tanning industry. It is a contaminator of cement. In industrial countries it is one of the most common sensitizers in men; most obtain their sensitivity from cement, but their greatest disability is due to the later inconvenience of being unable to wear leather footwear containing chrome. Ferrous sulphate can be used as an additive in cement to convert hexavalent chromium to the less sensitizing trivalent form.

Cobalt sensitivity is commonly found in association with nickel or chrome sensitivity. Jewellery, and possibly metal prostheses for hip replacements, may be responsible.

Nickel is used in various metal alloys, electroplating, enamels, and glass. It is easily absorbed through the skin and its presence in body-piercing rings or studs and in buttons and clips probably accounts for the high incidence of metal dermatitis. Sensitization is particularly common with jewellery made of nickel-containing alloys; gold of 14 carats and above is considered safer. There is a general worldwide trend towards increased nickel sensitivity, which contributes substantially to hand dermatitis. Simply handling nickel-containing money or pots and pans does not seem to be responsible. However, the abrasive cleaning of such in washing-up water releases nickel, and is a reason for blaming this occupation or for recommending the use of running water.

Employment and contact dermatitis

It will be seen from the above that many people working in industry are liable to contract specific types of 'contact dermatitis'. Some industries are particularly susceptible.

Hairdressers

During their apprenticeship, the hands of hairdressers suffer from the very abnormal wear and tear of frequent shampooing. The skin of atopic subjects almost always break down. Nickel dermatitis is particularly common. When the rash only affects the palmar surfaces, contact dermatitis is more likely than irritant dermatitis. The latter commonly affects the more tender dorsa of the hands and between the fingers.

Bakers

Dough, sugars, and fruit and vegetable peels are irritants often causing considerable skin damage in atopic subjects. Many of the flour additives can cause contact urticaria.

Builders

Cement is highly irritant but skin quickly hardens. Severe alkaline burns of the lower legs from calcium hydroxide in wet cement is now well recognized, especially in the amateur using ready-mixed cement.

Chrome dermatitis may be very similar to constitutional patterns, including seborrhoeic and stasis eczema, and for this reason anyone in the building industry who has any pattern of eczema should be patch-tested.

Agricultural and horticultural workers

Carelessly used fungicides and pesticides are frequent causes of dermatitis. This particularly occurs on isolated farms in developing countries.

Patch-testing

The principle of patch testing is to apply the suspect agent to the patient's skin, but avoiding irritants, and observe its effect on cell-mediated immunity. It involves:

1. applying the agent on a carrier material such as aluminium foil on filter paper, and covering with adhesive tape;
2. using a non-irritant concentration of the agent in white soft paraffin in water or ethyl alcohol; for most chemicals this is 0.1 to 1 per cent (in the case of cosmetics or medicaments the concentration used in the whole product is suitable);
3. applying (1) to the patient's back, which gives a more consistent response than the arms or legs; and
4. removing the covering adhesive tape and filter paper with aluminium foil 2 h before reading at 2 and 4 days.

Most practitioners obtain reagents from Trolab, Karen Trolle-Lassen, Land, Pharm 6B AN, Hansens Alle, 2900 Hellerup, Denmark, and replace them about every 6 months.

False-positives result from sweat gland occlusion, sensitivity to adhesive tape, irritants, and generally increased irritability of the skin, usually due to active eczema but exposure to ultraviolet irradiation can also be causative.

A positive patch test is a papular and a palpable erythema, which may be vesicular (Fig. 38).

Fig. 38 Contact for about 48 h with the allergen to which the patient is sensitive can be used as a test at any site on the skin. This is the basis of the patch-test reaction. In this case a finger dermatitis due to an allergen in cigarette smoke could be proved by applying a smoked filter paper to the patient's back.

Treatment of contact dermatitis

The level of complaint is often lessened by good industrial relations or a happy home. Those who are well satisfied with life may call their problem merely roughness of the skin; those who are unhappy or dissatisfied may well call their problem dermatitis. Especially in those who have atopic eczema or psoriasis, emotional stress is considered to be a factor worth controlling if possible. Such stresses are often no more than the anxieties and irritations of daily living and employment in a complex society.

Elimination of known irritants or allergens must be attempted but, as in the case of poison ivy in the United States or some of the Compositae in Asia, complete avoidance may be impossible. For less severe allergens, such as chrome or nickel, the skin can settle to a tolerable degree merely by removing obvious sources in clothing or jewellery. Dermatologists can encourage cleanliness and ventilation in working environments and the substitution of less allergenic materials in industrial processes. It is not always advisable to make workers change their jobs; this particularly applies to chrome sensitivity in building industry workers, since once they are sensitized, most other jobs are equally difficult. However, most sufferers can manage by taking a little more care at work and with the help of emollients. Anti-inflammatory agents, such as steroid creams, are always of help and can help the affected person stay at work, particularly where exposure is just short-term (for example, during the training of hairdressers or nurses).

Severe chronic allergy can be relieved by immunosuppressive drugs such as azathioprine. Chelating agents, such as Antabuse®, have been used in cases of severe nickel dermatitis.. Nickel-free diets are complicated but much less unpleasant than drug therapy.

The prognosis for contact dermatitis is often good. Thus 30 per cent of nickel dermatitis of the hands is healed in 6 years. Only 25 per cent of apprentice hairdressers with hand dermatitis have to change their job. Only rarely, as with certain plant allergies, is the problem a persistent and intolerable problem affecting many persons in the community.

Contact urticaria—latex gloves

This is an acute swelling developing within a few minutes to half an hour of contact with certain agents. In atopic eczema there is an particular susceptibility to this phenomenon, but it is also well recognized in non-atopic subjects and is particularly common as a result of the application of cosmetics. Many agents commonly applied to the skin will produce irritation in certain sites, such as the eyelids or scrotum, and this is not always an immunological phenomenon. Urticaria from latex occurs within 15 to 30 min of wearing the glove. It is IgE-mediated. The rash may extend beyond the area of exposure. Doctors and dentists are at particular risk, as are patients frequently exposed to latex gloves such as spina bifida patients who self-catheterize. Patients may crossreact to condoms or medical instruments such as intubation tubes, as well as some fruits and vegetables such as bananas and avocados. Severe sensitivity may induce anaphylaxis and such patients should always carry adrenaline (epinephrine). In extreme cases anaphylaxis can occur to airborne contact with latex particles in procedure rooms, and affected doctors may need to seek an alternative vocation. Diagnosis is by radioallergosorbent testing (**RAST**); prick-testing should only be done where resuscitation equipment is available. Prevention by the use of non-powdered, high-quality rubber gloves or vinyl gloves is prudent, especially when the hands are already damaged.

Atopic eczema

This is a constitutional disorder of the skin affecting about 10 per cent of the population. It is one of the most common diseases of childhood and one of the main reasons for loss of work in industry. It accounts for about 50 per cent of cases of hand eczema. Its inheritance is discussed in Chapter 23.2.

Atopic dermatitis is a multifaceted disease, the cause of which is still unknown. Patients with atopic dermatitis frequently have an elevated IgE level. Allergic respiratory disease affects about 50 per cent of eczema sufferers, and 70 per cent of patients are aware of other family members with the disease. Other associations include dry skin, facial pallor, low finger temperature, pronounced vasoconstriction on exposure to cold, white dermographism, and a susceptibility to cutaneous viral and bacterial infections. Ophthalmological manifestations of atopy include infraorbital folds, infraorbital darkening of the skin, conjunctivitis, keratoconus, and cataract formation. Hyperpigmentation of the lateral neck is known as atopic 'dirty' neck. Drug reactions of the anaphylactic type are more common and abdominal symptoms due to food allergy are frequently described. Contact urticaria is common. Alopecia areata may be more severe and less likely to respond to treatment. Around 60 per cent of patients present within the first year of life, and for 90 per cent the disorder starts within the first 5 years of life. In the majority, the eczema gradually improves but the skin remains vulnerable to physical and chemical irritants throughout life.

Data from the International Study of Asthma in Childhood have shown a global prevalence of 2 to 16 per cent of children aged between 6 and 7 years over a 1-year period.

Pathogenesis

Atopic dermatitis is essentially an exaggerated response to environmental irritants and allergens. The basis of this exaggerated response is immunological, with an altered T-cell response and consequent production of proinflammatory cytokines. In atopic patients, CD4-positive T-helper cells, and in particular class 2 helper cells (T_H2), recognize antigens and secrete IL-4, IL-10, and IL-13, which stimulate B-cell growth and IgE and mast-cell production. In addition, T_H2 cells produce IL-5 which leads to eosinophilia. This may provide atopic patients living in tropical areas with relative protection from parasitic infections. T_H2-derived IL-10 inhibits T_H1 cytokine production, while IL-4 promotes T_H2 differentiation. T_H1 cells produce interferon-gamma (IFN-g), IL-2, and IL-3. IFN-g produced by T_H1 cells enhances the development of T_H1 cells and inhibits T_H2 cells. Reduced childhood exposure to infections and intestinal bacteria or parasites, as well as increasing vaccination and immunization, are proposed as causes of T_H1 and T_H2 imbalances favouring atopy.

Epidemiological studies have incriminated a number of allergens that may trigger this immunological response, including pollution, central heating, and house dust mites. Unfortunately, the identification and avoidance of allergens in atopic dermatitis has proven to be more complex than in asthma and hayfever. Skin tests by pricking various antigens into the skin result in weal-and-flare responses that are often multiple and strongly positive. However, there is a poor correlation between the skin-test response and the activity of the eczema, which may even be in remission during, for example, the hayfever season in spite of strong reactivity to skin testing with grasses.

The role of food allergy is difficult to test accurately in such a fluctuating and multifactorial disease. Neither prick tests nor allergen-specific IgE tests can be used to predict those most likely to benefit from dietary elimination. Exclusion diets and food challenges rarely detect meaningful dietary allergens and are therefore reserved for the most severely affected patients. Exclusive breast feeding is of benefit, but is not necessarily due to the avoidance of dietary factors. Breast milk contains much IgA. Complete avoidance of cows' milk during the first 6 months of life in a child born of atopic parents is believed to be beneficial, but nevertheless there are many who fail to benefit.

Humoral immunity

T cells infiltrating the skin in atopic eczema are predominantly IL-4/IL-10/IL-13-producing Thy-2 responses that encourage B cells to produce excessive IgE. IgE reagenic antibody is elevated in over 80 per cent of patients with atopic dermatitis, often to over 2000 units/ml. However, the significance of this finding remains uncertain, since atopic eczema can occur in agammaglobulinaemia and normal levels are found in many actively eczematous patients. Of course, serum levels need not reflect the level of activity of the IgE surrounding the mast cell in the skin itself. Complexes with antigen and the mast cell are often, after all, the basis of the IgE-mediated weal-and-flare response. There is an increased frequency of the presence of specific reaginic IgE antibody also known as the test reagent radioallergoabsorbent test (RAST) to numerous allergens in the sera of atopic people.

Reactivity of the immune system

About 80 per cent of atopic patients demonstrate an excessive reactivity of their immune system, reacting to certain foods and to house dust with immediate itching and swelling of the tissues. The agents to which 90 per cent of atopic patients react differ from those usually encountered in allergic disease—these include a number of animal and vegetable proteins from milk, meat, and corn. Eczema itself is most typically a consequence of delayed or cell-mediated immunity; however, T-cell function seems to be depressed in atopic skin, leading to a greater susceptibility to viral, bacterial, and fungal infections. Herpes simplex, vaccinia, warts, *Staphylococcus aureus*, and *Trichophyton rubrum* infections are most favoured; 90 per cent of atopic subjects carry *Staphylococcus aureus* in their skin, compared to 10 per cent of normal subjects. Fortunately, the atopic subject is not as susceptible to strains responsible for impetigo, toxic epidermal necrolysis, or furunculosis. There is also decreased reactivity to other common allergens such as poison ivy, *Candida* spp., or dinitrochlorbenzene (**DNCB**).

An atopic eczema-like syndrome is also a feature of immune deficiency diseases; for example, the Wiskott–Aldrich syndrome, the hyper-IgE syndrome of Buckley, Jobs, and Jung, and thymic aplasia, as well as the DiGeorge and Nesselof syndromes which also demonstrate high levels of IgE and decreased cell-mediated immunity. It is possible that immaturity of the humoral antibody system results in defective T-lymphocyte regulation, and that IgE production is increased as one consequence.

Characteristics

Atopic patients have an inherently dry and irritable skin. Itch and scratching are responsible for most of the skin changes seen clinically and histologically.

A low itch threshold

A diagnosis should not be made if there is no history of itching. Besides the usual causes of itching, many minor irritants, such as woollen clothing or a change in climate, cause scratching. Scratching causes excoriations and ulceration, as well as thickening of the epidermis and swelling and redness of the underlying dermis. The broken surface is sore and further irritated by soaps, some ointment bases such as sorbic acid, sea-water, or citric fruit juices. It has been found, using intradermal trypsin as a test of itch, that atopic patients have a prolonged itch reaction, although it may be that other patients with other forms of eczema are similarly affected.

Dry and lined skin

In non-excoriated areas the skin is often dry and lined. This is more obvious in hard-water areas in temperate climates. The palms are particularly heavily lined and cause embarrassment even to the fortune teller! About 70 per cent of adult patients have a hand dermatitis that usually spares the palms. In nursing mothers, nipple eczema may be a problem during breast feeding. It seems there is a deficiency in sweating and sebum excretion leading to chapping, wear, and tear, particularly from solvents or water. In industry, people with atopic dermatitis are less tolerant of contact with primary skin irritants and therefore more likely to develop occupational dermatitis. Another feature of atopic dryness is keratosis pilaris, which is a perifollicular hyperkeratosis.

Vasodilatation

The vasculature too readily vasodilates in the popliteal and cubital fossas, thereby heating the skin and hence inappropriately lowering the itch threshold. When scratched, rubbed, or stretched, the skin blanches for a few minutes, beginning 12 to 15 s after injury. This is partly due to upper dermal precapillary shutdown and also to persistent inflammatory oedema. Deeper vessels often dilate so that the skin is warm. This combination of hot but pale skin accounts for the itching as well as the atopic pallor.

Clinical features

Itching is the chief feature and becomes apparent during the first 2 to 6 months of life. The face is usually first affected and scratching begins between the second and third month. Sore lips from licking and chapping as well as conjunctivitis with ectropion are common; 70 per cent of patients have a skin fold or wrinkle just beneath the margin of the lower lid of both eyes (Fig. 39). When the child begins to crawl, exposed surfaces such as the knees and hands become the most involved. The papules are scratched and become exudative and so secondary infection associated with lymphadenopathy is a common finding. Lymphadenopathy can sometimes be so gross as to lead to the suspicion of some dire malignant disease. From 18 months onwards the sites most characteristically involved are the flexures of the elbows, knees, sides of neck, wrists, and ankles (Fig. 40). Local areas of lichenified skin may persist at such sites, and the face, too, may be heavily lichenified. Rubbing the eyes does not fully explain why keratoconus and anterior subcapsular cataracts are featured in severe cases. Seasonal influences on the disease are mainly climatic, due to sunlight and humidity and the use of central heating, but are probably also related to seasonal allergies. Pollen is a feature of spring and early summer, while house dust seems to be a feature of late summer allergies.

Fig. 39 Atopic eczema in an adult, showing the characteristic skin fold just beneath the lower eyelid and the loss of eyebrow hair, as well as thickening of the skin due to rubbing.

Fig. 40 Typically thickened and excoriated skin of the chronic prurigo of atopic eczema.

Prognosis

Most children develop their eczema within the first 6 months of life, but about one-fifth of patients may have a delayed onset, even into adult life. Generally, there is a tendency for gradual improvement, with many children 'growing out' of their atopic dermatitis around the age of 3 to 4 years. Complete clearance without breakdown when in contact with skin irritants is unusual, but most people, in the absence of major irritants, are clear by the time they are teenagers.

Management

In the absence of any treatment that permanently modulates the immune response, the main focus of treatment is to reduce exposure to environmental irritants and to prevent overheating. It is useful for parents to have access both to the doctor and nurse as well as to the literature provided by patient groups. All factors that irritate the skin should be even more avoided by atopic patients, and these include various primary irritants such as soap, wool, and extremes of climate. Moisturization of the skin is good, but evaporation is bad. Wet wrapping is the application of wet dressings over moisturizing creams, which are then covered by dry dressings. Liberal washing with soap substitutes based on emulsifying ointments is mostly helpful, and these are most effective if applied at least four times a day. The common-sense avoidance of jobs involving large amounts of primary irritants should be advised. Attempts should be made to avoid contact with herpes simplex, molluscum contagiosum, and other viruses affecting the skin; however, vaccination poses no particular problems for children with atopic dermatitis and should not be withheld, unless the child is being treated with systemic immunosuppressants. It is still difficult to know how to remedy an immunological defect. While breast feeding is to be recommended for all infants, it may be particularly important for babies with a strong family history of eczema. There is evidence that breast feeding may reduce the incidence of atopic eczema by up to two-thirds, though not all authors agree. It is postulated that a period of transient immune vulnerability exists during early life, during which exposure to food antigens, perhaps by complexing with IgG, IgM, and IgE instead of IgA, results in allergic sensitization and the subsequent development of atopic eczema. The effect of breast feeding may be due to its low antigen load compared to cows' milk. Breast milk is also rich in IgA, which may modify the absorption of food antigens. Breast feeding should continue for an extra 3 to 4 months, since any supplement exposes the immature gut to foreign protein. Especially to be avoided is any supplement given in hospital during the first week of life. Further benefit might be gained by avoiding eggs and cows' milk in the mother's diet, since foreign protein can be transmitted through the mother's milk. When breast feeding is impossible, milk substitutes are second-best since they are expensive and require care to prevent bacterial contamination. Some paediatricians believe cows' milk should be avoided for 1 year and eggs for 18 months.

Some patients appear to benefit from a regime of antigen avoidance, although this is not always the case. Neither RAST tests nor skin-patch tests are reliable in selecting patients who are helped by dietary modification, since even those known to benefit from antigen avoidance may not show specifically raised IgE levels nor positive skin tests.

Elimination diets must be carefully assessed to obtain complete avoidance with, at the same time, adequate nutrition, and since they are not without risk in this respect they should be reserved for the most severely affected children. Some authors recommend the avoidance of eggs, chicken, milk, and artificial colouring agents or preservatives. Goat's milk has lost favour on nutritional grounds. Careful studies of the use of Chinese herbal teas have shown an improvement in generalized dry eczema in children, but users should be aware of the potential hepatotoxicity of these drinks.

Other environmental allergens shown to be important for some children include the house-dust mite. Avoidance includes removing dust-collecting fabrics such as carpets, curtains, bedclothing, and soft-furnishings, and using high-powered vacuum cleaning rather than brushing. A cold and dry environment discourages the mite. Polished floorboards, hydronic rather than ducted heating, blinds rather than curtains, plastic mattress and pillow covers, washable cotton blankets rather than duvets are all appropriate (albeit often expensive) measures in severe cases regardless of whether a house-dust mite allergy is established. Cats and dogs should always be kept off the bed, and avoided all together if contact with them worsens the dermatitis.

Topical therapy

Apart from the liberal use of emollients, steroid creams are effective antipruritic agents. Ointment bases are preferred for dry dermatitis, while creams are used in flexures and for weeping infected or acute dermatitis. Prescribing habits have changed over the past few years. Certainly there was a period when overprescription resulted in systemic side-effects as well as local atrophy of the skin; however, underusage, often encouraged by the dispensing pharmacist, is now far more prevalent. Withholding of steroids deprives the child of the one effective therapy. Short, sharp bursts of effective therapy with strong steroids may be entirely justified, but prolonged daily usage of weaker, partially effective steroids is bound to lead to complications. However, special care is required on the face and flexures. Topical steroids are stored in the skin, and for this reason once-daily application may be sufficient. It seems an inexplicable fact of life that ringing the changes with ointments is of benefit, and a skilled practitioner will always have an alternative preparation on which the worried parents can pin their faith. Secondary infection is so common and bacterial allergy so important that vigorous treatment of infection is justified, and topical antiseptics and systemic antibiotics should be given according to the sensitivities of the bacteria. Erythromycin is particularly valuable; mupirocin, topically, is as effective. The matter of climatic therapy remains unpredictable; undoubtedly a change of climate does effect great improvements in some children, whether it be exposure to sunlight or to the sea or to a mountain top.

Ascomycin macrolactam derivatives formulated as a topical cream inhibit the release of inflammatory cytokines from T cells and show great promise as a topical therapy.

Severe cases of eczema, as with asthma, may have to be controlled by systemic steroids, either in the form of prednisolone or corticosteroid injections. This may be simply to help the patient over an acute period, although a small minority of patients may require long-term therapy for several years. Azathioprine is an effective steroid-sparing agent. Ciclosporin controls severe eczema but provides little long-term benefit. Periodic hospital admission with intensive topical therapy can provide months of respite. Ultraviolet light in air-conditioned cabinets is helpful for many people. An initial worsening often requires cover with prednisolone. Traditional herbal remedies are popular and controlled studies have shown some benefits from Chinese medicinal plants, but it should not be assumed that because they are 'natural' they are safe. Significant hepatic toxicity has been documented and a carcinogenic potential of some of these agents is suspected.

Other patterns of dermatitis

Infected dermatitis

Increasing evidence suggests that bacterial allergy plays a part in the development of an eczematous response in the skin, *Staphylococcus* spp. being particularly implicated. Bacterial allergy may play a part in all types of eczema, but occasionally it is the single cause. This is most frequently seen as a rather well-demarcated patch of eczema with crusting and scaling on an exposed area. There may be small pustules on an advancing edge. It is seen around discharging wounds, around ulcers, and occasionally around a paronychia or in a flexure, subject to sweating and maceration; it is particularly common around the ear or at sites of occlusion such as under a hat-band or between the toes. An underlying pediculosis may be one trigger. Black skin commonly seems to develop a similar condition that principally affects the shins. Management includes the use of local antiseptics and wet soaks, or dyes, such as gentian violet, combined with an appropriate systemic antibiotic.

Herpes simplex infection often presents with a sudden inexplicable flare of atopic dermatitis, often monthly, but this may be difficult to prove as vesicles are rapidly

excoriated. Swabs for immunoperoxidase staining or viral culture may need to be frequently repeated. A trial of prophylactic oral antiviral therapy can be considered in cases with a suggestive history.

Seborrhoeic dermatitis

Adult seborrhoeic dermatitis is different to the infantile disorder bearing the same name. It mainly affects the scalp and face, but can also involve the upper trunk and flexures including the axillas, groins, scrotum, and anus. The aetiology is unknown but the distribution does appear to be in the areas of sebaceous activity. There is a strong association with neuroleptic-induced parkinsonism, idiopathic parkinsonism, spinal injury, as well as with AIDS. *Pityrosporum orbicularis* may be the responsible pathogen. The oval blastosphere is predominant in AIDS, whereas the hyphal form is increased in pityriasis versicolor. The most characteristic lesion is a dull or yellowish-red and greasy plaque with a marginated scale. On the scalp it produces dandruff. On the face it tends to involve the medial cheeks, nose, nasolabial folds, and eyebrows. It is the most common cause of a 'butterfly rash'. Seborrhoeic dematitis affects the axillas and groins with well-defined brownish-red scaly areas deep into the folds, on the front of the chest and in the middle of the back there may be small brown follicular papules covered by greasy scales or multiple discrete patches. Rarely, a widespread eruption resembles pityriasis rosea with oval lesions with peripheral scale. Severe cases of seborrhoeic dermatitis develop marked crusting and scaling, particularly of hair-bearing areas and the genitalia. Otitis externa is one manifestation. The disorder tends to recur and may be chronic.

Management includes an attack on local infection and the removal of crusts with wet soaks. Preparations, such as vioform hydrocortisone, sulphur, and ichthammol in a variety of water-miscible bases, usually in 1 to 2 per cent concentrations, have traditionally been prescribed. Lithium succinate ointment is recently favoured. Imidazoles control pityrosporum overproduction, which is thought to play some part in the diathesis. Antiyeast shampoos with zinc pyrithione or ketaconazole are effective, as are tar shampoos.

Nummular (discoid) eczema

The main feature of this eczema is that it is discoid or composed of rounded lesions scattered, often symmetrically, over the body. They are intensely vesicular and intensely itchy. Undoubtedly endogenous, external influences play little part in their development, although occasionally sensitivity to metals, such as nickel or chrome, may produce a similar picture. Onset is usually in adult life, although Asian children seem prone to this form of dermatitis. Patients are no more likely to be atopic, but dry skin and overheating are important aggravating factors. Secondary infection is common; sometimes nummular eczema is as a reaction pattern to a localized primary irritant such as an insect bite.

Pityriasis alba

This is a pattern of eczema quite common in children, often in those with darker skins, in which a very low-grade dry eczema with shedding of pigment transiently gives rise to a white patch of skin (see Fig. 64). It may be associated with drying out—reduced sebum—around the hair follicles, known as keratosis pilaris.

Fig. 64 Pityriasis alba caused by a mild dry eczema. Slightly scaly areas of depigmentation are a common cause of discoloration.

Itch without rash (pruritus)—mechanisms and causation

'Pruritus' is the term used when itching (the most prominent symptom in skin disease) is the primary complaint, which leads to scratching in the absence of visible evidence of lesions predisposing to itch. Itch is a sensation largely dependent on superficial nerve endings—unmyelinated C fibres—in an intact upper dermis and epidermis. These are very thin fibres, but rich in terminal branching. Thinly myelinated nerves in lateral spinothalamic tracts and secondary neurones to the thalamus relay both pain and itch, and the cerebral cortex can modify these responses. Itch is induced by a number of agents including histamine and histamine releasers such as substance P, opioid peptides, cytokines, bradykinin, bile salts, and proteases, and is potentiated by prostaglandin E. It can be disassociated from pain in hypoalgesia. Central neurological and emotional psychiatric factors control the threshold to itch and pain. Awareness is a complex attribute modifying or intensifying the response to the itch. The itch itself may cause irritability, depression, or invoke the attitude of the masochist who wears a 'hair shirt'.

Itching is usually worse when the skin is heated to normal body temperature and when there is little else to distract the sufferer—a combination common at night. Vasodilatation in the cubital or popliteal fossas partially accounts for the lower itch threshold at such sites in people with atopic dermatitis.

The itching threshold is lowered by isolation, including the common accompaniments of ageing such as blindness, deafness, and loneliness. Endogenous depression is often missed in the elderly and should be treated. Paroxysmal itching may originate in the central nervous system and provoke deep scratching, which is pleasurable but injurious. It is a feature of cocaine addiction.

The itch of different dermatoses evokes different types of scratching. Urticaria is almost never scratched but usually rubbed or pinched, perhaps because the exact site of the itch is difficult to pinpoint. Similarly, excoriations are rare in lichen planus (see 'Localized pruritis', below). Where intense itching is exactly located it is often persistent and deeply excoriated.

A common factor is dryness and desiccation of the stratum corneum, common in the elderly and worse in winter. Sweat retention also causes intense pruritus such as prickly heat. People recently engaged in insulating their roof with fibreglass suffer from pruritus caused by the almost invisible spicules of fibreglass (see above and Fig. 34).

Pruritic conditions

Parasitic causes of itching (scabies) (see Chapter 8.2)

Parasites are an important cause of pruritus, but those experienced at examining the skin will usually observe primary urticarial or papular lesions in amongst the scratches. Onchocerciasis, trichinellosis, and schistosomiasis cause severe pruritus, usually with marked eosinophilia as well as urticaria, prurigo, and depigmentation. In onchocerciasis, loss of elasticity and the development of a leather-like skin hanging in folds is one consequence.

Delusions of parasitosis are common, affected people usually present to pest exterminators and museum entomologists rather than to doctors. This condition is a monosymptomatic delusional disorder, and patients often function well in other aspects of their life. Follie aux deux is common, and the entire family may be drawn into the delusional framework. Referral to a psychiatrist is often resisted. It is best treated with antipsychotic drugs such as pimozide.

Aquagenic pruritus

This occurs after contact with water—fresh, salt, or sweat. In some people it starts from the moment of contact and lasts 15 min. In others, it is less immediate and

longer lasting. Treatment with acetylcholine or histamine antagonists or ultraviolet rays sometimes help. A common similar reaction in the elderly, due to rapid drying out after prolonged hydration, is helped by shortening the period of hydration. It is a premonitory sign of myeloproliferative disease.

Generalized pruritus and systemic disease

Hepatic disease

Obstructive jaundice causes severe pruritus. It is particularly an early feature of biliary cirrhosis, and bile salts rather than bilirubin have been held responsible for the itch. The degree of jaundice need not be great. Bile salts in the skin can achieve a relatively higher concentration than may be indicated by serum levels. A bile-salt concentration of 1 mmol/l causes itching when applied to a blister base; dihydroxy salts, especially chenodeoxycholate, are responsible.

Contemporary studies look to opioid metabolism as a cause of the pruritus, and these early studies on bile salts are only part of the story. Oestrogen-induced pruritus of pregnancy or from the contraceptive pill often shows little or no jaundice in spite of intrahepatic biliary obstruction, severe pruritus, and a much increased alkaline phosphatase level. Chlorpromazine and testosterone can have the same effect.

Blood disease

Iron deficiency has also been blamed for itching even when the patient is not anaemic—though in iron deficiency, which is common, itch is rarely found to be so associated. Some thinning of hair is a frequent complaint. Polycythaemia is frequently associated with itching, particularly after a hot bath. It is believed to be related to blood histamine levels and occasionally to iron deficiency, and hence the reported positive response to iron therapy within 2 to 10 days. Lymphatic leukaemia is another cause of pruritus often long-lasting before it becomes clinically overt.

Carcinoma of the internal organs and lymphoma

Carcinoma of the bronchus in particular may very rarely present with generalized pruritus. Pruritus occurs in 25 per cent of patients with Hodgkin's disease, often burning in quality and associated with icthyosis.

Chronic renal failure

No matter how uraemic is the patient, itching is not a feature of acute renal failure or even of malignant hypertension. Patients with chronic pyelonephritis or chronic glomerulonephritis usually suffer greatly from pruritus, which is not necessarily relieved by haemodialysis. Parathyroidectomy, for reasons that remain obscure, may relieve itching in those in whom removal of the gland is necessitated by secondary hyperparathyroidism. The cause of pruritus in renal failure is unknown, but raised histamine levels, endogenous opioids, and dryness of the skin are factors. Mast cell numbers are also increased in patients with chronic renal failure.

Endocrine disease

Pruritus is sometimes a presenting symptom of diabetes mellitus but generally this is principally localized to the vulva. About 1 in 10 patients with hyperthyroidism complain of itching. Dry skin in hypothyroidism often itches.

Drugs

Morphine, allopurinol, or those causing cholestasis should be enquired about.

Management of pruritus

Overheating should be avoided as should vasodilators such as alcohol and hot drinks. Calamine lotion is used as a cooling agent: all topical therapy is more cooling if kept in a refrigerator. Evaporation is increased by the enhanced surface area provided by the powder. Dryness of the skin should be discouraged by the use of emollients. Oily calamine or 0.5 per cent menthol in aqueous cream are preferred when xerosis coexists with itch. In dry conditions, such as the hospital ward, a moist microenvironment can be enhanced by appropriate clothing. A sensation of cooling can be achieved with 1 per cent menthol or camphor and 1 per cent phenol, both of which have a mild anaesthetic effect. Menthol is also an antihistamine. Nails should be kept short and together with occlusive bandaging may reduce the vicious circle of itch and skin damage. In general, woollen clothing is itchy, cotton clothing is not. Too frequent bathing or showering should be discouraged unless emulsifying ointments are added to the bath as soap substitutes. Bath salts should be avoided. Proprietary bath oils are more cosmetically acceptable but tend to be expensive for regular daily use.

Obviously, any known cause of the pruritis should be treated accordingly. Class I antihistamines, which pass the blood–brain barrier, may principally act through their sedative and anticholinergic effects, and they also reduce awareness. Class II antihistamines, which do not pass the blood–brain barrier, cause no sedation; but as histamine is one of the most prominent mediators of itch, they should always be tried and are often most effective in higher dose than indicated in the National Formulary. The role of increased histamine release and its mediation of itch in senile pruritus justifies the prescription of a class II antihistamine. Chlorpromazine may reduce the reactivity to the itch. Plasma exchange has been used to control sweats and pruritus. The anion-exchange resin cholestyramine, 6 to 8 g daily, or oral activated charcoal helps to relieve the pruritus of liver disease and sometimes its use in patients with chronic renal disease or polycythaemia has been helpful. Suberythema doses of UVB irradiation twice weekly, and even natural sunlight, often ameliorate pruritus, reducing mast cells and some of the cytokine activity inducing inflammation; they have also been used to treat the itching associated with uraemia and with certain acute exanthems such as pityriasis rosea. Use of hydroxyethyl rutosides (Paroven®) and thalidomide have been advocated in the treatment of patients in renal failure. Pentoxifylline (oxpentifylline) is reported to relieve the pain and itch of keloids. Opioid activity can be blocked by opioid antagonists or competitors such as codeine; these have been advocated for the treatment of pruritus of liver disease. The H_2-receptor antagonist cimetidine is sometimes helpful in Hodgkin's disease.

Localized pruritus

Localized intensely itchy areas of skin having no obvious causation are a common problem in the dermatology clinic. The nape of the neck, upper back (Fig. 41), genitalia, lower leg, elbow, and outer thigh are easily accessible sites liable to persistent rubbing and scratching. Such injury to the skin results in thickening, purple-brown violaceous coloration due to dilated vessels and postinflammatory pigmentation. The normal line marks of the skin are exaggerated and excoriations are usually numerous. This is termed 'lichen simplex' or 'neurodermatitis', and the fairly well-defined patches cause paroxysms of itching and emotional upsets with anxiety or irritability, which, in themselves, are also promoting factors. Capsaicin ointment, which reduces substance P in the skin, may relieve localized pruritus after several applications. The burning initially induced by this therapy can be reduced by the prior application of local anaesthetic creams (for example, Emla (lidocaine (lignocaine) and prilocaine cream)).

Fig. 41 Prurigo nodularis is a form of scratched lesion which is very exactly localized. The upper back is a common site for such persistent excoriation.

Nodular prurigo is an unexplained reaction to scratching, evoking severe, very localized pruritus. The nodules are 1 to 2 cm in diameter and scattered over accessible areas. It is sometimes a consequence of a partially resolved, more generalized pruritus arising from atopic eczema or parasitic infestation. Freezing with liquid nitrogen is helpful, but this may lead to depigmentation in pigmented races.

Local steroids are helpful and anything that protects the skin from scratching may eventually allow healing. Occlusive tape or bandaging is occasionally helpful but secondary infection is a problem, especially in hot countries.

Intralesional injection with triamcinolone causes rapid resolution in some cases but this may be only a temporary response, and where the lesions are large or multiple such inoculation is not without the side-effects of steroid therapy. It is always worth admitting such patients to hospital and treating them with traditional dermatological therapies such as tar bandages. A more recent suggestion is that some of these lesions are an immunological response and this has led to therapies as far ranging as azathioprine and thalidomide.

Pruritus ani

Pruritus ani is common in White adult males. It is rare in Blacks except as a manifestation of infestations such as oxyuris, lice, and scabies. Psoriasis, atopic dermatitis, seborrhoeic dermatitis, tinea cruris, candidiasis, and streptococcal infection can all be found in the anal region, albeit rarely, and should be excluded. Extramammary Paget's disease is a rare cause of itch. People with diabetes are prone to pruritis ani for reasons not entirely clear. An important cause is soiling of the perianal skin. Haemorrhoids, fissures, and fistulas contribute to this problem, as can rectal carcinoma. The anal sphincter relaxes in response to anal distension too readily in some sufferers; in others, incomplete bowel evacuation leaves some residual faeces in the folds of the anus. Because soft stools are more likely to cause irritation, fibre intake needs to be carefully balanced to keep the stool firm while at the same time preventing constipation. Pruritis ani is commonly exacerbated by hot, spicy foods: curry and coffee should be limited. Bacterial and fungal contamination is common, and anxiety may lead to excessive hygiene measures that irritate the skin or result in supervening lichen simplex. Both allergic and irritant contact dermatitis may result from the common use of multiple medication.

Often, the perianal skin needs to be cleaned immediately and an hour or two after the bowels have been opened. Weak- or medium-strength local steroids are the mainstay of treatment, and can be mixed with anticandida or antiseptic agents to deal with or prevent secondary contamination and infection.

Pruritus vulvae and vulvodynia

The vulva has a generous innervation and is highly sensitive. Itch or pain or both are common when the skin is irritated or inflamed. It is socially unacceptable to scratch one's vulva in public and these symptoms are often associated with guilt, a sense of being unclean, dyspareunia, and marital disharmony. Furthermore, sexuality is central to a woman's psyche and primary psychological problems or guilt over an extramarital affair may somatize with a vulval or vaginal complaint. When marital problems exist, a vulval problem may be the justification to reject sexual advances, and sympathy from the doctor rather than a cure may occasionally be sought.

The vulva is a favoured site for candidiasis, tinea cruris, atopic dermatitis, psoriasis, seborrhoeic dermatitis, lichen sclerosis, and lichen planus. In addition, physiological vaginal discharge or semen may irritate inflamed skin. This is much more common when the discharge is altered in nature or amount by an infection such as candidiasis, trichomoniasis, or another sexually transmitted disease. Pruritus ani and vulvae are rare in regions where malnutrition is common, except as a manifestation of an orogenital syndrome due to vitamin B deficiency: the pruritus is then associated with dermatitis and angular cheilitis. Threadworm infection is common in children, while urinary tract infections are common in adults and children and are associated with urethral stinging and burning and will also aggravate a pre-existing complaint of vulval itch or pain. Sexual intercourse, in particular unaroused sexual intercourse, produces local mechanical trauma that rarely initiates dermatitis but invariably aggravates it. Anticipation that vaginal intercourse will be painful leads to further complications such as vaginismus that may continue for many years after the precipitating event has resolved.

Sufferers use a large number of agents to relieve their pruritus, some of which cause contact dermatitis. Pruritus vulvae may also be caused by sensitivity to the rubber of condoms or spermicidal jelly, or even to deodorants. Local anaesthetics and local steroids are much used; however, the latter encourage secondary infections, with fungus usually spreading on to the buttocks and down the thighs. Potent fluorinated steroids may lead to a rosacea-like pustular perioral facial dermatitis.

Management includes a thorough examination to exclude the above and to recognize skin diseases such as psoriasis, seborrhoeic dermatitis, lichen sclerosis, atopic dermatitis, and lichen planus. Vaginal swabs should routinely be taken to look for candidiasis and trichomonas infection, and other sexually transmitted diseases when indicated. Skin swabs and scrapings for the detection of secondary fungal, bacterial, and viral (herpes simplex) infection are useful. A full history of topical medicaments and other preparations should be elicited, and patch-testing performed if required. Detailed instructions regarding local hygiene should be given to patients, including advice on the need to avoid excessive ritual washing, particularly with soap. Counselling regarding sexual intercourse may be needed.

Pruritis vulvae usually responds well to potent topical steroids. The risk of atrophy is small if the itch is confined to the vulva. Secondary infection may be prevented by the concomitant use of a topical antiyeast preparation such as nystatin or antiseptic such as Vioform (clioquinol), which tend to be non-irritating. Maintenance treatment with a weak topical steroid may be required.

Recurrent vaginal candidiasis may be recalcitrant to therapy. It relates to oestrogen levels and is not seen before the menarche or after the menopause, except in women receiving hormone replacement therapy. Long-term oral antifungal agents may be required, particularly when topical preparations irritate the skin. Occasionally, menstruation and endogenous oestrogen production may need to be interrupted by depot medroxyprogesterone acetate (Provera).

Atrophic vaginitis should be sought and treated in postmenopausal women presenting with dyspareunia. Primary vulvodynia has been described with vulval vestibulitis, vulval pain syndrome, and pudenal neuralgia. These are complex and controversial entities for which there is no satisfactory treatment. Tricyclic or one of the newer antidepressants in full dosage may help either in altering sensory perceptions or treating an underlying depression. Compliance is often difficult.

Psoriasis

In temperate zones, psoriasis affects between 1.5 and 3 per cent of the Caucasian population. It is less common in sunny climates and among certain ethnic groups, such as Asians, native Americans, and Samoans. Around 30 per cent of patients have a positive family history and there is 75 per cent concordance among monozygotic twins, compared with 20 per cent concordance with dizygotic twins. It is a polygenic trait with two patterns of inheritance. Type 1, with a strong family history and early onset, shows linkage disequilibrium for human leucocyte antigens CW_{6}, B_{13}, and BW_{57}. It affects 30 per cent of patients and is possibly an IL-Ira gene defect. Type 2 occurs as a late-onset disorder and is linked with CW_{2}, B_{27}, and CW_{6}.

Known triggers for expression in genetically susceptible people include trauma, stress, infection, pregnancy, hypocalcaemia and dialysis, HIV infection, alcohol, and certain drugs such as lithium, b-blockers, antimalarials, NSAIDs, and steroid withdrawal. Paradoxically, sunlight may worsen psoriasis in some individuals.

Pathogenesis

The pathogenesis of psoriasis includes a tenfold increase in the speed of epidermal-cell proliferation. Since the cells pass upwards through the epidermis at a faster rate and do not seem to have time to produce a horny layer, they remain nucleated even when exfoliated. Numerous problems beset the measurement of the cell-cycle time in human epidermis. For example, there are the technical difficulties of counting and the exact recognition of different stages of the cell cycle and differentiation. Do all cells in the germinal layer have the potential to divide or is the potential greater in psoriasis? Is the actual cell cycle faster in psoriasis? The answer is probably that it is and that more cells enter the cycle per unit time in psoriasis. Moreover, cell-cycle inhibitory factors may be reduced and stimulatory factors increased. The kinetics of keratinocyte turnover are clearly essential to our understanding of psoriasis. Probably there is no single cause, but neutrophils, which are attracted in large numbers into the epidermis, may play a part. Streptococcal antigens crossreact with skin antigens, thereby stimulating an autoimmune response. The role of the lymphocyte has long received consideration and has been encouraged by the observations of exacerbations of psoriasis in patients with

AIDS, its control by ciclosporin, and the possible immunosuppressive effects of other effective therapies, such as corticosteroids or PUVA. Psoriasis in those with AIDS is most pronounced at intermediate levels of immunodeficiency, and is diminished or lost in terminal profound immunodeficiency states. At the biochemical level, almost every aspect of cell kinetics is a candidate, including the availability of cyclic AMP, increased cyclic GMP, fatty acid deficiency, eicosanoids, phosphorylating mechanisms, polyamines, putrescine, spermidine, and calcium-modulating enzymes such as calmodulin and vitamin D analogues. How cells stick together and how adhesion is modulated during migration and mitosis introduces many other concepts, ranging through the role of interleukins (IL-1, -2, -6, -8), interferons (IFN-g), transforming growth factors-a and -b, to the interaction with proteases, since in psoriasis the proteinase–antiproteinase balance seems to be disturbed. Psoriasis is not merely a disorder of the keratinocyte. Thus arthritis cannot be explained on such a basis. Within the dermis, some hypothesize that the fibroblast, the mast cell, or even the endothelial cell are prime targets for whatever it is that fires the psoriatic process. Recent greater understanding has added neuropeptides to the list of potential triggers, since they induce mast-cell degranulation and fire the interaction between the fibroblast and keratinocyte.

The lesion-free skin in people with psoriasis is not normal. Psoriasis is readily induced and various medications, such as chloroquine, practolol, and lithium, can produce a flare-up. Oddly, glycogen levels, so high in the psoriatic lesions, may be lower than in the normal surrounding skin. The dermis is not normal, and the earliest signs of any abnormality following injury are infiltration by mast cells and macrophages.

The microvasculature in psoriasis is characterized by tortuous and leaky capillaries, generous protein exudation, and poor clearance through immature lymphatics.

Koebner phenomenon

The 'Koebner phenomenon' is a term given to psoriasis developing in traumatized skin; this occurs at some stage in about half of all the patients with psoriasis, and is most common when the psoriasis is active. It is an all-or-nothing phenomenon on the skin surface. After the initial repair stimulus, the epidermis gradually thickens and there is accentuation of the papillary interdigitations and the rete ridges. An early heavy infiltrate by neutrophils forming microabscesses within the epidermis is preceded by increased numbers of mast cells and macrophages in the dermis. High turnover of the epidermal cells results in a less-compact and still partially nucleated scale known as parakeratosis. The reverse Koebner phenomenon, where trauma initiates clearing of psoriasis can also occur, and is probably more common than the true Koebner phenomenon.

Clinical appearance

Psoriasis can affect all age groups, but has a peak age of onset between the ages of 5 and 9 years in girls and 15 and 19 in boys. The commonest lesion is a sharply marginated plaque with silvery scales (Fig. 42). These mask the underlying redness from the tortuous convoluted capillaries that lie close to the surface of the skin. The edges of the lesion are usually the most active and there is commonly clearing in the centre (Fig. 43). Since itching is common, scratching may modify the appearance, increasing shedding of scale and causing bleeding.

Fig. 42 A psoriasis plaque showing the silvery scales, well-defined border, and predilection for the elbow.

Fig. 43 Psoriasis that is less stable than in Fig. 42. The lesions are erupting and more active at the periphery while healing in the centre.

Sites most commonly affected are the elbows, knees, and scalp, areas that normally have a higher rate of epidermal turnover. The face is less often affected. Spontaneous fluctuations are common and remissions occur in about one-third of cases per annum. As there are several well-recognized patterns, it is important to examine the patient thoroughly until a completely recognizable lesion of psoriasis can be detected. Many lesions and some patterns may be quite atypical, especially during the development of psoriasis (Fig. 44) or during its resolution.

Fig. 44 A still more unstable form of psoriasis, tending to be more exudative and exfoliative and not retaining its rapidly produced scale. While tending to be symmetrical, new ill-defined lesions are erupting. There are some linear lesions on the trunk suggestive of the Koebner phenomenon or a reaction to a skin injury, in this case probably from scratching.

Guttate psoriasis

This term is derived from the Latin *gutta*, meaning a drop. The skin looks as though it has been splashed by the psoriasis. It often follows a streptococcal sore throat or vaccination and is especially common in children. The lesions are scattered over the entire body and tend to be no more than a few millimetres in diameter. They may include the face and are often red slightly scaly spots. Guttate psoriatic lesions appear less well defined and less obviously covered by silvery scales than in classic types of psoriasis. In the absence of a family history the prognosis tends to be good.

Nummular discoid

This is probably the commonest form of psoriasis, in which coin-shaped lesions of various sizes (Fig. 45) are scattered over the body in a completely symmetrical distribution. Such lesions are usually well defined and chronic.

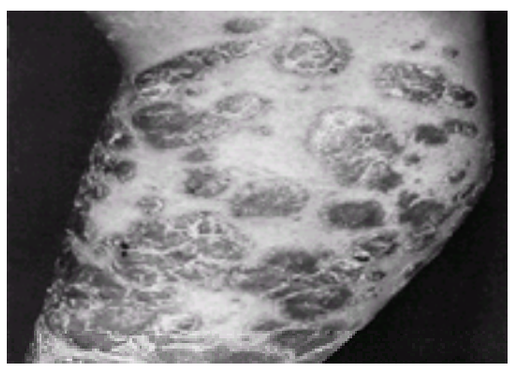

Fig. 45 Discoid lesions still well defined but becoming almost confluent.

Palmar and plantar psoriasis

This may be typical of lesions elsewhere (see Fig. 4), but the psoriasis is often modified due to the nature of the palmar and plantar skin. The scales tend to be more adherent and less silvery and are more likely to develop deep cracks because of the thickness of the epidermis at these sites (Fig. 46). Neutrophils tend to collect into larger abscesses trapped by the thicker surface layers of the stratum corneum, the sterile pustules so formed are often the most obvious feature. Although this pattern may be seen as part of a more generalized disease, in many cases it only affects the hands and feet. There is some evidence that it is a different disease, since the above-mentioned HLA associations are absent and there is no obvious increase in the rate of epidermal turnover. Where the psoriasis is an occasional and acute response to infection, it is known as pustular bacterid.

Fig. 46 Psoriasis of the palms may not have the typical scale. It is sometimes pustular or, as in this case, hyperkeratotic with a tendency to form deep cracks (see Fig. 4).

Psoriasis of the nails

Some 25 per cent of patients with psoriasis have nail disease. Among those with psoriatic arthritis this figure is in excess of 75 per cent. Pin-point pitting is usual but can be seen in other disorders affecting nail growth (see Fig. 66). Onycholysis with brown discoloration of the base of the uplift of the nail, known as brown onychodermal band, is probably even more characteristic. Salmon-pink circular discoloration in the nail-plate, likened to oil drops, are only seen in psoriasis. Sometimes the nail growth is distorted, thickened, and friable and difficult to distinguish from a fungus disorder affecting the nail (see Fig. 69).

Fig. 66 Pits of the nails are due to very localized accelerations in growth such that the nail keratin is less well knit. Such pits are very common in psoriasis.

Fig. 69 Severe growth changes of the nail are often a consequence of psoriasis or eczema of the fingertips. The latter may resolve while nail growth disturbance may

persist for many months.

Flexural psoriasis

When psoriasis affects the groins, natal cleft, or axillas, it is usually less scaly. The bright-red plaques are shiny and liable to cracking and maceration. They may be very well defined.

Erythroderma

This may present as a medical emergency due to fluid loss, septicaemia, or lowering of body temperature. The elderly may develop high-output cardiac failure. Oedema is a consequence of capillary leak, low albumin, and heart failure. When psoriasis affects the entire skin there is generalized redness, the well-defined margins are lost, and the scales are profusely exfoliated. The erythroderma may be indistinguishable from that found in eczema or lymphoma. Bacteraemia commonly ensues when the normal protective function of the skin is lost. The loss of water is difficult to estimate and prerenal failure can develop very rapidly. The vasodilatation and the obstruction to the sweat ducts by the proliferating epidermis results in impaired thermoregulation. Hyperthermia is very common in hot climates, while hypothermia can occur in cold climates. Internal organs such as the gut and liver may be impaired and loss of protein both from the skin and the gut is an important complication.

Generalized pustular psoriasis

In this condition, which is relatively rare, waves of bright erythema develop within a few hours together with a fever, arthropathy, and leucocytosis. Myriads of pustules (see Fig. 17) quickly develop and equally quickly disappear. This disorder may occur in the absence of a previous history of psoriasis and even occasionally as a viral exanthem. However, most commonly it is only a complication of psoriasis that has been treated by systemic or local steroids. It is an acute rebound phenomenon of steroid withdrawal.

Acute generalized exanthematous pustulosis occurs in patients with no previous or family history of psoriasis and has been blamed on mercurial drugs and antibiotics. Another rare cause of pustular psoriasis is hypoparathyroidism. Cutaneous drug eruptions may mimic this condition, and any suspected drug should be stopped. Generalized pustular psoriasis is potentially life threatening and therefore admission to hospital is required. Oral retinoids are helpful, as is methotrexate. Oral steroids are best avoided due to the potential for rebound flare when they are stopped.

Arthropathic psoriasis (see Section 18)

The incidence of polyarthritis in those with psoriasis is about 7 per cent in hospital series; 4 per cent of all patients with inflammatory polyarthritis have psoriasis. Up to one-third of patients with pustular psoriasis develop a polyarthritis. There is a long-standing debate concerning the association of psoriasis with inflammatory polyarthritis; it is still uncertain whether it is a chance association, possibly related to a genetic linkage disequilibrium. Since psoriasis is a common disorder, patients with a positive Rose–Waaler test can have coincidental rheumatoid arthritis.

Management

By far the most disabling aspect of psoriasis is its appearance, and patients' lives can be completely taken over by manoeuvres designed to avoid exposing the affected skin to the public eye. Management includes a sympathetic hearing and, when necessary, admission to an outpatient or inpatient unit where others with psoriasis are being treated.

Psoriasis can usually be controlled with therapy. While the skin can be made to return to normal, the inherited susceptibility is fixed, and so patients remain vulnerable to relapse. Some environmental triggers have been identified and should be avoided. These include infection (streptococcal, HIV), trauma to the skin (Koebner phenomenon), psychological stress, and drugs such as lithium, chloroquine, and b-blockers; however, many triggers are unknown and therefore unavoidable.

It is common to combine treatments, either different topicals together, or topical agents with oral preparations or ultraviolet therapy. The response to treatment is variable, and those that were previously effective may no longer be so, and vice versa.

The aims are to depress epidermal cell turnover, suppress skin inflammation, reverse angiogenesis, and remove hyperkeratosis without irreversibly damaging the skin or other organs. It is important that the treatment chosen is appropriate for the type and site of the psoriasis. In mild cases, emollients (for example, 10 per cent glycerine in sorbolene cream) or keratolytics (for example, salicylic acid 3–10 per cent in aqueous cream) may suffice, but disabling or disfiguring psoriasis may warrant the use of systemic antimetabolite or immunosuppressive drugs.

Local steroids

Topical corticosteroids are anti-inflammatory, immunosuppressive, and antiproliferative. Steroid creams and ointments are often used as the first-line treatment for all types of psoriasis because of their ease of use. The stronger halogenated steroids are the most effective. A response may be seen as early as 1 to 2 weeks. Complete resolution generally takes 4 to 6 weeks and occurs in around two-thirds of those who use it. Relapse on cessation of therapy is common and one-third of patients need to continue once- or twice-weekly application. Care is required on the face and flexures to prevent the formation of stria and telangiectasia. Other side-effects associated with continued use are skin atrophy, gradual extension of the psoriasis, and greater instability of the skin so that psoriasis erupts whenever the therapy is partially or completely withdrawn. Eventual widespread usage and systemic absorption complicates the increasing addiction of the skin for the stronger steroids. Some patients so treated show no remission until all such therapy is withdrawn; although in a few this can be done with no immediate worsening of the psoriasis, in most patients withdrawal leads to a rapid worsening of their skin condition.

Tar

Tar is antiproliferative, antipruritic, and anti-inflammatory. Tar has been known to be effective and safe for more than 50 years. Follow-up of patients treated with tar between 1917 and 1937, using the Danish Cancer Registry of all cell cancers from 1943 to 1990, found no overall risk of skin cancer; however, recent rulings by the European Commission have limited its availability in some countries. The smell, colour, and stain of crude coal tar (**CCT**) make it cosmetically unsatisfactory and it may be irritant on more vulnerable skin such as the face and flexures. Less irritating and more cosmetically acceptable varieties of tar include liquor picis carbonis (**LPC**), ichthammol, and oil of Cade; however, these are comparatively less effective than crude coal tar. CCT (2.5–6 per cent) or LPC (2–10 per cent) may be prescribed in a base of aqueous cream, sorbolene cream, or liquid paraffin. A keratolytic such as salicylic acid can be added to augment its efficacy. Many proprietary formulations are available in most countries.

The preparations are applied once or twice daily; but diluted by 50 per cent if they are irritant. Generally little response is seen for 1 to 2 weeks. Complete resolution takes between 6 and 8 weeks; however, subsequent remissions may be prolonged. Occasional patients are allergic to one or more of the constituents. The general principles of when to use a lotion, ointment, or paste are discussed below. Acute or inflamed psoriasis responds to ichthammol, which has a milder action than coal tar.

Dithranol

Dithranol is antiproliferative and mildly anti-inflammatory. It is more effective than coal tar in the treatment of psoriasis, especially if the plaques are large, well-defined, and few in number, but is more irritant, especially to the eyes and genitalia. However, an acceptable diluted concentration can generally be found, and the concentration can then usually be gradually increased. The dithranol is mixed in zinc oxide and salicylic acid paste (Lassar's paste) in a concentration of 0.1, 0.25, 0.5, 1, or 2 per cent. Weaker preparations are used in the more sensitive occlusive flexures. It is safe in pregnancy.

Non-lesional skin may be protected by Vaseline, and it is usual to apply dithranol paste accurately to the active parts of the skin lesion. Powdering fixes the paste and a gauze or nylon dressing protects the overlying clothing from dithranol's staining property. Patients tolerating this regimen are cleared in about 3.5 weeks on average. Staining is inevitable and short lived and is a sign of effectiveness. Irritation, feeling like a mild burn, is treated by stopping treatment for 1 or 2 days. Various proprietary brands are slightly easier to manage and include Vaseline-based preparations and creams or sticks. The 'minute regimen' is a system using 1 to 5 per cent dithranol in Vaseline and 2 per cent salicylic acid. It is only applied for about 80 min, then removed with an oil. Dithranol is suitable for those whose employment requires their skin to be free of ointments for most of the day.

Calcipotriol

Calcipotriol, a vitamin D analogue, is a safe and cosmetically acceptable, effective topical treatment, which inhibits proliferation and enhances epidermal differentiation. It is applied twice daily at a rate of no more than 100 g/week. However, calcipotriol is irritant for about 10 per cent of users, particularly when used on the face. Its combination with betamethasone valerate in popular.

Tazarotene

Tazarotene is a topical synthetic retinoid that also has some efficacy in the treatment of psoriasis. In general, it works best in combination with other topical agents, but is commonly irritating on the skin.

Phototherapy

Natural sunlight is helpful in about 75 per cent of patients and probably accounts for a decreased incidence of psoriasis in sunny climates. Suberythema doses of UVB are a useful substitute, and its effectiveness can be increased by prior bathing or an application of tar which sensitizes the skin to the UVB.

PUVA therapy, which is a combination of long-wave ultraviolet rays (UVA or black light) and 8-methoxypsoralen tablets (0.5 mg/kg) taken 2 h before exposure, produces effective clearance and a bronze skin in most patients. A 15- to 30-min exposure two or three times per week succeeds in clearing the psoriasis in 6 to 10 weeks. The treatment is stopped on clearance of the psoriasis. Patients who relapse quickly may be considered for maintenance therapy either once a week or once every 2 weeks. Recurrences are no less frequent than with other forms of therapy. Dryness, atrophy, and other expected changes of irradiation are a consequence. The risk of skin cancer is as yet difficult to estimate, but it is not insignificant. In male patients receiving more than 200 treatments, the incidence of squamous-cell carcinoma was 30 times greater than that found in the general population in Sweden. As the risk of melanoma in these patients may also be increased, further long-term studies are required. The risk is especially great in those who have arsenical keratoses or other evidence of a previous intake of arsenic. Concurrent treatment with methotrexate is also considered a risk factor.

Broad-band UVB therapy has been used for much longer and is similarly effective as PUVA. Increased carcinogenicity, although not proven, is suspected. Narrow-band UVB (311 mm) is thought to be less irritant and highly specific for psoriasis. By screening out the shorter wavelengths within the UVB spectrum it is assumed to be safer than broad-band treatment.

Climatotherapy is the combination of natural sunlight (or a filtered form of sunlight in the case of the Dead Sea area) with sea salts and/or other constituents—sulphur, black mud, and bromides—present in different geographical regions. It is effective, but no more so than other regimens that provide topical medicaments and mental relaxation. The Dead Sea may be exceptional in the number of its peculiar features, such as low humidity, increased atmospheric pressure, UVB filtration, and minerals in high concentration.

Systemic therapy

When psoriasis is widespread, severe, or causing disfigurement or disability, systemic therapy is indicated. This may take the form of drugs that have antiproliferative or anti-inflammatory, or immunomodulatory effects. The main agents used are acitretin, methotrexate, and ciclosporin. A host of other agents such as hydroxyurea, sulfasalazine, tioguanine, mycophenolate mofeate, tacrolimus, and azathioprine have some efficacy in psoriasis. Human anti-IL-8 antibody may prove to be a new approach to the management of psoriasis.

Acitretin affects cell proliferation and differentiation mechanisms and is also an anti-inflammatory agent. It may be used in psoriasis as monotherapy in the control of palmoplantar and other hyperkeratotic forms of the disease, as well as pustular erythrodermic and atypical presentations of psoriasis, or in combination with phototherapy to augment its efficacy. The usual dose is 0.5 to 1 mg/kg daily; however, many patients cannot tolerate this dose but lower doses may be similarly effective. The major adverse effect of acitretin is teratogenicity, hence contraception is mandatory for women of childbearing age for the duration of therapy and for at least 2 years after the completion of a course of treatment. This makes acitretin undesirable for use among premenopausal women. Other adverse effects of acitretin include all those of hypervitaminosis A; cheilitis, hair fall, photosensitivity, elevation of liver enzymes, and increase of serum lipids.

Methotrexate slows epidermal-cell proliferation and is an immunomodulator. It is the most commonly prescribed antipsoriasis drug. The usual dose is 0.2 to 0.4 mg/kg orally once weekly. Toxicity is more common in the elderly and in patients with reduced renal clearance, therefore lower doses may be required. Patients should abstain from alcohol while being treated with methotrexate. Adverse effects include nausea, pancytopenia, and elevation of liver enzymes. Nausea may be controlled by the concomitant administration of folic acid. Long-term use of low-dose methotrexate may induce liver fibrosis, which seems to be more common in patients treated for psoriasis with methotrexate than in those being so treated for rheumatoid arthritis. Monitoring of patients includes regular full blood and liver function tests. Liver biopsy may be considered in patients with abnormal liver function tests after a cumulative dose of methotrexate between 2 and 4 g to exclude the liver cirrhosis that occasionally complicates the fibrosis.

Ciclosporin A inhibits selectively activated T-helper cells and reduces the production of cytokines. It is very effective in controlling psoriasis at doses between 2 and 5 mg/kg per day. However, ciclosporin A does not produce long remissions and recurrence follows discontinuation. It is not recommended for continuous use beyond 12 weeks, twice per year, because of long-term adverse effects such as hypertension, deterioration of renal function, hypertrichosis, gingival hyperplasia, and the development of neoplasia (specifically, skin squamous-cell carcinoma and lymphoma). It is reserved for the most difficult cases when other treatments have failed or been deemed unsuitable.

On the basis of preliminary reports, one can predict that monoclonal antibody therapy against adhesion molecules and against interleukin-2 receptors will have increasing advocates.

Pityriasis rosea

Pityriasis rosea is a relatively common, self-limiting, inflammatory skin condition that characteristically affects young adults. The cause is thought to be a virus (possibly human herpesvirus-7). The eruption begins with a herald patch that may be mistaken for ringworm. This is followed about 2 weeks later by the development of multiple, scaly, salmon-coloured macules, each about 1 to 2 cm in size and oval in shape. The macules are confined to the trunk and upper limbs and are arranged along the skin creases to create an appearance reminiscent of a Christmas tree. Itch is variable. The rash disappears spontaneously, usually within 6 to 8 weeks.

The aim of treatment is the palliation of any associated itch while awaiting spontaneous resolution. In the absence of itch, reassurance may suffice. First-line therapy to relieve itch consists of topical antipruritic agents such as calamine lotion, 1 per cent menthol in aqueous cream, or a moderately potent topical corticosteroid cream. UVB phototherapy can be used to relieve itch and may hasten resolution of the rash.

Lichen planus and lichenoid eruptions

Lichen planus is an idiopathic inflammatory condition. It may affect the skin, hair, nails, and oral and genital mucosa. Alopecia occurs if the scalp is involved, and nail damage and destruction are seen when the nail matrix is affected. Occasionally lichen planus can be triggered by drug ingestion or hepatitis C infection.

Lichen planus and lichenoid eruptions are characterized by violaceous papules that are usually flat-topped and shiny and heal leaving pigmentation. Histology shows

damage to the basal layer of the epidermis and an intense infiltration of lymphocytes and a few histiocytes situated immediately below the epidermis (Fig. 47). A T-cell-mediated CD4+ attack on the epidermis may be triggered by viral, drug, or neoplastic processes. Lichen planus thus presents a model for the elimination of damaged and normal keratinocytes. Cytokines, interferon-g, and tumour necrosis factor-b play a critical role. Lymphocyte and keratinocyte molecules subserving adhesion are activated and, in the mouse, lichen planus can be blocked by monoclonal antibodies. The disturbances in epidermal growth that result from this damage range from extreme atrophy with ulceration and almost no epidermal-cell turnover to considerable hypertrophy and hyperkeratinization, giving rise to thick nodules meriting the name 'hypertrophic lichen planus'. Most patients are between the ages of 30 and 60 years and it is extremely rare in children. More-erosive forms are seen in the elderly, and pigmented skin tends to develop more hypertrophic varieties.

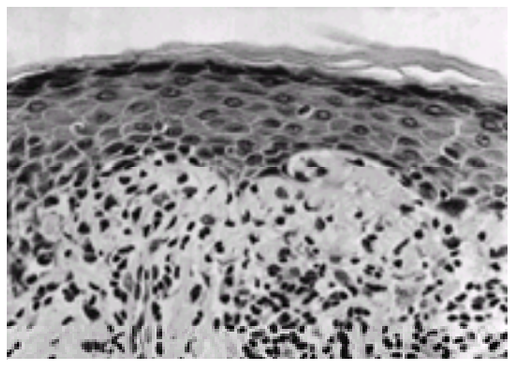

Fig. 47 Lichen planus. There is thickening of the granular layer and necrosis of the basal-cell layer. Pale cells at the lower edge of the epidermis are destroyed epidermal cells. The predominant white cell is a lymphocyte. The infiltrate is often confined to the upper dermis.

HLA-A3 and -A5 occur more often in patients with lichen planus than in controls. The graft-versus-host skin reactions following bone marrow transplantation often present with an identical pattern of pathology to that of lichen planus. There is some clinical pathological overlap with the appearance seen in lupus erythematosus. Although immunofluorescence studies show heavy deposits of fibrin and immunoglobulin, these could be entirely non-specific. There is some evidence of defective carbohydrate metabolism and abnormal glucose tolerance, but the basis of this association still has to be explained. A lichen planus-like drug eruption may also be produced by a variety of medications, particularly antihypertensive and antimalarial agents, gold and organic arsenicals, antituberculous therapy, chlorpromazine, as well as from contact with colour developers.

Clinical features

The classical lesion is a shiny, flat-topped papule (Fig. 48) described as polygonal and violaceous. Small white dots or lines in such papules (termed 'Wickham striae') are due to a mixture of oedema, white-cell infiltrate, and vasculature disturbances. The papules may become confluent and heal in the centre, giving rise to annular (Fig. 49) lesions or plaques with varying degrees of epidermal response. This may result in either atrophic skin or extreme hypertrophy. A lacy-white appearance (Fig. 50) is common in lesions of the mouth or the glans penis. Hair-follicle involvement may give rise to keratosis pilaris and actual destruction of the hair follicle. Thus, lichen planus is one cause of scarring alopecia. Healing of the lesion is often followed by pigmentation due to melanin in the dermis. Warty hyperkeratotic lesions may be very persistent, as may ulceration, particularly of the peripheries or of the oral mucosa. The initial lesions are commonly found on the front of the wrists, in the lumbar region, or around the ankles. The palms and soles may be involved, in which case the appearance may even suggest a vesicular eruption. Involvement of the mucosa and tongue, which occurs in between 30 and 70 per cent of cases, may extend to the genitalia and perianal area, and has even been described in the rectum, stomach, and larynx. Severe itching is common. Ridging of the nails is essentially due to cessation of nail growth, producing longitudinal linear depressions.

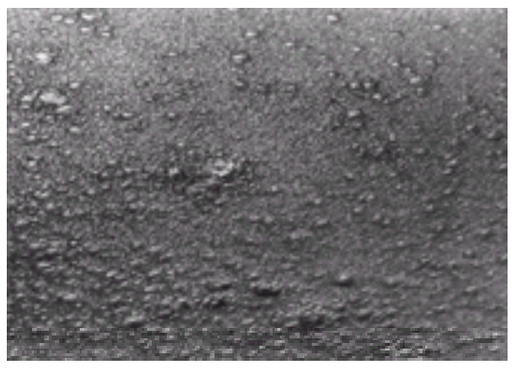

Fig. 48 A black skin affected by the shiny, flat-topped, often polygonal, papules of lichen planus.

Fig. 49 Lichen planus may heal in the centre, leaving atrophy and pigmentation. The edge is slightly raised; which gives rise to the annular form of the condition.

Fig. 50 Lichen planus of the mouth is one cause of mucosal whiteness. Unlike candidiasis the lesions cannot be removed by scraping. They are characteristically

'lacy' in appearance.

Prognosis

The mean age of onset is during the fifth decade. It may be very explosive or insidious in onset. Most cases clear slowly: 66 per cent of cases take up to a year to clear; 85 per cent clear in 18 months. Mucous membrane lesions or extremely hypertrophic lesions on the legs often persist for years, and there is a risk of squamous epitheliomatous changes, particularly in ulcerated mucosal lesions.

Treatment

Treatment is mainly aimed at relieving the itching, and local steroid creams are perhaps the most effective. Occasionally, a course of prednisolone or ACTH is justified for the treatment of a very severe widespread lichen planus. Probably it does not influence the course of the disease but merely its intensity. As with all itching conditions of the skin, cooling evaporating lotions such as calamine lotion may be helpful. Persistent ulcerated lesions can be excised or grafted. Lesions in the mouth can be treated with local steroid creams, those containing Orabase (a carmellose and gelatin paste) being particularly effective. An asthma-type spray may be a more effective way of administering steroids to the oral mucosa, but must be used without inhalation.

Acne vulgaris

Acne is a common, chronic inflammatory disease of pilosebaceous ducts, that affects a high proportion of the population. An onset around puberty is usual and it tends to resolve within 10 years if untreated. Its onset coincides with major changes in the life of an adolescent and may have a negative impact on the psyche of the sufferer and cause profound psychological effects. Physicians should not underestimate the effects acne may have on an individual's body image. Even minor acne may cause depression and negative feelings in particular individuals. It is strongly familial and monozygotic twins show high concordance. It is seen less in some races (Blacks, Japanese, Inuits). The disease may vary at presentation from one to two evanescent lesions occurring at a time, to a severe inflammatory disorder that can result in disfiguring scarring.

Commonly involved areas are those with the highest concentration of sebaceous glands, that is the face, neck, chest, shoulders, and upper back. The primary lesion of acne is the comedo. This non-inflamed lesion may be open (blackhead) or closed (whitehead), and may be accompanied by inflammatory lesions (papules, pustules, and cysts).

Aetiology

The three main processes contributing to acne are: increased sebum secretion; pilosebaceous duct obstruction; and inflammation.

Under the influence of local sex-hormone metabolism, androgens stimulate an increase in the size of the sebaceous glands and, hence, more sebum is produced (see below). These large glands themselves produce more active androgen metabolites through the activity of type 1, 5a-reductase; one effect of these metabolites is to further enlarge the sebaceous glands. Sebum acts in partnership with bacteria to produce keratinization and hence blockage of the pilosebaceous duct and comedo formation.

The principal organism responsible is *Propionibacterium acnes*, which increases in number during flare-ups and is important in the change from non-inflammatory to inflammatory acne. This bacterium produces many inflammatory substances, such as lipases, proteases, hyaluronidases, and chemotactic factors that play a role in producing lesions. Therapy that lowers the *Propionibacterium acnes* count plays a pivotal role in management, but resistance of the bacterium to some antibiotics, especially erythromycin, is an emerging problem in acne therapy.

Acne may also be drug-induced, particularly secondary to anabolic and corticosteroids, iodides, lithium, phenytoin, streptomycin, and isoniazid. Sebum consists of triglycerides, wax esters, squalene, and sterol esters. The fatty acids in sebum are inflammatory and are formed by the lysolytic enzymes of bacteria, even in healthy skin, from unsaturated 14- to 16- or 18-carbon components of the triglycerides. It is possible that acne in people living in the tropics is due to a secondary response in the rate of turnover of the follicular lining, perhaps induced by occlusion under a belt or braces in such hot environments. The acne of Cushing's disease may also be due to an increased rate of such turnover. Chlorinated hydrocarbons also cause acne. Chloracne is an important symptom of poisoning and was present in 168 cases of poisoning in the Seveso industrial accident. The exact way in which the inflammation is produced is uncertain; as the follicle contains fatty acids and bacterial proteases which activate the classical alternative pathway of complement and attract neutrophils, this may be one mechanism.

Sebaceous gland activity is regulated by hormones and, in particular, by androgens from the testes and adrenals, which stimulate, and oestrogens, which seem to suppress activity. In the adult male the glands are normally maximally stimulated, leading to more severe in boys than in girls. The skin itself is a major site for androgenic conversion similar to that observed in the prostate gland and in the male genitalia. Dihydrotestosterone, rather than testosterone, may be the end-organ effector and is formed within the target cells where it stimulates lipogenesis as well as mitosis. Eunuchs do not develop acne. Oestrogens reduce the size of sebaceous glands and sebum production is diminished.

Clinical features

Closed comedones (whiteheads) are the first stage of acne, seen as tiny white nodules below the surface especially when the skin is stretched (see Fig. 7). These may rupture giving rise to irritation of the dermis (that is, inflamed papules) or form the open comedo (blackhead) by pushing open the mouth of the follicle (Fig. 51). Because the black material is melanin, blackheads are blacker in dark skins and white in the albino; melanin is transferred to the keratinocytes before these cells are shed into the sebaceous follicle. Acne cysts (Fig. 52) occur as the result of ballooning of the distended follicle, often leading to destruction of the walls of the cyst and hair and sebaceous apparatus. Adjacent cysts often form fistulas and sinuses, which rupture, displacing epithelium in the dermis, and forming irregular channels or foreign-body reactions.

Fig. 51 greasy skin is a common accompaniment of acne, as is comedo formation, or 'blackheads', as seen on the forehead of this young man. Whether either are wholly responsible for the consequent inflammation and scarring also seen in this photograph is debatable.

Fig. 52 Large cystic lesions are the most disfiguring aspect of acne vulgaris.

Atrophic or hypertrophic scars of all types may be seen; frequently, excoriations, picking, and squeezing contribute to the irregularities of pigment and to the epidermal or dermal thickening. Rarely, young males develop suppurative and highly inflamed lesions in the skin over the chest with pain, fever, and accompanying polyarthralgia, probably mediated by immune mechanisms and the activation of complement.

Acne usually presents before the menarche and without treatment usually resolves within 8 to 10 years. A more persistent form—particularly affecting the chin—may last until middle age, especially in women who have premenstrual exacerbations. Some women with adult acne also have the polycystic ovary syndrome.

Cosmetics

In many parts of the world cosmetics contribute to acne, the lesions of which may be confined to the site of application. Vaseline-type preparations or medicated oily shampoos used by young men and women with long hair, are a well-known cause.

Management

The withdrawal of aggravating factors such as cosmetics and drugs is paramount where they appear to be involved in the aetiology of acne. Most patients with acne, however, have no such triggers. Trauma, such as picking and vigorously squeezing acne lesions, can aggravate the condition; in some cases of acne excoriée the effect of trauma dominates the clinical picture. Large superficial pustules can be evacuated by gentle pressure without deleterious effect, and the removal of loose comedones with a comedo extractor is commonplace in the practice of dermatology.

Local preparations

All local preparations produce some erythema and occasional pustulation before the acne comes under control. Sulphur is a time-honoured agent, producing local irritation and causing peeling. It is helpful for the treatment of pustules, but may not be so good for comedones which precede pustulation, often by several months. Comedones are reduced by topical retinoids, azelaic acid (20 per cent cream), and by 10 per cent salicylic acid in ethanol. Topical retinoids help the follicle-lining cells to slough off without plugging the follicle. They can be applied in cream, lotion, or gel formulations, and are indicated for comedones rather than for pustules or cysts. Side-effects of the topical retinoids include irritation, redness, and peeling.

Long-acting oxidizing antiseptics such as benzoyl peroxide reduce sebum excretion, reduce comedo production, and inhibit *P. acnes in vitro.* They are the topical treatment of choice, are a mild irritant, and may produce mild peeling after several days' application. It is best to start sparingly with 2.5 per cent preparation, and later to increase the amount applied or the concentration to 5 or even 10 per cent.

Topical antibiotics such as clindomycin (1 per cent), erythromycin (2 per cent), and tetracycline can be used to reduce the population of *P. acnes* in the pilosebaceous duct. In view of emerging bacterial resistance and the possibility of transfer of resistant genes between bacteria via plasmids or transposons, prolonged therapy, and in particular prolonged monotherapy, with these agents is not recommended. When used, they should be combined with topical benzoyl peroxide to inhibit bacterial resistance.

Oral therapy

Antibiotics used include tetracycline, minocycline, doxycycline, erythromycin, and trimethoprim (either trimethoprim alone or as co-trim-oxazole). The treatment is prophylactic and the onset of action is delayed for 6 to 8 weeks. Patients can expect a 60 per cent improvement after 3 months and an 80 per cent improvement after 6 months. Relapse is common on cessation of the treatment, however maintenance topical therapy may suffice.

Gastric upset, diarrhoea, and vulvovaginal candidiasis are the most common problems encountered with antibiotics. Photosensitivity to doxycycline and drug-induced hepatitis from minocycline are both uncommon side-effects. Morbilliform drug eruptions due to co-trimoxazole are relatively frequent. Tetracycline may produce discoloration of the teeth in the fetus and in children, hence oral erythromycin is the treatment of choice during pregnancy. Rarely, Gram-negative folliculitis occurs, particularly around the nose or in persistent cysts. This results in sudden worsening with considerable inflammation and may warrant a course of ampicillin.

The oral contraceptive pill is frequently prescribed for women with acne, as the oestrogen component suppresses sebaceous gland activity and decreases the formation of ovarian and adrenal androgens. However, the progestogen component can aggravate acne and therefore contraceptive agents with a low-progestogen dose are preferable. The newer progestogens, such as norgestimate, gestodene, and desogestrel, have less androgenic effects and are therefore the agents sought in a contraceptive pill where an anti-acne effect is desired. Oral contraceptives containing a combination of cyproterone acetate (see below) and an oestrogen (for example, 2 mg cyproterone acetate and 35 µg ethinyl oestradiol), are also an effective treatment of acne in women. While they are more effective than the low-progestogen oral contraceptives, they also have more adverse effects. The onset of action is slow, however they may be suitable for long-term therapy. They are usually more effective when used in combination with other therapies rather than as an isolated treatment. Cyproterone acetate and spironolactone can be used for their antiandrogenic properties in the control of severe acne in women not planning to become pregnant. They are most commonly used when there are associated symptoms of virilization, for example in the polycystic ovarian syndrome.

Where the acne is resistant to treatment or persistently relapses, and in cases of severe cystic acne and acne where scarring is likely, oral isotretinoin (0.5–1 mg/kg) is the treatment of choice. This vitamin-A derivative acts by correcting the keratinization defect in acne, decreasing sebaceous gland activity, and reducing the population of *P. acnes*. It is also anti-inflammatory. A cumulative dose of 120 to 150 mg/kg over a period of 4 to 6 months is usually required and one course is usually sufficient for most patients, although approximately 10 per cent of cases need a further course. Isotretinoin is teratogenic, so strict avoidance of pregnancy is of paramount importance whilst taking the drug and for one full reproductive cycle after discontinuation. Prescription is usually limited to dermatologists. Adverse effects of some degree are universal, including dry skin, eyes, and lips, as well as epistaxis, facial erythema, joint stiffness, myalgia, headaches, in addition to an initial flare of the acne on commencement of the treatment. Prednisolone can be used to ameliorate this initial flare. Other side-effects such as depression and paronychia are rare. The severity of the side-effects are dose-dependent and are generally ameliorated by a reduction in dose. Most adverse effects settle within 2 weeks of discontinuing the drug, and many patients cope better with the annoying adverse effects of cheilitis, xeroderma, and photosensitivity as their course progresses.

Diet

Studies of the effects of starvation in the obese or the malnourished show little evidence of the effect of diet on acne vulgaris, even in pellagra where some plugging of the follicles around the nose is an early sign. Chocolate worsens acne in some individuals, but this has not been shown in trials of larger populations. Nutrition may influence the age of onset of puberty and hence overeating may result in earlier acne.

Acne surgery

Comedo extraction is the expression of a follicle's contents by the application of pressure on the surface, often with a special device called a comedo extractor. The benefits of active attack on the lesions, thereby counteracting stasis and build-up of the contents, has to be weighed against the fact that suppression is always incomplete and a tendency to rupture into the dermis may promote inflammation. Cryotherapy destroys the lining of large cysts. Deep sinuses may require externalization. Solitary inflamed lesions benefit from intralesional inoculation of steroids. Persistent acne cysts sometimes resolve with the injection of small amounts of intralesional triamcinolone.

Pigmentation

The principal pigments in the skin include melanin (black), phaeomelanin (reddish-yellow), haemoglobin (red) and its by-products bilirubin (red) and biliverdin (green), as well as haemosiderin which produce colours of yellow, green, red, and brown. Longer wavelengths such as red penetrate deeper and are absorbed by melanin. Since blue does not penetrate so deeply it is not absorbed and is reflected back, which is why dermal pigment appears blue—hence blue naevus. Although racial causes of pigmentation are common, physical causes are also important since white skin may visibly tan in the sun. Tanning and burning are independent events, with different time courses (albeit overlapping), due to the interaction of ultraviolet radiation with distinct chromophores in the skin. Tanning consists of two phases: (1) immediate pigmentary darkening and (2) delayed pigmentation. Immediate darkening occurs within seconds to minutes of exposure, and is due to oxidation of melanin granules stored within keratinocytes in the skin. Delayed darkening is due to the increased melanin production within melanosomes, increased transfer of melanosomes from melanocytes to keratinocytes, and acanthosis of the epidermis. It begins 8 h after exposure, reaches a maximum at 24 h, and in the absence of re-exposure resolves over days to weeks.

Some pigmented lesions are naevi (Table 11, Table 12, and Table 13, Plate 1, Plate 2, Plate 3, Plate 4, Plate 5, Plate 6 and Plate 7, Fig. 53, Fig. 54, Fig. 55, Fig. 56, Fig. 57 and Fig. 58, and see Fig. 106), others result from pigment 'incontinence' which increases the amount of pigment in the dermal macrophages and is commonly postinflammatory.

Fig. 54 Becker's naevus is due to melanin in the dermis and is often segmental and usually hairy. It may only become overt after childhood.

Fig. 55 Crossbow pattern of chloasma in encephalitis, an association that has been described but may be incidental.

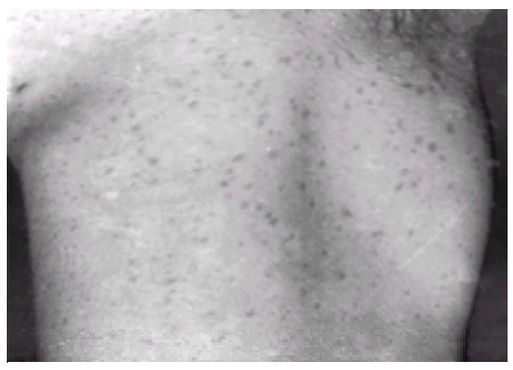

Fig. 56 In neurofibromatosis freckles extend into the axilla. This is a diagnostic feature in incomplete penetrance, important in the genetic counselling of white-skinned, but less reliable in black-skinned, patients.

Fig. 57 Syndrome of progressive darkening of numerous lentigos associated with cardiovascular and neurological abnormalities.

Fig. 58 Pityriasis versicolor due to the organism *Malassezia furfur* causes redness and slight brownish coloration of very pale, white skin, and depigmentation in dark or sallow skin. It favours the upper trunk.

Fig. 106 Erythema gyratum repens in a patient with adenocarcinoma of the colon.

Pigmentation as a feature of systemic illness is most significantly due to endocrine dysfunction affecting the melanocyte-stimulating hormone. In countries where malnutrition and infections are common, protein and vitamin deficiency, as well as cachexia from a variety of causes, account for disturbances in skin colour.

'Tinea' or pityriasis versicolor is due to a superficial fungus known as *Malassezia furfur.* It usually affects the upper trunk and may spread on to the neck or arms. The lesions are slightly scaly, off-white, pink, and brown. 'Pityriasis' is the term for a bran-like powdery scale and 'versicolor' implies the variation in the colouring (Fig. 58).

In leprosy, hypomelanosis is a feature of tuberculoid and borderline tuberculoid types (See Fig. 59 and Chapter 7.11.24). Light touch and later pinprick sensation are impaired. There is often a lack of sweating and there may be loss of hair. An adjacent enlarged peripheral nerve may be palpable, which may be mistaken for an enlarged lymph node.

Fig. 59 Hypopigmentation, especially with a hyperpigmented border, should always be tested for loss of sensation. This lesion is typical of tuberculoid leprosy.

Pigmentation of the buccal mucosa, tongue, or fingernails is significant only in white skin since it is a normal finding in dark races.

Depigmentation

'Leucoderma' is a term used for any whiteness of skin, and ranges from a partial hypopigmentation to the complete depigmentation characteristic of vitiligo. Microbial diseases such as pityriasis versicolor (Fig. 58), leprosy (Chapter 7.11.24) (Fig. 59), and syphilis are important infectious causes of hypopigmentation. Pinta should be suspected in people from central or southern America showing a succession of erythematous hyperpigmented lesions progressing to warty or atrophic plaques of depigmented skin. The late stage resembles vitiligo. Naevus anaemicus is a hypovascularity of the skin observed in white skins (Fig. 60); it is not a disorder of melaninization.

Fig. 60 Not all whiteness is due to loss of pigment. Decreased vasculature has been present since birth in this case of naevus anaemicus.

Vitiligo

This common, autoimmune skin disease results in the destruction of melanocytes and the total depigmentation of affected skin. However, an association with other autoimmune diseases and a family history of such is found in one-third of cases. The cause is unknown, but the melanocyte seems to be damaged by some, as yet,

unidentified antibody or toxin. Although vitiligo is most likely due to an immunological attack on the melanocyte, there are theories based on oxygen free-radical metabolism. In many parts of the world where skins are deeply pigmented, vitiligo is a principal cause of attendances at a dermatology department. Vitiligo affects up to 1 per cent of the United Kingdom population but 8.8 per cent in India. It presents during the first decade of life in 25 per cent of those affected. Except in those people unable to protect themselves from bright sunlight the disability is purely cosmetic, but it causes more concern and social handicap than almost any other common disease.

Occupational vitiligo is a well-recognized effect of exposure to certain chemicals used in the rubber industry—monobenzyl ether of hydroquinone, *p*-tertiary butylcatechol, and *p*-tertiary butylphenol. The hands are usually the first part of the body to be involved along with the genitalia, presumably through contact with the chemical excreted in the urine.

Clinical features

The initial depigmentation often occurs at sites of trauma, particularly the knuckles of the hands, and sometimes forms a white halo around a naevus (Fig. 61 and Fig. 62). The face and neck are usually affected early. In white-skinned people the first complaint often occurs during the summer when the unaffected skin is at its darkest from sun exposure. There is usually marked symmetry; the axillary folds and genitalia are commonly affected; the eye is not involved. Transient hypopigmentation is sometimes observed in evolving lesions; however, depigmentation of the lesion is ultimately total (Fig. 63) and should cause no confusion with the hypopigmentation of diseases such as leprosy. Such areas are never anaesthetic as in leprosy. Pigment may accumulate and be well defined at the borders of the lesion, giving a hyperpigmented edge. Melanocytes of hair follicles are usually unaffected and repigmentation, when it occurs, is often from such sites (Fig. 63(b)).

Fig. 61 Vitiligo is complete depigmentation and not merely hypopigmentation; it often begins at sites of minor trauma such as the knuckles. As with all essentially endogenous disorders it is symmetrical.

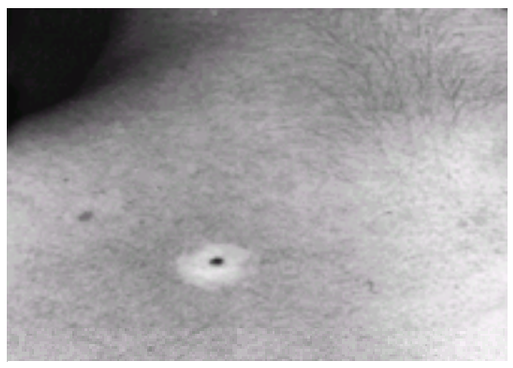

Fig. 62 Vitiligo often begins around a pigmented naevus—a halo naevus.

Fig. 63 (a) The pigment loss in this once dark-skinned woman is almost complete. Satisfactory cosmetic management would be depigmentation of the few residual areas of normal skin. (b) Although repigmentation of the skin in vitiligo is usually from the follicles, it is slow, unpredictable, and incomplete.

The clinician should be aware of associations with diabetes mellitus, pernicious anaemia, Addison's disease, myxoedema, and thyrotoxicosis. Less than one-third of patients show spontaneous repigmentation. In most cases the loss of pigment gradually extends. Depigmentation of the vulva, penis, and neck is sometimes persistent and of a localized variety, but need not necessarily progress to generalized vitiligo. It should be distinguished from the more atrophic lichen sclerosis which may also cause whitening of the skin at those sites.

Management

Patients are usually much distressed by the cosmetic disability. It is helpful to explain that there is a 30 per cent chance of spontaneous cure. Offering advice on camouflage make-up (many dermatology units have advisors specially skilled in this art) gives the patients an opportunity to help themselves, especially for important social occasions. But such camouflage is tedious and difficult to apply effectively for everyday use. There is no special advantage in the purchase of more expensive cosmetics since the basic constituents are cheap. The best effect is achieved from powder and grease mixtures with a powder finish patted gently into the skin after application. Dihydroxyacetone is the basis of many artificial (fake) suntan lotions, but again these are difficult to apply satisfactorily without overpigmenting the adjacent unaffected skin.

Patients should be told to avoid occupations which injure the skin (such as playing with animals that scratch) to prevent vitiligo from the Koebner phenomenon. The cosmetic effect of removing the remaining pigment is sometimes preferred by those whose skin is almost completely depigmented. The formulation used by the Sheffield Royal Infirmary is prepared as follows: hydroquinone 30 g; hydrocortisone BP 6 g; retinoic acid 600 mg; butylated hydroxytoluene 300 mg; and methylated spirit and polyethylene glycol in equal parts to 600 ml. Monobenzyl ether of hydroquinone may also be used to induce permanent hypopigmentation.

Psoralens and sunlight are one of the most ancient remedies used in medicine, UVA (black light) and selective UVB are recently developed extensions of the older remedy. Psoralens, methoxy- or tri-psoralen, are taken by mouth 2 h before exposure to light, or they may be applied topically 30 min before exposure. The simplest

regimen is a combination of meladinin paint and sunlight. It is necessary to test reactivity with short-time exposure and always to expose the skin at the same time of the day to avoid burning the skin by an unexpectedly high intensity of UVA. The chances of remission are in the order of 50 to 60 per cent, but success may take 2 to 3 years to accomplish. As might be expected from an autoimmune disorder, local steroid preparations are sometimes helpful, particularly in early or evolving disease. Although they have been advocated in combination with psoralens, therapeutic triumphs are difficult to assess, and the requirement to use these agents for years rather than days makes side-effects very likely. Local steroids are sometimes used to stabilize a rapidly progressive early stage of the disease. Cosmetically disabling local patches can be treated with light dermabrasion and the application of autologous split-skin grafts from pigmented skin. In Asia many clinics have treated thousands of patients in this way and there are several traditional herbal remedies prescribed for widespread lesions.

Other forms of pigment loss

Albinism

This is a group of at least 15 genetically distinct syndromes, determined not by absence of melanocytes but by their inability to synthesize melanin (see Chapter 23.2). Since melanin is important not only in the skin but also at such sites as the cochlea and retina, and also because the body's capacity to transfer organelles other than melanin is sometimes impaired, there are a number of associated defects affecting vision, hearing, and the delivery of lysosomes. In some societies where inbreeding is usual, albinism is common (San Blas Islands, Tanzania, southern Nigeria). Albinos in many countries are outcast, poor, underfed, and often die from skin cancer.

Albinism can occur in two forms: partial and complete albinism. Partial albinism occurs in piebaldism and albinoidism, a group of conditions where pale skin is seen without associated eye changes. Complete albinism is subdivided into ocular and oculocutaneous albinism. Skin changes are not seen in ocular albinism, but deafness is common in the autosomal dominant and autosomal recessive forms as well as one of the X-linked recessive forms. Oculocutaneous albinism (pale skin together with eye changes) is subdivided into tyrosinase-positive and tyrosinase-negative forms, according to whether incubation of hair bulbs with tyrosine induces pigmentation. In practice, this test is rarely performed. The tyrosinase-negative forms of albinism are all inherited as an autosomal recessive trait, while the tyrosinase-positive forms may be dominant or recessive.

Phenylketonuria

This cause of whiteness should not be forgotten. It results in elevated levels of phenylalanine which compete for tyrosinase.

Halo naevi

These are characterized by a loss of pigment around benign (see Fig. 62), or very rarely, malignant melanocytic naevi. It is a common first sign of vitiligo (see above). The central naevus should be assessed on its merits and need only be removed if there is a progressive enlargement, bleeding, and irregularities in the pigment, shape, or size of the naevus.

Tuberous sclerosis

The oval macules, which look like a thumbprint and are tapered at one end, sometimes known as leaf-like (Fig. 65), are present in about 90 per cent of affected babies. They are easier to see using Wood's light (UVA; see above).

Idiopathic guttate hypomelanosis

This is characterized by small, depigmented, sharply defined, often polygonal macules in light-exposed areas. It is probably caused by sun damage, and is almost universal amongst ageing Whites living in sunny climates.

Postinflammatory depigmentation

This is probably the commonest cause of leucoderma. Pigmented skin retains less pigment when there is accelerated epidermal turnover as in wound repair, eczema, or psoriasis, but the lesions are not as white as in vitiligo. One particular form commonly seen on the face but here illustrated in the cubital fossae is known as 'pityriasis alba' (Fig. 64), which is, in fact, a variant of a dry eczema causing mild hypopigmentation. It may be sharply circumscribed and have a halo of surrounding inflammation. Pityriasis alba is usually slightly scaly and there is follicular prominence due to hyperkeratosis. The cheeks and upper arms are most commonly affected and atopic children are the most frequent sufferers.

Discoid lupus erythematosus (**DLE**) is a common cause of depigmentation in some parts of the world. It is preceded by the itching, deep-violet erythema of light-exposed skin. Hair loss from the scalp is common, usually of the scarring type.

Diseases of nails, hair, and sweat glands

Nails and hair adorn our bodies. In addition, nails aid in picking up small objects. The handicap of disease of hair or nails is greatest in those who are most conscious of their 'looking good'. Beauty is not only in the eyes of the beholder but it is also an image in the mind. Hence, most consultations concerning hair are about too much or too little in comparison to the norm for a particular population. Excessive sweating and body odour is also a cause of great distress.

Nails

Nails grow continuously throughout life. The germinative epithelium is in the nail matrix, which is protected from the environment by a waterproof seal created by the cuticle. The structural integrity of the nail unit requires an intact cuticle and solid adhesion between the nail-plate and the nail-bed. Normal fingernails grow at the rate of approximately 1 cm in 3 months, with toenails taking anything from 9 to 24 months to grow as much. The nails grow more rapidly in psoriasis and more slowly in cold, ischaemia, or severe systemic illness.

There are only a limited number of ways in which injury, infection, inflammation, metabolic disease, and neoplasia may present in a nail. The important physical signs are alterations of the nail-plate, such as thickening, thinning, abnormal curvature, onycholysis (lifting of the nail-plate), pitting (Fig. 66), ridging (Fig. 67), discoloration (Fig. 68), and growth changes (Fig. 69). Other possible presentations include paronychia (or inflammation of the skin of the nail-folds) and destruction of the nail unit (Table 14).

Fig. 67 Longitudinal ridging is usually due to decreased growth, and the nails are often thin and poorly made (idiopathic dystrophy).

Fig. 68 Transverse white nails, in this case idiopathic, may also indicate arsenical poisoning.

Paronychia

Paronychia may be acute or chronic. Acute paronychia is painful and is due to bacterial (usually staphylococcal) or viral (herpes simplex) infection. Chronic paronychia is painless and is a traumatic nail dystrophy. Pushing back the cuticles, or removing the cuticles using keratolytics (as used by manicurists), damages the waterproof seal between the proximal nail-fold and the nail-plate that protects the nail matrix. Once damaged, water and debris can enter the nail matrix and produce inflammation of the undersurface of the proximal nail-fold. Cuticle loss is an essential feature of the diagnosis; if the cuticle is intact, consideration should be given to other causes of swelling of the proximal nail-fold. Habit tic deformity is commonly associated.

Secondary infection with *Candida* spp. is common and for a long time was thought to be important in the initiation of paronychia. Whilst it may aggravate the problem, it does not cause it, and paronychia should be thought of as essentially a problem caused by nail manicure. Chronic paronychia may be aggravated by episodes of acute paronychia caused by secondary infection with staphylococci. The proximal nail-fold becomes painful and pus may be expressed.

Treatment involves addressing any associated infection with either topical antifungal preparations or oral antibiotics and antiviral agents.

Tinea unguium (onychomycosis)

See Chapter 7.12.1 for further discussion.

Hair

The hair cycle

Knowledge of the normal hair cycle is fundamental to understanding hair disorders. Hair growth on the scalp is cyclical, with each follicle producing a number of different hairs during a person's lifetime. The anagen growth phase lasts about 3 to 5 years on the scalp, during this phase hair grows at a rate of approximately 1 cm per month. The duration of anagen varies from person to person and is the prime determinant of how long one's hair will grow if not cut. The length of anagen decreases in androgenetic alopecia on the scalp and increases with hirsutes on the face and body. Lengthening of the eyelashes and eyebrows is seen in AIDS, malnutrition, and in chronic liver disease.

The anagen phase is followed by an involutional stage known as 'catagen', which lasts 2 weeks and leads into a 3-month long dormant phase known as 'telogen'. During telogen the hair remains anchored into the follicle but no longer grows. At the end of telogen the follicle awakens and commences production of the next anagen hair. As the new hair grows it displaces the old telogen hair from the follicle. Thus every 3 to 5 years each of the 100 000 hairs on the scalp is shed and replaced. In animals the growth cycle is synchronized leading to a scheduled moult. In contrast, human hair growth is unsynchronized and so, rather than replacing all scalp hair at the end of the growth cycle, between 50 and 100 hairs are lost every day, most of which go unnoticed.

Examination for other causes of hair loss

The scalp should be examined for evidence of disease such as scaliness, redness, injury, or scarring with its associated loss of follicles (Fig. 70). Severe seborrhoeic eczema, which produces diffuse and excessive dandruff, is often associated with hair thinning. Psoriasis, on the other hand, tends to leave some scalp unaffected and mostly the hair grows well. In very thick plaques, hair may get broken off or its growth is occasionally inhibited. Lichen planus and discoid lupus erythematosus both destroy the hair follicles and, respectively, produce a violaceous or red colour as well as scarring. Tinea capitis (see Fig. 19) is a common cause of hair loss in many parts of the world. The acute, painful, boggy, inflammatory swelling of cattle ringworm, known as kerion, is sometimes mistaken for a bacterial abscess and is inappropriately incised—closer examination would show satellite lesions which are clearly not abscesses. Kerions of the head often heal with scarring and some permanent loss of hair. Equally classic in presentation are groups of children with discoid patches of slightly scaly red areas of broken hairs due to other forms of animal ringworm. Fortunately, most adult scalps are resistant to these fungi, though *Trichophyton tonsurrans* infection is on the increase—as are all types of infections—in HIV-positive patients. Tinea capitis is, however, particularly a problem for children. In many parts of the world *T. violaceum* is responsible in black-skinned children, and *M. canis* in white. White scales and scarring in dark heads is often due to favus (a type of tinea capitis). In Africa and the Middle East, favus is due to *T. schoenleinii.* Infection of the scalp with *Streptococcus* spp. or *Staphylococcus* spp. is common in parts of the world where generalized impetigo is common. The scalp may carry a persistent staphylococcus in persons who scratch or pick at their scalp, sometimes known as 'tycoon scalp'. The rash of secondary syphilis often causes a patchy pattern of hair loss scattered over the scalp like numerous 'glades in a wood'. Loss of eyebrows is a feature of lepromatous leprosy (Fig. 71).

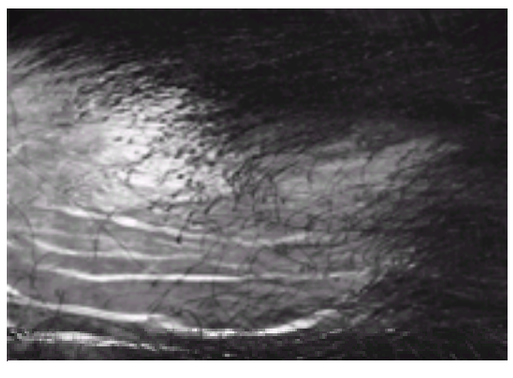

Fig. 70 Scarring is an important prognostic feature because hair loss is irreversible. This pattern of hair loss may be due to a number of chronic inflammatory processes, including lichen planus.

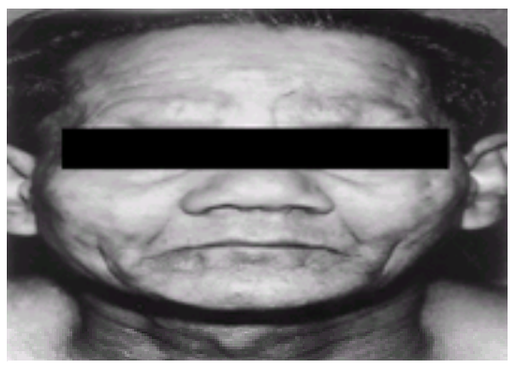

Fig. 71 Loss of eyebrows is a feature of lepromatous leprosy. The skin of the face is thickened but the patient may be unaware of the disease, and for this reason the loss of eyebrows could be the first reason for complaint. Nasal mucosal swelling and erosion is usually obvious.

Hair pulling (trichotillomania) or twisting with subsequent breaking is a common habit in infants and in people with learning difficulties, or occasionally in those who are psychotic (Fig. 72). It is not always consciously done, and if the hair is then eaten there may be little evidence of where the hairs have disappeared to!

Fig. 72 Trichotillomania, or hair pulling, gives rise to hair loss and the hair length varies because it is broken irregularly. It is a common habit of children, but in the adult it is usually an indication of a personality disorder.

Alopecia areata, alopecia totalis, and alopecia universalis

'Alopecia' is a generic term for hair loss; areata is the plural of area. 'Alopecia areata' is a descriptive term for a disorder characterized by one or more discrete circular areas of hair loss (Fig. 73(a) and (b)) which can occur anywhere on the body. Alopecia totalis and universalis are variants of alopecia areata, differentiated only by the extent of the hair loss.

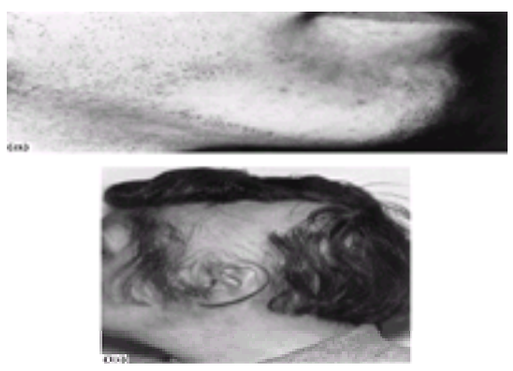

Fig. 73 (a) Alopecia areata is characterized by abortive hair growth and the formation of a short, stubby, 'exclamation mark' hair at the edge of the area of hair loss. (b) Alopecia of the temple or occiput has a poorer prognosis for regrowth.

Telogen effluvium

Diffuse shedding of telogen hairs from the scalp is common. It occurs when anagen hair growth is interrupted, causing follicular hair production to cease and hairs to enter the telogen rest phase of the hair cycle. The telogen phase lasts 3 months before anagen hair growth is resumed. The new anagen hairs push out the old telogen hairs which are shed *en masse*. An acute telogen effluvium almost invariably occurs after pregnancy and may also follow acute illness, major surgical procedure, a crash diet, or on discontinuing or changing the type of oral contraceptive pill. The shedding occurs 3 months after the trigger and may persist for up to 6 months.

Anagen effluvium

Anagen effluvium is the dramatic and rapid hair loss most commonly seen in association with cancer chemotherapy and radiotherapy to the scalp. Other causes are: high-dose colchicine; thallium, mercury, and arsenic poisoning; and cantharadin. The insult to the hair follicle is sufficiently severe to cause an immediate metabolic arrest with complete cessation of hair production. The hair may come out by the root or, if the insult is brief, the hair shaft will narrow, providing a point of weakness that subsequently snaps off. The follicle may remain in anagen, in which case recovery is quick, or move into telogen, in which case regrowth will be delayed by about 3 months.

Androgenetic alopecia

Androgenetic alopecia is a progressive patterned baldness, which is sufficiently common among both men and women to be considered a secondary sexual phenomenon. It is also called common baldness, male-patterned baldness, and female-patterned alopecia. When it occurs prematurely in a man, it can be an unwanted and distressing event and patients may present for treatment. Among women it is usually both unwanted and unexpected at any age and women commonly present for both diagnosis and treatment.

Hirsutes

While unwanted hair occurs in both men and women, men rarely complain of this to doctors. Unwanted hair in a female or hirsutes is difficult to define objectively due

to racial, cultural, and fashion norms. Superfluous hair on a woman in a distribution that mirrors the development of secondary sexual hair in a male is common. Most cases are due to hair-follicle hypersensitivity to normal levels of circulating androgens, while a proportion will be due to elevated levels of circulating androgens. Such patients will usually have other features of systemic androgen excess, such as menstrual irregularity, severe acne, and premature androgenetic alopecia.

Hirsuitism should be distinguished from hypertrichosis (Table 15), which is the widespread overgrowth of non-androgen-dependent hair and that does not respond to antiandrogen therapy. Hypertrichosis may be primary (in which case it is usually apparent prior to puberty) with the hair evenly distributed over the back and limbs. Although prepubertal hypertrichosis is commonly familial, a positive family history is not always found. Secondary causes of hypertrichosis include drugs such as minoxidil, diazoxide, ciclosporin, and phenytoin.

Sweat glands

Apocrine

Apocrine glands occur throughout the skin surface in the embryo, but subsequently disappear to leave just those in the axillas, areolas, and anogenital region in adults. The secretions are formed by the dissolution of apocrine gland cells which are discharged in the hair follicles close to the surface of the skin. They are not active until puberty. Bacterial decomposition accounts for body odour, while the secretions are important in animals for identity and marking out territorial areas. They are also important sexual organs. All such functions are vestigial in man. People sometimes present complaining of body odour. Washing with soap and water is the first phase of management. Deodorants reduce the bacterial flora. Eating garlic and betel nuts should be discouraged since these 'perfumes' are excreted in apocrine sweat. Apocrine sweat is sometimes coloured. If staining is severe and uncontrolled by deodorants, it may be necessary to excise the glands. Retention of apocrine sweat and extreme irritation, known as Fox–Fordyce disease, is similar to prickly heat. Treatment may include the use of topical steroids, destruction with cryotherapy, or excision.

Hydradenitis suppurativa

This is a relatively common and often misdiagnosed condition of the skin characterized by boils, pimples, sinus formation, and comedones (Fig. 74) in the axilla, groin, and submammary areas. It is also known as apocrine acne, as these are the sites of apocrine glands. The lesions often heal with scarring, which may be pitted and cribriform. It may occur alone or in association with severe cystic acne of the trunk, pilonidal sinus, and dissecting cellulitis of the scalp, which are all part of the follicular occlusion tetrad. Dissecting cellulitis of the scalp is a severe folliculitis rather than a true bacterial cellulitis. Hydradenitis suppurativa is very commonly associated with obesity, and may be seen in women along with other features of androgen excess.

Fig. 74 Axilla showing dusky or violaceous erythema overlying cystic 'blind' boils. The follicular prominence and comedone formation is characteristic of early hydradenitis.

Boils should be treated as they develop and prophylaxis given to guard against the development of new lesions. However, there is considerable person-to-person variation in the severity and frequency of the development of the boils, which will determine the need for prophylaxis. Boils may be incised and drained or injected with steroid as they tend to be inflammatory rather than infective, although a short course of oral antibiotics may be indicated based on the results of culture and sensitivity testing. Antibiotic prophylaxis is modelled on the principles of acne therapy. However, because antibiotic resistance does seem to be a problem, they are generally rotated every 4 to 6 months to prevent the emergence of resistance. Those antibiotics shown to be effective include minocycline, co-trimoxazole, metronidazole, erythromycin, tetracycline, cefalexin, and clindamycin. Other therapies that can be used for resistant cases include cyproterone acetate, spironolactone, and isotretinoin. If these treatments are unsuccessful, wide surgical excision or liposuction (which disrupts the glands) may be considered.

Eccrine

Humans possess about 3 to 4 million sweat glands, equivalent in weight to one kidney. The secretory coil produces a plasma-like fluid, which can be secreted at a maximum rate of 2 to 3 l/h. Sodium is reabsorbed in the sweat duct.

While eccrine sweat glands occur in all areas, those in the hands, feet, axillas, and face frequently sweat profusely in the absence of general sweating. Humans rely on evaporation rather than insulation or panting for protection against a hot environment. Generalized sweating occurs when the body temperature rises and is a feature of fever as well as thermoregulation in a warm climate, and when the metabolic rate is increased, as in exercise or thyrotoxicosis.

Eccrine sweat glands are largely innervated by unique postganglionic sympathetic fibres that release acetylcholine at the neuroglandular junction. The control centre is located in the hypothalamus. It is important to consider whether the sweating is appropriate for the degree of stimulus (Table 16).

Emotional- or anxiety-induced sweating is commonly inappropriate for the degree of anxiety. Many teenagers complain of sweaty hands and feet as well as the smell resulting from the bacterial breakdown of skin and clothing. The fear of being unwelcome increases their anxiety and subsequent sweating. It may summate with thermoregulatory sweating and therefore be worse in hot weather or at a dance. Winter clothing is often more troublesome than the loose garments of summer. Sweating of the hands and feet occurs with acrocyanosis and with some forms of keratoderma.

Segmental, unilateral sweating is often due to irritating lesions of the spine and requires a neurological opinion.

Excessive sweating (hyperhidrosis) contributes to tinea pedis and to eczema from footwear.

Treatment of hyperhidrosis

A sympathetic listener is helpful, as is simple advice on hygiene, washing, keeping cool, and appropriate clothing. Basic points of management include the avoidance of obesity, relaxation exercises are helpful if the patient is unduly self-conscious. Cotton-fibre clothing, for example, is more appropriate than non-absorbent fibres. Many shoes, including their linings, are now made from materials that prevent the absorption of sweat and keep the foot and sock wet. Frequent changes of socks prevents bacterial overgrowth, and wearing leather shoes or sandals reduces discomfort. Tranquillizers are sometimes helpful and propantheline, 15 mg every few hours, may be of benefit or can be reserved for a social occasion. The abolition of sweating carries a risk of hyperthermia.

Hypohidrosis

This occurs in the newborn and in premature children during the first month of life, and is also seen in infants as a result of sweat-duct occlusion, especially in the flexures of skin folds on the neck. It may also result from exfoliative dermatitis or erythroderma and is a feature of hypohidrotic ectodermal dysplasia (see Chapter 23.2). Such patients are usually male and are susceptible to heat stroke, and therefore early diagnosis of the affected baby in a hot climate is important. Absence of

sweating causes loss of skin moisturization and impaired grip. Examination of the palmar surface of the fingers with a magnifying lens will show the absence of duct orifices.

Miliaria, prickly heat

Miliaria crystallina is a superficial obstruction of sweat glands, producing clear vesicles. This may occur when more sweat is produced by the glands than the ducts can absorb. Miliaria is commonly seen in patients with high fever. Deeper obstruction gives rise to red, itchy papules known as prickly heat. Around one in three people exposed to hot climates are affected; while prickly heat sometimes begins within a few days of arrival in hot climes, it is commonly a problem 2 to 6 months later. Occlusion of the skin by impermeable clothing aggravates the condition. Bacteria may play some part in its generation and in the complication of staphylococcal abscesses. It is a contributory factor to extreme thermal stress in unacclimatized people. This is also a feature in people working in hot industries around furnaces or in underground mines. Relief from sweating even for a few hours is essential. Loose, non-occlusive clothing and exposure of the skin folds as much as possible is beneficial. Vitamin C (1 g daily) was advocated by dermatologists in the British Army in Malaysia. It is important to realize that severe hypohidrosis of the trunk and limbs may be missed as a cause of asthenia if the face is sweating. The small particles of powder in calamine shake lotions promote cooling by increasing the surface area. A localized loss of sweating ability may be due to tuberculoid leprosy, syringomyelia, and diabetes mellitus.

Skin disorders affecting the genitalia

A diagnosis of disorders affecting the genitalia cannot be made without looking. Natural shyness on the part of the patient or lack of zeal on the part of the doctor are common. Racial and religious grounds for incomplete examination must be overcome by appropriate selection of the examiner and chaperone, as well as an interpreter.

It may be inappropriate to delve into the sexual, gynaecological, or medical history of the patient, and so initial questioning may be limited until an examination has indicated the nature of the disease. A contact dermatitis may require the most detailed and searching questioning.

Many skin conditions of the vulva or penis can be best diagnosed by examining the rest of the skin. For example the knees, scalp, and elbows in psoriasis, the front of the wrists and shins in lichen planus, the mouth in pemphigus, or the neck, breasts, and wrists in lichen sclerosis et atrophicus.

Infections

Infections are commonly transmitted by sexual intercourse and tend to be associated with vaginal or urinary meatal symptoms (see Chapter 21.7).

The pubic region is commonly affected by nits and crab lice, and viral molluscum contagiosum causes smooth, pearly, umbilicated papules (see Fig. 111).

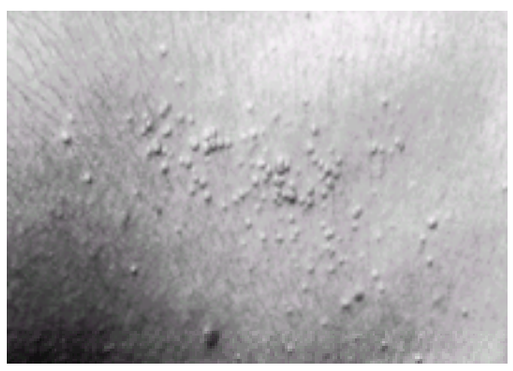

Fig. 111 Molluscum contagiosum: groups of virus-induced papules characterized by a central punctum.

Genital warts

See Chapter 7.10.18 for further discussion.

Candidiasis

See Chapter 7.11.1 and Chapter 21.4 for further discussion.

Herpes simplex

See Chapter 7.10.2 for further discussion.

Adult intertrigo

Obesity and sweating predispose to mixed irritation and infection in the occluded skin under the breasts and in the axillas and groins. The affected area is moist, red, fissured, and malodorous. Attempts at keeping the site dry and free of excessive infection have been improved by preparations such as miconazole and hydrocortisone, and ZeaSORB® powder which acts as a drying agent without too much caking. Washing and gentle drying is the most important therapy. Blind boils and comedones are likely to be due to hidradenitis suppurativa.

Psoriasis in the flexures is usually well defined, bright red, and, unlike at other sites, is non-scaly. It is worth treating initially for 3 days with a strong steroid because this sometimes clears the psoriasis. More often the lesions persist, in which case strong steroids are then harmful since they cause so much atrophy. Hydrocortisone can be used but is only mildly effective. It is important to protect the skin from excessive infection by regular washing.

Dermatitis of the genitalia is commonly due to contact with the agents listed in Table 17, some of which are added to the bath and inadequately mixed with the water. Certain deodorant sprays may cause a considerable immediate contact swelling. Mixed-type infections may contribute to the problem. Persistent pruritus and scratching is a very common disorder, producing thickening of the skin and a range of colours from white-fissured areas to pigmented and violaceous plaques.

In uncircumcised adult males a persistent reddish brown, somewhat fixed balanitis, is heavily infiltrated with plasma cells. This benign condition, known as Zoon's balanitis, is cured by circumcision.

Leucoplakia versus the atrophy of lichen sclerosus et atrophicus

This is often confusing, since it is possible for the skin of the genitalia to be thinned but nevertheless to be covered by a thickened scale. The lesion of lichen sclerosus is well defined (Fig. 75), white, and may have a violaceous border. Small haemorrhagic blisters are common, especially in children, and should not be mistaken for sexual abuse. The perianal areas are always involved, especially in children (Fig. 76). Intractable itching, burning, or soreness of the perineum or genitalia is unfortunately common. In young women it usually slowly improves; in older persons it persists. Lichen sclerosus et atrophicus responds well to high-potency local steroids.

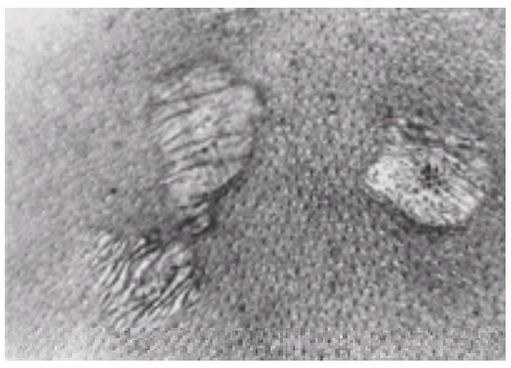

Fig. 75 Lichen sclerosis causes tissue-paper-like crinkling or atrophy of the skin. The border is often violaceous but the centre of the lesion is white.

Fig. 76 Lichen sclerosis of the vulva in a child tends to clear at puberty. In the elderly it is a persistent cause of irritation.

Histologically, lichen sclerosus et atrophicus is characterized by an extremely thin epidermis with a thickened scale and an acellular homogenized upper dermis. By contrast, leucoplakia and lichen simplex are composed of a greatly hypertrophied epidermis and usually thickening of the underlying dermis as well. A biopsy should be performed where there is diagnostic doubt, but leucoplakia and lichen sclerosus may coexist in as many as 24 per cent of patients. Although lichen sclerosus et atrophicus, especially when damaged by scratching, may develop a squamous-cell epithelioma, there is no advantage nor relief of discomfort by prospective vulvectomy.

In the case of leucoplakia, vulvectomy is usually advocated as there is much greater chance of the development of a squamous epithelioma. However, since the skin is predisposed to lichen sclerosus in areas well beyond the genitocrural folds, simple vulvectomy is not a satisfactory treatment for lichen sclerosus itself. Attention to hygiene is important, as is exclusion of mixed infections or contact dermatitis. Rarely, perineal discomfort and eczema may be due to vitamin B_2 deficiency. The main treatment of lichen sclerosus is with strong topical steroids.

Well-defined asymmetrical plaques of red pigmented skin should be biopsied to exclude intraepidermal carcinoma to which this site is predisposed.

The term 'kraurosis vulvae' is now obsolete since it does not differentiate senile atrophy from the now well-recognized lichen sclerosus.

Urticaria

Urticaria is a transient swelling and/or flushing of the skin. The underlying vasodilatation and accumulation of tissue fluid in the dermis is due to a succession of inflammatory mediators acting mainly on the small blood vessels. The time taken to bring their effects under control varies, and thus the inflammatory response varies from the very transient to a more persistent inflammation overlapping with vasculitis.

The knowledge that histamine plays a part in immediate-type (anaphylactic) hypersensitivity has led to the widespread misconception that all urticaria must be allergic. A non-immunological pharmacological explanation is more likely in most cases.

Immunology

Allergens of the type commonly incriminated in sufferers from atopic disease bind to IgE antibodies attached to the surface of mast cells or basophils, these cells then release various mediators including histamine, serotonin (5-hydroxytryptamine), and the slow-reacting substance (leucotriene) of anaphylaxis. Such allergens include egg white, cows' milk, house dust, dandruff, feathers, and tomatoes. It is commonly a contact-type reaction, affecting the lips during eating or some other parts of the skin when in contact with animals or house dust. Transfusion reactions and some drug rashes are due to complement-fixing antibodies attached to blood cells.

The urticaria of serum sickness, penicillin reactions, the acute illness of systemic lupus erythematosus, and many infectious diseases are partly due to immune complexes of immunoglobulins and allergen with subsequent complement activation.

Complement activation

Although complement is activated by immunological reactions, it is also activated enzymatically by proteases (such as plasmin) when there are insufficient natural inhibitors of this mediator in the serum and tissues. Congenital or acquired deficiencies in inhibitor levels account for some forms of angioedema, and for hereditary angioedema in particular. The activation of complement by the alternative pathway may explain the aetiology of some non-familial cases.

Histamine liberators

Some drugs and foods release histamine from mast cells, or at least make such release more likely by inhibiting controlling factors: inhibition of prostaglandin activity may be one such mechanism. Examples of mast-cell stimulators include morphine, codeine, thiamine, polymyxin, and D-tubocurarine. Bee venom, strawberries, and shellfish as well as aspirin, salicylates, benzoates, and tartrazine are enhancers of an urticarial tendency, bringing it to the fore in susceptible subjects as well as occasionally initiating the eruption.

Genetic factors

Familial urticaria is a well-recognized phenomenon. There are reports of hereditary angioedema affecting many members of large families. In this condition the angioedema occurs without associated urticaria. The autosomal dominant pattern of inheritance is mediated through an absence of the C_1-esterase inhibitor. Familial cold urticaria is another autosomal dominant disease, and has been described in several families in the United States, France, and The Netherlands. A low level of chymotrypsin inhibitors was detected in one family. Studies of HLA antigens have been rewarding. BW35 has been associated with acute ordinary urticaria, while HLA-B1*04 (DR4) and its associated allele, DQB1*0302 (DQ8), are raised in patients with chronic idiopathic urticaria compared with a control population.

Careful studies have incriminated candidiasis, though it is not so important a factor in the experience of the majority of practitioners.

Types of urticaria

Variations are observed in the number, size, and depth of weals, as well as in the sensation experienced by the patient. Moreover, the lesions vary in their degree of persistence. Such features allow the classification of different types of urticaria, but there is considerable overlap in their aetiology and pathogenesis.

Only a minority of cases are due to an early, avoidable, and identifiable cause. Although some are due to autoantibodies, non-immunological pharmacological causation is not rare. The majority remain of unknown aetiology.

Contact urticaria

This is a weal-and-flare reaction lasting for 20 to 40 min after the application of certain agents to the skin. Some reactions may be IgE-mediated, such as those produced by animal dander, saliva, or seminal fluid, but most are probably non-immunological, as with the nettle or jellyfish sting, or the solar or aquagenic varieties of urticaria. Often there is a consequent or associated dermatitis, as in atopic eczema. Many of the ointments used to treat dermatitis contain bases such as sorbic acid or polyethylene glycol which cause immediate stinging and a slight swelling.

Cholinergic urticaria

Cholinergic urticaria is characterized by numerous, superficial, small swellings that sting, smart, or itch and are surrounded by a blush lasting for only a few minutes (Fig. 77). The cause is unknown. The commonest pattern is found in adolescents and young adults and, like blushing, is brought on by emotion, exercise, and hot baths.

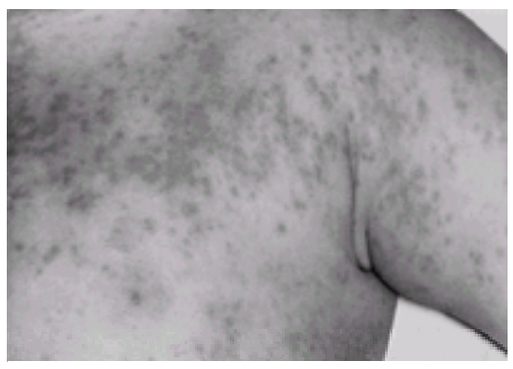

Fig. 77 Cholinergic urticaria is like blushing brought on by emotion, exercise, and heat. It is transient, lasting no more than about 15 min, and may be associated with small, superficial weals with a prominent flush. These tend to sting rather than itch.

Heat urticaria

This is a rare local response to heat in which histamine is released or complement activated.

Angio-oedema

A few, deep, large swellings, which may be tender and often itchy, sometimes preceded by redness, lasting several hours or even days are characteristic. Proteases such as complement, plasmin, and kinins are incriminated.

Ordinary urticaria or hives

This is characterized by numerous weals of all sizes, and varying degrees of pallor or redness, which itch and last for one or more hours, but not usually for more than a day. Successive lesions may account for long illness: chronic urticaria is arbitrarily defined as continuous or recurrent lesions of more than 3 months' duration. Histamine is the principal mediator. Current evidence supports the view that skin blood vessels have both H_1 and H_2 receptors.

Time of onset

Cholinergic urticaria (see above) develops abruptly and instantaneously within minutes of the triggering event. Ordinary urticaria also develops within minutes of the release of the mediator. However, foodstuffs and certain allergens, or drugs such as aspirin, have to be digested and absorbed before the mediators are released. Ordinary urticaria is often difficult to relate to events in the patient's life for this reason. Delayed onset is a well-recognized phenomenon of some of the physical urticarias (see below). Thus delayed dermographism is the development of redness and slight wealing occurring several hours after scratching the skin. Delayed-pressure urticaria is a tender swelling appearing 2 to 12 h after localized pressure injury to the skin. It is possible that the insult localizes noxious agents such as soluble immune complexes, or that mechanisms such as transient ischaemia and the release of proteases bring to light homeostatic defects (for instance, a deficiency of inhibitors of complement or other proteases).

Physical urticaria

Several types of urticarial eruptions are only caused by specific physical insults: for example, from sunlight, cold, heat, pressure, scratch, or stretch.

Solar urticaria is uncommon. A weal develops within 30 s to 3 min of exposure to the sun; however, tolerance may develop in such habitually exposed sites as the hands and feet. The differential diagnosis of porphyria, lupus erythematosus, or photosensitivity following drug ingestion has to be considered, in which case the urticaria is more persistent, and because the longer, more penetrating ultraviolet rays are responsible, it can occur even on a cloudy day or when the skin is protected by glass, clothing, or sunscreens.

Familial cold urticaria is an autosomal dominant disease, usually presenting in infancy, in which the rash develops up to several hours after exposure to, for example, cold winds. Fever and joint pains accompany the rash and there is a leucocytosis. Low levels of a chymotrypsin inhibitor have been demonstrated. It may not be induced by the application of ice to the skin.

Acquired cold urticaria is the most common form of cold urticaria and occurs within a few minutes of plunging into cold water or after applying ice to the skin; this is one cause of sudden death in young people plunging into ice-cold water. Mast-cell degranulatation is a feature.

Papular urticaria

This is the only form of urticaria to have a persistent epidermal component. Most often papular urticaria is caused by insect bites. The epidermis is either damaged directly or by mediators in the upper dermis which evoke an eczematous response, so that oedema of the epidermis and a proliferative repair effect results in a typical itchy and persistent papule. Such lesions are usually excoriated, whereas most urticarias are not deeply scratched but merely rubbed. They often blister (see Fig. 90).

Fig. 90 Typical multiple blisters due to insect bites during the rainy season in India.

Scaling is not a feature of urticaria. While acute dermatitis and some erythema initially appear to be urticarial in nature, the development of scaling immediately excludes such diagnoses.

Distribution of the rash

Cholinergic urticaria favours the head and upper trunk. Angio-oedema most commonly involves mucocutaneous junctions such as the lips, eyes, and penis. The physical urticarias clearly relate to sites of exposure; solar urticaria affects the face and the dorsum of the hands, or, if tolerance has developed, at sites exposed for the first time during the summer. Pressure urticaria favours the soles of the feet when walking or digging, or the backs of the thighs or lumbar region when sitting.

Bizarre patterns

Evolving and resolving urticaria inevitably exhibits a changing morphology. The redness of the vasodilatation merges with the veiling pallor of the oedema. Healing in the centre and peripheral spread often produces bizarre gyrate or circinate and serpiginous patterns, but they are transient and never scaly, unlike similar patterns in the erythemas or epidermal diseases such as psoriasis.

Investigations

History-taking is the most effective investigation of urticaria. It is important to establish whether there is urticaria and angioedema, or angioedema alone. In simple cases, the individual weals last for less than 24 h. Persistence beyond 24 h, and in particular resolution with bruising, is highly suggestive of urticarial vasculitis and justifies a biopsy. The chronicity of the urticaria is also important. Acute urticaria lasts less than 6 weeks and investigations are not required, a drug and dietary history generally suffice. If the lesions have been appearing for more than 6 weeks, further questioning is important, and some investigations may be considered. Trigger factors should be specifically asked for to detect the physical urticarias.

Exercise or a hot bath reproduces the lesions of cholinergic urticaria. Intradermal histamine, 1 µg in 0.1 ml saline, produces a weal that should disappear within 1 h. This disappearance is delayed in pressure urticaria and in immune-complex disease. Localization of a noxious agent results in a persistent lesion. In practice, avoidance of cause can be advised only if this is recognized after taking a history and examining the patient. The two most helpful investigations are a full blood count and the erythrocyte sedimentation rate (ESR). An eosinophilia should alert one to parasites such as microfilaria or trichiniasis, while a raised ESR is due to a systemic illness such as sepsis, malignancy, or 'collagen' disease.

Rubbing or scratching the skin with a fingernail produces a weal and flare in the dermographic subject within 5 min. A 4- to 6-kg weight hung for 10 min over the shoulder on a bandage or belt causing a tender swelling 2 to 8 h later, reveals delayed-pressure urticaria. A biopsy at this stage for immunofluorescence studies may confirm the localization of immune complexes. The white cell count at the time of the biopsy may show neutrophilia, especially if there is accompanying fever. A reduction of serum C_1-esterase inhibitor should be looked for in patients with angio-oedema, especially if initiated by minor surgery, associated with abdominal pains, and if other members of the family affected. Complement levels are not a reliable guide to the participation of proteases and hardly influence the management of urticaria.

Chronic urticaria is a known symptom of filariasis and strongyloidosis, but in ascariasis and enterobiasis it occurs, if anything, more often in controls. Urticaria is such a difficult disease to assess that possible aetiological factors, such as parasitic disease, are worth treating in their own right rather than in the expectation of resolution of the eruption.

About 25 per cent of cases of acute hepatitis B present with urticaria.

Foci of infection as a cause of urticaria are statistically difficult to support, but dental and sinus infections continue to be described as aetiological factors based on impressive case histories.

Bee stings

See Chapter 8.2 for further discussion.

When should urticaria be taken more seriously?

Urticaria is life-threatening when it is part of anaphylaxis, when angio-oedema involves the upper respiratory tract, or when it is part of a systemic immune-complex disease and is associated with more dire pathology such as meningococcal septicaemia or lupus erythematosus. The latter type of urticaria is recognized by its more persistent lesion, lasting at least 1 to 2 days, and often tender and ultimately purpuric. It should be remembered that all acute urticaria may be very widespread and be accompanied by joint pains, stomach aches, and fever. However, if the individual lesion lasts for only a few hours it is less likely to be due to a noxious circulating trigger such as an immune complex or infective organisms.

Management

Removal of the known physical factor and the known trigger is helpful, but no cause is found in the majority of adult cases of chronic urticaria. Insect repellents and topical steroids play some part in the management of papular urticaria. Elimination diets require the exclusion of suspected foods for at least a week, followed by their reintroduction for a week; this cycle should be repeated at least three times to be confident of a real effect, which, however, is convincing in only about 5 per cent of patients with urticaria. Functional autoantibodies against the high-affinity IgE receptor (FceRI), or less commonly IgE, have been demonstrated by autologous-serum skin testing and *in vitro* histamine release from basophils, and Western blotting and an enzyme-linked immunosorbent assay (**ELISA**), in over 30 per cent of patients with chronic 'idiopathic' urticaria. It may respond to immunotherapy. Some European centres rely on studies of the gastrointestinal tract to reveal the presence of *Candida albicans*, *Campylobacter* spp., and other infections as possible causes of urticaria. Food, medicines, and infectious or parasitic diseases are the commonest suspected factors. However, in Europe and the United States physical urticaria accounts for more than half of the patients in some series. Cold, heat, and solar urticaria often respond to the induction of tolerance by subthreshold desensitization. It is useful to try different antihistamines because of much individual variation response and in their side-effects. Antihistamines are often prescribed in too low a dosage to be effective, and patients should be encouraged to rest at home taking a rather higher dosage. The evidence that skin blood vessels possess both H_1- and H_2-receptors has encouraged trials with a combination of their antagonists. At present, the financial cost and large number of pills that have to be taken every day is a disadvantage. Most H_1-antihistamines are cheap and free of serious side-effects. Drowsiness is often troublesome, but the variations in response are considerable. Otherwise, they are effective in the majority of patients, providing they are taken regularly to prevent the urticaria rather than to treat the existing weals. Long-acting antihistamines are worth trying when short-acting ones fail. Although the value of combined H_1- and H_2-blockers (4 mg cyproheptadine and 300 mg cimetidine, four times daily) remains unproven, like all regimens it has resulted in some

individual successes. Hydroxyzine (10–25 mg, three times a day) or cetirizine 10 mg, once or twice a day, is often effective in treating dermographism or cholinergic urticaria. Nifedipine in conjunction with antihistamines has its advocates. Avoidance of known urticaria triggers, such as aspirin, tartrazine, benzoate, and other salicylates, often requires a rather complex diet. Prednisolone should be reserved for a few days' treatment for severe acute urticaria or exacerbation of chronic urticaria.

For impending upper respiratory obstruction, adrenaline (epinephrine) 1/1000, 0.5 ml (adult dose), is first given intramuscularly and hydrocortisone 100 mg intravenously. Such an acute emergency requires maintenance of the airway, if necessary by intubation or tracheotomy, and the administration of oxygen.

Management of autosomal dominant hereditary angio-oedema

This should be suspected if there is a family history of angio-oedema or a few long-lasting swellings precipitated by trauma. Signs include a transient erythema followed by the oedema, and a recurring colicky abdominal pain is often a feature. The diagnosis should be confirmed by looking for low serum levels of functional a-neuroaminoglycoprotein, C_1-esterase inhibitor (normal 18 ± 5 mg/100 ml, although levels vary).

Prophylaxis includes care to protect against trauma, especially in the region of the mouth and neck after dental manoeuvres. Danazol or stanazolol prophylaxis may be appropriate if episodes are frequent. Methyltestosterone, 10 mg as linguets after breakfast and another when there is a suspicion of developing oedema, often aborts attacks. Fresh plasma, containing C_1-esterase, may be given before surgery or at the initiation of an attack. Unlike other forms of chronic urticaria, adrenaline (epinephrine), antihistamines, and corticosteroids are of only little benefit. Intravenous Trasylol is an inhibitor of proteases and is sometimes helpful, as is epsilon-aminocaproic acid (**EACA**) 12 to 18 g daily in divided dosage. The most effective treatment is danazol, which may be supplemented by fresh plasma during an attack or, if available, a C_1-esterase inhibitor concentrate.

Cutaneous vasculitis

The broadest definition of vasculitis is 'the response of small blood vessels to injury'. No other definition encompasses its great variety, which ranges from a transient increase in permeability or wealing, to coagulation and necrosis of the vessel wall. It is caused by agents such as immune complexes, toxins, or by physical stimuli such as cold and heat, as well as impaired perfusion.

The term 'vasculitis' includes many diseases described elsewhere in this book, such as Henoch–Schönlein purpura, polyarteritis nodosa, nodular vasculitis, Wegener's granulomatosis, hypersensitivity angiitis, and allergic granulomatosis. Examples of diseases sometimes included within this term are Behçet's syndrome, pyoderma gangrenosum, purpura fulminans, thromboangiitis obliterans, erythema nodosum, chilblains, atrophie blanche, and livedo reticularis.

Vasculitis overlaps with urticaria and with infarction or gangrene. To use some of the older terminology, some authors have described urticaria as the predominant feature of Henoch–Schönlein purpura in children, and a number of vasculitic syndromes have more recently been described in which urticaria is the only skin manifestation. At the other end of the spectrum, 'necrotizing angiitis' and 'polyarteritis nodosa' are labels often given to infarctive or more destructive patterns of vasculitis.

The physical signs of the skin disease are more or less recognizable as distinct patterns. The names they have been given are of dubious value when it comes to managing the disease. It is possible to explain these patterns and to decide what aspects of the physical signs are the most useful clues to pathogenesis.

Pathology and nomenclature

When a vessel is injured a response ensues which removes or neutralizes the cause of the injury, followed by repair. The response depends on the intensity of the injury, on the efficiency of the inflammation, and on the rate and effectiveness of the repair. Herein lies one of the main reasons why a particular injury does not always produce the same rash. The inflammatory response is a very complex sequence of events (Fig. 78), subject to considerable modification by each individual's particular range of mediators. Important factors explaining variability are local-tissue architecture and previous disease experience, such as scarring or even temporary exhaustion of mediators by prior injury. Formerly, authors used to describe sites of lowered resistance. We now know that such sites comprise areas of non-homogeneous blood supply with hypoxia, leakiness, and blood stasis, as well as exhausted mast cells and endothelial cells undergoing various stages of repair, or upgrading of cell-wall adhesion factors for white cells. Paralysis of the mononuclear phagocytic system is also important.

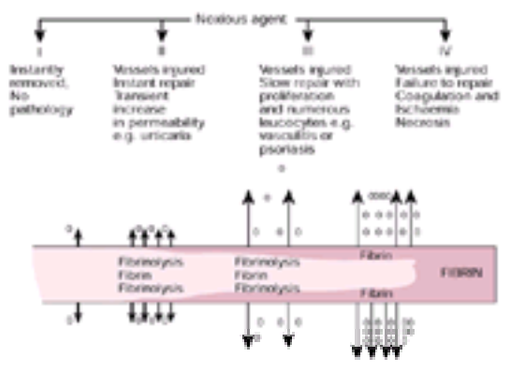

Fig. 78 A spectrum of inflammatory events ranging from a transient wealing, or almost physiological permeability through inflammatory neutrophilic infiltration and oedema, to complete necrosis of the vessel, due to thrombosis, and coagulation or destruction of its wall.

This variation in the inflammatory response can be superficial or deep, and is modified by the distribution of the injury—gravitational, light-exposed, cold-exposed, or at sites of pressure or abrasion; this is one explanation of the physical signs that make up classifiable rashes. A rash with urticarial, purpuric, nodular, pigmented, and necrotic lesions is better not given an eponymous name to any particular combination of physical signs.

Another reason for the later delineation of different syndromes such as Behçet's triad, cutaneous polyarteritis nodosa, or limited Wegener's granulomatosis was the recognition that vasculitis may be confined to either one or more organs. But this, too, is of dubious value: Behçet described mouth, eye, and genital lesions, but the disease is often more widespread; Wegener's granulomatosis affects the respiratory tract but the skin and kidneys are also frequently affected.

One other point of debate is the value of the term 'arteritis'. Smooth muscle in the arterial wall is damaged by ischaemia, which, in most small vessels, is attributable to vasoconstriction, coagulation, and thrombosis, or to obstructed flow due to a more distal vasculitis. Thus 'malignant hypertension', 'coagulation', 'embolism' (Fig. 79), 'thrombotic thrombocytopenia', or 'vasculitis' are often sufficiently appropriate diagnostic terms and are more helpful when considering prognosis, aetiology, or management. The histological diagnosis of arteritis is similarly unsatisfactory. Damaged venules can themselves look like small arteries; even when an artery is clearly involved, it is rarely possible in the same section to see the more distal vasculitis responsible for the obstruction to blood flow and consequent ischaemia.

Fig. 79 The white infarct characteristic of embolization or arterial block. Most cutaneous vasculitis labelled as 'arteritis' is, in fact, venular, but the white infarct is characteristic of arterial occlusion.

Harmful agents responsible for vasculitis

Immune complexes, infective agents, drugs, food additives, and circulating particulate matter all injure blood vessels. It is probable that these are present in small amounts in all of us some of the time, but it is likely that the injuries are often so mild as to be imperceptible and quickly repaired.

Immune complexes

The 'defensive' system of antigen-clearing involves complexing the antigen with antibody and complement to make phagocytosis by macrophages more inevitable. As this is a system that is used to remove damaged tissue, it is often difficult to distinguish whether damage preceded or is a consequence of the immune complex. It is the process of complexing that activates complement not the complex itself. Free and poorly complexed antigen may indeed have a greater potential to cause damage than well-complexed material. Trapping antigen in a tissue and its exposure to immunoglobulin and complement is determined by local events having little to do with what circulates in the bloodstream.

Immune complexes follow the ingestion of food, the presence of a fetus in the pregnant, invasion of the body by parasites such as scabies, or a neoplasm such as breast cancer, and can be demonstrated in everyone following the most mild of virus infections. For this reason, the mere demonstration of immune complexes is not enough to blame them for coincidental vasculitis. Excess antigen is released when infections are overwhelming or when tissues are broken down by immune attack or neoplasia, and sometimes as a consequence of food or drugs.

Immune complexes are mostly harmless but become harmful when they are of certain size and shape or composition. Actual harm is observed only when, and as, they are localized at a site ill-equipped to deal with them and slow to repair the damage done by them.

Often an alteration in host response prevents adequate neutralization of even mildly noxious agents. Recent exposure to similar noxious agents, exhaustion, and insufficient time for recovery of fibrinolytic mechanisms or the phagocytic potential, and the secretions of the mononuclear phagocytic system explain why repeated or continuous exposure to harmful agents precipitates vasculitis. Such an explanation most often explains localized recrudescence in the nose, in Wegener's granulomatosis, or in legs affected by gravitational eczema, ulcers, or atrophie blanche. Factors such as severe infection, foods, drugs, diseases promoting coagulation (for example, hepatitis), and malignancy often alter the inflammatory response and need not act as specific triggers. Immune complexes circulating in a patient known to have disseminated lupus erythematosus may suddenly become damaging when any of these other factors affect the patient. Localization of the defective inflammatory process is often determined by environmental factors: cold exposure, abrasion, or pressure on the skin causing mild stasis and ischaemia are well-known examples met clinically; these conditions are also used experimentally to demonstrate the localization of harmful agents from the bloodstream.

In recent years the discovery of congenital defects in complement and other protease inhibitors has explained why harmful agents are inadequately neutralized in some people. Hereditary angio-oedema is a good example of such a disease. There is a congenital absence of a complement inhibitor, but only in certain circumstances is this important. Trauma or infection sets off the sequence of events, which in this case includes the activation of complement by plasmin, dependent in its turn upon the secretion of plasminogen activator by damaged endothelium. Normally this is balanced by other inhibitors and by absorption into small amounts of fibrinogen and fibrin.

Local deficiencies in the sequence of events triggered by injury depend upon blood flow and diffusion, not only of activators but also of inhibitors. Injury usually releases fibrinolysis activators from endothelium, and heparin, histamine, and hyaluronidase, etc., from adjacent mast cells. These increase permeability and diffusion but prevent coagulation and complement activation. Repeated inoculation of histamine can itself cause vasculitis. It is not always necessary to invoke an immunological mechanism. When the mast cells and endothelium are more or less exhausted, and when activating or inhibiting products are released by adjacent epidermal injury, the proteases, complement, kinins, and materials like fibrin or C-reactive substance occur in sufficient quantities to perpetuate the inflammation and to attract white cells in large numbers.

Diagnosis

Almost essential to the diagnosis is the presence of purpura (Fig. 80), but a tender urticarial lesion that lasts for more than 12 h and leaves a slight bruise on resolution falls within the term 'vasculitis' (Fig. 81). The histology of such a lesion often shows more perivascular neutrophils than the common short-lasting urticarial weal. At the other end of the spectrum is obliterative or sclerosing thromboangiitis in which total occlusion of a small vessel often prevents exudation, and because there is no neutrophilic infiltrate, there may not be such acute destruction of the vessel wall. A similar appearance may be observed in disseminated intravascular coagulation (**DIC**) (Fig. 82) and in platelet embolic diseases.

Fig. 80 Typical purpura of the lower leg of adult Henoch–Schönlein purpura. The lesions are palpable and inflammatory.

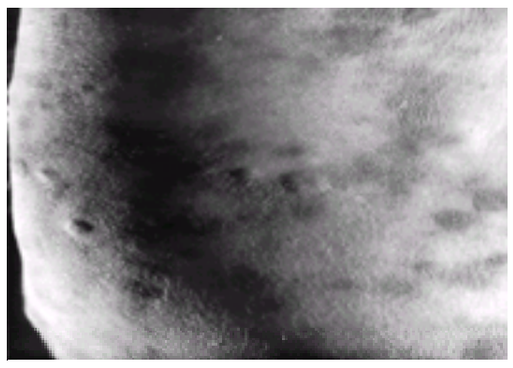

Fig. 81 Typical urticarial initial lesion of vasculitis, often proceeding to purpura and later to necrosis. However, in some types, hypocomplementaemic vasculitis, a persistent urticaria, is the only lesion.

Fig. 82 The blue-to-black discoloration of the extremities in disseminated intravascular coagulation meningococcaemia.

Vasculitis affecting the deep dermis or fat and subcutaneous tissues most commonly produces a nodule, sometimes overlaid with redness or violaceous skin. Blistering and pustulation, when they occur as manifestations of vasculitis, are usually part of a superficial polymorphic eruption in which at least some of the lesions are palpable purpura, thus distinguishing the eruption from other more monomorphic blistering diseases. These physical signs are illustrated in Fig. 83. Very heavy infiltration with eosinophils is a feature of eosinophilic cellulitis, which is sometimes a reaction to arthropod bites.

So far as the diagnosis of purpura is concerned, the traditional classification of thrombocytopenia (Fig. 84) versus non-thrombocytopenia is useful. Vasculitis is included within the latter term, and the purpura is more often palpable.

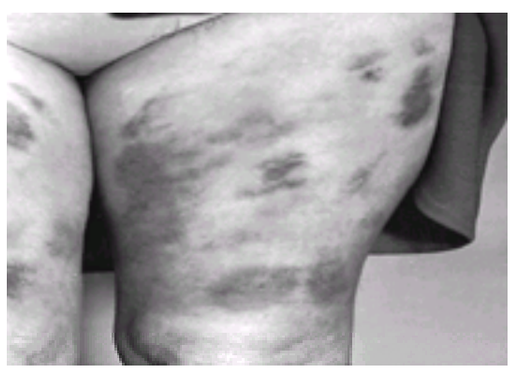

Fig. 84 Bruising or ecchymosis is most commonly due to thrombocytopenic purpura, but it is also a feature of the painful bruising syndrome.

Vasculitis in which immune complexes have played a causative role is more likely to be 'leucocytoclastic'—a term used to describe numerous disrupted neutrophils at the site of the damaged vessel (Fig. 85). It is now well recognized that a mononuclear variety of vasculitis also occurs, sometimes termed 'lymphocytic vasculitis', in which complement activation seems less significant but where upgrading of cell-wall adhesion factors is a response to cytokines and other pharmacological agents, such as histamine. It is a feature of drug eruptions and also of damage to vessels sometimes prior to the deposition of immune complexes, that is within 2 h of a cutaneous capillary fragility test. In fact macrophages rather than lymphocytes could be the more injurious infiltrate, depending on the stage of maturation and their secretion. Much of the pathology of vasculitis is that of ischaemia. Whatever the cause of the vessel damage, there is usually some impairment of blood flow. Hypoxia and infarction are quite capable of causing equally extensive pathology.

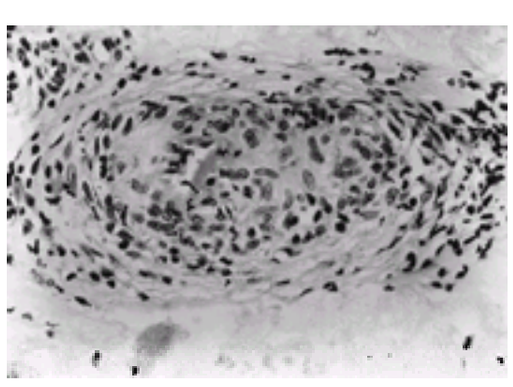

Fig. 85 A damaged vessel surrounded by broken-up neutrophils is typical of the hypocomplementaemic pattern of vasculitis.

The significance of eosinophils in some forms of vasculitis is not known and they are no guide to prognosis or therapy.

Detection of cause

The first investigation required is a full blood count to exclude thrombocytopenic purpura. Efforts should also be made to exclude septic vasculitis due to meningococcaemia and gonococcaemia. Other viral, bacterial, and fungal diseases will also need to be considered in the context of AIDS. Allergic vasculitis has a characteristic histology, showing leucocytoclasis and endothelial damage with fibrin deposition. A skin biopsy should be taken for direct immunofluoresence studies at the same time. Demonstration of IgA deposition (usually IgA1) is required for a diagnosis of Henoch–Schönlein purpura. A serum antineutrophil cytoplasmic antibody

(**ANCA**) test should be ordered. A perinuclear ANCA indicates microscopic polyarteritis and a need to monitor renal function carefully. A diffuse cytoplasmic ANCA is associated with Wegener's granulomatosis.

From the patients' point of view the most worthwhile investigation is that which results in improved management. Certain noxious agents should always be looked for in order to eliminate them therapeutically. Bacteria are the most important of these: the streptococcal sore throat is still the commonest precursor of vasculitis in children, and otitis media, dental caries, cystitis, and sinusitis occasionally play a role; in many countries tuberculosis or leprosy is the commonest cause; bacterial endocarditis and meningococcal septicaemia are often missed. Other treatable infections occasionally causing vasculitis are syphilis, neisseria, rickettsiae, and mycoplasma. Although viruses cannot usually be eliminated, any history of a recent 'flu-like illness or vaccination may be relevant. Hepatitis B virus is a well-recognized cause.

Screening for connective tissue disease with an ANA and rheumatoid factor is useful. Lupus erythematosus and rheumatoid arthritis are common causes of immune-complex vasculitis. But, as mentioned above, it is the exposure of antigen so that its complexing can activate complement that is important, not the complex itself.

Drugs such as penicillin and sulphonamides, allopurinol, amiodarone, streptokinase, thiazides, and warfarin have often been incriminated, but many other drugs appear less likely to be allergens than modifiers of the host response. Similarly, some foods may act as allergens, while others have a more obscure enhancing action. Enquiries should be directed towards headache pills, throat lozenges, purgatives, health foods, any medicine given for a specific illness, and any recent intake of food or drugs to which the patient is known to be sensitive. Questions should also be asked about recent vaccination, radiological investigation with contrast medium, or radiotherapy.

Cold agglutinins, cold fibrinogens, and cryoglobulins should also be looked for. It is now clear that many patients have cold-precipitated immune complexes. Perhaps even more have soluble immune complexes that are localized by blood stasis due to cold, pressure, vasoconstriction, or prior inflammation. The number of patients in whom an antigen has been isolated is small, and in still fewer has it been possible to eliminate the antigen, except in the case of bacteria sensitive to antibiotics. It is not particularly helpful to find a cryoglobulin; it does not alter management since, in any case, every patient should be kept warm. One of the difficulties is that it is often the antibody to the infective agent that in its turn becomes recognized as foreign. Infection may initiate this problem but after elimination of the organism the antibody persists as an autoantigen.

Even after extensive investigations there will remain a proportion of patients in whom everything appears to be normal and no cause for the vasculitis is found. Most often this is seen in women with cold, fat legs, and some degree of venous insufficiency. In these women there is decreased resistance to the deposition of antigen–antibody complexes and decreased clearance. Sometimes even the normal load of complexes generated by a meal or a trivial viral infection overwhelm the cutaneous defences. In such patients rest and compression stockings are particularly valuable.

Factors that modify the inflammatory response

These are very numerous and include any known chronic illness, such as malnutrition, diabetes mellitus, blood disorders, rheumatoid arthritis or other forms of collagen disease, chronic respiratory disease, disorders of the bowels or liver, and hypertension. Malignancy, whether carcinoma or lymphoma, is not an unusual factor and recent surgery, pregnancy, and unusual anxiety are also included in this list.

The mechanisms involved include coagulation and thrombosis, and, since these are treatable, a full blood count should always include a platelet count and other simple relevant tests, especially estimation of prothrombin time, fibrinogen titre, and fibrin degradation products.

Prognosis

The difficulty of naming a constellation of physical signs may force the physician to produce labels traditionally linked to a poor prognosis. One example is the term 'polyarteritis nodosa', another 'Wegener's granulomatosis'.

For all patterns it is useful to use the term 'vasculitis' supplemented by the terms 'limited' or 'local', implying a mild process affecting one locale or organ, and 'complicated' meaning severe and affecting many organs. Such adjectives, by describing the severity of the disease, give a lead to its management.

Management

Avoid all further injury

This allows healing to take place so preventing further damage to already inflamed tissue. Rest is essential for all cases of acute inflammation, but blood stasis should be counteracted by adequate elevation and movement of the limbs. Cold and direct sunlight should also be avoided since both injure the skin and affect blood flow. Women's legs are particularly at risk, depending on the fashion for long or short skirts or trousers.

Scratching, pinching, pressure, and constriction of the skin by ill-fitting clothing or bandages should be discouraged. Patients lying in bed will develop vasculitis on the buttocks, elbows, and over the greater trochanter unless they shift their position every few minutes. Venepuncture sites become inflamed in some forms of vasculitis, particularly in Behçet's disease and pyoderma gangrenosum, and also in severe generalized leucocytoclastic angiitis.

Eliminate circulating noxious agents, especially if they are antigens

Vasculitis following a severe streptococcal sore throat, meningococcal or gonococcal septicaemia, or tuberculosis should be treated with the appropriate antibiotics. Foci of infection, once so popular, are now too rarely thought of; when found they need to be eliminated, sometimes even by surgery. Certain bacterial diseases, such as bacterial endocarditis or leprosy, are not easily eliminated and require prolonged supervision. Although viral diseases are increasingly incriminated, there is no satisfactory way of dealing with them as yet. Immune-complex disease, sometimes as a manifestation of rheumatoid arthritis or lupus erythematosus but more often having no particular association, is now the most often suspected cause of vasculitis. Usually there are no specific measures for dealing with the problem, but immune complexes become less damaging if the factors localizing them are eliminated. Plasmapheresis is practised by a few specialized units. Drugs and food thought to be responsible can be omitted.

Provide specific treatment

Acute short-lasting itchy weals often respond to antihistamines. Acute tender swelling due to progressive tissue oedema may need to be treated with steroids. Painful swollen joints, acute optic neuritis, temporal (giant cell) arteritis, erythema nodosum, tender persistent weals, and tense painful swellings at the edge of pyoderma gangrenosum all usually respond to corticosteroids.

Fulminant vasculitis affecting more than one organ and brought about by a known trigger (allergens, drugs), should be covered by steroids once the cause has been eliminated. Immunosuppressive drugs such as azathioprine, cyclophosphamide, and methotrexate are used as a last resort in persistent chronic vasculitis, but they are of doubtful value except in granulomatous forms affecting the lung where they are the treatment of choice. Necrosis and gangrene are usually due to ischaemia. While inflammation alone may account for this in small vessels supplying superficial lesions, hypertension, coagulation, and thrombosis, as well as the cause of cardiac or peripheral vascular disease in general, sometimes underlie large areas of necrosis. The causes of vasculitis are also, for the most part, the causes of local or disseminated intravascular coagulation. Heparin is probably the drug of choice when fibrinogen, platelets, and prothrombin have been consumed and the levels of fibrin degradation products are raised. It is probably the most useful anticoagulant in malignant disease. Aspirin's anti-inflammatory effect is well known and is particularly effective when platelet aggregation is suspected. Dapsone, enhancers of fibrinolysis, and potassium iodide have had their successes and failures in recurrent nodular forms of vasculitis. Good management includes giving advice on smoking cessation, oral contraception, high blood pressure, and hyperlipidaemia. The prognosis depends on the presence of complications: particularly important are those affecting the eyes, central nervous system, and kidneys. Examination of the eyes for papilloedema and of the urine for red cells, protein, and casts is imperative.

Other vasculitides

Erythema nodosum

It is convenient to include erythema nodosum under the heading 'Vasculitis', though some still prefer to call it panniculitis. There is injury to small blood vessels in the deep dermis and subcutaneous tissue. However, primary injury to the blood vessels from a noxious agent, such as soluble immune complexes, is difficult to prove. Erythema nodosum is characterized by tender red swellings on the front of the shins (Fig. 86) and often also on the thighs and forearms. Bruising is common, but necrosis, scarring, and atrophy of the tissues are not features.

Fig. 86 Tender erythematous swelling on the front of the legs with ill-defined borders is characteristic of erythema nodosum.

Erythema nodosum is a reaction pattern to infection (viral, bacterial, and mycotic) and sometimes to drugs. Neoplasia, pregnancy, and sarcoidosis are other causes. The causes are listed in Table 18. By far the commonest is a streptococcal sore throat. Sarcoidosis and tuberculosis are common causes where the incidence of these diseases is high. Ulcerative colitis and Crohn's disease are common associations seen in teaching hospital practice. Worldwide, erythema nodosum is commonly due to lepromatous leprosy. This is a widespread and often very persistent reaction to local antigen and is not typical of erythema nodosum in general. It may become pustular and necrotic. Erythema nodosum is often preceded by or accompanied by fever, malaise, fatigue, loss of weight, and arthralgia. Although it sometimes resolves in 2 to 3 weeks, the presence of persistent and recurrent forms over several months may suggest an alternative diagnosis. It is important not to label the disease as polyarteritis nodosa or rheumatic fever, for instance, merely because it is persistent and the patient is ill for several months, or the ESR is unusually high. The number, size, and chronicity of the lesions is variable. They can be few and as large as a hand, or multiple and the size of a thumbnail. They can be acute, tender, and last only a few days; or they can be chronic, less tender, and migratory, tending to heal in the centre and spread peripherally as a swollen ring. The more chronic lesions are less red and may be violaceous, or any of the colours of a resolving bruise. The front of the leg is a site of poor lymphatic drainage where foreign protein and bacteria are only slowly removed, especially in the deep dermis and adipose tissue. The underlying tibia splints the overlying tissue so that massage of the lymphatics is reduced. Pretibial cellulitis, pretibial myxoedema, and erythema nodosum have similar localizing factors explaining their pathogenesis.

Investigations

Investigations are required to confirm the diagnosis and extent of disease, to look for a cause, and to ensure the safety of treatment. A skin biopsy will show a lobular panniculitis. Occasionally, granulomas may be seen in patients with sarcoidosis, thus enabling a specific diagnosis to be made. A chase for the source of infection should include a history of possible contacts at home and abroad, human or animal. An anti-DNAase B will demonstrate a recent streptococcal infection. A Mantoux test may have a place, but intradermal testing for sarcoidosis is no longer available. Chest radiography is essential and the most useful for a diagnosis of sarcoid, tuberculosis, or mycoplasma pneumonia. Exclusion of tuberculosis by chest radiography is also useful prior to corticosteroid treatment. A fall in the ESR, which is often initially above 100 mm/h, is a useful guide to complete recovery.

Treatment

This is one of the diseases in which ultimate recovery is to be expected. While for the first 2 to 3 weeks it is possible to keep the patient at rest and to prescribe acetylsalicylic acid, the difficult period is often several weeks after the initial illness when the patient has to be mobilized. Firm support bandages or stockings give some relief for persistent aching and swelling legs. Steroids reduce swelling and fever but do not affect the length of the illness.

Pyoderma gangrenosum

As the name implies this is a necrosis of the tissues, often with a heavy neutrophilic infiltrate; but it is not primarily an infection, rather it is a reaction pattern in which venous and capillary engorgement, haemorrhage, and coagulation feature prominently. The exact pathogenesis is uncertain. In many cases there is an associated depression of the immune system demonstrable by *in vitro* and clinical tests. Failure of macrophages to respond to tissue injury or to clear noxious agents is another feature. Its associations are an important guide to its possible causation, these include ulcerative colitis, Crohn's disease (particularly of the colon), rheumatoid arthritis, seronegative arthritis with paraproteinaemia, Wegener's granulomatosis, and plasma-cell dyscrasias including myeloma. A bullous variety is associated with leukaemia, primary thrombocythaemia, and with myelofibrosis. Nevertheless, up to half of the cases seen in dermatology clinics have no significant association. The clinical features are initially varied, but all ultimately become turgid and ulcerate. These features include a tender red or blue nodule suggestive of erythema nodosum, vesico pustules, or an acneiform folliculitis. The swollen red or blue edge is often acutely tender; blistering may be considerable, especially in the leukaemic variety. The necrosis follows no particular pattern and, like a carbuncle, may have multiple centres. It is usually undermined, and exuberant granulation tissue sprouts from the base of the ulcer. Although the calves, thighs, buttocks, abdomen, and face are favoured, no site is immune.

There is considerable toxicity associated with the acute varieties. Dermatologists see the chronic variety, which is not obviously associated with underlying disease and in which the general health of the patient is not impaired. The ulcerated lesions are not necessarily tender but they are irregular and persistent, often for years. Dermatitis artefacta is often suspected, and the personality of the patient disabled for many months may be consequently affected and encourage the suspicion.

Synergistic gangrene is one cause of very similar acute pathology. Unlike pyoderma gangrenosum, which is often multiple, synergistic gangrene is more clearly associated with a recent wound (for example, an operation on the gastrointestinal tract), and the area of gangrene is acute, solitary, and an extension of the wound. Aerobic and anaerobic culture should be performed in any form of pyoderma gangrenosum for amoebiasis, tuberculosis, buruli ulcer, and deep fungus infections such as nocardiosis or blastomycosis.,

The treatment of choice is oral high-dose corticosteroids. The management of underlying diseases, such as ulcerative colitis or leukaemia, is essential. Any suspicion of an infective causation such as amoebiasis requires the appropriate investigations and treatment. For cases responding poorly to steroids, dapsone 100 mg daily or clofazimine is worth a try. Colchicine, cyclophosphamide, and ciclosporin also have their advocates. Various subacute presentations respond to locally applied steroids by inoculation or under an occlusive dressing.

Behçet's disease

See Chapter 18.10.5 for further discussion.

Vesicoblistering diseases

A vesicle is an elevated circumscribed lesion, usually no larger than 0.5 cm in diameter, filled with serum and sometimes blood and pus. Above this size a vesicle is called a bulla or blister.

Predisposing factors

These include congenital diseases such as epidermolysis bullosa and metabolic disorders such as porphyria.

Causes

Friction and minor knocks can produce blisters in the predisposed person or at sites unaccustomed to wear and tear. The hands and feet are most often affected. Friction is increased by damp, sweating skin.

Ischaemia

Prolonged pressure obliterating the blood supply for more than 2 h causes damage to the smooth muscle of small arterioles and to underlying fat. The epidermis can survive more than 6 h of ischaemia, and much longer periods may be survived in cool skin with a decreased metabolism. Unconscious patients or those with sensory loss, especially from barbiturate poisoning, are particularly vulnerable, but most cases occur from peripheral vascular disease with acute interference of blood supply.

Acute sweat-pore occlusion

This occurs especially with fever or in hot climates. Numerous small transparent vesicles are seen, especially in the flexures or in parts of the body in which the stratum corneum is unduly thick. In the fingers or feet this is called pompholyx.

Burns

Burns can occur from cold (Fig. 87), as in frostbite, and by cryotherapy, heat, or ultraviolet irradiation (photosensitivity from plants, porphyria, or pellagra) (Fig. 88). Dermatitis artefacta is often induced by burning the skin; it is clearly self-induced but usually denied, and is often of a bizarre pattern. Cigarette burns are amongst the commonest induced lesions.

Fig. 87 Urticarial lesions, in this case due to cold; they often blister, especially on the lower legs.

Fig. 88 Blistering on the front of the neck due to an ultraviolet light burn. Self-induced by a home lamp.

Chemicals

These may be toxic, for example mustard gas and cantharidin. Sometimes an allergic dermatitis from contact with chemicals also produces vesicles due to separation of the epidermal cells by inflammatory oedema. Plant dermatitis is amongst the most common of causes; for example, from the primula in Europe and poison ivy in the United States.

Fixed drug eruptions

These can cause erythema and blistering and appear and reappear at the same site whenever the causative drug is ingested; usually itching occurs within 6 h of ingestion.

Infections

(See also under the appropriate chapters in Section 7.)

Viral disorders including herpes simplex (Fig. 89), herpes zoster, chickenpox, and smallpox, or bacterial diseases most commonly cause blisters, particularly *Staphylococcus* and *Streptococcus* spp.

Fig. 89 Blisters on the cheek due to herpes simplex virus infection.

Fungus infections commonly present as blistering on the soles of the feet, and insect bites give rise to papular urticaria that often blisters on the lower legs (Fig. 90). Blisters, pruritus, and fever have been described in ornithologists bitten by ticks carried by marine birds on the Middle East coastline. Arthropods, like the brown recluse spider, give rise to necrotic blisters, while the hairy caterpillar, for example, secretes a toxin in its hairs that can produce blistering. Some infarctions can produce a vasculitis or disseminated intravascular coagulation, which may also present as vesicular or haemorrhagic blisters. Where the Cantharidine beetle is common, avoid injury to it when alighting on the skin and let it fly away.

Specific skin disorders

Erythema multiforme

This, as the name implies, can present with a variety of patterns. The classic pattern affects the hands and feet more than the trunk. Such lesions have an erythematous and coin-shaped presentation which is more intense and blistering in the centre—a target-shaped lesion (see Fig. 10(b)). Several toxic erythematous eruptions overlap with the classic pattern and sometimes the classic distribution and even the target lesions are missing. Involvement of the mucosa is common so that the mouth, eyes, and genitalia may be affected in varying degrees. Where the blistering and mucosal lesions are severe, the disease is termed the 'Stevens–Johnson syndrome' (Fig. 91). This is usually associated with high fever and sometimes also with anterior uveitis, pneumonia, renal failure, polyarthritis, or diarrhoea.

Fig. 91 Stevens–Johnson syndrome, or severe erythema multiforme, resulting in severe erosions of the mouth and conjunctivitis.

Aetiology

The commonest cause is herpes simplex virus infection. Herpes simplex DNA has been demonstrated by polymerase chain reaction (**PCR**) in around 75 per cent of cases. Other infections such as mycoplasma, orf, streptococcus, typhoid, and diphtheria may be incriminated. Drugs also cause this disorder and sulphonamides are amongst the most common. In fact, any infection and any drug can probably give rise to erythema multiforme, usually after a latent period of 1 to 3 weeks. Other causes include neoplasm and its treatment with drugs or radiotherapy, as well as certain other systemic diseases such as AIDS, rheumatoid arthritis, lupus erythematosus, and ulcerative colitis. One of the difficulties is the overlap with the other patterns of toxic erythema and their causation. The erythema of pregnancy may sometimes be called erythema multiforme.

Pathology

There is vacuolar degeneration and apoptosis of the basal cells of the epidermis; vesicles develop between the cells and the underlying basement membrane. Vasodilatation and a lymphocytic infiltrate around the upper dermal vessels are observed.

Treatment

Any known cause should be removed, and systemic steroids prescribed if the patient is very uncomfortable and toxic. Recurrent attacks should also be treated by eliminating the cause if known: for instance, treating the earliest stage of herpes simplex with aciclovir, famciclovir, or valaciclovir and avoiding triggers like bright sunlight. Viral resistance and long-term side-effects of frequent or long-term usage have not, so far, been demonstrated. In the absence of randomized clinical trials, strong debate continues as to whether steroids, plasmapheresis, ciclosporin, and intravenous immunoglobulins are helpful or harmful. Indeed, a combination of high-dose prednisolone with cyclophosphamide given for 3 days each month seems to be effective and almost without side-effects. It is certain that fluid replacement, antimicrobial management, nutritional support, local comfort, and keeping the patient warm are essential life-saving manoeuvres.

Toxic epidermal necrolysis (TEN)

This is a rare variety of erythema with acute epithelial necrosis apoptosis affecting all areas of the skin. This is sometimes called 'scalded skin syndrome' because of its clinical appearance. It is usually acute in onset and may be preceded by various patterns of toxic erythema or blistering. Pressure and shearing stresses on the skin tend to encourage the extension of the blisters. There are two varieties of the disease: the first, originally described by Ritter, is due to a staphylococcus, often phage type 71, and particularly affects children—the blistering and resulting erosions are very superficial and they are due to a split at the level of the stratum granulosum; the second is a drug reaction or a toxic consequence of malignant disease or its therapy. The entire epidermis is necrotic. European physicians have found it of epidemiological value to define TEN as more than 30 per cent of skin detachment and the Stevens–Johnson syndrome as less than 10 per cent, with an overlap syndrome of between 10 and 30 per cent.

Sometimes sulphonamides, barbiturates, phenytoin, pyrazolone derivatives, and phenolphthalein are responsible, while a number of other drugs are also blamed, albeit more rarely.

The use of human intravenous immunoglobulin containing anti-Fas antibodies, and therefore protective against apoptosis, shows promise. Pulse therapy with intravenous gammaglobulin is also under investigation, using 0.4 g/kg for 5 days.

Rarer blistering disorders

These include diseases like pemphigus, pemphigoid, and dermatitis herpetiformis. At one time these were all grouped together, for their pathogenesis has only recently become clearer. The main distinction is in the level of the blister, which determines both clinical and histological features—pemphigus is an intraepidermal blister, whereas the other disorders tend to be subepidermal. Resulting cleavage within the dermis produces dermal inflammation, oedematous papules, infiltration with white cells, as well as bleeding into this blister. The more superficial the blister, the more erosive the appearance: the skin lesions may be red and glistening, whereas deeper dermal blisters tend to be tense and less easily broken. The type and site of immunoglobulin deposition is a further diagnostic feature.

Pemphigus

Pemphigus vulgaris

This is a blistering condition favouring the mucosa as much as the skin. Separation of epidermal cells above the basal layers of the epidermis always occurs in association with an antibody having an affinity with intercellular material in the epidermis. The separated epidermal cell is large, basophilic, and rounded and is termed an 'acantholytic cell'.

Aetiology

The pemphigus antibody will cross the placental barrier and promote neonatal blistering. It is also pathogenic *in vitro.* This antibody reacts with a specific 85-kDa protein, plakoglobin, and a 130-kDa protein in pemphigus vulgaris, but in pemphigus foliaceous (see below) it reacts with a 160-kDa protein, an extracellular epitope of desmoglein. The 130-kDa polypeptide is an epidermal cadherin. The loss of adhesion occurs because of the important adhesive role of these components in the desmosome. (See Chapter 23.2, Fig. 1.)

It is assumed to be an autoimmune disease, possibly associated with HLA-A10 and DR4, and is found more commonly in the Jewish race. Moreover, in Asia, it is one of the commonest causes of admission to a skin hospital. The more superficial variety that affects Brazilians may or may not be a separate, genetically determined reaction pattern. The antibody that binds with complement both *in vivo* and *in vitro* is specific for an, as yet unidentified, intercellular material which activates proteases that lyse intercellular adhesive materials. Several investigators have found that the antibody can frequently cause intraepithelial clefting *in vitro* in human, rabbit, and monkey epithelium. There is an association with thymoma as well as with lymphoma and carcinoma. Not surprisingly, therefore, it occurs with lupus erythematosus and myasthenia gravis.

Penicillamine has been responsible for the development of pemphigus in about 9 per cent of patients treated for rheumatoid arthritis. Captopril and rifampicin as well as meprobamate have also been incriminated.

Clinical features

Erosions of the mucosa of the mouth are the initial problem in more than half the cases. The erosions are often misdiagnosed as mouth ulcers, but close examination reveals a friable mucosa with no well-defined aphthous ulcers. Actual blisters may be missed because they are so quickly eroded. On the skin, the superficial nature of the blisters also determines that the principal lesion is a more painful erosion and the flaccid blisters quickly burst. The base is red and bleeds easily. The epidermis at the edge of the blister is easily dislodged by sliding pressure (Nikolsky sign). There are many reports of clinical and histological overlap with pemphigus foliaceous or pemphigoid. In all such cases pemphigus vulgaris proves to be the final diagnosis.

Treatment

Corticosteroids are lifesaving; without them the disease is one of the most dangerous in dermatology. Very high dosage is required; prednisolone 120 mg daily is a common starting dose and failure to control the eruption within a week merits doubling of even this high dose. As soon as there are no new blisters the steroids are reduced by large increments about every 3 days. Withdrawal is more gradual below 30 mg daily. Most practitioners now add azathioprine, methotrexate, or cyclophosphamide as a steroid-sparing immunosuppressant.

In contrast to the presteroid era, cure now seems possible and many patients are off all treatment after 2 years. However, the side-effects of the therapy are considerable. Death from gastrointestinal haemorrhage is not infrequent. Thromboembolic disease is probably a consequence of the disease as much as the therapy. Steroid-induced osteoporosis with consequent vertebral collapse is a frequent and irreversible side-effect. Bacterial infection of the eroded skin is inevitable and septicaemia is common. The sore mouth and eroded skin require expert nursing—dressings tend to stick to the skin and their removal causes further skin damage. Oral fluids should not be strongly osmotic and soft diets should not include particles that lodge under blister roofs or in crevices.

Pemphigus vegetans

Pemphigus vegetans is a reaction to the erosions in which the repairing epidermis becomes hypertrophic and the dermis is granulomatous; small pustules surround the vegetations. This disease is common in the axillae and groin and the angles of the mouth and nose (Fig. 92). It may be encouraged by steroid dependency.

Fig. 92 Pemphigus vegetans showing the typical granulomatous hypertrophy underlying erosions at the angles of the mouth.

Pemphigus foliaceous

This is a more benign variant of pemphigus in which the blisters are more superficial. The bullae are subcorneal and scaling and crusting may be a principal feature (Fig. 93). The face and upper trunk are most often affected. Localized forms may look more like seborrhoeic warts because of their chronicity and definition. Oral lesions are unusual. Antibodies against intercellular epithelial material are present as in pemphigus vulgaris, but basement membrane antibody and antinuclear antibody are also frequently observed. An association exists with lupus erythematosus and with thymoma and myasthenia gravis.

Fig. 93 Pemphigus foliaceous blisters, so superficial that they merely look like crusting of the erosions. In this case it would have to be distinguished from an intertrigo and secondary monilial infection.

Fogo selvagem

This is a form of pemphigus foliaceous is commonly seen in people working in the rural peanut farms of Brazil. Many members of one family may be affected. Progression to a generalized erythroderma is usual and the mortality is almost 50 per cent, due as much to treatment as from the disease. An immunological reaction to an insect vector has been proposed, based on the study of the black-fly bites and the hypothesis of crossreactivity between the epidermal antigens and the antigen of the fly. Topical steroids may be preferable to high-dose systemic therapy in those who cannot be closely supervised.

Pemphigoid

The bullae in pemphigoid are subepidermal and acantholysis is not a feature. About 80 per cent of patients are over 60 years of age. Pemphigoid is about twice as common as pemphigus. There is a specific antibody (usually IgG) for the basement membrane zone of the epidermis and this is present in about 70 per cent of patients. Complement is bound *in vivo.* The basement membrane remains in the floor of the bullae in most cases. Two large epidermal polypeptides are the major antigenic target of bullous pemphigoid (**BP**) antibodies. The *BP230* gene is localized to the short arm of chromosome 6 and the *BP180* gene to the long arm of chromosome 10. Both protein products of these genes are components of the hemidesmosome. BP180 is a transmembrane glycoprotein with an external terminal ectodomain consisting of collagen triple-helical domains, which bind keratin to the hemidesmosome. (See Chapter 23.2, Fig. 1.)

Clinical features

Initial features of pemphigoid are often non-specific and confusing. It can be eczematous or urticarial. The lesions often begin around a site of damage such as a leg ulcer or burn. After 2 or 3 weeks blisters may erupt abruptly. They favour the flexures and are tense and dome-shaped, often containing blood. Small blisters in the mouth are rare and tend not to erode as in pemphigus. Patients with pemphigoid are distressed by itching, and oedema of the skin may be troublesome, but their general health is usually unaffected.

Treatment

The treatment of choice is prednisolone, 60 to 80 mg daily, until there are no new blisters. Since morbidity in the elderly is great, azathioprine, methotrexate, dapsone, minocycline, or cyclophosphamide may be used to allow a lower maintenance dose of the steroid. Osteoporosis, gastric ulceration, and diabetes mellitus are particularly common complications of steroid therapy. However, complete remission after 1 year is common.

Specific disorders

Cicatricial pemphigoid

Also called 'benign mucosal pemphigoid', the cause of this disorder is unknown, but its immunology includes autoantibodies to an 180-kDa protein. Although mortality is low, cicatricial pemphigoid is responsible for great discomfort. It affects older adults, and the subepidermal bullae favour the mucosa of the mouth, conjunctiva, and the perineal orifices. The base of the lesions are heavily infiltrated with lymphocytes and plasma cells and there is eventual fibrosis. Those adhesions occurring between the bulbar and palpebral conjunctiva result in eventual shrinkage, and entropion is followed by blindness. The skin is less often involved and the sparse lesions often heal by scarring. The scalp is more often affected than other sites.

Treatment

No treatment is very effective, but steroids and azathioprine are usually prescribed.

Dermatitis herpetiformis

This is a vesicobullous disorder associated with the granular deposition of IgA in the dermis and a usually symptomless subtotal villous atrophy of the small intestine. The IgA is believed to be derived from plasma cells in the intestine. As in coeliac disease, HLA-A8/DRW 3 is associated and may be responsible for a defective Fc receptor status. It is probable that gluten hypersensitivity results in circulating immune complexes with an affinity for material in the upper dermis (this is possibly reticulin or transaminases related to gliadin), and that the Fc-receptor dysfunction impairs the removal of the immune material by macrophages. Histology of the skin shows fibrin, neutrophils, and eosinophils in the dermal papillae.

Clinical features

The eruption is characterized by intensely itchy, grouped papular or vesicular lesions that lie on an urticarial or erythematous base. The elbows, knees, sacrum, and shoulders are favoured (see Fig. 9), with the face and scalp more commonly affected than in the case of pemphigus or pemphigoid. The itchy vesicles are quickly excoriated since this relieves the pruritus. The eruption waxes and wanes, sometimes being in remission for many months. However, for most people it remains a lifelong disorder. An increased incidence of lymphoma is well documented.

Treatment

Dapsone (100–200 mg daily) or sulphapyridine (0.5 g, three times daily) are remarkably effective and can be used as a diagnostic test since itchiness is relieved within 48 h. The maintenance dose should be titrated to suit each patient: it may be as low as 50 mg of dapsone per week. Haemolytic anaemia is common on higher dosage and especially when, in some cases, 400 mg of dapsone per day is needed to control the eruption. A gluten-free diet strictly adhered to controls some but not all disease; 70 per cent pf patients can stop taking dapsone after 2 years of such dieting.

Steroid therapy is strangely ineffective and heparin oddly effective. Inorganic arsenicals (Fowler's solution) are effective and were once very popular, and are probably justified in elderly patients much troubled by the disease and unable to tolerate dapsone or sulphapyridine.

Specific disorders

Juvenile bullous pemphigoid

This is a bullous disorder characterized by a predilection for the face and perineum. Linear IgA is deposited on the basement membrane of the epidermis. It is neither associated with enteropathy nor with HLA-A8. The response to dapsone, sulphapyridine, or steroids is unpredictable.

Pemphigoid gestationis

This differs from the common toxic erythema of pregnancy in having large blisters, often periumbilical, beginning as a degeneration of the epidermal cells. Pemphigoid gestationis is associated with HLA-B8/DR3 and an IgG1 autoantibody that avidly binds C3. Thus, it is a blister above the basement membrane, believed to be due to a specific antibody to the basal cell; the antibody is present in umbilical cord blood and binds with a 180-kDa glycoprotein in the basement membrane of the amnion. This disorder occurs during or immediately after pregnancy and usually ceases fairly abruptly within weeks of parturition. It recurs in subsequent pregnancies and as an effect of oral contraceptives.

Other causes of blistering

Lichen planus and lichen sclerosis et atrophicus both rarely blister. Bullous disease and malignancy are a debated association, since so much bullous disease occurs in an age group in which malignancy is common. However, individual case histories of uncontrollable bullous disease with atypical immunofluorescence are

impressive.

Trophoneurotic blisters are another debated association. Unconscious patients seem predisposed to produce these subepidermal blisters even at sites not affected by pressure or shearing forces. This is an important hazard often causing unjustified accusation of mismanagement in the nursing care of such patients.

Diabetes mellitus is a cause of intraepidermal blisters without immunofluorescent material and showing no acantholysis (Fig. 94).

Fig. 94 A haemorrhagic blister on the foot in a patient with diabetes mellitus.

Abnormal vascularity of the skin: angioma and telangiectasia

Patterns of blood vessel development that are inappropriate for the needs of the skin or for thermoregulation include both overgrowth and atrophy. An excess of capillary and venular vessels is a characteristic of wound healing and of many hyperproliferative conditions of the skin (for example, psoriasis). These usually present as redness and individual vessels cannot be seen by the naked eye. Proliferation is still more extreme in strawberry haemangioma, granuloma telangiectaticum, also known as pyogenic granuloma, and in certain malignancies such as Kaposi's sarcoma and angioendothelioma.

On the other hand, telangiectasia is characterized by the dilatation of individual capillaries or venules so that they are visible to the naked eye. There is little evidence that the endothelial cell is at fault and it is more likely that the basic defect is an atrophy or loss of supporting tissue.

Proliferative vasculature is more unstable than that observed in telangiectasia and the natural history is for it to resolve, often completely. Vessels and wounds or angiomas are vulnerable, and the growing phase may be associated with necrosis as a result of thrombosis secondary to a surface injury of the skin. On the other hand, telangiectasia has no tendency to thrombose and the overlying skin rarely ulcerates. The natural history of such dilated vessels is to persist until extreme old age when they may be partially absorbed.

The pulsed dye laser has revolutionized the management of vascular lesions of the skin, but it has also shown the need for a multidisciplinary approach to the diagnosis of cellularity, depth of lesion, haemodynamic changes, and involvement of organs other than the skin. The perfect result is elusive.

Naevi

Strawberry naevi

Although these are almost never present at birth, they may be preceded by a small area of blanching observed at birth. From a few days after birth the lesion consists of rapidly proliferating nests of granulation tissue. After a few weeks the rate of growth becomes less rapid and some vessels become dilated and cavernous. A stable period of no growth often occurs between about 9 months and about 1 year, after which gradual absorption by fibrosis is to be expected. Management consists of reassuring the parents and emphasizing its satisfactory natural resolution (Fig. 95).

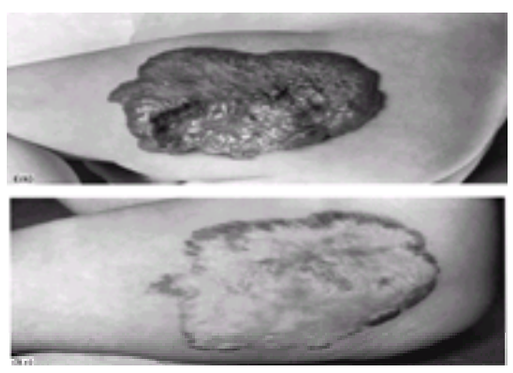

Fig. 95 Strawberry' naevus. (a) A proliferative but benign neoplasia which, after a rapid phase of new growth, stabilizes and eventually regresses. The lesions often ulcerate if traumatized. In this case, ulceration has hastened resolution but there is more residual scarring (b) than usual.

However, there are exceptions to this policy of non-intervention. For example, plastic surgery may be advised where involvement of the eyelid interferes with sight. Some large haemangiomas sequester platelets, thus giving rise to a bleeding tendency (the Kassabach–Merrick syndrome). High-dose steroids (3 mg/kg) are lifesaving. On withdrawal, rebound overgrowth may be observed, justifying a second or third course of treatment. Ulceration of the haemangioma is common, especially in the nappy area and when there is a primary irritant rash. Bleeding is easily controlled by light pressure. The ulceration often accelerates resolution.

Sometimes haemangiomas have a deep element in which arteriovenous shunts are a complication. Interference with underlying structures is not common, but joint involvement warrants surgical advice and management.

The treatment of haemangiomas has included radiotherapy; more recently, systemic steroids, interferon-a, pressure pads, excision, and, currently, embolization. The latter requires angiographic control and siting of sclerosing adhesives at the appropriate site. The delineation of vascular endothelial growth factors and their receptors is opening up new approaches to therapy.

Port wine naevi

This is a pattern of vascular birthmark present at birth and is usually segmental. It is unwise to make a prognosis at birth because pale naevi and segmental patterns of erythema may look similar and often fade. The majority of port wine naevi persist for life. Arteriovenous shunts and gravitational stasis often cause some increase in the vasculature during adult life. A pale plaque of macular telangiectasia in the nape of the neck is present in the majority of normal babies, and persists in more than half of those affected.

Variants of port wine naevi affecting deeper vasculature range from the Klippel–Trenaunay disorder causing enlargement of the limb, to a reticulate and more atrophic pattern sometimes associated with shortening of the limb. Asymmetrical gigantisms and disturbances of pigment are associated with some developmental patterns of

widespread segmental telangiectasia. Telangiectatic vessels on the upper face and nose may be associated with eye or brain defects, presenting as glaucoma or epilepsy.

Telangiectasia

Telangiectases are enduring dilatations of blood vessels. They are usually less than 1 mm in length and may be point-like or punctate, linear, spider, or stellate, forming flat, square, oblong, or oval plaques, or mat-like with an eccentric punctum. They blanch completely when compressed. Telangiectasia is not new-vessel formation—indeed, new vessels in wounds are not unduly dilated.

Telangiectases are probably always secondary to mesenchymal connective tissue dysplasias. However, they can be congenital and naevoid, acquired and genetic (in other words, familial or inherited), as well as being secondary to 'collagen' diseases such as lupus erythematosus, scleroderma, or dermatomyositis, or the result of radiation damage.

All dilatations of small vessels are made worse by blushing, as is seen in rosacea, carcinoid diseases, and oestrogen and related hormonal imbalances (for example, in pregnancy or liver disease). They are also made worse by a loss of supporting tissue, as in steroid atrophy, solar elastosis, ageing (Fig. 96), and Cushing's syndrome.

Fig. 96 Ageing is accentuated in light-exposed skins. One feature of ageing is the poor collagen support of skin vasculature. Telangiectasia is a common consequence.

Telangiectasia is often associated with increased melanin pigmentation and brown spots may be predominant, even in hereditary haemorrhagic telangiectasia; but poikiloderma is a typical example of atrophy, telangiectasia, and pigmentation. Some telangiectasias may be insufficiently dilated to be recognized by the naked eye. However, if they involve most of the vessels in an affected area they may appear as a persistent erythema (for instance, the red cheeks of young children), or as capillary naevi affecting the eyelids, nape of the neck, or forehead, known as salmon patches or stork bites. The erythema may be pale pink or deep purple in colour. The darker the lesion, the more likely the dilated vessels will be inhomogeneous, making some visible to the naked eye. Naevoid lesions usually affect well-defined segments of the skin, though not necessarily dermatomal or unilateral in pattern (Fig. 97). The best known are naevi affecting the trigeminal nerve (Sturge–Weber syndrome) or sometimes an entire limb.

Fig. 97 Segmental telangiectasia of punctate-spider naevoid type.

Diffuse polymorphic patterns that develop in childhood or in young adults favour exposed areas such as the face and forearms, probably because sunlight exaggerates connective tissue dysplasia. However, haemodynamic factors such as gravitational stasis of the venous system also play a part, and the distribution of spider naevi may depend on drainage into the superior vena cava. Gravitational stasis particularly determines the patterns of stellate and arborizing telangiectasia on the legs. While 5 per cent of the population has between two and ten telangiectases on the lips, fingers, palms, and soles, grosser patterns of telangiectasia in disease may involve these sites. Dermatomal or unilateral patterns are rare. A high incidence, up to 40 per cent, of telangiectasia affecting the trunk is described in aluminium workers, apparently associated with the electrolytic processes used in the industry.

Although diffuse and acquired patterns of telangiectasia are commonly familial, sporadic cases account for about 20 per cent, even in the well-known hereditary haemorrhagic telangiectasia. A benign variety of this disease is not associated with severe bleeding and is also probably dominantly inherited. Telangiectasia confined to the lips may also present a dominant pattern of inheritance. However, no large-scale study has been undertaken to rule out polygenic inheritance in any of these disorders. The haemorrhagic diathesis has been recorded as a dominant gene, with many large pedigrees described; but even so, 10 per cent of probands with telangiectasia do not bleed. Severe epistaxis and severe bleeding after tooth extraction or cuts and even heavy menstrual bleeding are characteristic of hereditary haemorrhagic telangiectasia. Minor but frequent nose bleeds are common with even the benign forms. Arteriovenous shunts are described commonly in association with hereditary haemorrhagic telangiectasia. These result in pulsating nodules of the skin, which may have severe consequences in the lung or brain. Arteriovenous shunts are occasionally seen in the non-haemorrhagic telangiectatic forms of the disease.

Histology

The dilated vessels are unremarkable. However, special studies have helped to show that the vessels are venules (that is, alkaline phosphatase-negative) and that they secrete generous amounts of plasminogen activator. The supporting tissue and overlying epidermis is usually atrophic.

Treatment

Although telangiectases are easy to camouflage with 'covermark' types of preparations, advice may need to be given on its application with respect to the use of cream and powder, blends, and matching of skin colour.

Telangiectases when small and localized can be destroyed by cryotherapy, cautery, electrolysis, or laser therapy; the latter can be endoscopic. Since the laser specifically burns haemoglobin, it is therefore more successful in the treatment of the larger blood-containing dilatations. Sclerotherapy is also possible.

Bleeding should first be treated by the simple first-aid measure of elevation and local pressure. Cautery is most effective only on a dry blanched area controlled by

compression. Patients can be taught to inflate a lubricated finger cot tied over the end of a small catheter to immediately control severe epistaxis.

Oestrogen therapy

Oestrogen therapy is sometimes advocated: for instance, ethinyloestradiol 0.25 mg daily, increased to 0.5 mg per day at the end of 4 weeks if epistaxis continues. However, its effectiveness has not been proved in controlled trials.

Percutaneous embolization

This is increasingly used to close unwanted vasculature. However, it requires careful angiographic control and skilled surgeons, and has not overcome the problem of rapid recanalization and opening up of collaterals. Nevertheless, percutaneous embolization is the treatment of choice for severe uncontrolled bleeding from arteriovenous shunts.

Facial erythema (flushing)

In temperate climates the weather-beaten face of the farmer or fisherman is largely a reflection of exposure to cold, as are the rosy cheeks and 'shiny morning face' of the schoolchild. The 'butterfly' area of the cheeks and bridge of the nose pick up hot and cold thermal irradiation. Marked telangiectasia of the cheeks in adults is a common consequence of rosy cheeks in childhood. It may be associated with thickening of the subcutaneous tissues.

Rosacea is usually associated with acneiform pustulation and lymphoedema. For unknown reasons, a keratitis is sometimes associated. Some physicians advocate the elimination of *Helicobacter pylori* with a 1-week course of 20 mg omeprazole twice daily, 400 mg metronidazole twice daily, and 250 mg clarithromycin twice daily. Tetracycline, 250 mg twice daily, or metronidazole gel and lotion are effective therapies for rosacea. A somewhat similar appearance may be seen in sarcoid, especially the lupus pernio variety in which a diffuse granuloma underlies dilated blood vessels filled with slow-flowing blue blood. Mitral or pulmonary stenosis also causes a persistent malar flush. In discoid lupus erythematosus, telangiectasia (Fig. 98(a)) is accompanied by atrophy (Fig. 98(b)), often with well-defined margins and follicular plugging. The borders of rosacea and sarcoid lesions tend to be more diffuse. Asymmetry can be a feature of all disorders.

Fig. 98 In lupus erythematosus—chronic discoid type—(a) telangiectasia and (b) erythema is common. There is follicular plugging and destruction of the skin, resulting in pigment loss and scarring.

Telangiectasia due to other collagen diseases varies from the redness and oedema of the orbit, characteristic of dermatomyositis (Fig. 99), to erythema of the backs of the hands and nail-folds, with persistent erythema such that vessels become increasingly inhomogeneous, and quite large dilated forms may be observed.

Fig. 99 Bright erythema and oedema of the face, especially periorbitally, is characteristic of dermatomyositis.

In scleroderma, especially of the adult acrosclerotic variety, telangiectasia in the form of flat macules, often with square or oblong shapes and fairly well-defined margins, are characteristic. Systemic sclerosis of the face usually causes stiffness and tethering of the skin to deeper structures over the nose and loss of suppleness in the perioral skin. There is, of course, the associated Raynaud's phenomenon and digital ischaemia.

A plethoric complexion is a feature of superior vena cava obstruction, and also of polycythaemia rubra vera and Cushing's syndrome.

Flushing of the face is a common complaint, particularly in the young who may suffer from transient blushing; in older age groups it is characterized by persistent rosacea. Carcinoid should be thought of when there is a prolonged blush associated with a bounding pulse, asthma, abdominal pain, and diarrhoea. Frequent applications of steroids to the face for atopic or seborrhoeic eczema produces gross diffuse telangiectasia; rebound eczematous changes often occur on withdrawal (Fig. 100) when the irritation may be severe. Treatment of this condition is the complete withdrawal of all steroids for 3 to 4 weeks, after which the condition tends to settle.

Fig. 100 Perioral dermatitis is a common consequence of the application of fluorinated steroids to the face.

Neurogenic flushing is accompanied by sweating, but this can be dampened with b-blockers. Local heating of the oropharynx is one physiological cause, for which sipping iced water gives relief. Nocturnal overheating causing restlessness and facial flushing; rubbing is another contributory factor.

Disorders of collagen and elastic tissue

The metabolism and diseases of collagen are described in Section 19. The fundamental defects are in its chemical structure, its crosslinkage between fibres, and its distribution and quantity.

There are at least 18 collagen types, hence there are many genetic diseases.

Signs of collagen defects

These include:

- Diminished skin thickness and increased transparency mean that deeper structures such as veins and nerves are visible and the sclerae are blue.
- Diminished resistance to shear allows the skin to split and tear, sometimes even without surface breaks. Purpura is usually associated and healing results in white stellate scars. Cutaneous striae are another pattern of skin stretching, with separation in this case. Diminished resistance of the skin is a feature of age; osteoporosis and rheumatoid arthritis are other recognized associations. Steroids are responsible for both stellate scars and cutaneous striae, which is the case whether they are endogenously produced, as in Cushing's disease, or prescribed for other diseases. Local application of steroid cream is probably now the commonest cause of these changes.
- Laxity is the failure of the skin to return rapidly to its former state after distortion by stretch. In some way it is caused by degeneration of elastic tissue but changes in water content and cellularity, as well as increased crosslinkage of collagen, play some part even when the total collagen is reduced.

Diseases due to defective collagen

Solar and senile elastosis

This affects white-skinned races, especially those employed in agricultural or marine work. Chronic exposure to ultraviolet radiation causes abnormal collagen having the histological staining characteristics of elastic tissue but not its properties. It is broken and aggregated and contributes to a thickened, yellow and wrinkled skin, especially on exposed areas during old age. The yellow plaques may be sharply marginated on the face. In the neck deep furrows form a rhomboidal network. The sebaceous glands and ducts are poorly supported, dilated, and patulous, forming giant comedones. On the neck the goose pimple, or plucked-bird, appearance is due to the protection provided by hair follicles shading the dermis against ultraviolet rays. Colloid milium is the abnormal production of a scleroprotein by fibroblasts giving rise to yellowish translucent papules or plaques in light-exposed skin. It may begin in childhood.

Striae

These are common but imperfectly understood; stretch is always a factor. The epidermis is thin and elastic fibres are scanty. Striae are seen on the back and thighs of adolescents during growth, especially when there has been a spurt and the child is athletic. It occurs more in girls than in boys. Striae are a feature of pregnancy and especially affect the abdomen and breasts, usually caused by excessive adrenocortical activity. Incomplete fibroblasts inhibition causes atrophy of collagen in response to glucocorticoids. When the collagen is ageing or degenerate, as follows irradiation or in diseases such as cutis laxa or the Ehlers–Danlos syndrome, striae are uncommon and may not appear even in the pregnant or those with Cushing's syndrome. Striae have also been described in those with chronic infections such as tuberculosis. They are only a diagnostic problem when they are newly formed, in which case they may appear to be weal-like and raised. Later they flatten and become bluish-red and still later, white and depressed.

Localized fibrosis, keloids, and hypertrophic scars

The connective tissue response to cutaneous injury exceeds the need for appropriate repair at that site, commonly giving rise, a few weeks later, to hypertrophic scars. If the scar continues to hypertrophy and extends beyond the limits of the injured skin site, especially after a period of 3 months after the injury, it is often then termed a keloid. Such scars tend to be more tender than hypertrophic scars. Keloids tend to be familial and are commoner in Blacks. They are rare in infancy and old age and tend to be less severe after the age of 30. Significant factors are the presence of foreign material in the wound and tension. Preferred areas are the ear lobes, chin, neck, shoulders, upper trunk, and lower legs. Keloids in their early stages may respond to strong local steroids applied locally or intralesionally. Compression therapy is sometimes helpful, as is cryotherapy in the early stages. Re-excision and radiotherapy to the edges of the wounds is now the treatment most preferred.

Pseudoxanthoma elasticum

This is a hereditary disorder of elastic tissue; of which there are four distinct types:

Dominant type I

Here, small, yellowish papules form linear or reticulate plaques, which in older persons are soft, lax, and hang in folds, they are flexually distributed, especially in the groins, axillas, and neck (Fig. 101). There is a severe degeneration of Bruch's membrane giving rise to the slate-grey, poorly defined 'angioid' streaks that form an incomplete ring or radiating lesions around the optic disc of the retina. There is early blindness. Vascular complications include intermittent claudication and coronary artery disease.

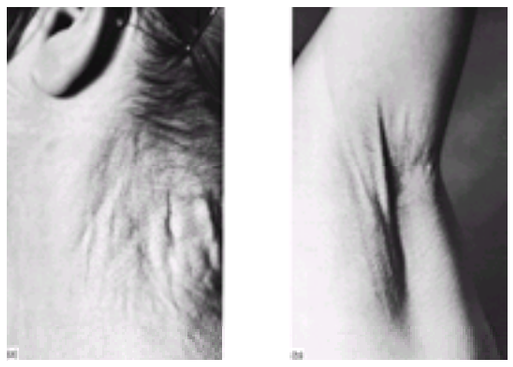

Fig. 101 (a) Yellowish papules and loss of elasticity of the skin of the neck in pseudoxanthoma elasticum. This may be a clue to gastrointestinal bleeding or even blindness. (b) Yellowish papules and loss of elasticity of the skin of the axillas in pseudoxanthoma elasticum. This may be a clue to gastrointestinal bleeding or even blindness.

Dominant type II

The small, yellowish papules are fewer and flatter than in dominant type I disease. There is increased extensibility of the skin. Vascular and retinal changes are mild.

The sclerae are blue and there may be a high arched palate and myopia.

Recessive type I

This resembles dominant type I pseudoxanthoma elasticum, but the vascular and retinal degeneration is mild. Haematemesis is especially common, and women are more often affected than men.

Recessive type II

This is a very rare form, but the skin changes are extensive and generalized. There tends to be no systemic complications. The pathology of pseudoxanthoma elasticum includes a deposition of calcium on the elastic fibres. The mid-dermal elastic tissue is fragmented and swollen.

Perforating elastoma

This is a condition of elastic fibre degeneration in the upper dermis, with a resulting foreign body reaction and extrusion through the overlying epidermis. This reaction gives rise to papules that develop a central plaque of extruded material. There is a tendency for the formation of annular and serpiginous patterns, particularly over the back and neck region. The disorder is associated with mongolism, Marfan syndrome, Ehlers–Danlos syndrome, pseudoxanthoma elasticum, and osteogenesis imperfecta.

Ehlers–Danlos syndrome: cutis hyperelastica

Ehlers–Danlos syndrome is a rare inherited disorder of connective tissue (see Chapter 19.2). The condition is usually recognized when the child begins to walk since there is hyperextensibility of the joints. Trivial cuts form gaping wounds and heal poorly. The skin feels soft and can be stretched, particularly over the knees and elbows. Arterial rupture, aortic dissection, and intestinal perforation have been described in severely affected individuals with deletions in the *COL3A1* gene on chromosome 3 affecting the length of collagen type 3.

Cutis laxa

This is a rare disease in which the skin hangs in loose folds due to the loss of elastic tissue. Severely affected individuals have associated pulmonary emphysema. Both dominant and recessive patterns of inheritance are seen (Fig. 102).

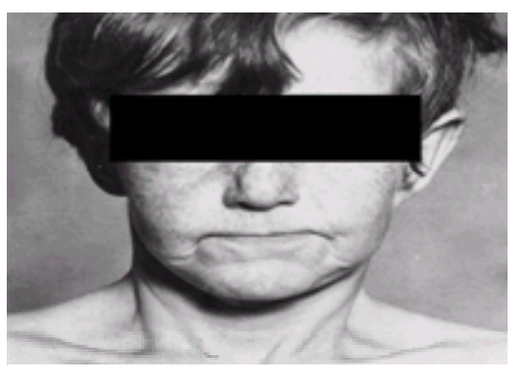

Fig. 102 Drooping of the facial skin of a 9-year-old boy is due to premature loss of elasticity. The diagnosis is cutis laxa.

Atrophy

Atrophy is characterized by thinning, loss of elasticity, loss of hair follicles, and a smooth surface to the skin. When pinched gently the skin produces fine wrinkles and may be compared to tissue paper. The upper dermal atrophy causes poor support to an atrophic vasculature and telangiectasia is often observed. At the same time there tends to be increased pigmentation within the dermis. Atrophy may be a consequence of inflammation following acute bacterial (particularly elastase-producing organisms) infection vasculitis or pancreatitis. It may be widespread, as in the chronic scarring of leprosy or onchocerciasis. Some circumscribed atrophies follow an urticarial vasculitic process, probably caused by an infection that destroys elastic tissue. Perifollicular atrophy or postacne atrophy is similarly due to elastase-producing strains of staphylococci. Syphilis is another cause of destruction of elastic tissue. Non-infectious causes include lupus erythematosus and localized scleroderma with its variants.

Poikiloderma

The combination of pigmentation, telangiectasia, and atrophy is known as poikiloderma (see Fig. 108), causes of which include irradiation, lymphoma, and collagen diseases such as lupus erythematosus and dermatomyositis. A congenital form is associated with light sensitivity, skin cancers, and dwarfism. It may follow lichen planus or stasis eczema. Poikiloderma is common on light-exposed areas of the neck and may be aggravated by cosmetics. It is also described in graft-versus-host diseases.

Fig. 108 Poikiloderma; atrophy, pigmentation, and telangiectasia, commonly preceding the development of lymphoma in the skin. The clinical appearance resembles radiodermatitis.

Morphea

Morphea is a localized form of scleroderma with a good prognosis for complete recovery (Fig. 103). It is not associated with any systemic disease, though subsets in Europe due to *Borrelia burgdorferi* cannot be ruled out. Occasionally a generalized form produces such tightness of the chest wall that breathing may be impaired. The generalized form of morphea also greatly restricts the limbs, and a combination of ischaemia and lymphoedema may result in ulceration of the peripheries.

Fig. 103 (a) Widespread hardness of the skin and brownish or violaceous plaques that are often atrophic are features of morphea—a localized form of scleroderma. (b) Pseudoscleroderma, identical to morphea, is also a consequence of post-thrombophlebitic fibrosis of the lower limbs.

Deep dermal and subcutaneous atrophy

The skin loses its subcutaneous or deep dermal tissue in a number of conditions. Such skin is waxy in colour and may be yellow, pigmented, or bluish with a loss of connective tissue. Deeper vessels may become more obvious, resulting in either telangiectasia or obvious cutaneous atrophy and linear stretch marks that are initially red and which sometimes protrude above the surface of the skin, but later there is always marked atrophy.

The atrophic skin may be tethered to underlying tissue or more obviously scarred. Such skin may feel hard or sclerosed (Table 19).

Other causes of deep dermal atrophy include the injection of insulin—this is commonly seen on the thighs or arms of diabetics. 'Anetoderma' is a term used for very discrete, round idiopathic losses of dermis.

Hemi- or generalized atrophy of a non-inflammatory origin is mainly of unknown aetiology. Partial lipodystrophy is associated with glomerulonephritis, hypocomplementaemia, and protease inhibitors. The Lawrence–Seip syndrome, or total lipoatrophy (with acanthosis nigricans, genital hypertrophy, resistant diabetes, and hepatomegaly), is a condition affecting infants. Atrophie blanche (Fig. 104) is an obliteration of single capillaries in the upper dermis, leading to very localized scarring, the causes of which are listed in Table 20.

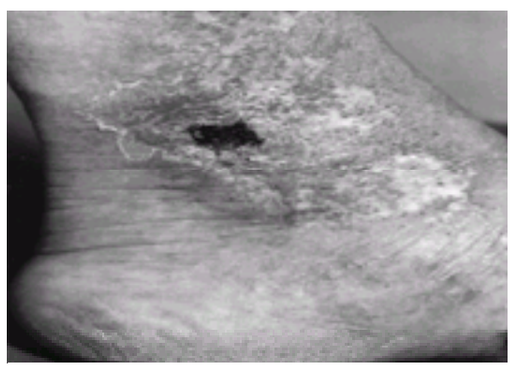

Fig. 104 Atrophie blanche is an obliteration of the capillaries in the upper dermis, causing sclerosis. Residual vessels are elongated and coiled. They are liable to thrombosis and overlying ulceration is a consequence.

Malignant disease

Infiltrations of the skin presenting as papules, *peau d'orange*, nodules, plaques, or ulcerating tumours of the dermis with destruction of overlying epidermis are a common terminal event of malignancy. Such lesions may arise from localized spread, as from a carcinoma of the breast, when they tend to be single or grouped and asymmetrical. More widespread haematogenous spread but with multiple lesions are a still more common terminal event. Certain metastases have diagnostic features, such as the scarring alopecia of breast carcinoma affecting the scalp or the pedunculated tumour of hypernephroma.

Signs of underlying malignancy

The three 'P's of pallor, pigmentation, and pruritus are common terminal events in malignant disease, any of which can also be a presenting sign, albeit rarely in the case of pruritis. Defective immunosurveillance predisposes to infections such as candidiasis or herpes simplex and herpes zoster. Although disseminated intravascular coagulation is a common terminal event of malignancy, it may be a presenting sign of lymphoma, leukaemia, or carcinoma of the pancreas. Rarer diseases associated with malignancy are given in Table 21, and include:

- Acquired ichthyosis, in which the skin becomes progressively drier and more scaly. The surface stratum corneum may crack, giving rise to reactive patterns of eczema craquelée (Fig. 20). Increasing scale eventually overlaps with exfoliative dermatitis but, unlike the exfoliative dermatitis due to drugs or psoriasis, the scale is more adherent, in other words it is less exfoliative. There is usually accompanying atrophy of the skin.
- Dermatomyositis is commonly caused by malignancy in white-skinned adults. In children or in Blacks it is more often a manifestation of autoimmune (collagen) disease. The muscle weakness is proximal. The skin signs include erythema (see Fig. 99), lichenoid, or psoriaform eruptions, and itching or tenderness may be considerable. Periorbital swelling and redness, as well as a streaky erythema on the backs of the fingers and ragged telangiectatic nail-folds, are other features.
- Acanthosis nigricans is the pigmentation and wartiness of the axillas and groins. There is a velvety brown thickness of the skin of the hands and at mucocutaneous junctions such as the lips (Fig. 105).
- Acquired hypertrichosis lanuginosa is a generalized increase in terminal hair. It should be distinguished from hirsutes, which is an increase in hair in sites normally associated with hair growth, such as the chin.
- Acute onset of multiple irritable seborrhoeic warts is known as the sign of Leser–Trélat.
- Superficial thrombophlebitis or migrating thrombophlebitis is particularly associated with carcinoma of the pancreas.
- Bullous pyoderma gangrenosum is a feature of leukaemia and myeloma.
- Bullous disease of erythema multiforme type, or occasionally more suggestive of pemphigoid, is more likely to be associated with malignancy if the oral mucosa is involved or if immunofluorescence studies are negative.
- Erythema gyratum repens (Fig. 106) is one of many patterns of erythema forming repeated concentric rings. The more bizarre and rapidly evolving the process, the more likely it is to be associated with malignancy. This is particularly so when it is generalized, oedematous, or scaling (see also Fig. 10(c)).
- Palmar keratoses are found in association with cancer of the bladder or lung.

Cutaneous lymphoma

Few aspects of dermatology have been more confusing than those concerning lymphoma. In some respects it has been simplified by the recognition and identification of B and T lymphocytes and the realization that terms such as 'reticulosis', 'prereticulosis', and 'reticulum cell' were misapplied. T cells normally traverse through the epidermis and upper dermis, producing a horizontal infiltrate and flat patches. B cells prefer the mid and deep dermis, and produce nodules. Expression on the keratinocyte of a3b1 integrin chains possibly explains epidermotropism. The Hassall's corpuscle in the thymus may have features in common with the cells of the epidermis, which explain helper T-cell, Langerhans-cell, and epidermal interaction. The epidermis also produces cytokines, which may account for lymphocyte

behaviour—attraction, differentiation, and proliferation. Classification and staging procedures are complex, and evolving with improved technology. The simplest classification into B-cell, T-cell, and non-B and non-T-cell lymphoma, with a single subgrouping into small cells indicating low-grade malignancy, and large cells indicating high-grade malignancy, is now largely accepted. However, neither morphology nor a panel of monoclonal antibodies have provided a system of identification by which treatment can be planned with absolute certainty and prognosis reliably determined.

Enzymatic, cytochemical, immunological, monoclonal antibody, gene rearrangement analysis, functional, and ultrastructural methods used in research are not routinely available for aiding clinical diagnosis, but they indicate that conditions in which the epidermis is eczematous, scaly, or crusting are usually infiltrated with T cells, especially of Thy-2 lineage and with reduced IFN-g signalling, as in mycosis fungoides, Sézary syndrome, and pagetoid reticulosis. This may explain the reduced capacity to control infection and secondary malignancies. Mononuclear phagocytes, including the Langerhans cells and eosinophils, often infiltrate the upper dermis. Most of the purple-red tumours that show no involvement of the epidermis and produce sharply demarcated infiltrates in the middle or deep dermis are due to B-cell proliferation. The late tumour stage is reflected in the progression to large, anaplastic, lymphoblastic cells.

The previously labelled reticulosarcomas starting as dome-shaped, deep-red solitary tumours are now thought to be lymphoblastic, more often B cell than T cell. Such less differentiated blast cells also give rise to heavy infiltrates in the whole dermis, and are less inclined to produce the nests of cells within the epidermis that are a feature of mycosis fungoides. There is destruction of blood vessels and fibrous tissue, whereas blood vessels are well preserved in mycosis fungoides and often characterized by prominent epithelioid endothelial cells as in postcapillary venules of lymph nodes. Benign lesions show a well-defined germinal centre.

All types of lymphoma may affect any organ, including lymph nodes and the blood, but mycosis fungoides, Sézary's syndrome, and pagetoid reticulosis favour the skin and often seem confined to it. The leonine facies is a peculiar, diffuse, deep nodular feature more often seen in B-cell lymphoma, as in chronic lymphatic leukaemia.

During the early stage of mycosis fungoides, the behaviour of the T cell cannot be proven to be malignant, and some suggest that it is merely hyper-reactive or overstimulated. The source of this stimulus could even be the skin macrophage known as the Langerhans cell, which increase in number in mycosis fungoides. Exactly when 'overstimulus' becomes 'lymphoma' has been debated, but no conclusions can be reached. Environmental infections such as retroviruses and *B. burgdorferi* as well as genetic susceptibility are possible incriminating factors.

The distinctive cell found in the tissues and blood of patients with the Sézary syndrome and in the epidermis of those with mycosis fungoides is a T cell with an usually, but not invariably, hyperconvoluted cerebri-form nucleus. This cell is also observed in a variety of non-lymphomatous dermatoses and should be equated more with the 'overstimulus' concept rather than with malignancy.

Clinical features of lymphoma

Dermatologists have long grappled with the problem of skin diseases suspected of culminating, often years later, in a malignancy of the lymphoid tissue. These diseases have features of chronic dermatitis and psoriasis (parapsoriasis) because there is a chronic reaction in the dermis and epidermis that is often indistinguishable from other causes of such a reaction. One feature that causes anxiety is a lack of symmetry in an atypical distribution; there is also inhomogeneity within the lesion. Infiltration with white cells suggesting tumour formation is another feature. Yet another, is the combination of atrophy or thinning of the dermis, telangiectasia, and pigmentation known as poikiloderma. Persistent superficial dermatitis, previously known as parapsoriasis in plaque (benign type), consists of flat, symmetrical, slightly scaly, red patches on the trunk or limbs that persist for years. They are round, oval, or finger-like and sometimes yellowish (Fig. 107). This is now thought to be a benign condition.

Fig. 107 Lower abdominal, persistent superficial dermatitis (parapsoriasis). These are fixed and persistent digitate (finger-like) patterns, erythematous, and slightly scaly.

Poikiloderma atrophicans vasculare, previously known as parapsoriasis (large plaque or lichenoides), resembles radiodermatitis in that there is atrophy, telangiectasis, and reticulate pigmentation (Fig. 108). It favours areas not exposed to natural sunlight such as the breasts or buttocks. Poikilodermal lesions may be composed of small papules or large plaques of any shape. Although the expected outcome, often many years later, is the cutaneous T-cell lymphoma known as mycosis fungoides, Hodgkin's disease is also a possibility.

B-cell lymphomas, when present in the skin, form firm pink-red or skin-coloured tumours, often in groups coalescing to produce annular or other patterns (Fig. 109).

Fig. 109 Fleshy tumours grouped and arising in the dermis without epidermal hyperplasia. This is characteristic of B-cell lymphomas.

Lipomelanic reticulosis is a non-specific enlargement of lymph nodes associated with widespread dermatitis or erythroderma.

Although mycosis fungoides is often initially no more than a non-specific dermatitis or, more commonly, poikiloderma atrophicans vasculare, occasionally it is a tumour from the start. The lesions may be symptomless, but severe pruritus is common. Affected areas become more infiltrated, scaly, and reddened (Fig. 110), and often they are annular, serpiginous, or have other bizarre shapes. Erythroderma and widespread ulceration is the final stage of the disease. The diagnostic histological feature is invasion of the epidermis by atypical lymphocytes, often in clusters—Pautrier abscesses—and a heavy pleomorphic infiltration of the upper dermis hugging the epidermis but causing less necrosis of individual epidermal cells than in lichen planus.

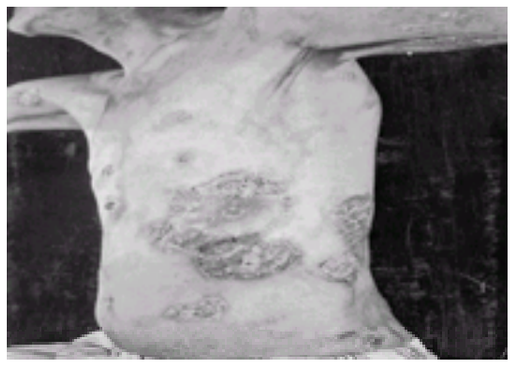

Fig. 110 Marked irregular epidermal reactivity is a characteristic response to T-cell lymphoma of the mycosis fungoides type.

Skin manifestations of Hodgkin's disease include infiltration of the skin with nodules of the disease. Pigmentation and pruritus are common. Prurigo with deep excoriations and secondary infection is one of its most distressing manifestations. Ichthyosiform atrophy as part of the terminal wasting disease is common. The scaling is often as severe as an exfoliative dermatitis, but shedding of the scale is less than that of psoriasis. Hair loss, herpes zoster, and, rarely, erythema nodosum are other complications.

Management of cutaneous lymphoma

The rate of progression is highly variable but usually slow. There is still no clear picture of the natural history of mycosis fungoides. With so many new therapeutic possibilities it should not be forgotten that Samman treated a series of patients conservatively and that only 45 out of 212 patients died of mycosis fungoides. Most of those who died had tumours, skin ulcers, or palpable lymph nodes at the time of presentation, and in the absence of these the prognosis tends to be very good. In patients with benign patterns of the disease it is important not to overtreat. 'Staging' is an attempt to record the extent and progression of the disease in the skin and lymph nodes using multiple biopsies and scanning of internal organs. Some localized forms of lymphoma, even when anaplastic, can be cured by excision. Extensive disease, when confined to the skin, responds well to radiotherapy and topical medication.

Radiotherapy

Small-field orthovoltage radiation has been standard therapy for many years and is very useful for controlling plaques and tumours resistant to other modalities. It is not unusual for patients to require a small dose of radiation to only one area at as little as yearly intervals. Electron-beam therapy is recommended for most patients with extensive infiltrated plaques or tumours. Although a high initial response rate can be expected in the majority of patients, they only remain free of disease for about 3 years.

Topical nitrogen mustard (mechlorethamine, HN_2)

This is a useful treatment for patients who have less-infiltrated skin lesions. Clinical response may be slow and maintenance therapy may be required for at least 2 years. The chief side-effect is allergic contact dermatitis, occurring in about 30 to 60 per cent of patients. Desensitization can be attempted but is difficult to effect. Although there is some debate as to whether an aqueous or ointment-based preparation is best, the latter probably produces fewer hypersensitivity reactions.

PUVA

Several reported series of the good effects of PUVA have resulted in most academic departments using this as a first-line therapy for widespread superficial lesions. However, PUVA penetrance is limited so that deep tumours are unlikely to be cleared. Erythrodermic (Sezary) patients do well with extracorporeal photochemotherapy.

Systemic chemotherapy

On the whole this is reserved for palliation in patients with systemic disease and deep tumours. There is usually some initial response, but clearance for more than 1 year is unusual. Cutaneous lymphoma is susceptible to immunosuppression and this is a rich field of investigation at the present time.

Viral warts

Warts are caused by the papovavirus (see Chapter 7.10.17), which enters the skin through small abrasions, particularly if the skin is moist and warm. Virus is found by electron microscopy in the differentiating cells of the upper epidermis rather than in the proliferating basal-cell layer. The incubation period is probably several months. A number of strains of wart virus give rise to different types of warts—common, plantar, mosaic, plane, and anogenital. Molluscum contagiosum is caused by a pox virus (Fig. 111).

The incidence of warts is increased in immunosuppressed patients, either from drugs or associated with lymphoma. However, cell-mediated immunity is more certainly a factor than humoral immunity. The peak incidence is in children between 12 and 16 years of age, and in recent years there seems to be an increase in infection rate in people living in Europe and the United States compared to Asia, Australia, and Africa.

Trauma may account for the distribution of warts on the hands and feet. Nail-biting in children and shaving in men, as well as ill-fitting shoes in adults, are all relevant factors. Some 20 per cent of warts disappear within 6 months and 65 per cent in 2 years, although plane warts and mosaic warts are slow to clear.

Common warts are firm papules with a rough horny surface. They occur singly or coalesce into large masses. The knuckles and nail-folds are particularly favoured, as are the knees and, more rarely, the penile shaft. They should be differentiated from warty tuberculosis, which is usually a solitary plaque with an erythematous border. Granuloma annulare of the knuckles does not have a horny surface. A persistent wart on the toes or fingers may be a reaction to a subungual exostosis. Squamous epitheliomas or keratoacanthomas are usually solitary and found in an older population.

Plane warts are smooth, flat, or slightly elevated and affect the face or back of hands. They may coalesce or form linear lesions in scratch marks. Lichen planus may be difficult to distinguish from plane warts but is unusual on the face and prefers the flexor surface of the wrists as well as the oral mucosa. The histology of plane warts is unexciting, whereas lichen planus shows destruction of the basal-cell layer of the epidermis and a heavy infiltrate of mononuclear cells.

Filiform and digitate warts are common in the beard area, on the lips, and in the nasal vestibule.

A plantar wart begins as a small 'sago-grain' papule. As it enlarges, paring the surface with a scalpel distinguishes the wart from the surrounding horny ring of normal epidermis and reveals the small capillaries in the tips of the elongated papillae. Most warts occur over pressure points. Clusters of small warts make up a mosaic. A wart which shows numerous thrombosed capillaries and is darker than usual is probably regressing. The fourth interdigital space is a common site for soft corns due to pressure of the little toe on the head of the metatarsal caused by a tightly fitting shoe, these are often seen in ballet dancers. Soft warts or even condylomata lata have been described at such sites.

Treatment

Most human papillomavirus (**HPV**) infections in the vagina and cervix are invisible to the naked eye but can be identified by painting the area with acetic acid (3–5 per cent); however, the demonstration of latent virus is of uncertain biological significance. Although infection with HPV is not sufficient to cause cancer, it may act as a

promoter. There is no successful means of eliminating HPV. Warts should be treated on the basis that they are unaesthetic and uncomfortable.

Spontaneous resolution is to be expected. Overall, 12 weeks is the usual time required to cure warts irrespective of the treatment used, and most standard treatments do no better or worse than this. Podophyllin and formalin or salicylic acid are standard therapies.

Podophyllin, 10 to 20 per cent in liquid paraffin or in tincture benzoic compound, is painted on to anogenital warts and the area then powdered. The podophyllin is irritant and some patients need to wash it off in 2 h, others feel no such discomfort. However, podophyllin should not be used during pregnancy since absorption sufficient to damage the fetus is a possibility. The treatment is repeated at intervals of 1 to 3 weeks.

Formalin (as a 10 per cent solution) can be applied as a soak to multiple warts on the soles of the feet, but dryness and fissuring may be troublesome.

Salicylic acid is the most reliable chemical for treating warts. Paints or plasters containing 20 to 40 per cent salicylic acid are best applied after a 5-min soak with warm soapy water and preferably after excess surface keratin has been removed.

Imiquimod, which induces interferon-a and other cytokines, is now available as a topical agent and is effective against anogenital warts and molluscum contagiosum.

Freezing is with liquid nitrogen, either in a special spray or by application from a cotton-wool bud on the end of an orange stick. The wart should be whitened for at least 20 to 30 s and blistering is a common consequence.

Local anaesthetic injected into the base of a wart to lift it up from the dermis can be followed by curettage. Compression with the thumb on immediate adjacent tissue prevents bleeding while silver nitrate is applied. The rim of horny tissues around the wart side should be cut away using scissors.

Curettage of molluscum contagiosum may be made painless in the majority of children, except at mucocutaneous junctions, by the use of a eutetic mixture of local anaesthetics (**EMLA**) applied under occlusion for 60 min.

Granulomas and other infiltrations of the skin

A granuloma is a compact accumulation of cells, comprising mainly monocytes or their variants, macrophages, epithelioid cells, and giant cells. Often there is subsequent fibrosis. Lymphocytes are more numerous in granulomas due to allergens to which the host is sensitive. Degeneration or the presence of foreign bodies encourage neutrophil and eosinophil participation.

Granulomas are classified as high or low turnover:

- *high turnover:* tissue-destructive, induced by toxic irritants or delayed hypersensitivity, continuous recruitment of macrophages and many mitoses, and frequent epithelioid and giant cells;
- *low turnover:* space-occupying but not destructive, induced by inert (bacterial) and non-degradable irritants, no continued recruitment but long survival of macrophages and few mitoses, and few epithelioid and giant cells.

The clinical features of granulomas are either space-occupying nodules lying in the dermis or, if close to the skin surface, they may be seen as yellow or brownish-red and sometimes translucent areas. The chronic changes in blood supply associated with the lesion cause a bluish colour and sometimes telangiectasia. If they are located in the upper dermis, there may be overlying epithelial hyperplasia or ulceration with extrusion of some of the granulomatous material. On the other hand, thinning of the epidermis may be considerable. In dark skins, pigmentary changes may include hypo- or hyperpigmentation.

A common cause of granulomas is persistent irritation of the skin by external trauma causing ulceration and pseudoepitheliomatous hyperplasia. Examples include granuloma fissuratum of the ear or nose due to ill-fitting spectacles. The ingrowing toenail, the pilonidal sinus, or the presence of extrafollicular but intradermal hair (as is seen in the interdigital clefts of barbers, and cattle or horse dealers) are other examples.

Granuloma gluteal infantum is seen in the nappy area due to incomplete resolution of an irritant rash to which steroid creams have been too extravagantly applied. Numerous agents acting as foreign bodies are causes of chronic granulomas in the skin. They include sea-urchin spines, silicates, cactus allergen, grit, and various chronic infections such as *Candida albicans*, *Trichophyton verrucosum* (Fig. 112(a)), coccidioidomycosis, atypical mycobacteria from fish tanks or swimming pools, tuberculosis (Fig. 112(b)), leprosy (Fig. 112(c)), leishmaniasis (Fig. 112(d)), and halogen granulomas (see Fig. 26).

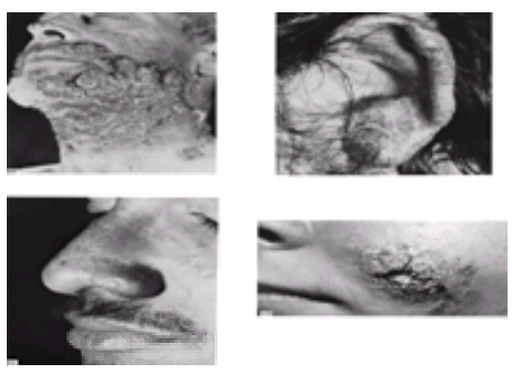

Fig. 112 (a) Chronic granulomas due to cattle ringworm: *Trichophyton verrucosum.* (b) The ear involved by lupus vulgaris (tuberculosis); a brownish-red granuloma inducing irritation in the overlying epidermis. (c) The nose is a common site for the granuloma of lepromatous leprosy. (d) Chronic granuloma due to leishmaniasis following a sandfly bite presenting as an ill-defined cresting and wartiness.

Sarcoidosis

See Chapter 17.11.6 for further discussion.

Urticaria pigmentosa or mastocytosis

Mast cells are normally present in the skin but the numbers vary greatly, with up to 80 per mm^3 found in the upper dermis. In mastocytosis they are greatly increased in number, and may be found as a single isolated mastocytoma, or as numerous nests scattered over the entire body (that is, the classic urticaria pigmentosa) or diffusely throughout the entire skin. Occasionally there is systemic infiltration of all tissues including the liver, spleen, and bone marrow. A very rare leukaemic variety is also recognized.

The mast cell releases histamine, leucotrienes, and heparin, all of which may have systemic effects. However, it is increasingly realized that the local contribution to mastocytosis is through the secretion of proteases from these cells.

In the infant, mastocytosis may present as blisters; more commonly, the lightly pigmented swellings in the skin are noted and observed to swell when scratched or following a hot bath or exercise. Rarely, there is generalized flushing and itching. The condition is most common during the first year of life or at birth, and an onset at this age is a good prognosis for eventual complete resolution by adolescence.

In adults, a late onset is associated with diffuse plaques and telangiectasia.

The systemic variety presents in 10 per cent of adult cases, causing osteoporosis or osteosclerosis. The spleen may be enlarged, and bleeding disorders are the consequence of either thrombocytopenia or from the effects of heparin. Involvement of the gut causes a variety of symptoms including colic and diarrhoea. Right-sided heart failure due to pulmonary hypertension is recorded. Urinalysis for histamine or prostaglandin D_2 may help to confirm the diagnosis when the skin lesions are absent.

Treatment

Treatment is unsatisfactory, but the increasing use of various combinations of H_1- and H_2-antagonists is proving beneficial in some cases. The prognosis for eventual resolution is good in children. A solitary or troublesome single lesion in an adult can be excised. The cosmetic appearance of pigmented lesions is helped by sun exposure or by the use of UVA and psoralens, but the number of mast cells is not reduced. Disodium cromoglycate helps some patients with systemic mastocytosis. The number of mast cells can be suppressed by high-potency steroids applied under occlusive dressings.

Cutaneous manifestations of histiocytosis X

The cutaneous lesions of histiocytosis X are small yellow-brown keratotic scaling papules. These coalesce to form a diffuse seborrhoeic dermatitis that is ulcerative, crusting, and purpuric. Granulomatous eroded plaques that are particularly found in the flexures and in the external auditory meatus cause great discomfort. The hair margins are commonly involved. The common association of diabetes insipidus and hepatosplenomegaly is described elsewhere. The diagnosis is confirmed by demonstrating pale-staining histiocytes devoid of lipid, which contain the Langerhans-cell granules.

Fibrosis, eosinophils, and giant cells are features of a more benign process.

Granuloma annulare and necrobiosis lipoidica

A partial necrosis of collagen- and connective-tissue cells associated with immunoglobulin and complement deposition results in a lymphocytic and histiocytic response known as a 'palisading granuloma'. This is entirely reversible over many months and years in patients with granuloma annulare, but in those with necrobiosis lipoidica it tends to result in fibrosis and scarring. The association with insulin-dependent diabetes mellitus and with AIDS is unpredictable, but is to be expected in more widespread forms, in older age groups with granuloma annulare, and in about 75 per cent of cases of necrobiosis lipoidica.

In children, granuloma annulare commonly appears on the knuckles (Fig. 113), fingers, and dorsum of the feet. Ears and elbows are quite frequently affected. Granuloma annulare may be mistaken for warts but the overlying epidermis, if closely inspected, is rarely papilliferous. The tendency to heal in the centre and spread centrifugally over many weeks gives rise to the annular appearance.

Fig. 113 Papules of granuloma annulare forming a ring around a now healed, but previously affected, area on the knuckle.

Necrobiosis lipoidica is commonly found on both shins (Fig. 114). Widespread forms of granuloma annulare may often be of the giant type, forming large violaceous plaques or rings. No treatment is necessary since eventual resolution of granuloma annulare is expected in 75 per cent of cases within 2 years, but intralesional steroids probably speed resolution, particularly sometimes aborting necrobiosis lipoidica. These disorders may respond to PUVA therapy.

Cutaneous amyloidosis

Systemic amyloidosis is described elsewhere. A waxy appearance of the skin and the ease with which purpura develops within the lesions on slight trauma are suggestive of the diagnosis.

Lichen amyloidosis consists of discrete, firm, hemispheroidal papules. Hyperkeratosis and pigmentation is common, suggesting a waxy infiltrated lichen simplex. The lower legs and outer thighs are involved (Fig. 115(a)). There is no systemic implication.

Fig. 115 (a) Lichen amyloidosis commonly affects the shins or outer aspects of the thighs. The brownish, waxy, lichenified skin is pruritic. (b) Rippled pigmentation of macular amyloid.

Macular amyloid is a common pigmented variant, often in a rippled pattern (Fig. 115(b)), affecting the shoulders and backs of Asian peoples. Local high-potency steroids under occlusive dressings have a temporary good effect.

Crohn's disease

This is a well-recognized cause of chronic granulomatous infiltration occurring perianally (see Fig. 21) or in the buccal mucosa.

Management of skin disease

Recent advances in treatment have been many. The understanding of cell recognition, adhesion, and the role of interleukins, tumour-necrosis factor, and interferons have led to the development of significantly successful antagonists, though they are not without side-effects. The skills of the dermatological surgeon have been refined, and laser therapy has provided a tool that can be both well and badly used. There will be gene guns in the future. The long reign of steroids may be coming to an end as more specific anti-inflammatory agents with less side-effects are trialled. It has to be said, however, that the basis of dermatological therapy is still empirical and randomized controlled trials rare. The principal symptom of itch remains poorly understood, and the 'look good, feel good' factor that contributes to well being is elusive.

Conventional dermatology is not the only resource for patients with skin problems: alternative and complementary medicine, some of it based on long tradition, has become increasingly popular.

General principles

Acute lesions require rest and elevation because this reduces swelling. Dressings should be applied lightly and evenly to the surface, and should support the inflamed area without drag or compression. All agents applied to the skin should be no stronger than necessary. It is very easy for instance, to make a potassium permanganate solution too strong or to use poorly mixed and inhomogeneous medicaments. Preferably, only substances whose components are known and prescribed by experts should be applied to the skin. This is particularly relevant to indigenous medicine. A simple agent used well and which is familiar to the prescriber is always safer than the haphazard prescription of a range of new and poorly tested agents.

Some of the oldest remedies, such as calamine lotion and tar preparations appearing in the *British national formulary* or *The WHO essential drugs list*, do least harm, but patients with chronic skin disease are unlikely to persevere with these unless they are educated and encouraged. This takes time. Remember, patients spend more time listening to other patients in the waiting room than they do to the doctor—and are often in a more receptive frame of mind then. Make sure that the advice given in the waiting room is correct by handing out leaflets and teaching groups of patients, for example with audiovisual aids. Many patients do best with printed sheets of instructions so that they can read at their own pace quietly, and away from the physician. When appropriate, they should be told that their disease is neither contagious nor cancer, nor passed on to their offspring by their genes.

There are a number of supporting organizations of value in the management of skin disease. A high proportion of patients with skin problems are found to be suffering from the stresses of their domestic environment (confused elderly relatives or delinquent teenage children, for example). For these patients the help of a medical social worker is often very successful. The British Red Cross Society in the United Kingdom now provides a 'beauty care' service that has been extended to the provision of camouflage make-up. Patients' associations often provide a great deal of education and support.

In hospital practice, inpatient treatment is only occasionally necessary and can be greatly reduced by adequate provision of a good outpatient service. Some units link this to their inpatient department in order to provide a service outside the unit's normal working hours—it is clearly more convenient for a working person to attend a department that is open in the evening.

Elimination of primary irritants or known allergens, or of infection, should be the aim of treatment. However, it is fruitless to attempt to make the skin and its diseases sterile at all times. Restoration of the skin barrier and the prevention of cracks and heaping up of scales and exudate reduces bacterial penetration. Scratching, rubbing, wrongly applied dressings, and unsuitable local medications are reasons for worsening of the skin condition and for the impairment of natural defences and repair mechanisms.

Chronic skin conditions are more difficult to cure, and a correct diagnosis is even more important. Spontaneous healing may not occur without the cause being eliminated, and therefore the chronic inflammation may be self-perpetuating. A biopsy for histological analysis is often helpful and bacterial or mycological analysis is clearly indicated where chronic infection is a possibility.

The handicap of the chronic lesion includes a feeling of being unwelcome, often leading to the accusation of being 'unclean' and to being 'outcast'. The physician and nurse can sometimes do more to alleviate the skin condition by paying attention to this aspect of the handicap, rather than using more specific measures. Sympathetic questioning along the lines indicated earlier will help to relieve the patient's suspicion that the dermatology team is not interested in the problem. Touching the skin during examination often does more to make the patient feel that the physician cares than any other manoeuvre.

When treating any skin disease, the overall objective is to create the body image that the patients hope for—not that which is perceived as ideal by the attendant—and when this fails, to help them to live with their problem and expect less. Every effort should be made to ensure that children remain willing to go to school, adults stay at work, and the old are kept comfortable. Remedies should be convenient and cosmetically acceptable, and if this is not possible, the social support should be that much more intensive. Attention to diet, camouflage measures, and regular careful attention to the skin can be very irksome for the patient, but can be made less so through cooperation with the doctor, nurse, or patient association, for example the obesity clinic supported by a weightwatchers' group.

It is essential that the skin be protected from further injury. Homely advice such as 'keep warm and out of the sun' and 'rest as much as possible with your feet up' is appropriate for much acute or severe skin disease, but the skin does not normally experience sustained rest. It is best to encourage movement such as intermittent stretching or compression. For a normal and healthy skin, movement promotes blood supply, lymphatic drainage, and a well-balanced structure that is water-containing and to which a well-attached epidermis is attached and supported by appropriately distributed fibres as skeletal support. The best movements are natural and not too vigorous, but they should provide a full range of flexion and extension over the joints.

Some chronic and incurable skin diseases become easier to tolerate when time is given to the education of the patient, thereby increasing patient understanding, satisfaction, and self-help.

The priorities of the patient with skin disease differ from those of the therapist. Thus the patient equates severity with social ostracism or the subjective itch, rather than with the percentages of body involved or systemic complications. Other people who should be drawn into the management of the patient with skin disease include parents, school teachers, employers, hairdressers, and the sporting fraternity—for example, swimming-pool attendants. A school report that, without these discussions, refers to weeping sores and scratching which interfere with the work of other children, should be a thing of the past.

Many chronic skin conditions are either hypertrophic or atrophic. Hypertrophic conditions require suppressive therapy, as described above in the section on psoriasis. Common suppressants are corticosteroids or radiotherapy. However, these are less suitable for treating atrophy. Another adage worth paying attention to is: 'If it is wet, dry it, and if it is dry, wet it!'

The management of skin disease in technically developed countries usually assumes regular follow-up. In developing countries in Africa or India, or with the nomads of the Middle East, there is almost no possibility of follow-up. Treatments with a high risk of side-effects or exacerbations on withdrawal are therefore not ideal. Because malnutrition and infection are so common, dietary supplements and antibiotics are of value in almost any disease in which host or constitutional vulnerability is a factor. Health education is always difficult, but the mother with children is usually the most receptive pupil.

New technologies—lasers and narrow-band UVB

The management of skin diseases is usually low-technology and low-cost. Economic forces have encouraged dermatologists to purchase high-technology equipment, some of which provides an advance in management for those who can afford it: laser therapy has proved excellent for vascular and pigmented lesions, and for the removal of hair. The technology requires a wavelength that is selective for a specific subcellular target, delivered in pulses with sufficient energy to be destructive for that target without at the same time damaging surrounding tissues. As the pulse is so short, there is no time for surrounding tissues to be heated. Many treatments are needed for some of the more troublesome conditions (for example, pigmentation), while some therapies (such as hair removal) are not permanent but partial. The technology has been improved by photodynamic therapy, whereby an agent such as protoporphyrin is added to the subcellular structure, which is then irradiated. Several tumours have been treated in this way. Dermatologists have always used ultraviolet light, either from sunlight or from ultraviolet lamps. The most recent innovation is the use of narrow-band UVB, which is as effective as UVA in the prophylactic management of polymorphic light eruption and is used in a number of other sun-induced dermatoses. While narrow-band ultraviolet light has been found to induce malignancy in animals, the lower dose required in humans compared to other

forms of light seems to induce remissions without significant tumour risk. It has been given to children and patients who are pregnant, but it is probably too early to say that it is entirely safe.

Local topical treatment

The fingertip unit

The 'fingertip unit' is the amount of ointment expressed from a tube with a 5-mm diameter nozzle, applied from the distal crease to the tip of the index finger—1 unit weighs 0.49 g and covers 286 cm^2 in men, and 0.43 g which covers 257 cm^2 in women. One unit will cover an area equivalent to twice the area of the hand, thus four hands is equivalent to two finger units, which is equivalent to about 1 g.

Drugs are dissolved or suspended in bases, which have properties of their own quite independent of the active ingredient. As shown in Table 22, bases were originally either powder, water, or grease. However, modern processes have prepared bases that are essentially much more complex than this, although they still retain the objectives of the primary agents. Powder may repel water or absorb it and allow further evaporation. Modern powders tend not to cake and abrade the skin as much as the original talc or starch. Watery lotions evaporate and cool, as well as wet and dissolve. Various agents, such as alcohol or glycerine, may be added to increase any one of these properties. Creams and emulsions of oil and water (aqueous or milky) or water in oil (butter or oily) are cooling, moisturizing, and emollient. The penetration of active agents through the skin is aided by the aqueous (vanishing) oil and water creams. Ointments based on Vaseline or paraffin are more occlusive and less quickly absorbed. They are better at softening dry surface scales.

There are various other water-soluble preparations, such as macrogels or emulsifying ointment in which a wax or animal fat is mixed with mineral oil. Pastes are powder and oil mixtures, such as talc and Vaseline, which are more occlusive and protective. They are useful for allowing the slow release of agents (such as dithranol) at the skin surface. As the addition of an active ingredient to a base often makes it unstable, various other agents are added as a preservative or to control pH. Further dilution usually makes the preparation still more unstable (that is, shortens its shelf-life). Much of the skill in preparing an ointment, cream, or paste lies in the use of the homogenizer by the pharmacist.

The actions and side-effects of topical steroids are listed in Table 23. Tar and dithranol preparations were discussed above in the section on psoriasis. Tacrolimus is a new topical immunomodulating agent related to ciclosporin. However, unlike ciclosporin, it can be used topically to treat conditions such as pyoderma gangrenosum or the more common psoriasis and atopic eczema. A new oral agent, mycophenolate mofetil—another immunomodulatory agent (1 g orally, twice daily) for psoriasis, pyoderma gangrenosum, bullous pemphigoid, pemphigus vulgaris, and systemic vasculitis—also shows some promise as a topical agent.

Skin cleaning

It is naïve to attempt to sterilize the skin, and the long-term consequences of obsessive washing or the use of local antibiotics are always worse than the original state of the skin. Antibiotic regimens are essential for acute complications such as cellulitis, or for specific infections such as erysipelas. Washing is important for reducing smell and for removing debris, but this is best done by soaking rather than scrubbing. Soaking is, in fact, one of the most effective of skin treatments for oozing exudative conditions. Management of skin conditions requires clean water fit for drinking; this can be obtained by a variety of sterilizing procedures, including boiling, pasteurizing for prolonged periods in the sun, adding antiseptics, charcoal, and other forms of filtering. Soaps irritate because they are alkaline and degreasing agents, and some patients are sensitive to perfumes and other additives in the soaps. Most skin will tolerate some soaping, but the amounts needed to degrease in hard-water areas can cause considerable dryness and cracking of the skin. Soft rainwater or boiled milk should not be despised. Bran is an ancient and harmless water softener: about a pound of bran or oatmeal tied into a muslin bag and soaked in boiling water produces a very thin, starchy emulsion. Because cold causes the stratum corneum to dry, shrink, and crack, cold water is not therapeutic for the skin. Dry skin is best treated at body temperature.

Emulsifying ointment is a useful soap substitute; it can be made into 'cakes of soap' or spooned out of a pot and mixed with hot water to soften it. Liberally applied it is a useful softener of crusts.

Bathing in water, often for prolonged periods several times a day, is an effective remedy for a generalized sore skin. However, the skin tends to dry excessively when all grease is removed and this can enhance pruritus. For this reason, emulsifying ointments and proprietary (oilatum) oils are usually added to the bath.

Although the use of antiseptics in the bath is of dubious value, weak solutions of potassium permanganate 1/8000 to 1/16000 are often used. Patients often use these agents too extravagantly. High concentrations of antiseptics poured into a bath may lie on the bottom of the bath and burn the skin, especially in sensitive areas such as the scrotum.

Bacteria are best dealt with by removing crusts and other debris, soaking does this even without the addition of antiseptics. In intertriginous areas soaking should be followed by drying. Organisms thrive in moist crevasses, for instance under the breasts, in the groins, and between the toes. Non-caking powders are helpful in drying such areas, and many proprietary brands of powders such as ZeaSORB® can be recommended. Like leather, treatment with grease prevents cracking and penetration by undesirable agents.

Softening crusts and exudates

Crusts and exudates (for example, as observed in impetigo, fungus infections, acute dermatitis, and psoriasis) require softening by prolonged contact with a wetting or greasing agent. The problem with wetness is that it quickly evaporates and dries. Wet soaks require absorbent dressings, but modern hospitals often supply only gauze, which is not particularly wettable. Old-fashioned linen or cotton sheets are ideal for wet dressings; usually these are applied in several layers and covered with a light ventilated dressing such as a hand towel or tubular gauze. Occlusive dressings are too heating. Polythene occlusion should not be used. Less rapidly drying agents include the ancient boric and starch poultice—30 g of starch and 4 g of boric acid mixed in 568 ml (1 UK pint) of water, cooled, and smeared on to linen strips to thickly impregnate them. This wet dressing is applied to the crusted area and changed every 4 hours. Vaseline ointments are also suitable for softening scales, as in psoriasis. Where the skin is dry and non-exudative, scaling is best softened with a paste made of 50 per cent Vaseline and 50 per cent talc (talc slowly releases the Vaseline over a number of hours).

Other treatment

Smell

Malodorous necrotic skin is always very difficult to deal with, but the removal of debris and dead tissues is essential. Antibiotics and local antiseptics cut down bacterial degradation, which is a cause of smell. Metronidazole 400 mg three times daily is sometimes used to reduce the smell of tumours as it is effective against various anaerobic bacteria. Charcoal dressings are also helpful. Social intercourse out of doors can be encouraged, while perfumes may be helpful indoors. Washing removes dirt debris and excess bacteria, making the skin less attractive to biting insects.

Diet

Widespread skin disease is a cause of water and protein loss. The tongue and degree of thirst are a good guide to water loss, as is the specific gravity of urine. High-protein diets are necessary, especially when there is great exfoliation.

Retinoids

The greatest advance in dermatological therapeutics of the last decade has been the introduction of systemic retinoids. The main retinoids available are *cis*-retinoic acid and acitretin. These modulate cell differentiation and growth, inhibit polymorphonuclear-cell chemotaxis, inhibit polyamine formation, and inhibit eicosanoid formation. They are effective in the treatment of acne, psoriasis, and genetic dyskeratoses. Their side-effects include teratogenesis, hyperostosis, lipidaemia, hepatitis, and the various minor skin, bowel, and neurological problems previously recorded with vitamin A prescribing. Retinoids are prescribed in combination with other topical therapies or PUVA therapy in an attempt to reduce their dosage and consequent side-effects.

Mood-controlling drugs

Apart from the value of psychotherapeutic drugs to control the secondary emotional reactions to skin disease (many such drugs are used to control skin symptoms), antipruritics are often sedative, but hydroxyzine and alimemazine (trimeprazine) are favoured. Delusions of parasitosis and obsessive concern with pruritus is relieved by pimozide.

The placebo

For many skin conditions, such as alopecia areata, there is no specific treatment, and for some patients the available effective remedies are inappropriate, such as the painful treatments for warts in very young children. Nevertheless, to do nothing at all is to encourage despair. Placebos such as mild lotions for alopecia areata or warts should be harmless, cheap, and given knowingly without self-deception.

Subjective symptoms such as itchiness are intolerable for some patients, but can sometimes be relieved by inert agents such as calcium lactate or vitamin B pills given with assurance and confidence.

Bed rest

It is hard for patients with skin disease to play the sick role, especially when they are otherwise well. When told to rest at home, sitting on a couch and pottering about are often only a partial acceptance of the sick role. Admission to hospital and complete bed rest often switches off skin disease such as atopic eczema within 2 or 3 days; for psoriasis, 2 or 3 weeks is often required.

Irritable and distraught, the patient and his family may need rest from each other as well as the knowledge that the illness is genuine and severe enough to take to bed. The patient's bed should be placed where there is no danger to other patients from cross-infection (exfoliative skin disease is a rich source of staphylococcal infection), which means that neighbouring patients should be selected both for their likely resistance to infection and for their likely good companionship. Modern hospitals include a high proportion of single cubicles for patients with skin disease, together with a day room for social mixing once the skin dressings have been completed.

Intertrigo

The treatment of intertrigo is essentially undertaken to protect the area from chafing and secondary infection, and to encourage dryness. Underlying disorders such as diabetes mellitus or obesity must be managed along traditional lines. Infection from bacteria, *Candida* spp., or fungi requires monitoring by appropriate swabs and scrapings. Bed rest and nudity are helpful. In hot climates a fan encourages evaporation and drying. Skin folds should be kept apart by ventilated loose-weave dressings. Acute eczema requires bland wet lotions, steroid creams, and simple antibacterial agents such as gentian violet or vioform cream. When dry, powdering is to be encouraged. Frequent bathing is always helpful.

Hand dermatitis

To provide healing and to prevent relapse of dermatitis of the hands, patients should use lukewarm water and emulsifying ointments when washing. If possible, running water is better than a prolonged soak in a bowl of detergent soap. Soap should be used sparingly and the hands thoroughly rinsed and dried carefully with a clean towel. As far as possible there should be no direct contact with detergents and other strong cleansing agents, shampoos, polishes, and stain removers. Oranges, lemons, grapefruit juices, and various other irritant vegetables should be avoided. Rings should not be worn during housework or other work even when the dermatitis has healed, because irritants often collect under them. Rings should be frequently cleaned on the inside with a brush and left in ammonia (one tablespoon (20 ml) to 500 ml of water) overnight, then rinsed thoroughly. If gloves are used for washing dishes and clothes, they should be made of plastic and not rubber since the latter often causes dermatitis. They should not be worn for more than 15 to 20 min at a time. If water happens to enter a glove, it must be taken off immediately. The gloves should be turned inside out and rinsed several times a week. Sprinkling with talc before they are used helps to dry them. Cotton gloves can be used under the plastic ones. They should only be worn a few times before they are washed.

Vulnerability

The skin in many diseases is vulnerable. This is manifested as the tendency to produce disease even from minor trauma. It is seen in the primary irritant dermatitis of the atopic eczema sufferer, the Koebner phenomenon of psoriasis, lichen planus, the hyperreactivity of the skin to needle puncture or pressure localization in vasculitis, and in the skin ulceration that results from minor knocks to the legs in gravitational stasis. The skin's vulnerability is severe in epidermolysis bullosa.

In all these diseases advice has to be given about protection of the skin. It can be given in the form of information sheets detailing the care of the hands or legs, or in booklet form for mothers of children with epidermolysis bullosa. The various patient associations produce excellent literature in this respect.

Management of leg ulceration

The cause of ulceration should be identified and, if possible, eliminated. However, the aetiology of an ulcer in an elderly woman living in a city is likely to be different to that of a young man in a rural area in Central Africa. The causes of ulceration are listed in Table 24.

Elevation

The leg being below the level of the heart, there is always a tendency to develop venous hypertension and stasis. Deep vein thrombosis, absence of valves in the deep veins, and shunting of blood from the deep veins to the superficial veins via perforators are a significant cause of congestive changes in the microcirculation supplying the epidermis.

Healing of leg ulceration is always helped by elevation. If there is a major degree of arterial disease, so that there are absent peripheral pulses, then the leg should not be raised more than about 23 cm above the level of the heart. In every other case, emptying of the distended veins and superficial venules is helped by lying the patient in a prone position and elevating the legs to an angle of at least 45°. This is best done by placing an object such as a chair under the mattress (Fig. 116). It is also best to elevate the leg during the day, because the patient cannot sustain such a position when asleep and will curl up into a bundle at the top of the bed.

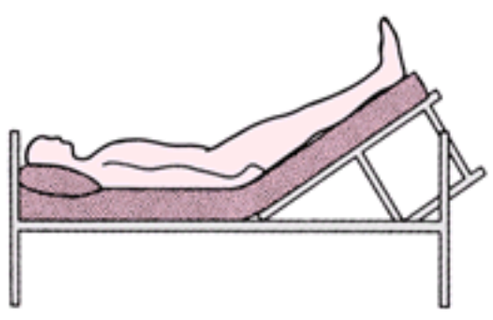

Fig. 116 Elevation of legs above the heart, necessary in the treatment of leg ulcers. A chair can be used to prop up the end of the mattress.

When stiff hips, heart failure, and obesity are factors preventing elevation of the legs, a compromise includes the use of compression bandages and attempts to make the most of any muscle pump in the lower leg. Intermittent positive pressure inflatable bags are commercially available. These are leggings that blow up and squeeze the legs at a pressure and rate that can be regulated.

Elevation is also a requirement for the treatment of lymphoedema, but the protein collecting in the tissues of a swollen leg usually fails to clear satisfactorily via the lymphatics. Movement such as massage, vibration, or ankle exercise is necessary to hasten the passage of protein out of the tissues into the lymphatics. Provided the solid elements of the skin (that is, collagen fibres) are moved, the massage or vibration need not be very sophisticated. In the absence of lymphatics the only other way protein can be removed from the tissues is by proteolysis and macrophages. To control venous hypertension, the pressure at the ankle should be 40 mmHg and there should be a gradient of decreasing pressure as one moves proximally. This gradient is aided by the increasing circumference of the calf. Each layer of bandage doubles the compression.

Arterial disease should always be excluded by examining the arterial system, especially by taking the blood pressure in the legs and arms or by an arteriogram. Stopping smoking and keeping walking is essential therapy.

Wound dressings should encourage moist wound healing, which favours epithelial migration and the development of granulation tissue.

Movement

Inflammation is aimed at removing injurious agents and promoting healing. In acute infection or injury there is often a need for immobilization. However, such immobilization should be localized to the site of injury. Gentle passive movement of the joints and active movement of the main muscles of the leg are encouraged by wriggling the toes or ankles, or by quadriceps exercises.

Unfortunately, many patients with leg ulceration continue to be immobile and to dread any movement that causes pain, long after any need for immobilization to contain the inflammation. Stiffness of the ankle and contractures at the joints are common and delay healing as well as considerably add to crippling.

Deep vein thrombosis is a consequence of immobilization, and this too contributes to morbidity as well as mortality. Thus, in general terms, the maintenance of mobility is essential in the management of leg ulcers.

Exercises in bed can be followed by exercises in the standing position aimed at maintaining an upright posture and ankle mobility, as well as strengthening the muscles of the calves which are so important in pumping blood through and away from the deep veins. For those who are able, walking should be encouraged. Special instruction should be given concerning the harm done by sitting with the legs dependent or crossed, or standing without movement at the ankle. Even a soldier standing to attention needs to maintain venous return by imperceptible, but nevertheless effective, wriggling of the toes. 'March at the sink' is a suitable war cry in the home.

Dressings and bandages

The objective of bandaging is to hold the dressing in position, to protect the leg from further injury, and to provide a sleeve against which movement of the underlying muscles can compress and empty the superficial veins.

The superficial vessels of the skin of the leg are often distorted and congested from chronic inflammation and gravitational stasis. Such vessels are often damaged and cause ischaemic ulceration as a result of external injury, arising from the kinks, wrinkles, and inequalities of an ill-fitting bandage, etc. It should be remembered that a leg that swells can develop severe ischaemia beneath a constricting bandage, even when it was quite loose before the leg became swollen. Large, swollen legs, as in lymphoedema or after deep vein thrombosis, can tolerate unskilled bandaging and tight compressive bandages. By contrast a thin, ischaemic or ageing skin suffers greatly from carelessly applied bandages. The leg is an awkward shape, particularly around the ankle, and many of the twists and the bulk of the bandage tends to be over the bony prominences where the skin is thin and ulcers are common. One system of bandaging is to use two layers—one as a dressing and the other as a cover. The bandage used as a dressing is made from strips of material, no longer than 1.5 times the leg circumference, that are impregnated with a paste. These strips may be applied from a bandage that is cut whenever the direction of the bandaging requires a change. Above the ankle, the bandage is folded at the side of the leg and reversed so as not to completely encircle the leg. Any strips of materials such as calico or linen similarly impregnated will do as well. The overlying covering bandage should be more stretchable than cotton—plasticity rather than elasticity is necessary for a thin leg. Large lymphoedematous legs may be covered by a stronger inelastic material (short stretch). This provides a low resting pressure that increases on desirable activity. Immobile patients may do better with a frequently reapplied, long-stretch elastic bandage, such bandages should be reapplied over orthopaedic padding.

The control of infection—what should be put on the ulcer?

If the cause of ulceration is eliminated, then healing should take place. However, healing depends on healthy epidermis at the edge of the ulcer. Often this is damaged by proteolytic enzymes from slough and infection. Unhappily common is the damage resulting from irritation or sensitivity to medicaments. For this reason, simple bland therapy aimed at reducing debris should be used. Debris will float off if softened. Hard adherent crusts are usually dry. The most effective remedy is wetness: saline is perfectly adequate, provided it is applied very frequently as a wet dressing. Surgical debridement should be performed with a scalpel or scissors if there is any non-viable tissue. This is not difficult as long as it is remembered that dead tissue has no sensation. In other words, trim away anything the patient is unaware of, provided the diseases causing neuropathy (for example, leprosy and diabetes mellitus) have been excluded, in which case only necrotic and non-adherent tissue should be removed. Antiseptics such as eusol, 0.5 per cent acetic acid (a 5-ml teaspoon of vinegar in 500 ml (about a UK pint of water)), or 0.5 per cent silver nitrate in aqueous solution are other wetting agents; however, while helpful for removing slough, they inhibit granulation tissue and are less often recommended.

Many antibiotics are applied to ulcers and they rarely control infection. It is naïve to believe that an ulcer can be made sterile. Antibiotics are commonly and rapidly inhibited by serum and debris under a bandage. It is also common for such agents to do damage to the epidermis. In this respect, it is sometimes forgotten that the health of the surrounding epidermis is more important for healing than the state of the ulcer bed. Tropical phagedenic ulcers often follow trauma, and relative avascularity encourages invasion by fusospirochaetal organisms.

Contact dermatitis

Healing is often delayed and ulcers may be enlarged by damage to the surrounding epidermis. Such dermatitis, so often evident around the ulcer, occurs either because of medicaments, bacterial toxins, or allergy. Table 25 is a list of common causes of contact dermatitis.

Toenails

Poor sight, apathy, stiff hips, and obesity are all reasons why toenails are uncut. It is surprising how the Western world has come to expect 'professionals' to deal with this problem when, in fact, toenail cutting is something any good neighbour can do. Clippers rather than scissors are to be recommended because they cut or fracture hard, thickened nail more effectively. The nails should be softened by soaking them in warm water for 10 min. Only the distal part of the nail protruding beyond the toe needs be cut. Good positioning of the cutter and patient and adequate light are essential. Only very distorted nails or the foot with arteriosclerosis and the consequences of diabetes mellitus need the attention of a chiropodist, where such is available.

Corns

These are due to thickening of the epidermis due to external pressure, or from pressure from underlying bony prominences. It should be possible to avoid external pressure by making adjustments to footwear and skilful padding, so that the weight is taken on less bony areas of the foot. Surgery is sometimes necessary to remove bony prominences. Skin thickening is self-perpetuated, but is greatly helped by careful paring away of excess keratin, avoiding damage to underlying blood capillaries which often project upwards to near the surface.

Carcinoma

Carcinoma develops in the hypopigmented margin of ulcers that have persisted for many years. Such ulcers often invade bone but rarely metastasize. Local excision and grafting is often preferable to amputation.

Surgery

Whereas in technically developed countries, amputation and a good prosthesis may help a disabled person regain their mobility, amputation is objected to by certain races (for example, the Bantu) and religions (such as the Hindu). It inevitably causes them to be rejected so that they are unemployable and outcast. Consideration of amputation must take into account social circumstances and the degree of subsequent aftercare, both available and needed for successful rehabilitation.

Injection of superficial veins with sclerosants (or their removal) is indicated only when the deep veins are patent. If the deep veins are blocked, then the superficial veins are the only venous drainage of the legs and should be preserved. Assessment of the proportion of flow returned through the superficial veins is greatly facilitated by the Doppler flowmeter. Surgical debridement and skin grafting is often a means of quickly healing ulceration but is outside the scope of this textbook.

The decubitus ulcer

The decubitus ulcer is a consequence of tissue distortion, often due to pressure obstructing blood flow. It occurs especially in patients with neurological disease, where painful stimuli from tissue distortion or ischaemia is not recognized. Because the pathogenesis of decubitus ulcers includes impaired blood perfusion, anything that affects the blood supply can contribute to the problem. Thus, in general, old patients who are ill or dying, and especially if they have vascular disease, are most likely to develop sores. Such sores are unusual in those with a purely motor neurological disease and no sensory loss, or in the very old who have a healthy vascular system.

Because it is distortion of the tissues rather than simply pressure that induces sores, shearing forces on the sacral area and heels also need to be taken into account. Such forces are increased by moisture from sweating or incontinence. Distortion of the tissues is enhanced by deformities such as kyphoscoliosis or contractures.

While the basis of management is the relief of tissue distortion by the frequent relaxation of stresses and strains on the tissues, best brought about by movement, attention must also be paid to factors contributing to poor perfusion. These include intercurrent illness causing hypoxia, hypotension, immobility, dehydration, and impairment of consciousness or peripheral sensation. Most acute illnesses requiring admission to hospital provide the necessary criteria for the development of a decubitus ulcer within the first hours or days. The chronic sickness that determines prolonged bed rest at home rarely produces this degree of tissue ischaemia, and thus the hospital nurse gets blamed for what has never occurred at home. The blame is partly misdirected because, for example, an old woman with a fractured hip may develop decubitus ulcers while immobile in the ambulance, on a hard trolley waiting for a bed, or on the operating table. All attendants should be taught the causes of decubitus ulcer.

All ill patients are best nursed in bed. Some of the worst pressure sores can occur while sitting in a collapsed state in a day room or during the postoperative phase of 'mobilization'. The basis of management is regular shifting of position, which has arbitrarily become the practice of turning the patient every 2 hours or intermittent shifts in the surface on which the patient is lying. The combination of heavy and uncooperative patients, together with inadequate staffing levels, especially at night, often result in a failure to prevent bed sores. Good equipment to modify pressure on the mattress is important, and may include a fleece under the patient's heels and buttocks, a bed cradle to take the weight of the bedclothes, a variety of soft surfaces, and a ripple bed to provide alternating pressure, preferably one with large ripples.

In countries where such equipment is unavailable, there is often a large contingent of relatives at the bedside whose attentiveness can be mobilized to assist in frequently turning and massaging the patient.

A long, severe illness is difficult to manage outside an intensive care unit because, as implied by the word 'intensive', there is a requirement for vigilance of all aspects of the patient's physical, conscious, and activity level. It is for this reason that some nursing schools demand that a checklist, known as the Norton pressure sore score, is regularly completed. But even this becomes less accurate each day as a long illness drags on. Once an ulcer has developed it becomes a problem of wound healing. Removal of dead tissue is essential, often by surgical debridement. The development of granulation tissue and re-epithelialization will follow only if the patient's general health improves and their blood supply is adequate. There are so many agents advocated for the healing of wounds that it is important to realize that none are essential and many are harmful to healthy tissue. Those that will remove slough may inhibit living cells. Granulation tissue is the best protection against infection but is discouraged by many of the strongest antiseptics. All wound dressings should aim to reduce debris, to keep the wound moist, and to promote granulation tissue perfused by an adequate supply of normal blood.

23.2 Molecular basis of inherited skin diseases

Irene M. Leigh and David P. Kelsell

We would like to thanks Drs Colin Munro and John McGrath for clinical photographs and to Gareth Magee for help with Fig. 1.

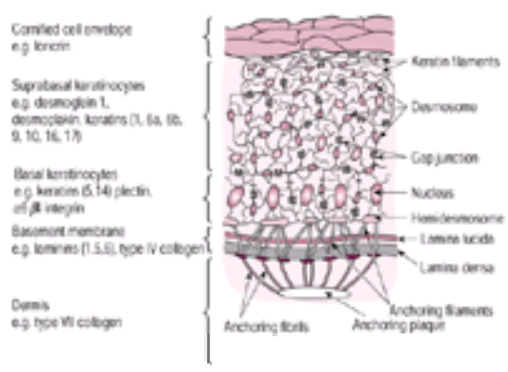

Fig. 1 A schematic representation of the epidermis indicating its organization, important structures, and site of expression of a number of skin-disease-associated proteins.

Introduction

Most patients referred by the general practitioner to the dermatology clinic will be seeking advice and treatment for a few common skin disorders including psoriasis, eczema, and acne. Although the genetic basis of these disorders is complex, putative susceptibility gene variants for some of these diseases have been identified, including the mast cell chymase gene in atopic eczema and the corneodesmin gene in the HLA-linked component of psoriasis vulgaris. In addition, several genes have been identified which predispose to malignancies of the skin including p16 and CDK4 in melanoma and the Patched gene involved in Gorlin's syndrome, in which mutation carriers have an elevated risk of basal cell carcinomas. There are a myriad of rarer epidermal disorders and syndromes for which the genetic basis has been elucidated. Here, we describe the current molecular understanding of these rarer traits which include blistering disease, ichthyosis, palmoplantar keratodermas, and the ectodermal dysplasias.

Structure of the epidermis

To understand the diseases it is first necessary to understand the basic biology of the epidermis and associated basement membrane zone. The basic structure of the epidermis is illustrated in Fig. 1. The epidermis is a stratified squamous epithelium comprised predominantly of keratinocytes. The remaining small percentage of intraepidermal cells are resident melanocytes, Langerhans cells, and migratory leucocytes. The keratinocyte undergoes a process of terminal differentiation which results in a stratum corneum, the critical component for the function of the epidermis as a barrier. It is a highly insoluble, non-viable cell made up of a cornified envelope enclosing keratin macrofibres separated by a highly lipid-rich, intercellular layer. This lamellated lipid is the predominant component of the barrier and is secreted into the extracellular space from membrane-coating granules synthesized in the stratum granulosum. The epidermis is separated from the underlying dermis by a complex basement membrane zone.

The basement membrane zone

When studied ultrastructurally, the basement membrane zone of the epidermis contains four distinct layers:

1. the basal cell membrane of the basal keratinocyte which contains electron-dense adhesion plaques called hemidesmosomes;
2. the electronlucent lamina lucida which is traversed by anchoring fibrils;
3. the electron dense lamina densa;
4. within the sublamina densa region the lamina fibroreticularis contains distinct anchoring structures called anchoring fibrils which insert into the lamina densa and loop around bundles of connective tissue collagens.

The hemidesmosome

Although ultrastructurally this organ appears to resemble desmosome morphology (see below), there are clearly differences in biochemical composition. Two major hemidesmosomal-associated proteins were identified initially by the characterization of autoantibodies arising in bullous pemphigoid, an autoimmune mechanobullous disease of late adult life. These proteins are known as bullous pemphigoid antigen 1 (230 kDa) and bullous pemphigoid antigen 2 (180 kDa). Bullous pemphigoid

antigen 2 has been identified as a unique transmembrane collagen, type XVII collagen, which has an extracellular domain containing the immunodominant epitope of bullous pemphigoid. Bullous pemphigoid antigen 1, like plectin, a further component of hemidesmosomes, is a member of the plakin family of proteins. These proteins have been thought to contribute to plaque structures within hemidesmosome. Other members of the plakin family, including desmoplakin, envoplakin, and periplakin, are found associated with the desmosome. Plectin and bullous pemphigoid antigen appear to interact with keratin intermediate filaments as they course towards the hemidesmosome and bind them into the hemidesmosome structure, acting as a protein clamp. This appears to provide a stable link between the intermediate filament cytoskeleton and the basement membrane zone. Basal keratinocytes also express a number of integrins which are a super family of receptors for extracellular matrix proteins. The major hemidesmosomal integrin is a6b4 integrin, although other areas of the basal cell membrane express a6b1, a5b1, a3b1, and a2b1 integrins.

The lamina lucida appears to contain a complex of laminin molecules, particularly laminins 5 and 6. It is thought that laminin 5 is the major component of the anchoring filament. The lamina densa is constructed of a meshwork of interacting type IV collagen. From this arise the anchoring fibrils of the basement membrane complex which are made of aggregates of antiparallel dimers of type VII collagen.

Keratins

The cytoskeleton of all epithelial cells contains a number of filamentous systems including actin, microfilaments, microtubules, and intermediate filaments. The protein characteristic of intermediate filaments of all epithelial cells is the keratin family of proteins. Keratin polypeptides segregate in two dimensional gel electrophoresis into acidic and basic polypeptides. Nineteen keratins can be identified by this procedure, with each protein being the product of an independent gene. The type II keratin gene family encodes the basic keratin polypeptides and the type I family the acidic keratin polypeptides. Each keratin is expressed in a body-site and cell-type-specific manner, for example K9 is only expressed in the suprabasal layer of the palmoplantar epidermis. The keratin genes are clustered in two chromosomal regions in the human genome: the type I keratins mapping to 17q12–q21 and the type II keratins to 12q11–q13.

A keratin filament comprises both type I and type II keratins. The fundamental building block of a keratin filament is a heterodimer, aligned along the length of its helical backbone, comprising four helical regions separated by non-helical linker regions with a non-helical head and tail domain. These heterodimers aggregate in a complex, antiparallel fashion to form the intact intermediate filament which associates with both hemidesmosomes and desmosomes to provide stability and integrity of the cell. In addition to keratin mutations associated with human disease, *in vitro* and transgenic models of keratin genes harbouring mutations have shown that there are critical regions for filament assembly; these are located particularly at the helix initiation and termination motifs. The function of the head and tail domains is not entirely clear.

Desmosomes

Desmosomal proteins form a complex structure which interfaces between adjacent epithelial cells. The desmosomal plaques of electron dense material run along the cytoplasm parallel to a junctional region in which three ultrastructural bands can be seen. The plaques contain plakoglobin (which is also found in adherens junctions and also thought to be important in cell signalling), desmoplakin, and plakophilin 1. In addition, the desmosomal cores are enriched in calcium binding glycoproteins, called desmogleins and desmocollins. The desmogleins and desmocollins are the adhesive proteins of the desmosome and are similar to the classical cadherins in their general structure, with five extracellular repeats that contain Ca^{2+}-binding sites, a single transmembrane region, and a cytoplasmic domain. To date, six human desmosomal cadherins have been identified and these are clustered in the chromosomal region 18q11–q12. The cytoplasmic domain has binding sites for plakoglobin, plakophilin 1, and desmoplakin, linking them to the intermediate filaments. Desmoglein 1 has been identified as the target antigen for the autoimmune bullous disease pemphigus variatious, and desmoglein 3 for pemphigus vulgaris.

Gap junctions

Gap junctions provide a mechanism of synchronized cellular response to a variety of intercellular signals by regulating the diffusion of small molecules (< 1 kDa), such as metabolites and ions, directly between the cytoplasm of adjacent cells. Connexins are the major proteins of gap junctions and these are encoded by a large gene family. All connexins have four transmembrane domains and two extracellular loops with the amino- and carboxy-terminus located in the cytoplasm. Each connexin assembles into hexameric hemichannels (termed connexons) in the endoplasmic reticulum and these are then transported into the lipid bilayer of the plasma membrane. A connexon then docks with a connexon of an adjacent cell to form a dodecameric, aqueous channel. These intercellular channels cluster in the cell to form the gap junctions. Connexons can form either homotypic or heterotypic channels, with various channel types having distinct molecular permeabilities. The majority of connexins have a wide tissue distribution. Those expressed in the skin include connexin 26, 31, and 43.

Diseases associations with the above structural proteins have provided a molecular classification of disease to complement the classical, morphological description of hereditary blistering diseases and disorders of keratinization, some of which are described below.

Epidermolysis bullosa

The genetic analysis of the heterogeneous group of mechanobullous disorders has given rise to enormous progress in understanding the function of proteins in the basement membrane at the dermo–epidermal junction and the role of keratins in the cytoskeleton (Table 1). The clinical phenotypes of epidermolysis bullosa correspond to different levels of separation within the basement membrane zone or basal keratinocyte, identified via electron microscopic examination. All cases of epidermolysis bullosa are skin disorders characterized by blistering of mucocutaneous sites following minor trauma, which are classified by a combination of laboratory and clinical criteria.

Epidermolysis bullosa simplex

In epidermolysis bullosa simplex, tissue separates within the basal keratinocyte, with or without aggregation of keratin intermediate filaments. This is the most common form of epidermolysis bullosa and is usually autosomal dominantly inherited. Mutations in the genes encoding the basal-cell-specific keratins K5 and K14 have been found to underlie epidermolysis bullosa simplex described, and these probably lead to cytoskeletal weakness and a tendency of cells to rupture on pressure. Three types of epidermolysis bullosa simplex are described below and clinical pictures are shown in Fig. 2 and Plate 1.

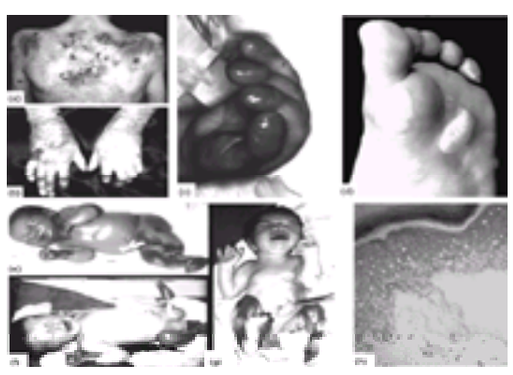

Fig. 2 Clinical photographs of the different forms of epidermolysis bullosa. (a) and (b) a patient with Hallopean–Siemans dystrophic epidermolysis bullosa; (c) the hand of an infant with Herlitz junctional epidermolysis bullosa; (d) blister on the foot of a patient with epidermolysis bullosa simplex?; (e) baby with epidermolysis bullosa simplex Dowling–Meara; (f) baby with Herlitz junctional epidermolysis bullosa; (g) baby with Hallopean–Siemans dystrophic epidermolysis bullosa; (h) intraepidermal blister from a Weber Cockayne epidermolysis bullosa simplex patient. Skin section stained with Richardson's stain. (See also Plate 1.)

Epidermolysis bullosa simplex Weber Cockayne

The soles and palms are mainly affected, rarely in other sites. The blistering occurs from infancy (with walking) and is exacerbated by heat and ameliorated by cold.

The blister heals without scarring.

Epidermolysis bullosa simplex Koebner

The blisters are widespread on scalp, trunk, arms, and legs in addition to the palmoplantar. These cases may represent autosomal recessive inheritance. Nail dystrophy, oral blisters, and dental caries are common.

Epidermolysis bullosa simplex Dowling–Meara (herpetiform epidermolysis bullosa simplex)

The blistering may be very severe and is potentially fatal in infancy. The blisters occur in groups on an erythematous bed, which heals without scarring but hyperpigmentation and milia formation may occur. Patchy keratoderma develops in later life.

Junctional epidermolysis bullosa

In junctional epidermolysis bullosa, the epidermis separates from the dermis through the lucida of the basement membrane zone. Most mutations lie within genes encoding the three subunit polypeptides of laminin 5 (*LAMA3*, *LAMB3*, *LAMC2*). Clinically this disease has been subdivided into two main categories—Herlitz (lethal) and non-Herlitz (non-lethal) forms.

Herlitz junctional epidermolysis bullosa

Blistering and erosions are present at birth and become widespread as the skin is so fragile that it peels away on contact. The resulting lesions are slow healing and tend to persist, becoming infected. The oropharyngeal mucosa is involved, often making feeding difficult. If the infant survives for a few months typical, crusted lesions will be seen on the nose, mouth, and jaw and across the rest of the skin in patches. The teeth have abnormal enamel and are lost easily, as are the nails. Infants usually die from overwhelming infection.

Non-lethal junctional epidermolysis bullosa

The patients show generalized skin fragility and blistering but mucosae are less severely affected. The lesions do heal leaving atrophic scars (generalized atrophic benign epidermolysis bullosa (GABEB)). Poor hair and tooth development occur and nails are dystrophic. Large hyperpigmented patches are seen.

Dystrophic epidermolysis bullosa

In recessive and dominant forms of dystrophic epidermolysis bullosa, separation occurs below the dermoepidermal region at the level of the anchoring fibrils and a large number of mutations have been discovered in the type VII collagen gene (*COL7A1*), which encodes the constituent protein of anchoring fibrils. In dystrophic epidermolysis bullosa, scarring and dystrophy are prominent features in addition to skin fragility and blistering.

Severe generalized recessive dystrophic epidermolysis bullosa

This is the most severe form of dystrophic epidermolysis bullosa and is very disabling in view of the deformities produced by scarring. Blisters are present at birth and recur readily at sites of trauma especially the hands, feet, neck, shoulders, and sacrum. They heal slowly with scarring and milia formation producing a 'mitten-like deformity' and clubbed feet. The severe oral lesions lead to microstoma and inability to protrude the tongue or open the mouth. Poor dentition leads to feeding problems. Scalp blistering and scarring gives permanent hair loss; eye involvement gives corneal erosions and opacities and general physical development is retarded. Oesophageal and perianal strictures lead to difficulty in swallowing and constipation. Although children often survive into adult life, multiple squamous cell carcinomas may develop in the chronically scarred skin and progress rapidly.

Dominant dystrophic epidermolysis bullosa

The skin is less fragile than recessive dystrophic epidermolysis bullosa and blistering much more difficult to provoke and so tends to be localized to bony prominences—knees, elbows, hands, and feet. Localized scarring with milia may replace the nails. Other areas (oral and anal) are much less affected.

Hemidesmosomal epidermolysis bullosa

Rarer forms of epidermolysis bullosa result from inherited defects in three hemidesmosonal components: plectin mutations in epidermolysis bullosa simplex with muscular dystrophy (epidermolysis bullosa simplex muscular dystrophy); type XVII collagen mutations in generalized atrophic benign epidermolysis bullosa; and a6b4 integrin mutations in epidermolysis bullosa with pyloric atresia.

Diagnosis and management of blistering in childhood

Early diagnosis is the key to management and prediction of prognosis. Diagnosis of a baby born with blisters is often difficult on clinical grounds, so diagnosis will rest on electron microscopy of a shave skin biopsy. Immunohistochemistry is likely to be indicative in recessive cases of gene knockout—LH7.2 antibody to type VII collagen and GB3 to laminin 5 being diagnostic reagents. There is no specific treatment for any form of epidermolysis bullosa so the management centres on wound care, avoidance of physical trauma, and general physical and psychological support. Specialist nurses can advise on nursing babies with silk-covered dressing pads and vaseline gauze dressings. Oral hygiene and dental care needs to be life long. High calorie and fibre diet is essential to improve growth. Gastrostomy feeding can also help maintain body weight in children unable to eat. Finger and hand contractures require splinting at night and regular surgical release by an expert surgeon. Now that the genetic basis of epidermolysis bullosa has been identified, prenatal diagnosis by DNA-based techniques and gene therapy by *ex vivo* techniques are being actively explored.

Hailey–Hailey disease and Darier's disease

The genetic basis if these two rare, autosomal dominant, intraepidermal blistering diseases have recently been elucidated and shown to be due to mutations in calcium pumps, *ATP2C1* in Hailey–Hailey disease and *ATP2A2* in Darier's disease.

Ichthyoses

Ichthyoses manifest as dry, rough skin with persistent scaling over most of the body which may resemble fish scales (ichthys, Greek fish). Congenital ichthyosis may be bullous or associated with other abnormalities (ichthyosiform syndromes). Ichthyosis can be acquired in later life, due to drugs such as hypercholesterolemic agents, chronic hepatic disease, lymphoma and other malignancies, thyroid disease, chronic renal hepatic failure, and malabsorption. It is sometimes difficult when a patient's ichthyosis has improved in adult life and then worsened again in late adult life to be absolutely sure whether they have a congenital or acquired ichthyosis. The progressive understanding of the molecular and cellular biology of the ichthyoses will aid in establishing their classification and potential treatment.

Autosomal dominant ichthyosis vulgaris

This commonest ichthyosis is associated with atopic eczema in up to 50 per cent of individuals. The condition improves in teenagers and young adult life and often worsens again with age. The clinical features present with dryness and scaling in the neonatal period but becoming progressively more obvious in childhood. Scaliness is small, flaky or brawny, and is most pronounced on the extensor arms and lower legs. Facial involvement is often minimal, although patients may have dandruff and they have increased markings on the palms and soles. Hyperlinearity of palm creases may be seen. It is usually very well tolerated symptomatically, with the dryness and roughness only being a problem. Treatments have therefore been aimed at removing the keratotic, retained stratum corneum with keratolytic agents such as salicylic acid (1–5 per cent lactic acid) and other hydroxy acids or buffered urea creams.

Histopathology shows hyperkeratosis with a diminished or absent granular cell layer but otherwise very little abnormality at both light and ultrastructural level. This disease is inherited as an autosomal dominant. However, genetic analysis has been hampered by variable penetrance and difficulties in ascertainment. The molecular basis of autosomal dominant ichthyosis vulgaris has centred on studies of filaggrin, the filament aggregating protein expressed in the keratohyalin granules in the stratum granulosum as a precursor protein, profilaggrin. Studies have shown alterations in the expression of profilaggrin although no disease-associated mutations have been identified in the gene encoding this protein. Therefore the genetic defect(s) underlying ichthyosis vulgaris may be in proteins involved in the synthesis or the degradation of profilaggrin rather than in the profilaggrin gene itself. Further studies are awaited.

X-linked recessive ichthyosis

This disorder is much less common than the autosomal dominant form and predominantly affects the male children of female carriers. The scaling is absent usually within the first week of life and progressively increases. The scaling tends to be prominent on the arms, thighs, and lower leg and very large, adherent, brown scaling may involve the flexures and the face. The pathology shows a normal granular cell layer and normal keratohyalin granules ultrastructurally. The molecular basis of this form of ichthyosis was derived from observations of low urinary oestriol secretion in the third trimester of pregnancy and the presence of reduced steroid sulphatase activity. Subsequently, the steroid sulphatase gene was mapped to the X chromosome and disease-associated mutations in this gene have been identified in the vast majority of patients. Steroid sulphatase mutations lead to the abnormal breakdown of cholesterol sulphate in the stratum corneum lipids, resulting in an increase in stratum corneum thickening. A small proportion of patients will have other manifestations of Kallman's syndrome, hypogonatrophic, hypogonadism, and neurological abnormalities. These are due to contiguous gene defects, usually a large deletion on the short arm of the X chromosome encompassing the steroid sulphatase locus.

Bullous ichthyosiform erythroderma or epidermolytic hyperkeratosis

This is a rare, autosomal dominant ichthyosis. At birth, there is a mild erythroderma and, at sites of minor trauma, blisters and peeling may occur. Large areas of denuded skin are often apparent after a difficult birth. In infancy, a yellow-brown hyperkeratosis develops, particularly at sites of joint flexures with cobble-stone keratoses present on the hands, feet, and trunk. Ridged scale may accumulate in skin creases, which are highly susceptible to bacterial and/or fungal infections leading to a pungent body odour. Histologically, there is lysis and clumping of the keratin filaments in the granular layer of the epidermis. Intercellular spaces are often apparent due to the rupture of suprabasal keratinocytes. Immunohistochemical studies revealed the specific aggregation of the suprabasal keratins of the epidermis, Keratin 1 and 10. Subsequently, mutations in either K1 or K10 have been shown to underlie the disease in many bullous ichthyosiform erythroderma patients. A clinical photograph of the feet of a bullous ichthyosiform erythroderma patient is shown in Fig. 3(a), and Plate 2.

Fig. 3 Clinical photographs of: (a) bullous ichthyosiform erythroderma (BIE) and three types of keratoderma: (b) focal palmoplantar keratoderma (PPK) associated with a keratin 16 mutation; (c) striate palmoplantar keratoderma associated with a desmoglein 1 mutation; and (d) constriction around the digit from an individual with Vohwinkel's syndrome associated with a Cx26 mutation. (See also Plate 2.)

Ichthyosis bullosa of Siemans

This is a rarer form of bullous ichthyosis. Neonatal disease is much milder with episodic, superficial blistering occurring throughout childhood, sometimes into adulthood. This blisters occur mainly on the flexures, lower limbs, and abdomen. At these sites, a rippled, grey hyperkeratosis may occur. Plate-like caling and a focal peeling (Mauserung) are usually found. There is an absence of palmoplantar keratoderma and erythroderma. Mutations in another suprabasal keratin, K2e, have been identified as the genetic basis of this condition. This type II keratin is expressed in many of the higher suprabasal keratinocytes.

Netherton's syndrome

Netherton's syndrome is a severe, autosomal recessive disorder, often resulting in infant mortality, which is characterized by ichthyosis with erythroderma and trichorrhexis invaginata (hair shaft abnormalities often termed 'bamboo' hair). Hair anomalies are a characteristic feature seen in patients with Netherton's syndrome. From scanning electron microscopy, plucked hairs from patients often display trichorrhexis invaginata, tortion nodule, pili torti, and trichorrhexis nodosa. Also, light microscopy reveals invaginated hair cuticle into the cortex. Recently, a genome scan of families with Netherton's syndrome mapped the disease to a locus on chromosome 5q32. Mutations in the gene encoding SPINK5, a serine protease inhibitor, have recently been identified.

Sjörgen–Larsson syndrome

Sjörgen–Larsson syndrome is inherited as an autosomal recessive trait and is particularly prevalent in north-western Sweden (1 in 10 000), occurring less frequently elsewhere. The syndrome characteristics include ichthyosis, spastic diplegia, and mild to moderate mental retardation. The skin disease presents as mildly erythrodermic at birth with scaling developing in the first few months. These persist with scaling particularly of the face and limbs. In the flexures, neck, and periumbilical folds, an orange/brown lichenification overlaid with hyperkeratosis is a characteristic of Sjörgen–Larsson syndrome. In early life, neurological defects, including upper motor neurone defects of the limbs, mental disability, and often ocular abnormalities (spots on the retina), are observed. Histologically, the affected skin displays orthohyperkeratosis, acanthosis, and papillomatosis. The genetic defect has been shown to be in the fatty aldehyde dehydrogenase (*FALDH*) gene which affects essential fatty acid metabolism.

Keratodermas

The inherited keratodermas are characterized by thickened skin on the palms and soles. Palmoplantar skin is specialized for high levels of weight bearing and friction, so the stratum corneum is much thicker (hyperkeratotic) than the rest of the epidermis. Keratodermas can be classified clinically according to the pattern of thickening on the palm and sole skin. Three distinct clinical patterns have been observed:

- diffuse—the hyperkeratotic thickening is evenly and symmetrically distributed over the palm and sole; it is usually manifest at birth;
- focal—hyperkeratotic plaques develop particularly at sites of weight bearing and friction; these are usually plaque-like callosites or linear thickening (striate keratoderma);
- punctate—multiple, bead-like keratoses which pepper the palmoplantar skin.

They can have autosomal recessive or dominant inheritance and may occur in syndromes. Keratodermas can be further subgrouped into:

- simple—palmoplantar involvement only;
- complex—associated with lesions of non-volar skin, hair teeth, nails, and sweat glands (including ectodermal dysplasias);

- syndromic—with associated abnormalities of other organs including deafness, cancer, cardiomyopathy, and adrenal insufficiency.

They can also be classified biologically by their recently-discovered genetic defects, for example see Fig. 3 and Table 2 and Table 3. This branch of the genodermatoses is genetically heterogeneous with mutations in genes encoding keratins, desmosomal proteins, connexins, and a protease.

Diffuse palmoplantar keratodermas

Simple: diffuse epidermolytic palmoplantar keratoderma (EPPK)

EPPK is characterized by epidemolytic hyperkeratosis with keratin filament clumping in suprabasal keratins. This autosomal dominant disease presents with symmetrical thickening, giving a cracked, crocodile-skin-like surface due to the underlying epidermolysis, which starts in early infancy. The majority of EPPK pedigrees are linked to the type I keratin cluster on chromosome 17q12–q21 and disease is due to mutations in the palmoplantar-specific keratin, K9, the majority clustering in the helix initiation domain of the protein.

Simple: diffuse non-epidermolytic palmoplantar keratoderma (NEPPK)

NEPPK is also inherited as an autosomal dominant trait and is often difficult to distinguish clinically from EPPK, due to the variability of finding epidermolysis by electronmicroscopy in EPPK. There is a waxy, uniform, yellow thickening over the palms and soles which may spread onto the dorsum of hands and wrists with a sharp cut-off. It is commonly aggravated by secondary fungal infection, which may require intermittent, oral antifungal agents. These often improve the keratoderma. In a number of families the defect has been linked to 12q11–q13. A single family has a mutation in the variable head domain of KRT1. However in the majority of NEPPK families, fine mapping of the 12q11–q13 locus has excluded the type II keratin genes, and a number of candidate genes in the area including a keratinocyte-expressed elastase have been excluded by sequencing.

Complex: erythrokeratoderma variabilis

Erythrokeratoderma variabilis is a rare, autosomal dominantly inherited skin disease characterized by diffuse palmoplantar keratoderma and transient, figurate, red patches at various sites and severity. Germline mutations in connexin 31 (*GJB3*) and connexin 30.3 (GJB4) have been identified in the affected members of some erythrokeratoderma variabilis families.

Focal keratoderma

Most focal palmoplantar keratodermas are characterized by discoid lesions and the majority can be regarded as complex palmoplantar keratodermas as they are often associated with abnormalities of hair, nails, teeth, and glands.

Simple: striate palmoplantar keratoderma

This focal palmoplantar keratoderma is characterized by distinctive linear streaks on palms and soles, over the ventral aspects of fingers and extending onto palms; it is often more extreme on the feet. Variable nail and hair involvement, with fragility or splitting, are seen. Recently, mutations in two desmosomal proteins, desmoglein 1 (18q11–12) and desmoplakin 1(6p21), have been described which result in a hemizygous gene knockout, resulting in haploinsufficiency of the gene product.

Complex: pachyonychia congenita type 1/ focal palmoplantar keratoderma with oral mucosal hyperkeratosis

This clinical overlap syndrome presents in childhood with nail changes (pachyonychia), typically a subungual hyperkeratosis trumpet-shaped nail, especially on the thumb and first finger and toe nails. The sole lesions are painful callosites over weight-bearing areas on the feet, with less prominent callosities on the palms. The mucosa shows milky hyperkeratosis over gingiva. Nutmeg-grater-like follicular keratoses also occur. Variable fragility and blistering can be associated with severe pain on walking. Milder nail involvement shows splinter haemorrhages at the onychocorneal bind. The pathological findings of epidermolytic hyperkeratosis with keratin filament clumping suggested that keratin gene mutations underlie this disorder, confirmed by the identification of mutations in *KRT6a* and *KRT16* in affected individuals from multiple families.

Complex: pachyonychia congenita type 2/ steatocystoma multiplex

The steatocysis palmoplantar keratoderma may be very limited although pachyonychia nail changes present early. Multiple epidermal cysts and steatocysis are seen. Woolly scalp hair and fuzzy eyebrows are seen and natal teeth can occur. The finding of keratin clumps in skin bearing keratin K17, particularly deep outer root sheath, suggested *KRT17* as the candidate gene and autosomal dominant mutations in hot spots have now been described. Mutations in *KRT6b* have also been described. The resulting pathology varies from keratin cysts, vellous hair cysts, to oil filled cysts.

Complex: Papillon–Lefevre syndrome

This focal palmoplantar keratoderma is inherited as an autosomal recessive and is marked by associated severe periodontitis and loss of primary and secondary dentition with opalescent oral mucosa. The inflammatory lesions often result in pocket formation seen pathologically. Linkage to 11q14 was demonstrated in a number of families. Recently, mutations in cathepsin C, a lysosomal protease, have been shown to underlie this disorder. It is postulated that cathepsin C may be important in the processing of key structural proteins, such as keratins, in the epidermis.

Syndromic keratodermas (multiple phenotypic)

Palmoplantar keratoderma and deafness

A number of families with palmoplantar keratoderma and sensorineural deafness have been described, which could have been due to a mutation of a single gene expressed in all affected tissues or cosegregation of two distinct gene mutations. One such disorder is Vohwinkel's syndrome; a mutating palmoplantar keratoderma with constrictions developing around and autoamputating fingers. In a small family with a Vohwinkel's pattern of keratoderma and profound sensorineural deafness, two distinct mutations in the gene encoding the gap junction protein connexin 26 (*GJB2*) were identified. One of the mutations was associated with the profound deafness, the other (*D66H*) segregated with the skin disease. This led to the important discovery that mutations in *GJB2* were causative in both autosomal dominant (DFNA3) and recessive (DFNB1) deafness, accounting for 40 to 60 per cent of hereditary sensorineural deafness world-wide. In other families with Vohwinkel's syndrome, the same palmoplantar keratoderma-associated mutation D66H in *GJB2* has been identified. Mutations in loricrin, a cornified cell envelope component of the stratum corneum, have also been identified in individuals affected with a variant form of Vohwinkel's syndrome, which is associated with ichthyosis and normal hearing. In addition, palmoplantar keratoderma and deafness has also been associated with mitochondrial mutations.

Palmoplantar keratodermas and cancer

Focal NEPPK and oesophageal cancer

Three pedigrees from United Kingdom, United States, and Germany have been studied in which a focal NEPPK with oral hyperkeratosis segregates with a high lifetime risk of squamous cell carcinoma of the oesophagus (40–91 per cent by age 70). In all three families, linkage to DNA markers mapping to 17q24–q25 has localized the disease gene to a region of less than 1 cM. The cornified envelope protein, envoplakin, lies in this region but has been genetically excluded as the candidate gene.

Huriez disease (sclerotylosis)

This is an autosomal dominant disease characterized by palmoplantar keratoderma, nail changes, and scleroatrophy of the distal extremities. Around 15 per cent of individuals develop aggressive squamous cell carcinomas, occurring in their thirties and forties. It is proposed that the scarring resulting from skin fragility predisposes

to the squamous cell carcinomas. Recently, the Huriez disease gene has been mapped to chromosome 4q23.

Punctate palmoplantar keratoderma

A weak association between punctate palmoplantar keratoderma and cancer has been observed in a family with a number of epithelial-derived tumours developing in members under the age of 50. As yet, the punctate palmoplantar keratoderma locus has not been genetically mapped though a number of candidate regions, such as the keratins, have been excluded by linkage.

Other palmoplantar keratoderma syndromes

Diffuse NEPPK, woolly hair, and arrhythmogenic venticular cardiomyopathy (which leads to heart failure and arrhythmias) is due to recessive mutations in plakoglobin. Recessive mutations in another desmosomal protein, desmoplakin, underlie a similar syndrome consisting of a striate PPK, woolly hair, and dilated left ventricular cardiomyopathy. In triple A or Allgroves syndrome, individuals have adrencorticotrophic-hormone-resistant adrenal insufficiency, achalasia, and alacrimia with a PPK due to mutations in aladin, a member of the WD-repeat family of regulatory proteins.

Ectodermal dysplasias

There are a very large number of ectodermal dysplasias which display abnormalities of the skin, hair, teeth, nails, and/or sweating. The clinical lassification is unsatisfactory but may become more transparent when the genetic basis of a significant number of these complexes have been classified. At present, there is limited genetic understanding. Two major subgroups are hidrotic and non-hidrotic ectodermal dysplasia. The concept of dysplasia in these diseases is developmental rather than premalignant.

Hidrotic ectodermal dysplasia (Clouston's syndrome)

Hidrotic ectodermal dysplasia is characterized by nail dystrophy with thick, slow growing, and discoloured, short nails. Diffuse palmoplantar keratoderma is variable but may be severe and spread to knuckles and finger joints. Scalp hair is sparse, fine, pale, and brittle with thin eyebrows and sparse body hair. The disease is inherited as an autosomal dominant. Disease in a large kindred from Canada was mapped to 13q11–12 which harbours a connexin gene cluster. Mutations in the gene encoding connexin 30 underlie this disorder.

Hypohidrotic ectodermal dysplasia

This X-linked, recessively inherited disease is characterized by a loss of sweat glands causing absent or reduced sweating (hypohidrosis) and total or partial loss of teeth. Patients may be very uncomfortable on exertion and are heat intolerant. The teeth are characteristically conical and the mouth dry. In severe forms, the facial appearance is altered with saddle nose, sunken cheeks, and sparse, dry, fine, short hair with absent eyebrows. The disease maps to Xq12–13.1 and is caused by mutations in the ectodysplasin anhidrotic protein. An autosomal recessive form is due to mutations in the ectodysplasin receptor.

Concluding comments

This chapter has focused on the rarer types of genetic skin diseases rather than the more common, genetically complex disorders such as eczema, psoriasis, and acne. This is largely because only a few potential disease-associated genetic variants have been identified with the more common epidermal disorders. In contrast, great advances have been made in understanding the molecular basis of the rarer blistering diseases, ichthyoses, and the keratodermas, with the identification of a number of important proteins involved in epidermal and also non-epidermal biology. In addition, these studies have revealed genetic heterogeneity with mutations in different proteins causing similar clinical manifestations, for example Vohwinkel's syndrome can be due to mutations in either connexin 26 or loricrin. With the imminent completion of the sequencing of the entire human genome, the capability for high throughput genotyping using to high density single nucleotide polymorphism (SNP) maps and new technology development, it is likely that the genetic basis of the more common epidermal disorders will be elucidated in the near future.

24.1 Introduction and approach to the patient with neurological disease

Alastair Compston

Clinical neurology uses intuitive conversation, structured examination, and selective investigation to formulate problems into an anatomical and pathological framework. The competent neurologist instinctively senses relevant components of the history, appreciates the most likely underlying mechanism, reliably elicits the physical signs, knows which investigations are necessary and relevant, and communicates the situation accurately and sensitively. This system has evolved over several centuries during which knowledge has accumulated on structure and function, localization in health and disease, the reliability of physical signs and laboratory investigations, and the nosology of disease.

The neurological history

Although patients usually start with an account of that which troubles them most, the neurologist prefers a history of the components in the order in which they occurred. It may take some time to establish this chronology. The first task is to assess the core symptoms and how they cluster. The neurologist asks enough questions to settle whether, for example, a reported episode of difficulty with speech refers to a disturbance of language (aphasia) or articulation (dysarthria); whether there are motor or sensory deficits in a 'heavy' limb; whether alterations of sensation are positive (tingling and paraesthesiae) or negative (numbness) symptoms; whether a disturbance of bladder function suggests neurological or urological disease; and whether double vision actually refers to diplopia or altered acuity. Some questions reflect the peculiarities of neurological anatomy; it may surprise the patient complaining of impaired vision on the right that the symptom is in fact unaltered by sequential closure of either eye—because it is hemianopic; or that awareness of temperature and the appreciation of pain may be disturbed in the 'good' leg in some forms of spinal cord disease (the Brown–Sequard syndrome).

Once the individual symptoms are accurately defined, they can be grouped and from this follows an interpretation of their anatomical basis suggesting the involvement of one or more sites. Recognizing these patterns is fundamental to interpretation of the neurological history and this synthesis directs attention to specific components of the subsequent examination. It is easy to conclude that the patient with cognitive impairment has disease of the cerebral cortex but a more detailed history will additionally indicate whether this is diffuse or focal and reflects involvement of the dominant or non-dominant hemispheres and the frontal, temporal, or parietal cortices. Inco-ordination of more than one motor skill (eye movement, speech, the limbs, and balance) necessarily indicates involvement of brainstem–cerebellar connections. The process causing a hemianopic field defect lies above and that resulting in lower cranial nerve palsies below the tentorium. The combination of motor and sensory symptoms in the limbs with altered sphincter function indicates spinal cord disease; for the male patient with an unreliable bladder, the significance of linking urgency and frequency to impotence and constipation may seem strange. In turn, the coexistence of diffuse distal symmetric motor and sensory symptoms, shoulder and pelvic girdle weakness, or ocular, bulbar, respiratory, and upper limb weakness steers the thinking towards peripheral nerve, primary muscle, and neuromuscular junction disease respectively.

As a generalization, abrupt events are vascular or electrical in origin; subacute symptoms are demyelinating or inflammatory; and symptoms which develop slowly suggest structural deficits or degeneration. The subsequent course also reveals the underlying process; self-limiting events are often vascular; paroxysmal symptoms tend to be electrical or demyelinating, depending on their duration; and progressive syndromes are compressive or degenerative. The circumstances may be suggestive of a particular pathophysiology: trauma, preceding infection, drug exposure, or pregnancy alert the observer to structural, demyelinating, toxic, and venous thrombotic mechanisms respectively. Dangerous for the beginner but nevertheless important to recognize are the inconsistencies of exaggeration, mismatch between the severity of symptoms and altered function, and anatomical impossibilities which usually feature in non-organic neurological disease. Together, these pattern recognitions are the stuff of neurological diagnosis.

The neurological examination

Examination of the patient with neurological disease needs to be structured and organized without exhausting the patient and examiner through obsessive attention to irrelevant detail. Much can be learned by astute observation without formal assessment. Gross defects of cognition do not need to be confirmed by reciting telephone numbers in reverse or assembling lists of former prime ministers; defects of speech will usually be evident in conversation; many neurological diagnoses are immediately apparent from the patient's gait; movement disorders can be observed whilst taking the history. That said, it is best routinely to adopt a basic core examination and do things in order since the detection of one abnormality will determine the interpretation of another. It takes only a few minutes for the experienced and adequately equipped examiner to confirm that corrected visual acuity is normal in each eye, that there is no gross field defect, and that the optic fundi are normal. Although more detailed assessment will sometimes be necessary, a full range of smooth following (pursuit) eye movements in the horizontal and vertical planes can rapidly be established: this will detect obvious ophthalmoplegia and can be supplemented by cover testing of each eye during fixation on the examiner's nose, and rapid gaze from right to left—very few significant defects of eye movement will escape this rapid screen. Movement of the lower face during forced eye closure, voluntary elevation of the palate, and rapid protrusion or side-to-side movement of the tongue take a few seconds to observe and effectively cover all the lower cranial nerves. It is rarely necessary to test the sense of smell or hearing and a tuning fork is most useful for establishing that deafness is conductive and therefore probably not relevant. Before moving to the limbs, it is worth testing neck flexion in patients where the history suggests muscular or neuromuscular disease.

A sufficient routine examination of the arms would start with posture (outstretched with the eyes open and then closed); a quick look for selective muscle wasting; tone in flexion–extension and supination–pronation at the elbow and wrist respectively; strength in flexion and extension at the elbow and wrist, spreading the fingers and abduction of the thumb; co-ordination during movement between the patient's nose and examiner's finger (or both hands if there is gross inco-ordination so as to avoid accidental ocular injury); and the tendon reflexes. This will take the experienced examiner less than a minute. It may be necessary to establish specific patterns of muscle weakness: global loss affecting the hand in cortical disease; selective involvement of extensor groups in upper motor neurone disease; the patterns of C5–T1 nerve root lesions; diffuse distal weakness of both extremities in peripheral neuropathy; and the subtle distinctions between radial, median, and ulnar neuropathies and C7, C8, and T1 root lesions respectively. Detailed sensory examination of the arms rarely achieves more than can be learned from establishing that crude protective sense (recognition of a sharp pin) or discrimination (position sense and the ability to distinguish two points or perform a simple task such as manipulating a button) are intact.

Although this may involve some rearrangement of clothing, it otherwise takes almost no time to swipe the abdominal reflexes in passing, before examining the legs. Here, the structured motor examination is as for the arms although increased tone is more easily detected by lifting the relaxed leg from the couch at the thigh, and testing internal and external rotation at the hip. Characteristic patterns of weakness are the involvement of flexors at all joints and eversion at the ankle in upper motor neurone lesions; the usual diffuse symmetrical distal involvement in peripheral neuropathy at a time when the hands may be normal; and difficulty in distinguishing injury of the lateral popliteal nerve from an L5/S1 root lesion (in which the ankle jerk is lost) in the context of unilateral foot drop. Proximal weakness is best detected by watching the patient walk, and the calf muscles are normally so strong as to be untestable except with the patient standing. As in the arm, co-ordination can only be assessed once the degree of weakness is established. Tendon reflexes in the legs may be brisk in isolation and often spread, so that in an upper motor neurone lesion when one is tapped several may respond—and in either leg. Even non-neurologists rarely forget to elicit the plantar responses.

Sensory examination of the legs tends to be more reliable for protective than discriminative sensation. In mapping a sensory level it is best to move from the relatively anaesthetic to the normal zone noting the band of hypersensitivity which usually exists at the boundary. It is a matter of fact that many patients confuse the examination by exaggeration or elaboration of physical signs; this most usually affects power and the usual clues are a mismatch between the ability to walk and findings on formal assessment of muscle strength (or vice versa) and simultaneous contraction of agonist and antagonist muscles. Sensory testing is subjective and so necessarily vulnerable to inaccurate reporting, but confirming that a sensory level is present both on the abdomen and back, and on the same side on each with a slightly higher level on the trunk, is a simple manoeuvre which may yield surprising discrepancies in the patient with non-organic deficits.

The overall purpose of the history and examination is to assess where and through what mechanism structure and function have been affected. Detecting these patterns becomes routine for the experienced neurologist but the process represents more than just a ritual of clinical neurology. From anatomical localization follows

a formulation of likely mechanisms and pathological conditions underlying the patient's symptoms and signs.

Investigation of neurological disease

The investigation of patients with neurological disease was revolutionized in the early 1970s with the introduction of computed axial tomography. Before then, only the most primitive structural details of the central nervous system could be detected by demonstrating indirectly the shape and placement of the ventricles and blood vessels, and usually at some discomfort to the patient. Function in the central and peripheral nervous systems was measured using neurophysiological techniques. Disruption of the blood–brain barrier and immunological activity in the central nervous system were assessed through analysis of the cerebrospinal fluid.

Investigation still does not replace clinical assessment but, as the sections which follow make clear, it is now possible to detect structural changes in most parts of the brain and spinal cord at high resolution; to distinguish many pathological appearances at these sites on the basis of differences in the magnetic resonance signals; to map function within regions of interest using changes in blood flow and the use of metabolic substrates; to show variations in efferent and afferent electrical activity in the central and peripheral nervous systems; and to detect an increasing range of soluble mediators of normal and pathological function in the cerebrospinal fluid. Taken together, these laboratory investigations still do no more than supplement clinical assessments and, in one sense, the high expectations of diagnosis make for additional difficulties in interpreting neurological illness when the images are normal compared with the era when authoritative statements from neurologists could never be validated and necessarily went unchallenged.

The value of many routine investigations lies in confirming normality and endorsing abnormalities already strongly suspected on clinical grounds. Given the increasing sensitivity of techniques for brain imaging, altered appearances which are not necessarily of pathological significance and genuine lesions which are not relevant in the particular clinical context need to be interpreted with common sense. Overall, the trend has been for the pendulum to swing from diagnosis without adequate laboratory evidence to diagnosis made in defiance of clinical intuition. Even when an imaging abnormality has been identified, its nature may require clinical discussion in order to resolve the most likely pathological substrate—the distinction between ischaemic and inflammatory tissue often proving difficult and not all neoplastic tissue being easily identified as such.

The management of neurological disease

The first issue that confronts the doctor looking after a person with neurological disease is when to discuss and name the diagnosis. Most wait until there is sufficient clinical or laboratory evidence to rule out misdiagnosis; telling people that they have a condition when they do not is bound to cause distress and has landed some specialists in the law courts. However, overcaution and avoidance of discussion can be equally damaging and there are many more patients who harbour bitterness over delay in learning the true nature of their illness than those who wish they had not been told so soon, or at all. The majority of individuals cope extremely well even with the prospect of conditions which are known to be life threatening or have a poor prognosis for disability. Advice may be needed on alterations in lifestyle resulting from neurological disease—for example driving in epilepsy, and the use of drugs in pregnancy. There is a basic human need to know why a thing has happened and most patients enquire about causation but, naturally, the uppermost question is whether symptoms can be treated or the natural history of disease usefully modified.

The chapters which follow document specific treatments for particular conditions but judgement is often required in deciding whether to deploy these remedies depending on age, significance of the symptoms for the individual, level of disability, security of the diagnosis, adverse effects, and the patient's own views. Drug treatment may be used, on an intermittent or regular basis, to suppress symptoms—for example, intravenous methyl prednisolone to educe inflammation, anticonvulsants to suppress epilepsy, g-aminobutyric acid agonists to deal with spasticity, or anticholinesterases to enhance transmission at the neuromuscular junction. Pharmacological options also exist for interfering with the mechanism of disease, again on an intermittent or routine basis—such as the use of triptans to relieve migraine, or the replacement of dopamine in Parkinson's disease. In other situations, the rationale of treatment is to modify the underlying disease process, for example by suppressing inflammatory processes in acute postinfectious polyneuritis using intravenous gammaglobulin, treating patients with multiple sclerosis using b-interferon, and using immunosuppressants such as methotrexate and cycophosphamide in polymyositis and vasculitis respectively. Many other illustrations could be given confirming that the age-old witticism concerning the therapeutic nihilism of clinical neurology is at best now only of historical interest and was always generally rather ill-informed. Beyond the present pharmacological achievements in drug treatment lie many opportunities for improving handicap and disability through the use of rehabilitation which increasingly assumes centre stage in the management of neurological disease through attention to the person with impairments in a particular social and cultural setting rather than focusing on the pathophysiology of disease in an individual void. For the future, there is the prospect of enhanced regeneration in the context of diseases affecting the central and peripheral nervous systems, restoring structure and function and thereby both limiting and repairing the damage.

24.2 Electrophysiology of the central and peripheral nervous systems

*Christian Krarup**

Introduction

In clinical neurophysiology, the core investigations in electrophysiological studies of the central nervous system (**CNS**) and peripheral nervous system (**PNS**), comprise electroencephalography (**EEG**), evoked potentials, electromyography (**EMG**), and nerve conduction studies. However, since these provide no direct information about pathological changes, it is often necessary to supplement findings by imaging or other laboratory studies, and it is mandatory to view the results in a clinical context. Furthermore, electrophysiological parameters provide information about changes over time obtained from various anatomical regions that may not be accessible to direct pathological examination.

Additional methods (including cardiovascular reflexes in the study of the autonomic nervous system, respiratory movements and oxygen saturation in polysomnographic studies of sleep disturbances, and recording of force in the study of voluntary muscle) are becoming increasingly important in clinical neurophysiology, recognizing that electrophysiological methods must often be supplemented by other investigations.

Electroencephalography (EEG)

At EEG the spontaneous ongoing activity from the cerebral cortex is recorded through electrodes placed over the scalp. In most routine studies, recordings are carried out over 30 to 60 min. In addition, specialized studies may be performed to diagnose patients with particular types of epilepsy, during carotid artery endarterectomy, or brain death. In patients with poorly described epileptic fits, the clinical features may require that both visual information and EEG evidence are obtained simultaneously (video-EEG). This may, in patients who are candidates for surgical treatment of medically intractable epilepsy, be carried out over many days. In some patients, additional information may be obtained with intracranial subdural or intracerebral depth electrodes. During epilepsy surgery, an electroencephalogram is recorded directly from the cortex, so-called electrocorticography.

Indications

The main indications for obtaining an EEG include paroxysmal events, convulsions, disturbed levels of consciousness, and neuroinfections. EEG is not well suited as a screening procedure in patients with suspected focal cerebral lesions, since deep-seated lesions show no abnormalities at EEG if the cortex itself or its afferent projections are unaffected. However, when the clinical picture in patients with focal brain lesions is complicated by periodic changes in consciousness, convulsions, or unexplained changes in focal weakness, EEG is necessary to establish the presence of secondary paroxysmal events. Furthermore, EEG is often indicated in patients with encephalopathy to ascertain whether the clinical features are complicated by additional ictal discharges.

Serial EEGs are often necessary to assess the prognosis in patients with diffuse brain lesions. When abnormalities obtained early during a cerebral disorder (for example, cardiac arrest associated with cerebral ischaemia) are followed by further deterioration of the EEG pattern, a poor prognosis is indicated.

Method

The recording takes place with the patient in a comfortable position in a quiet room. After placing surface or needle electrodes over the scalp according to an international, standardized system (the 10–20 system Fig. 1), the technician ensures that the impedance of the electrodes is less than 5 kW. The patient's age, clinical state, and medication is indicated on the record, in particular whether the level of consciousness is normal. The session includes recordings while the patient is awake, during activation procedures, and, if possible, during drowsiness and sleep. During the recording the technician makes notes about the patient's awareness and state of consciousness, but fully describes any events that occur during the recording.. Activity is evaluated at different electrode montages, including both bipolar and unipolar recordings. Bipolar recordings are of value for localizing abnormalities in focal brain areas, whereas unipolar recordings are necessary for examining more widespread and generalized disturbances.

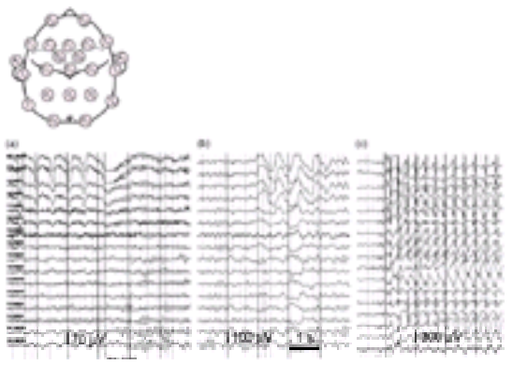

Fig. 1 Examples of EEG curves recorded using a common reference recording montage. The top panel shows the electrode placement using the 10–20 international system (with permission from Niedermeyer and Lopes da Silva). (a) EEG from a 20-year-old normal man (aviation candidate). Eye blinking was carried out to the left of the stippled line. At the stippled line he closed his eyes and the 10-Hz background activity became prominent, mainly over the posterior regions. (b) A 72-year-old female with progressive gait abnormalities, dementia, and urine incontinence. The CT scan showed cerebral atrophy and hydrocephalus. The EEG showed high-amplitude delta waves over the frontal regions. The background activity was slowed to 7 Hz. (c) An 8-year-old boy with absences. The EEG showed generalized 3-Hz spike–wave paroxysms.

During recording the awake patient is asked to relax with closed eyes to assess the background activity. The EEG waveforms are characterized by summated continuous postsynaptic de- and hyperpolarizations of large numbers of cortical cells by input from other brain areas and are, on an empirical basis, described in

terms of their frequencies. The frequency contents of the EEG are classified into activity with frequencies of 8 to 13 Hz (a-activity), 3.5 to 7.5 Hz (q-activity), 3 Hz or less (†-activity), and activity above 13 Hz (b-activity). Interpretation of the EEG should include a description of the background activity, the presence of abnormal wave forms ('transients') during rest and activation procedures, and whether any changes in the background or the occurrence of abnormal waveforms occur diffusely, synchronously, or in a focal pattern (Fig. 1(b), Fig. 1(c), and Fig. 2). Advanced algorithms to localize the distribution of waveforms (brain mapping) are now used for both diagnostic purposes and research on epileptic and non-epileptic syndromes, and they are of particular relevance in the temporal and spatial development of transient abnormalities.

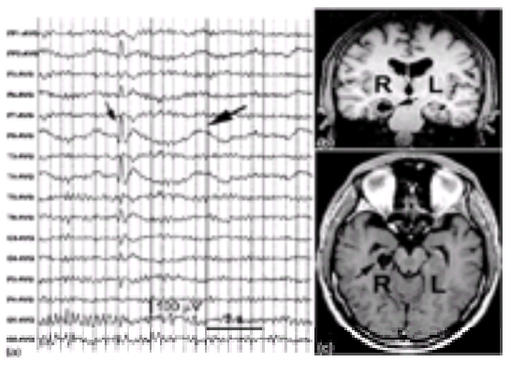

Fig. 2 A 31-year-old man with a history of complex partial seizures. (a) The EEG showed a spike focus over the right pre- and midtemporal regions (small arrow). In addition, there was a slow wave (1–2 Hz) focus over the same regions (large arrow), highly suspicious of a focal brain lesion. An average reference electrode montage was used. (b) Coronal *T*1-weighted MRI after contrast injection. (c) Transverse reconstructed section. Arrows indicate the site of a cystic-ring enhancing lesion in the right hippocampal region. (MRI by courtesy of the Danish Research Centre for Magnetic Resonance, Hvidovre Hospital, Copenhagen University Hospital.)

Activation procedures include hyperventilation: here the patient breathes deeply at a rate of 20/min for 2 to 4 min and changes are followed up to 2 min after hyperventilation. In children and young adults, this may elicit q- and †-activity (activities considered to be abnormal in individuals over 30 years of age), while patients with absences may develop spike-and-(sharp)-wave patterns during hyperventilation (see Fig. 1(c)). The possible epileptogenic effect of photic stimulation is evaluated by stimulating with variable frequencies when the eyes are opened and closed. In susceptible individuals, spike activity limited to the occipital regions is not associated with epilepsy, but spikes or sharp waves in a more widespread distribution are indicators of a lowered epileptogenic threshold.

The normal EEG

The frequency content in the normal subject is highly dependent on age, the level of awareness, and medication. In the normal awake adult with closed eyes, the EEG is dominated by a-activity. The a-activity is most pronounced over posterior parts of the head (Fig. 1(a)), and is subject to modulations by changes in vigilance; for example, it disappears when the subject opens the eyes.

In the newborn, the EEG is characterized by low-frequency activity and variable amplitudes. In premature children, the EEG may be dominated by burst-suppression activity which does not occur in the normal, full-term baby. During maturation, the background frequencies move into the a-range by the early teens. Even in normal young adults, intermittent posterior slowing may be seen over the occipital regions, which becomes enhanced and spreads to other regions during hyperventilation. This slow activity during hyperventilation is augmented by low glucose levels in the blood, so that glucose should be given by mouth to subjects with excessive amounts of slow activity during hyperventilation.

During drowsiness the a-activity is diminished and disappears, first intermittently and subsequently completely, to be replaced by q-activity (stage-1 sleep). During stage-2 sleep (light sleep), sleep spindles (bursts of 12–14 Hz activity), sharp waves over the vertex, and K-complexes (high-amplitude, slow-wave activity) are recorded in addition to q-activity. At deeper levels of sleep (stages 3 and 4), increasing amounts of high-amplitude †-activity are recorded (often designated 'delta sleep'). The EEG may be badly misinterpreted if drowsiness is not recognized during the recording session, therefore the technician must monitor the level of awareness at all times.

The abnormal EEG

The abnormal EEG may be characterized by changes in the background activity, the presence of low-frequency waveforms, epileptiform activity, or by periodic phenomena. The EEG is evaluated for the presence of abnormal frequencies or wave forms, either intermittently or constantly, whether these are localized diffusely or focally, and whether they occur in a synchronous or an asynchronous distribution. Preservation, distortion, or loss of normal background patterns are evaluated.

Abnormal frequencies

Slowing of the normal background activity occurs diffusely in patients with encephalopathy (for example, ischaemic or metabolic brain disease) or degenerative brain disease (for instance, Alzheimer's disease). Focal slowing (see Fig. 2) and attenuation of background activity is highly suggestive of focal brain disease (for example, stroke, tumour, or subdural haematoma).

Generalized, diffuse, and focal abnormalities

Generalized abnormalities occur synchronously throughout the brain, though the amplitudes and wave forms may vary at different recording sites (see Fig. 1(c)). Diffuse abnormalities are also present over large brain areas, but the low-frequency activity or spikes/sharp waves may occur independently. It should be considered if the generalized changes occur in recordings with a single reference electrode, since this may erroneously give rise to the impression of generalization.

These abnormalities are considered to have a central origin if the generalization occurs from the onset, but they may also be due to a focal cortical lesion if generalization occurs as a secondary phenomenon. So-called intermittent rhythmic †-activity (Fig. 1(b)) may occur over widespread areas of the brain due to raised intracranial pressure and have little localizing value. Diffuse low-frequency abnormalities, often associated with triphasic waves, indicate widespread cortical abnormalities in metabolic encephalopathies.

Spikes, sharp waves, and periodic complexes

The central role of EEG in the diagnosis and follow-up of patients with epilepsy justifies the attention paid to the identification and localization of epileptic discharges. The features characteristic of epileptiform events consist of waves of various forms, usually spikes (potential duration, 70 ms or less) or sharp waves (potential duration, 70 to 200 ms) in a rhythmic pattern, that are of high voltage compared to the background activity and reflect hypersynchronization of neuronal discharges (Fig. 1(c)). Spikes may be followed by a negative wave, the so-called 'spike–wave complex'. Since it is unusual for an epileptic seizure to coincide with the EEG, the diagnosis therefore relies on the presence of epileptiform discharges during interictal recordings: the examination at the first EEG may be negative in up to 50 per cent of patients. Repeat studies or prolonged recordings (possibly under video control) are frequently indicated, and proper activation procedures, such as hyperventilation, photic stimulation, and possibly sleep deprivation or the use of sedatives to ensure sleep during the study, may be needed. The diagnostic yield of repeated EEG studies has accordingly been found to show abnormalities in more than 90 per cent of patients with a clinically established diagnosis of epilepsy.

Paroxysmal discharges may be focal or generalized in distribution according to the underlying aetiology. Recently developed focal epileptic symptoms (Fig. 2) may be evidence of a brain tumour and should be thoroughly investigated with appropriate imaging studies. Epileptic activity may develop abruptly in patients with primary generalized seizures (Fig. (c)). It is, however, important to evaluate this development closely to distinguish primary from secondary seizures that develop focally and then spread to adjacent cerebral regions, and possibly with generalization to the whole brain. Detection of focal epileptic activity may require specialized electrode montages. For example, an epileptic focus in the temporal lobe may require recording through electrodes placed over the zygomatic arch or through a needle

sphenoidal electrode placed at the foramen ovale. Such focal epileptic activity may, moreover, not become apparent until the patient becomes drowsy or goes to sleep.

The electrophysiological activity is usually not unambiguous for subgroups of epileptic seizures, though the particular combination of clinical characteristics, the EEG changes during seizures, and the interictal activity may be distinctive for epileptic syndromes, hence the term 'electroclinical diagnosis' has been coined. Generalized 3-s spike–wave complexes are considered pathognomonic for generalized absence seizures (petit mal, Fig. 1(c)), and hypsarrhythmia (high-voltage, irregular slow waves interspersed with spikes) occurs almost exclusively in infantile spasms. Periodic, lateralized epileptiform discharges (**PLED**) give a trace of continuous focal spike activity with a frequency of 0.5 to 3 s, seen in connection with acute severe brain disease. Periodic generalized complexes of sharp waves are characteristically seen in patients with Creutzfeldt–Jakob disease, herpes simplex encephalitis, and subacute sclerosing panencephalitis, and may be present in patients with severe brain anoxia.

Evoked potentials

Evoked potentials are specific CNS potentials obtained by stimulation of particular sensory receptors or fibre tracts and are carried out to examine the integrity of afferent and efferent pathways. The sensory pathways routinely examined include the visual system (visual-evoked potentials, **VEPs**), fibre tracts in the brainstem (brainstem auditory-evoked potentials, **BAEPs**), and somatosensory pathways in the dorsal columns (somatosensory-evoked potentials, **SSEPs**). Motor-evoked potentials (**MEPs**) are elicited by magnetic stimulation of the motor cortex and used to study the corticospinal tracts. Methodological questions and pathophysiological findings are discussed below; however, a detailed description of the methods used are considered beyond the scope of this chapter and the reader is referred to the Further reading list.

Near-field and far-field responses

The responses discussed in this chapter are the modality-specific components of the evoked potentials (**EPs**) that reflect the propagation of action potentials in fibre tracts and cortical areas. The so-called 'event-related' potentials, although time-locked to a stimulus, are not modality specific but reflect the activity in neuronal networks involved in cognitive processing (for example, P300), they will not be described further.

The electrical responses recorded close to the source are the so-called 'near-field potentials', which may arise from axons or be of postsynaptic origin. These include action potentials recorded from peripheral nerves, the spinal cord, or cortical areas. However, the activity recorded from scalp electrodes with a non-cephalic reference also reflect activity in deeply located structures, known as 'far-field potentials'. The origin of a number of these EP components is incompletely known, and the latencies and amplitudes of only some of these are of clinical relevance in routine practice.

Indications

The main purpose of evoked-potential studies is to ascertain the presence of pathological processes localized to myelinated fibre tracts or to the synaptic connections through which messages are relayed. The conduction velocity of the fibres is gauged by the latencies of the responses, and these are particularly susceptible to abnormalities in the myelin sheath. Hence, evoked potentials are of particular use in demyelinating disorders, for example multiple sclerosis. However, conduction abnormalities are not specific for a particular disease, and delayed conduction may be seen in a variety of disorders including hereditary diseases, compression of nervous tissue (such as spondylotic myelopathy), and infectious diseases (such as in patients with the acquired immunodeficiency syndrome, **AIDS**). Thus, the constellation of EP abnormalities, the clinical setting, and other paraclinical or laboratory findings are all important factors in a diagnosis.

The amplitudes of responses are influenced by the number of conducting fibres; in disorders characterized by fibre loss without involvement of the myelin sheath, abnormalities may be confined to a reduction in amplitude. However, because of the amplification that occurs at synaptic relays, the amplitude of the evoked potential is a poor indicator of the degree of fibre loss. Thus, a cortical response may still be recordable at SSEP testing in patients with a severe neuropathy and an absent peripheral nerve response. Finally, conduction may be delayed in disorders characterized by axonal loss, possibly related to delays at synaptic transmission. Thus, in patients with amyotrophic lateral sclerosis (**ALS**), the MEP recording often shows a delayed central conduction time even though the disorder is characterized by fibre loss rather than demyelination.

SSEP and MEP investigations have proved to be valuable intraoperative monitoring tools during surgery on the vertebral column for scoliosis and on the spinal cord for tumours or vascular malformations. Both a reduction in amplitudes and a prolongation of latencies have proved reliable indicators of impending damage to the spinal cord, and hence the need to take measures to avoid permanent damage. Additionally, the use of electromyographic recordings from relevant muscles is helpful during scoliosis operations in warning the surgeon that a root may be in danger of damage from screws or other hardware.

Visual-evoked potentials

Method

Visual-evoked potentials (VEPs) are evoked by either a diffuse stroboscopic flash (flash-VEP) that stimulates the whole retina or by pattern-reversal stimulation (pattern-VEP), where a black-and-white checkerboard reverses position at a frequency of 2/s. The patient is seated at a distance of 1 m and gazes at the centre of the checkerboard projected either on a screen or a TV monitor. The pattern-VEP is sensitive to the co-operation of the patient, whereas the flash-VEP can be used to ascertain whether functional connections exist between the retina and the occipital lobes. The size of each square is either 9 mm or 18 mm, depending on the visual acuity. The pattern-VEP is generated mainly by the central 10° of vision. The responses are recorded over the occipital lobes. At least 100, and preferably 200, sweeps are averaged to yield responses of adequate resolution.

Each eye is stimulated in turn, and in routine studies the whole visual field is stimulated. In some conditions, however, it is more revealing to stimulate part of the visual field: in which case, the half-field is usually stimulated. Half-field stimulation is particularly useful in conditions where lesions are localized in the visual projections behind the chiasm, but its interpretation requires considerable expertise.

Measurements

The pattern-VEP comprises three main components, of which the positive phase at a latency of about 100 m is the most constant (Fig. 3). In clinical practice, the latency of this phase and the amplitude of the response are measured. In flash-VEP, the latencies of the N70, P90, and N120 phases are measured.

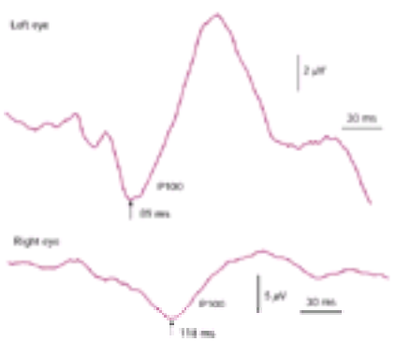

Fig. 3 Pattern-reversal, visual-evoked potentials (checkerboard stimulation) from a 64-year-old man showed a normal pattern-VEP with a P100 latency of 89 ms from the left eye and an abnormal pattern-VEP from the right eye with a latency of 118 ms (27 per cent prolonged, upper normal limit 103 ms). The findings indicated the presence of a right-sided optic nerve lesion.

Clinical correlations

Flash-VEP is reduced in patients with retinal disease. It is a useful test in patients with retinosa pigmentosa, and in those who cannot co-operate, in particular in children.

Monocular, full-field, pattern-VEP with prolonged latency to the P100 component in one eye indicates that the lesion is localized anterior to the optic chiasm (Fig. 3). Although this is most frequently due to demyelination of the optic nerve, it may be due to retinal degeneration, optic nerve compression, or glaucoma. In some patients with mild optic neuritis, the latencies only show an abnormal interocular difference. The interpretation is more uncertain if bilateral prolonged latencies are found, since this may be due to lesions anywhere along the visual pathways. Interocular differences in patients with bilateral retrochiasmal lesions (for example, spinocerebellar syndromes) are within the normal range. Marked latency differences in patients with bilateral abnormalities suggest bilateral optic nerve lesions. Retrochiasmal lesions may be further examined by partial-field (half-field) studies of the individual eye.

Electroretinography

The electroretinogram (**ERG**) is the electrical response evoked in the retina by a flash and is due to depolarization of the interstitial Müller cells and pigmented epithelium. The ERG is recorded by a contact-lens electrode or with an infraorbital surface electrode. The state of light and dark adaptation can be used to separate the function of the rods and cones. The ERG is usually carried out when the VEP pattern is missing and it is uncertain whether this may be due to a retinal problem. In such cases, the ERG may be evoked by a routine flash. Dark-adapted ERG is carried out in the differential diagnosis of retinal degenerations and is a specialist task usually carried out in collaboration with a neuro-ophthalmologist.

Brainstem auditory-evoked potentials (BAEPs)

Method

The auditory brainstem response is elicited by passing short-lasting clicks, at an intensity of 75 to 100 dB, through earphones to each ear separately. The responses of interest include the time-locked far-field responses with latencies of less than 10 ms. The brainstem-derived response consists of several phases (usually numbered as positive waves PI–VI), which indicate conduction along peripheral pathways in the cochlear nerve and different relay stations of the lateral lemniscus pathway within the brainstem.

Measurements

The waves of interest are the positive peaks PI to PVI; PI, PIII, and PV are usually recorded, whereas the remaining waves may be missing even in normal subjects. PI is generated in the cochlear nerve, PII in the cochlear nucleus, PIII in the pons, and PV at the midbrain level. For clinical purposes, the latency of PI is measured to ascertain peripheral conduction and that of PI to PIII, PI to PV, and PIII to PV to ascertain the central conduction time within the brainstem.

Clinical correlations

BAEP recording is helpful in investigating the integrity of the brainstem; it is used to confirm brain-death in some laboratories. Its main usefulness lies in the localization of lesions at the cochlear nerve, at the entry into the brainstem (cochlear nucleus), and at different sites within the brainstem. Central abnormalities are found in 50 per cent of patients with multiple sclerosis.

Somatosensory-evoked potentials (SSEPs)

Method

These responses are evoked by repetitive stimulation (2–5/s) of the median nerves at the wrists and the tibial nerves behind the medial malleolus (Fig. 4), using a stimulus duration of 0.2 ms at a strength just sufficient to elicit a slight motor response. Differentiation between peripheral and central disease is obtained after stimulation of the median nerve by recording peripheral nerve responses through surface or subcutaneous needle electrodes at the supraclavicular fossa (Erb's point, designated the N9 response), from the spinal cord at C6 (designated the N13), and over the contralateral hemisphere (the potential is designated N20). On stimulation of the tibial nerves, recordings are carried out from the peripheral nerve at the popliteal fossa (or at the gluteal fold), at Th12 (designated the N23), and over the brain (onset response and P40 response). Up to 1000 responses are averaged depending on the level of noise and the size of the response. The average is carried out in two bins to ensure reproducibility.

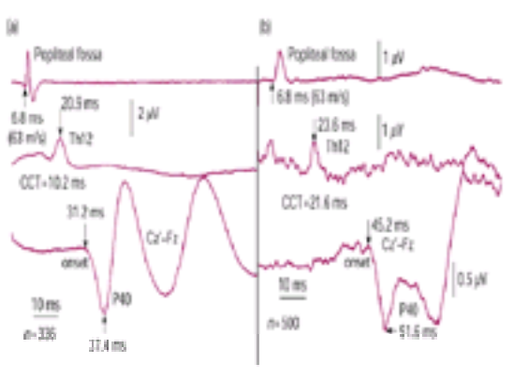

Fig. 4 Somatosensory-evoked potentials from (a) the right leg of a 25-year-old normal woman (a) and (b) the left leg of a 55-year-old man with signs of myelopathy. The tibial nerve was stimulated at the medial malleolus and responses recorded from the peripheral nerve at the popliteal fossa, from the spine (Th12), and the scalp. In both subjects, the peripheral conduction velocities and spinal latencies were normal. The latencies of the cortical responses to both the 'onset' and the P40 were normal in (a) and 31 per cent and 25 per cent prolonged, respectively, in (b). The central conduction time (CCT) was calculated as the difference between the spinal latency and the onset latency. The central conduction time was normal in (a), whereas it was 98 per cent prolonged in (b), consistent with myelopathy.

Measurements

The latencies to the onsets of the peripheral nerve responses are measured to calculate the peripheral conduction velocities (Fig. 4), to the negative peak of the spinal response, and to the first negative response at the cortex after the median nerve and to the onset and the P40 responses after tibial nerve stimulation.

The central conduction time is calculated as the differences in latencies between the spinal responses at C6 and the peak of the N20 response after median nerve stimulation, and between the spinal responses at Th12 and the onset latency (or the P40 latency) after tibial nerve stimulation. The values are compared to height-matched controls.

Clinical correlations

SSEPs from median and tibial nerves are helpful when very proximal nerve disorders or central nervous system disorders are suspected. A prolonged latency of the spinal responses evoked from the tibial nerves indicates the presence of proximal lumbosacral plexus or root lesions, and may be differentiated from a peripheral neuropathy by a normal peripheral nerve response at the popliteal fossa or the gluteal fold. Similar information is obtained regarding the brachial plexus and cervical roots at C6 from median nerve stimulation. SSEP studies may be extended by dermatomal stimulation in the legs and the arms to diagnose monoradicular lesions.

SSEPs are, however, particularly useful for identifying spinal cord disease; the central conduction time obtained separately from the upper and lower limbs may be used to determine the probable localization of myelopathic lesions (Fig. 4(b)). The central conduction time often shows marked prolongation in patients with multiple sclerosis.

Motor-evoked potentials (MEPs)

Motor-evoked potentials are obtained by activating focal motor cortical areas by a short-lasting, strong magnetic pulse of up to 2 tesla, which induces a current within the excitable tissue of the cortex. In some laboratories, electrical stimulation rather than magnetic stimulation is employed. However, electrical stimulation is painful; moreover, the electrical stimulus activates fibres deeper within the cerebrum than does the magnetic stimulus. The two methods therefore yield results that cannot be directly compared. The descending waves from the cortex consist of D-waves from cortical neurones followed by I-waves that arise transynaptically. In addition, stimulation is performed at cervical and lumbar spinal levels. At magnetic stimulation, excitation occurs at the proximal spinal nerves rather than at the spinal cord.

The motor responses are recorded from muscles of the upper and lower limbs (including proximal and distal muscles) using surface electrodes to evaluate the compound muscle action potential (**CMAP**). Facilitation of cortical neurones by slight voluntary contraction is necessary for obtaining 'maximal' motor responses.

Measurements

The amplitudes and latencies of the CMAPs are measured at both cortical and spinal stimulation (Fig. 5). The central conduction time is obtained by calculating the differences of these latencies; however, since excitation at spinal stimulation occurs at the proximal peripheral nerve, the central conduction time includes conduction along the roots. The central conduction time has therefore also been calculated using the F-wave latency to obtain a measure of the peripheral conduction time. In central lesions, the central conduction time is prolonged compared to height- and age-matched controls (Fig. 5(b)). In addition, the CMAP amplitudes of the cortical response may be reduced, indicating central axonal loss, conduction failure, or increased temporal dispersion along corticospinal fibres. The shape of the CMAP recording in patients with multiple sclerosis is often polyphasic, indicating dispersion along demyelinated central pathways.

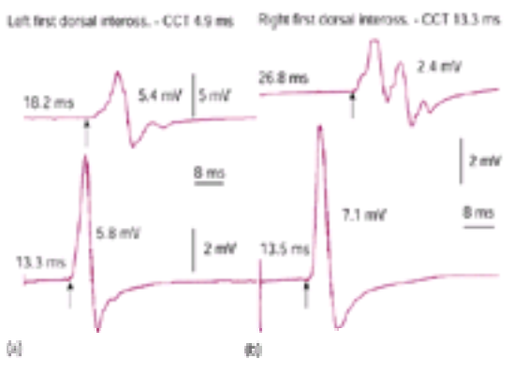

Fig. 5 Motor-evoked potentials obtained by magnetic stimulation from (a) the left and (b) the right first dorsal interosseous muscles in a 60-year-old woman suspected of having multiple sclerosis (the pattern-VEP and the SSEP were also abnormal). Lower traces: compound muscle action potentials (CMAPs) evoked by stimulation of the cervical spine. Upper traces: CMAPs evoked by cortical stimulation. The latencies of the responses (shown above the traces) at spinal stimulation were normal on both sides, whereas cortical latency was normal in (a) and 36 per cent prolonged in (b). The central motor conduction time (CCT, indicated above traces) was calculated as the difference between the cortical and peripheral latencies. The central conduction time in the left arm was normal in (a), whereas it was 86 per cent prolonged in (b), consistent with a central lesion.

Clinical correlations

The central motor conduction time is prolonged in demyelinating disorders and the investigation is of particular value in patients suspected of having multiple sclerosis (Fig. 5(a) and Fig. 5(b)). However, slowing of central conduction is a non-specific abnormality that may also be seen in patients with other causes of CNS motor disorders. In amyotrophic lateral sclerosis for example, the central conduction time is often abnormal in an irregular pattern, though the prolongation is usually only slight. The MEP should therefore be supplemented with other evoked potentials (pattern-VEP and SSEP), MRI, and spinal fluid examinations.

In some patients with peripheral nerve disorders, in particular acute or chronic inflammatory demyelinating neuropathy, the MEP examination may show abnormalities indicating central as well as peripheral nervous system involvement. This may be an erroneous finding due to slowed conduction along spinal roots. Due to the stimulation of peripheral nerves distal to the intervertebral foramen, the conduction along the spinal roots is included in the central conduction time, and slowing at this segment may therefore erroneously be localized to the CNS.

Studies of the peripheral neuromuscular system

Indications

Electromyography (**EMG**) is used to establish whether weakness is due to a primary disease of muscle fibres (myopathy) or to a loss of a-motor fibres (neurogenic disorders). Nerve conduction studies are carried out to ascertain the loss of motor or sensory axons or the disturbed function of myelinated fibres. Both types of studies are usually needed for a differential diagnosis, and since the findings are rarely specific for particular disorders, the interpretation relies on inferences from several criteria of abnormality. The degree to which the findings should be supplemented and confirmed by light or electron microscopy of nerve- or muscle-biopsy specimens and other laboratory studies depends on the clinical setting. EMG and nerve conduction studies should be viewed as an extension of the clinical examination and form part of a neuromuscular consultation. EMG and nerve conduction studies assist in answering specific differential diagnostic questions relating to focal or generalized disorders of the peripheral neuromuscular system. Even though subclinical involvement has important implications in the diagnostic interpretation in several conditions (for example, neurogenic changes in non-weak muscles where amyotrophic lateral sclerosis is a possibility), the use of these studies to 'rule out' neuromuscular involvement in diffuse or focal pain problems should be discouraged.

Disturbances of neuromuscular transmission require specialized studies, including the recording of compound muscle responses evoked by repetitive stimulation of motor nerve fibres. In single-fibre EMG, the action potentials from individual muscle fibres are recorded during voluntary activity or during repetitive stimulation to measure the stability of neuromuscular transmission.

Electromyography

Method

EMG is carried out using needle electrodes. In routine studies, most laboratories either use concentric needle electrodes and a core recording lead with a surface area of 0.07 mm^2 referenced to the cannula, or insulated monopolar needles with a surface recording area of 0.17 mm^2 referenced to a surface electrode. The results obtained with these electrodes differ in regard to the amplitude of the motor-unit potential (**MUP**), whereas its duration only differs slightly. The baseline is somewhat more unstable when recorded with a monopolar electrode than a concentric needle. The signals should be recorded via a high-impedance amplifier with a frequency range of between 2 and 10 kHz.

Measurements

Recordings are carried out at rest, during weak voluntary activity, and during maximal voluntary activity (Table 1).

During rest, both the presence and type of spontaneous activity are characterized. During weak voluntary effort, individual MUPs are recorded without disturbance by other MUPs. The duration and amplitude of the MUP are also measured. The duration of the MUP reflects the activity of muscle fibres of the motor unit at a distance from the recording electrode. In contrast, the very few muscle fibres placed at the tip of the concentric electrode determines the amplitude of the MUP. The mean amplitudes and durations of at least 20 different MUPs recorded from 10 different sites at three different insertions are obtained. The shapes of individual MUPs are evaluated and designated as simple (less than five phases) or polyphasic (five or more phases). The findings are compared to age-matched control values from the investigated muscle, and the percentage deviation is calculated to ascertain whether the findings are normal or consistent with myopathy of chronic partial denervation (Table 1 and Table 2).

During a maximal voluntary contraction, all motor units in the muscle are activated. The MUPs from individual motor units cannot therefore be distinguished, but they form an interference pattern which, according to the degree of overlap, is measured semiquantitatively as a 'full', 'reduced', or 'discrete' recruitment pattern. Although a full recruitment pattern occurs in normal muscle, it requires the patient's full co-operation. It should therefore be noted whether the activity is recorded during maximal or submaximal effort. In addition to the degree of overlap, the envelope amplitude of the main activity is measured to distinguish myopathy and neurogenic involvement.

Clinical correlations

Recordings at rest

The sarcolemma of the denervated muscle fibre undergoes changes, including a gradual spread of acetylcholine receptors, and the resting membrane potential is reduced. Spontaneous discharges of denervated fibres occur in a cyclical pattern, and they appear as fibrillation potentials or positive sharp waves (Fig. 6). Fibrillation potentials have a triphasic shape and a duration of 5 ms at most, and the discharge pattern may be regular or irregular (Fig. 6(a) and Fig. 6(b)). Positive sharp waves are considered as arising from damage to the cell membrane and indicate a propagation block at the needle recording electrode (Fig. 6(b)). No particular pathological significance is assigned to whether the denervation activity consists of fibrillation potentials or positive sharp waves.

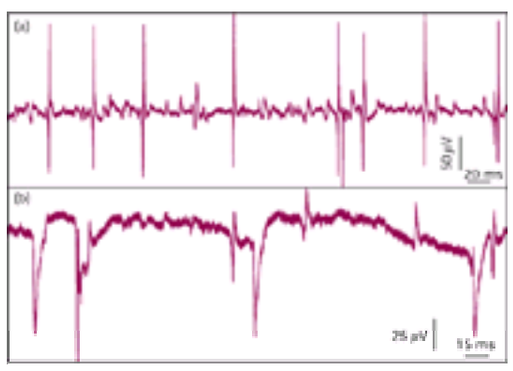

Fig. 6 Fibrillation potentials (a) and (b) and positive sharp waves (b) recorded from a muscle with profuse denervation activity. Fibrillation potentials arise from single muscle fibres and have a triphasic shape, duration of £ 5 ms, and variable amplitudes depending on the distance to the recording electrode. Positive sharp waves are thought to arise from damaged muscle fibres with conduction block at the recording electrode.

Continuous, non-propagated, miniature endplate potentials (**m.e.p.p.**)—and, in addition, irregular, spontaneous, endplate potentials (**e.p.p.**) with negative onset—are recorded from the resting normal muscle within the endplate region. Such single-fibre potentials cannot be distinguished from fibrillation potentials when recorded outside the endplate region. Therefore, spontaneous single fibre activity in normal muscle may be recorded at up to two out of ten recording sites (Table 1).

Denervation activity arises with a delay after the nerve lesion, and the lag is dependent on the length of the distal nerve stump: that is, it occurs within 5 to 10 days at very distal lesions. Similarly, after a nerve root lesion, denervation arises after few days in paraspinal muscles and after 2 to 3 weeks in distal extremity muscles. The presence of denervation activity indicates that the denervation is ongoing, but it may continue for years after occurrence of the lesion if reinnervation does not take place. However, denervation activity also occurs in muscular dystrophy, inflammatory myopathy (polymyositis, dermatomyositis, inclusion body myositis), and some metabolic myopathies (for example, acid maltase deficiency), whereas it is rare or absent in mitochondrial myopathy. In myopathy, denervation is due to segmental muscle-fibre necrosis, thus leaving a segment of the muscle fibre denervated. Denervation activity is a non-specific sign of neuromuscular disease (Table 1).

Whereas denervation activity arises from single muscle fibres, other types of spontaneous activity are due to discharges in groups of muscle fibres, possibly the whole motor unit. These include fasciculations (defined as irregular discharges with short or long intervals of less or more than 3 s (Fig. 7), myotonic discharges (defined as burst of activity with gradually waxing and waning frequencies, often elicited by percussion, needle movement or voluntary activity, and with a decreasing incidence after repeated contractions), complex repetitive discharges (defined as bursts of activity of variable duration with sudden occurrence and drop-out of discharge components that may arise from single fibres), and myokymia (defined as fasciculations, doublets, or triplets occurring with variable and sometimes high frequencies; neuromyotonia belongs in this category of activity).

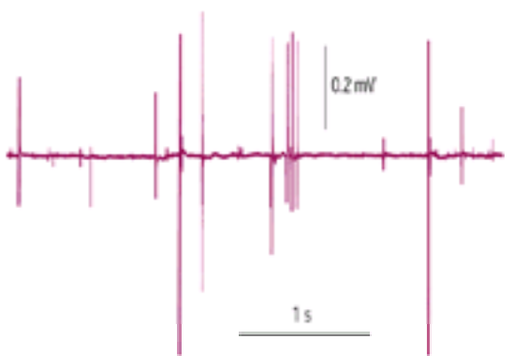

Fig. 7 Fasciculations recorded from the extensor digitorum communis muscle of a patient with multifocal motor neuropathy. The discharges arise from groups of muscle fibres or whole motor units and occur with irregular intervals.

Recording at weak effort

The smallest functional unit in the muscle is the motor unit, which differs quantitatively by several orders of magnitude in different muscles; in lower extremity muscles the motor units have 1000 to 2000 muscle fibres, whereas they have between 5 and 10 in extraocular muscles. The motor units also differ according to the biochemical characteristics of the muscle fibres in fast-contracting motor units (type II fibres) and in slowly contracting motor units (type I fibres). The diagnostic power of EMG mainly depends on the assessment of the structural changes of the motor units as evidenced by evaluation of the MUP. Reliance on the EMG has varied considerably over the years: quantitative measurements of MUPs may be used to gauge the overall size of the motor units and therefore as a diagnostic indicator of whether weakness is due to neurogenic abnormalities or to myopathy; as opposed to qualitative evaluation, which can only give an impression of the MUP changes. The use of quantitative measurements is now more widely used and accepted as the introduction of computerized measurement devices has enabled adequate numbers of MUPs to be sampled. This may increase the use of the MUP to differentiate between neurogenic and myogenic abnormalities.

MUP parameters measured include the duration, amplitude, and shape of the MUPs (Fig. 8). The motor units in myopathic muscle are reduced in size due to the functional loss or degeneration of individual muscle fibres, and this is reflected in reduced durations and amplitudes of the MUPs (Fig. 9 and Fig. 10). In contrast, the motor units in neurogenic lesions are enlarged due to collateral reinnervation of muscle fibres, and the mean duration of the MUPs is prolonged and the amplitude is increased (Fig. 9 and Fig. 10). These changes, which indicate the presence of chronic partial denervation, tend to be more pronounced in very chronic conditions. However, in motor neurone disease, MUPs may be gigantic even in muscles without clinical weakness. In specialized multielectrode studies, the motor-unit territory in myopathy is reduced, whereas the territory in neuropathy and amyotrophic lateral sclerosis is increased.

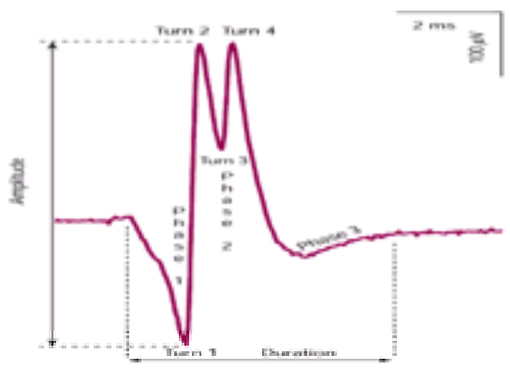

Fig. 8 Motor-unit potential (MUP) to illustrate measurements. The duration is measured from the first deflection from the baseline to the return to baseline. The amplitude (negative sign upwards) is measured peak-to-peak. The MUP has three phases and four turns (potential reversals of >100 µV). This potential is simple in shape (less than five phases). (From Simonetti *et al.*, with permission by Lippincott, Williams & Wilkins.)

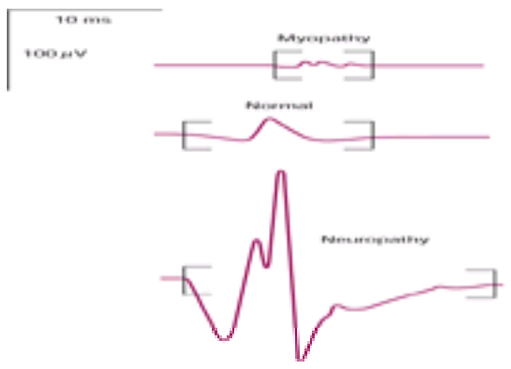

Fig. 9 Examples of MUPs from patient with myopathy (top), normal subject (middle), and neuropathy (bottom).

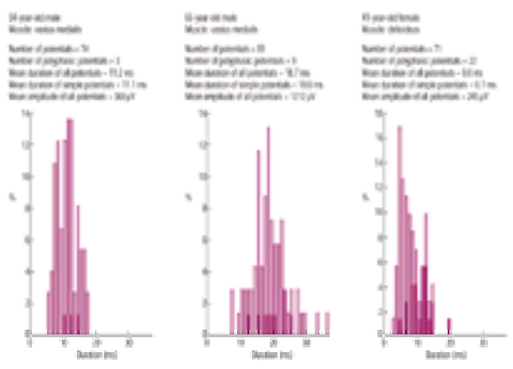

Fig. 10 Quantitative measurements of MUPs from a normal subject (left), a patient with neuropathy (middle), and one with myopathy (right). The total number of MUPs analysed, the number of polyphasic MUPs, the mean duration of all MUPs, the mean duration of simple MUPs, and the mean amplitude of all MUPs are indicated above the histograms. The histograms show the distribution of the durations of simple MUPs (open bars) and of polyphasic MUPs (filled bars). The amplitude and duration were markedly increased (duration, +51 per cent; amplitude, +427 per cent) in the patient with neuropathy. The duration was 29 per cent diminished and the amplitude was normal in the patient with myopathy. The incidence of polyphasic MUPs was slightly (13 per cent and 25 per cent) increased in the patients with neuropathy and myopathy, respectively. (Modified from Simonetti *et al.*, with permission by Lippincott, Williams & Wilkins.)

Whereas the changes in duration and amplitude are specific for either a myopathy or a neurogenic lesion, an increased incidence of polyphasic MUPs occurs both in myopathy and in neurogenic lesions, and is therefore a non-specific sign of neuromuscular involvement (Table 2). It is claimed that long-duration polyphasic MUPs are characteristic of neurogenic lesions, whereas short polyphasic MUPs are seen in myopathy. However, polyphasic MUPs in myopathy have two mechanisms: loss of muscle fibres in the motor unit, which results in short-duration MUPs; and degeneration of muscle fibres followed by regeneration and subsequent reinnervation, resulting in long-duration MUPs. With disease progression, muscle fibre regeneration cannot keep pace with degeneration, and long-duration MUPs become less frequent with advanced disease. The long-duration MUPs in myopathy may obscure the interpretation of the EMG, and it is therefore necessary to calculate the mean duration of simple MUPs (less than five phases) to avoid error.

The EMG examination should include a number of muscles according to the likely clinical diagnosis, since involvement of different muscles may vary in different disorders. In myopathy, proximal muscles in the upper and lower extremities should be examined. Some muscles show clear abnormalities characteristic of the disorder, whereas others show only non-specific changes (for example, fibrillation potentials and increased incidence of polyphasic potentials), and several criteria should therefore be collected. In neurogenic lesions on the other hand, distal muscles are most severely affected and may show abnormalities at an earlier stage than proximal muscles. In this connection it should be considered that some distal muscles may be affected due to focal non-related causes. The extensor digitorum brevis muscle, for example, should be avoided in elderly people due to frequent neurogenic changes caused by compression of the deep peroneal nerve by footwear. In patients suspected of having amyotrophic lateral sclerosis, both clinically weak and non-affected muscles should be studied; as a rule, both show signs of chronic partial denervation often with such pronounced changes that this supports the diagnosis (Table 2). Since amyotrophic lateral sclerosis often has a focal distribution at presentation, it is important to exclude spinal root compression and peripheral nerve lesions as causes of the neurogenic involvement; therefore, it is customary to study several muscles in different extremities to ensure that any changes are widespread.

Maximal voluntary contraction

The number of motor units is normal in myopathy, and therefore the loss of muscle fibres is associated with a full recruitment pattern with reduced amplitude (Table 2). In severely weak myopathic muscle, the loss of muscle fibres may eventually result in a reduced recruitment pattern (see above). Where there is neurogenic involvement, the loss of motor units results in a reduced recruitment pattern, often with increased amplitude due to collateral reinnervation. In advanced denervation, the number of motor units is so depleted that the recruitment pattern becomes discrete (Fig. 11(c)). This is considered a specific sign of neurogenic involvement, whereas a reduced pattern may occur in either myopathy or neurogenic disease. With motor neurone involvement, the reduced or discrete pattern has a markedly

increased amplitude, often of more than 8 mV, which is considered typical of motor neurone disease (Table 2; Fig. 11(c)).

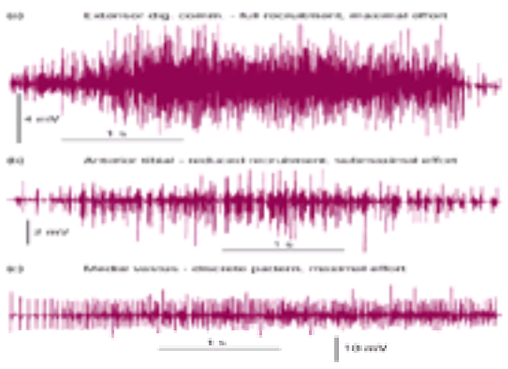

Fig. 11 Electrical activity recorded during voluntary effort. The recruitment pattern in (a) was full and had a normal amplitude of 3.5 to 4 mV, whereas it was reduced in (b) due to incomplete co-operation by the patient (submaximal effort) as shown by the uneven discharges that occurred in bursts. In (c) the recruitment pattern was discrete due to the loss of motor units, and the amplitude was markedly increased to between 8 and 10 mV due to collateral reinnervation (46-year-old man with motor neurone disease).

Specialized recordings

As indicated in Method section, the amplitudes of the MUPs, in particular when recorded with a concentric needle, are markedly variable and dependent on the distance between the recording area and the closest two or three muscle fibres of the motor unit. An increased or decreased amplitude is therefore a relatively insensitive indicator of motor-unit abnormalities. To record more evenly from the whole motor unit and hence obtain a more reliable measure of the MUP amplitude, the macroelectrode (which consists of 15 mm of the non-insulated cannula of the needle electrode to increase the recording surface area), has been introduced. This has been useful in serial studies designed to follow the disintegration of the motor unit in patients with postpolio syndrome.

In contrast to the macroelectrode, the single-fibre electrode has a small recording area of 25 µm, which allows recording of the action potential from individual muscle fibres in the motor unit. The main use of the single-fibre electrode has been in the recognition of disorders of neuromuscular transmission. The timing of the discharges of two (or more) muscle fibres in the motor unit is followed during repetitive activity. Whereas the discharges are quite stable in normal muscle, they become unstable in myasthenia gravis or the Lambert–Eaton syndrome. The larger variance of the discharges is termed 'increased jitter'; in more severely affected neuromuscular transmission disturbances, some of the discharges may fall out altogether, so-called 'blocking'. Increased jitter is also encountered in myopathy. In neurogenic lesions, where the activity of several muscle fibres may be recorded simultaneously, groups of discharges may become unstable, indicating that conduction along immature terminal sprouts may have a diminished safety factor.

Quantitation of the MUP relies on the ability to distinguish the individual MUP from the activity in other motor units. This may introduce a bias regarding the type of motor unit that a diagnosis is based on. Thus small, fatigue-resistant motor units are recruited during weak effort, whereas large motor units are activated at higher levels of activity. Methods have therefore been developed that quantitate the electrical activity during higher levels of activity. These methods have been used to investigate patients with myopathy and neurogenic involvement, and have been found to supplement the findings obtained using quantitative evaluation of MUPs.

Nerve conduction studies

Motor and sensory nerve conduction studies of peripheral nerves are performed by recording the propagated responses evoked by supramaximal electrical nerve stimulation. The responses reflect the summation of action potentials from individual sensory nerve fibres (the compound sensory action potential, **CSAP**) or motor units (the compound motor action potential, **CMAP**), and their amplitudes represent a semiquantitative measure of the number of activated myelinated fibres. The CSAP amplitude is an expression of activity in large fibres with diameters greater than 7 µm, whereas small fibres in the nerve contribute only slightly to the response. The CMAP amplitude is a reflection of the number of a-motor neurones. A reduction of the CSAP or the CMAP amplitudes is an indicator of fibre loss. However, the CMAP amplitude is also influenced by the size of the motor-unit response. During chronic axonal loss, collateral spouting causes an increase of the MUP, which partially or completely may compensate for the fibre loss. Since reinnervation does not have the same effect on sensory nerves, the CMAP is a less sensitive measure for determining the degree of fibre loss in chronic axonal lesions than the amplitude of the CSAP. Conduction studies are supplemented with EMG to ascertain whether motor fibres are affected by the pathological process.

Method

Investigations of motor and sensory fibres are carried out separately.

Motor conduction studies

The nerve is stimulated by an electrical pulse of 0.1- to 0.2-ms duration applied to the nerve at well-defined sites, with the cathode (depolarizing electrode) being placed over the nerve distal to the anode if a longitudinal electrode placement is used. It is essential that the stimulation pulse is supramaximal, defined as being 10 to 20 per cent above the stimulus strength that elicits a maximal CMAP. This stimulation strength requires that the output of the stimulator provides a stimulus at least four times higher than threshold when surface electrodes are used, and ensures that all fibres in the nerve remain activated even though the stimulation electrode may move slightly. The CMAP is recorded from the muscle, preferably using surface electrodes or a subcutaneous needle electrode to ensure that activity from all the muscle fibres in the muscle can be 'seen' by the recording electrode. Usually a belly-tendon montage is used, with the reference electrode being placed over a remote site. Recording of the CMAP with a concentric electrode is usually discouraged since the amplitude is highly dependent on how close the electrode is in relation to the active muscle fibres. However, a concentric needle electrode is useful in very atrophic muscles, as it allows a sharp deflection from the baseline to be measured. The response is amplified at a frequency band between 10 (or 20) Hz and 10 kHz.

Measurements

The parameters include latencies, conduction velocities, amplitudes, areas, durations, and shapes of the CMAPs (Fig. 12). The latency is measured to the first deflection from the baseline, which is negative when the CMAP is recorded from the endplate zone. Motor nerve conduction velocities (**MNCV**) between two sites of stimulation are calculated by dividing the distance between stimulation sites by the difference in latencies (Fig. 12).

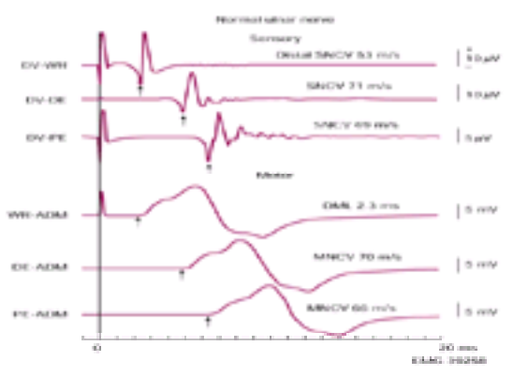

Fig. 12 Motor and sensory conduction studies of a normal ulnar nerve from a patient with diffuse complaints from the arm. Above: compound sensory action potentials, evoked by electrical stimulation at digit V (DV), were recorded via needle electrodes at the wrist (WR), below the elbow (DE), and above the elbow (PE).

The latencies were measured to the first positive peak (arrows) and the sensory nerve conduction velocities (SNCV), indicated above the traces, were calculated as indicated in the Method section. Below: compound muscle action potentials, evoked by stimulation at the wrist (WR), below the elbow (DE), and above the elbow (PE) were recorded via a surface electrode over the abductor digiti minimi muscle (ADM). The latencies were measured to the first deflection from the baseline (arrows). DML (distal motor latency) and MNCV (motor nerve conduction velocities), indicated above the traces were obtained as described in the Method section.

Distance between stimulation sites (mm)Difference between distal and proximal latencies (ms) = MNCV (m/s)

An MNCV is not calculated for the most distal site of stimulation since the latency includes conduction along terminal motor-axon branches and the neuromuscular transmission delay. In this instance, the delay is designated the distal motor latency (**DML**) (Fig. 12).

The CMAP amplitude (in mV) is measured either at the negative phase or peak-to-peak. The negative phase is usually preferred since it is less subject to influence by the positioning of the reference electrode. The area and duration of the negative phase are useful in evaluating temporal dispersion or conduction block.

Sensory conduction studies

In contrast to the CMAP, the compound sensory action potential (in μV) is recorded directly from active nerve fibres, and it is therefore only about 1/500th to 1/1000th of the CMAP amplitude. The response may be recorded through surface electrodes placed on the skin above the nerve or through needle electrodes placed close to the nerve. Surface electrodes are easy to apply but have a lower sensitivity than needle electrodes. In some normal, elderly people a CSAP from the lower limbs may, therefore, not be recorded through surface electrodes that have a resolution of about 1 μV, whereas near-nerve needle electrodes allow the recording of responses with an amplitude as low as 0.1 μV. In addition, the use of needle electrodes allow simultaneous recording from several sites along the nerve, which are usually not possible using surface electrodes (Fig. 12).

Sensory responses may be recorded antidromically (proximal stimulation, distal recording) or orthodromically (distal stimulation, proximal recording). The recording and reference electrodes may be placed longitudinally in relation to the nerve (bipolar recording), or the reference electrode may be placed transversely at a remote site (unipolar recording). The recording arrangements have advantages and disadvantages: the main advantage of bipolar recording being a smaller stimulus artefact; and the main disadvantage that the potential recorded by the reference electrode influences the CSAP shape and amplitude. Due to the low amplitude of the CSAP, electronic averaging is usually required to obtain a clear response that is suitably free of noise.

Measurements

The parameters include latencies, conduction velocities, amplitudes, and shapes of the CSAPs. The latency is measured to the first positive phase of the CSAP. This indicates conduction along the largest fibres in the nerve. Since the conduction path between the sites of stimulation and recording does not include synaptic transmission, a distal sensory nerve conduction velocity (SNCV) may be calculated (Fig. 12):

Distance between stimulation and recording sites (mm)Latency (ms) = Distal SNCV (m/s)

When the orthodromically conducted CSAPs are recorded at several sites along the nerve, the SNCV is calculated using a similar procedure as that used to calculate the MNCV:

Distance between proximal and distal recording sites (mm)Differernce between proximal and distal latencies (ms) = SNCV (m/s)

In some laboratories, the latency of the CSAP is measured to the first negative phase. This is to be discouraged, since this part of the response is a summation of both large and small fibres. A change in summation due to temporal dispersion therefore precludes measurements to the same group of fibres.

The amplitude of the CSAP (in μV) is measured peak-to-peak. The shape is usually bi- or triphasic. In both axonal and demyelinating neuropathies the shape may become dispersed, and when recorded with a needle electrode, the shape may become polyphasic. Due to temporal dispersion, the conduction distance has a marked influence on the shape of the CSAP. At long conduction distances a polyphasic shape may be normal.

Clinical correlations

The motor and sensory nerve conduction velocities (MNCV, SNCV) are measures of conduction of the largest motor and sensory fibres in the nerve. These limitations should be considered when the results of the studies are interpreted as, for example, a small-fibre neuropathy may escape detection. Similarly, if just a single large motor fibre is preserved, the motor conduction velocity may remain normal, indicating that the conduction velocity cannot be used in isolation to establish the presence of a neuropathy.

Focal nerve lesions

The number of patients referred to the clinical neurophysiology laboratory with possible focal nerve lesions due to compression or entrapment at root level, or along the course of the nerve, far outweighs that for other neuromuscular disorders. In entrapment and focal compression neuropathy, the main pathological abnormalities comprise demyelination at the site of the lesion, which is complicated by axonal loss in advanced lesions. Accordingly, the electrophysiological findings display a disproportionate slowing of conduction at the site of the compression, and also, in some cases, a loss of fibres as demonstrated by reduced amplitudes of the CMAP and the CSAP. This is illustrated in Fig. 13 from a patient with ulnar nerve entrapment at the elbow; the MNCV and SNCV across the elbow were markedly reduced compared to the conduction velocities distal to the elbow, consistent with a focal demyelinating lesion. The CSAP amplitudes were, in addition, markedly diminished, thus indicating axonal loss (Fig. 13(b)), and the slight reduction in SNCV distal to the elbow is commensurate with a loss of large fast-conducting fibres. The apparent sparing of the CMAP amplitude is due to collateral reinnervation masking the motor fibre loss revealed by EMG examination (see above). The slight MNCV reduction distal to the elbow is due to the fibre loss (Fig. 13(a)). Similar methods are used to study focal nerve lesions in patients with compression of the peroneal nerve at the fibular head and in patients with Saturday night palsy (compression of the radial nerve in the spiral groove).

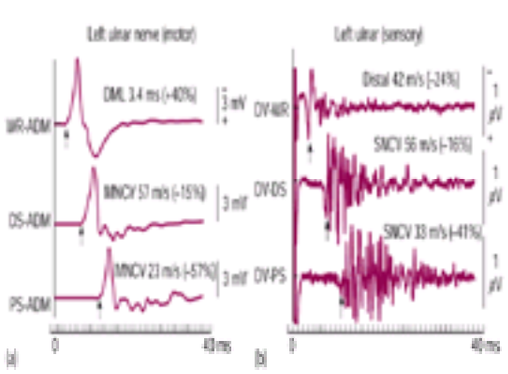

Fig. 13 Conduction studies in a patient with clinical signs of an ulnar nerve lesion. Both (a) motor and (b) sensory conduction showed a marked reduction of conduction velocities across the elbow (57 per cent and 41 per cent reduced between distal to the ulnar sulcus (DS) and proximal to the sulcus (PS), respectively). In addition, there was motor and sensory axonal loss, as indicated by the reduction in amplitudes of the CMAP and the CSAPs. The mild–moderate slowing of conduction distal to the elbow was probably due to a loss of large fibres.

In patients with carpal tunnel syndrome, the distal motor latency of the CMAP to the abductor pollicis brevis muscle, evoked by stimulation at the wrist, is prolonged, indicating a slowing of conduction beneath the flexor retinaculum. However, because it is difficult to stimulate motor fibres distal to the entrapment, differential attenuation of the MNCV is therefore not assessed. To ensure that the median nerve is selectively affected, the latency to the non-affected ulnar nerve should be normal. The SNCV, by contrast, may be tested both distal to and across the carpal tunnel, and is disproportionately reduced along this segment of the nerve compared with that distal to it. Variations on the study paradigm have been devised to increase the sensitivity of the electrophysiological studies.

On the other hand, it is usually not possible to directly study conduction across the compressed nerve segment in patients with very proximal lesions located at spinal roots or the brachial plexus across a cervical rib or band. In these situations, the anatomical distribution of EMG signs of chronic partial denervation is important in the differential diagnosis. For example, EMG findings in patients with apparent involvement of the ulnar nerve due to a C8 lesion or a thoracic outlet syndrome include abnormalities in non-ulnar nerve innervated muscles (for instance, the abductor pollicis brevis and the extensor digitorum communis muscles). This distribution of motor axon loss, and the absence of focal MNCV changes at the elbow (Fig. 14(a)), show that a single nerve lesion is not the cause of the clinical deficit, but it does not distinguish between a radicular and a brachial plexus lesion. By contrast, sensory conduction studies in root lesions usually remain normal, provided that the lesion is located proximal to the dorsal root ganglion, whereas the CSAP from digit V in the thoracic outlet syndrome is diminished due to sensory fibre loss at the level of the brachial plexus (Fig. 14(b)).

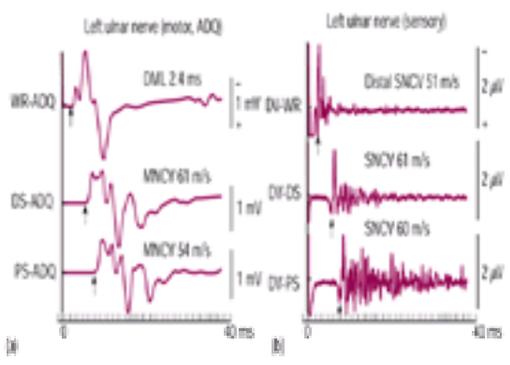

Fig. 14 Conduction studies in a patient with clinical signs of an ulnar nerve lesion that was clinically localized at the brachial plexus or the spinal roots, as indicated by the extent of sensory complaints along the medial forearm and upper arm. Both (a) motor and (b) sensory conduction showed normal conduction velocities distal to and across the elbow. However, the amplitudes of the CMAPs and the CSAPs were markedly decreased, indicating diffuse axonal loss. The loss of sensory fibres is inconsistent with a root lesion and indicates entrapment at the brachial plexus.

Generalized nerve lesions (peripheral neuropathy)

The electrophysiological study in patients with suspected polyneuropathy should document that pathological abnormalities are widely distributed. It is therefore a prerequisite that several motor and sensory nerves in the upper and lower limbs are investigated. However, the study should be individually tailored to delineate the distribution of changes, and the strategy should reflect the symptoms and clinical findings and hence address the question of the differential diagnosis. For example, it may be necessary to investigate certain nerves bilaterally if the symptoms are asymmetrical. This would allow the investigation to show whether the patient may have a mononeuropathy, a multiple mononeuropathy, or a polyneuropathy with asymmetrical features.

Axonal polyneuropathy

The underlying pathology in most patients with peripheral neuropathy is axonal loss in a symmetrical distribution, primarily located at distal nerve segments and more pronounced in the legs than in the arms. The electrophysiological characteristics in these patients are due to a loss of nerve fibres, that is associated with EMG signs of chronic partial denervation and conduction studies that show diminished amplitudes of evoked CMAPs and CSAPs. The remaining fibres in the nerve may conduct normally, and the MNCV and the SNCV in these patients may therefore be normal or show a reduction consistent with a large-fibre loss (Fig. 15). In some patients, the pathological changes may primarily be present at the distal nerve segments, thus studies of these segments will also be required (Fig. 15).

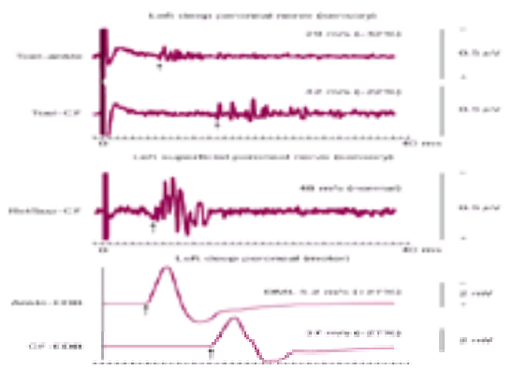

Fig. 15 Motor and sensory conduction studies of the peroneal nerve in a patient with diabetic neuropathy. The findings in this patient were consistent with axonal loss, primarily present in the very distal segment of the nerve. Top panel: orthodromic compound sensory action potentials (CSAPs), evoked at the deep peroneal nerve in the first dorsal interstice (ToeI), were recorded at the ankle (ankle) and the fibular head (CF). The amplitudes were more than 95 per cent diminished. The SNCVs were moderately diminished due to large-fibre loss. Middle panel: CSAP of the superficial peroneal nerve evoked at the superior retinaculum (RetSup) at the ankle and recorded at the CF. The amplitude was slightly diminished, and the SNCV was normal. Lower panel: compound muscle action potentials (CMAPs) of the deep peroneal nerve, evoked at the ankle and the fibular head, were recorded at the extensor digitorum brevis muscle (EDB). The distal motor latency (DML) was prolonged and the MNCV was reduced due to fibre loss.

Only motor or sensory fibres are involved in the rarer types of neuropathy, and demonstration of such a distribution may have important implications in the differential diagnosis. A sensory neuronopathy in a 47-year-old woman with profound sensory ataxia is illustrated in Fig. 16. The motor nerve conduction studies and the EMG were normal, but the sensory conduction studies were profoundly abnormal, and the sural nerve biopsy showed a 95 per cent loss of myelinated fibres (Fig. 16(a) and Fig. 16(b)). The SNCV was at the lower normal range, consistent with the slightly diminished diameter of the largest remaining fibres being around 10 µm (Fig. 16(b) and Fig. 16(c)). These findings were consistent with an autoimmune sensory neuronopathy.

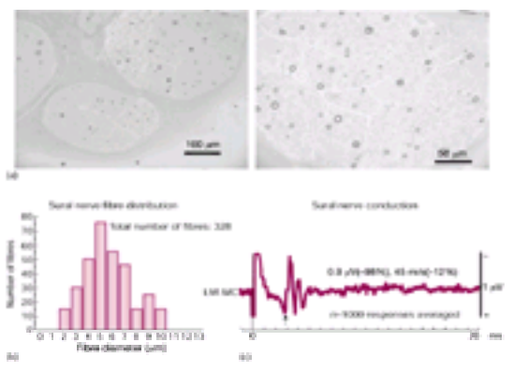

Fig. 16 Morphometric and electrophysiological studies of the sural nerve in a 47-year-old woman with sensory neuronopathy. (a) Transverse semithin sections of the sural nerve showed a generalized severe fibre loss without evidence of degeneration or regeneration. (b) A total of 328 myelinated fibres were counted in the whole nerve. The fibre-diameter distribution showed a loss of both small and large fibres with a maximal diameter of 10 to 11 µm. (c) Conduction studies in the sural nerve showed a pronounced reduction of the CSAP amplitude and a dispersed shape. The SNCV was at the lower normal limit, consistent with the diameters of the largest fibres at morphometry. (Histological studies by courtesy of H. Schmalbruch, University of Copenhagen.)

Demyelinating neuropathy

Primary demyelination usually has a hereditary, inflammatory, or autoimmune basis. Although demyelinating neuropathy is rare compared to axonal neuropathy, it has become increasingly important to be able to diagnose acquired demyelinating neuropathy with a high degree of certainty since acute or chronic inflammatory demyelinating neuropathy may respond to immunomodulatory therapy. The primary electrophysiological sign of demyelination is a markedly reduced conduction velocity that is beyond the diminution caused by large-fibre loss. In hereditary motor and sensory neuropathy, type I and III, the MNCV and the SNCV are markedly diminished to less than 50 per cent of the lower limit of normal throughout the nerves, consistent with primary demyelination. In these conditions the amplitudes of the CMAPs and the CSAPs are, however, also markedly reduced and nerve biopsy confirms a marked loss of myelinated nerve fibres. Pure demyelination without axonal loss does not occur in these hereditary conditions and is extremely rare in acquired demyelinating neuropathy. The distinguishing features in acquired demyelinating neuropathy include widespread demyelination, often in a multifocal pattern, as indicated by focal temporal dispersion or conduction block or both of CMAPs and CSAPs. Criteria have been established to assist in the diagnosis of these demyelinating neuropathies (Table 3).

A weakness or sensory loss does not result solely from a diminished conduction velocity, but also as a consequence of nerve fibre loss or a block of conduction between the CNS and the target muscle. Conduction block is a partial or complete inability of fibres to propagate action potentials along a segment of the nerve, and is demonstrated by recording a larger motor or sensory response more distal to than proximal to the site of the block (Fig. 17(a)). This reduction in amplitude should be greater than that associated with a temporal dispersion of the conducting fibres. Therefore to demonstrate a block of motor fibres, the CMAP should show a reduction of at least 50 per cent (Fig. 17(a)). Conduction block may occur in acquired acute or chronic inflammatory demyelinating neuropathy and in some cases of monoclonal gammopathy. It does not occur in hereditary demyelinating neuropathy and probably not in gammopathy with IgM anti-MAG antibodies. However, demyelination due to compression may also cause a conduction block, and in demyelinating neuropathy a conduction block must therefore be demonstrated outside the usual sites of entrapment or compression. The pathophysiological changes in inflammatory demyelinating diseases usually show a multifocal pattern, with some nerves showing pronounced changes while other nerves or nerve segments have normal conduction.

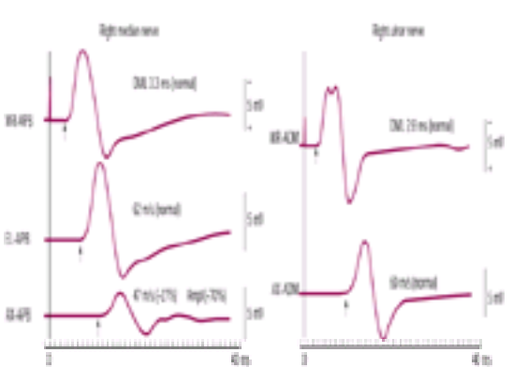

Fig. 17 Motor conduction studies of the median and ulnar nerves of a 29-year-old woman with electrophysiological signs of demyelinating neuropathy and clinical signs of relapsing chronic inflammatory demyelinating neuropathy. Clinical examination showed marked weakness of the thenar and forearm median innervated muscles. The force in ulnar innervated muscles was normal. Left panel: CMAP recorded from the abductor pollicis brevis muscle (APB). Stimulation at the wrist (WR) and elbow (EL) elicited normal CMAPs and the DML and MNCV along the forearm were normal. Stimulation at the axilla (AX) resulted in a markedly reduced CMAP amplitude and a reduced MNCV between the elbow and axilla, consistent with a partial conduction block. Right panel: stimulation of the ulnar nerve at the wrist and axilla evoked CMAPs at the abductor digiti minimi (ADM) of normal amplitudes, DML and MNCV, indicating that motor fibres were not affected.

Apparent conduction block may be found in acute neuropathies due to vasculitis. However, conduction along the nerve segment distal to a focal lesion may continue for several days before Wallerian degeneration takes place, and repeated studies should therefore be carried out to exclude this possibility.

Motor disorders (motor neurone disease and motor neuropathy)

Conduction studies in motor neurone disease are normal at early stages of the disease, but at late stages the CMAP amplitudes are reduced. The distal motor latencies of weak and wasted muscles are often prolonged, and the MNCV slightly to moderately reduced due to a loss of large a-motor axons. In ALS, sensory conduction studies are usually normal, though the CSAP amplitudes may be slightly diminished. Therefore, conduction studies are mainly of use in the diagnosis of ALS in that they are normal in the face of widespread neurogenic changes at EMG. However, patients with X-linked bulbospinal muscular atrophy (Kennedy's syndrome) are characterized by a marked reduction of CSAP amplitudes, while the EMG examination shows abnormalities characteristic of motor neurone disease (fasciculations, widespread denervation, markedly enlarged and prolonged MUPs, and discrete high-amplitude recruitment at maximal effort).

Asymmetrical or focal weakness, atrophy, fasciculations (see Fig. 7), without or with only slight sensory symptoms, due to multifocal motor neuropathy may be mistaken for the early stages of spinal forms of motor neurone disease. The course is, however, prolonged over several years, and there is no involvement of bulbar muscles and no signs of corticospinal involvement. The electrophysiological features in these patients are distinct, with conduction block of motor fibres indicating focal demyelination. Usually there is also EMG evidence of chronic partial denervation, indicating fibre loss. The sensory conduction studies through affected nerve segments are normal. These patients frequently have high titres of anti-GM1 antibodies, and often respond clinically and electrophysiologically to intravenous infusions of immunoglobulin. Patients with chronic inflammatory demyelinating neuropathy may have mainly motor symptoms, with only minimal sensory deficits. Motor conduction studies in chronic inflammatory demyelinating neuropathy show signs of mixed demyelination, including conduction block, and fibre loss; sensory conduction studies are abnormal, with small CSAP amplitudes and often reduced SNCV. This is an important distinction, since patients with chronic inflammatory demyelinating neuropathy may respond to treatment with corticosteroids and other immune-modulating strategies that have no effect on multifocal motor neuropathy.

24.3 Brain and mind: functional neuroimaging

Richard Frackowiak

Introduction

The sensory input to the brain is generally organized into sets of separate, functionally distinct, maps in the cerebral cortex. That much has been known for many years from neurology and animal studies. Can deductions based on non-human primate experiments be assumed to hold true for the brains of humans? For one thing there are obvious differences in the size of the brain between species, and certain areas such as the frontal lobes seem greatly developed in humans. Certain functions, for example spoken language and silent speech, are apparently unique attributes of the human brain. There may be a species-specific organization of specialized cortical areas to account for such human cognitive attributes.

The aim of functional neuroimaging is to describe the activity of neuronal populations and how they are organized into brain networks and systems. This systems-level approach seeks a biological understanding of how integrated brain functions are embodied in the physical structure of the brain. Important areas of enquiry include an understanding of how sensory inputs map onto the brain, and where subsequent signal processing occurs when complex percepts are experienced. Other examples include how sensory and motor systems interact during sense-guided movement, such as reaching under visual control, or how cognitive functions, such as memory and language, are organized and what is the basis for their modification by emotional state.

Functional neuroimaging methods fall broadly into two classes—those that provide information about synaptic activity and those that provide information about neurochemistry or neurotransmission. The former methods usually depend on measurements of the distribution of local cerebral blood flow (often known as perfusion maps) or, when comparisons between successively recorded distributions in different brain states are made, as activation studies. Local perfusion is a surrogate marker for local synaptic activity because of a tight coupling between it and local cerebral glucose metabolism both at rest and with activation. Such measurements can be accomplished with positron emission tomography and with functional magnetic resonance imaging, although in this method the images depend less clearly on perfusion alone as the signal is dependent on blood oxygen level. Radioactivity is not used in functional magnetic resonance imaging, which can therefore be safely repeated an unlimited number of times in any individual. Both positron emission tomography and functional magnetic resonance imaging localize changes in local brain activity to a millimetre or so. The second class of functional neuroimaging methods relies on mapping the distribution of chemical species of interest with positron emission tomography after injection of appropriately specific radiotracers, or by identification of unique magnetic signatures of compounds of interest with magnetic resonance spectroscopy. It is also possible to map non-invasively the distribution of electrical or magnetic signals coming from the brain. The anatomical precision with which this can be done is markedly worse than with positron emission tomography and functional magnetic resonance imaging, but brain activity can be followed millisecond by millisecond, a temporal resolution that is not possible with the other two methods.

There are clinical uses for functional neuroimaging, such as preoperative assessment of the functional integrity of peritumoural tissue and non-invasive assessment of language and memory dominance in patients undergoing temporal lobe surgery for epilepsy. Positron emission tomography and functional magnetic resonance imaging have had an apparently less spectacular impact on clinical practice than have anatomical imaging methods such as computed tomography and conventional magnetic resonance imaging. This is because functional neuroimaging is used to discover disease mechanisms of general significance, relevant to groups of patients, while computed tomography and magnetic resonance imaging provide information of direct relevance to the diagnosis, prognosis, and management of individual patients. Nevertheless, there are some striking examples of the impact of functional neuroimaging on clinical practice. For example, the definition of the haemodynamic and energetic consequences of preclinical and clinical carotid artery disease and the description of the time course of the natural transition from ischaemia to infarction have modified views about surgical treatment and about pharmaceutical approaches to stroke therapy, and have also affected the design of clinical trial protocols. Functional neuroimaging is able to detect preclinical degenerative brain disease and to distinguish between different clinical disorders. Positron emission tomography has also been invaluable in assessing the therapy of Parkinson's disease by monitoring fetal mesencephalic graft survival and the effects of subthalamic and pallidal lesions and chronic subthalamic nucleus stimulation.

From sensation to cognition

The visual system has been relatively well studied by some of the modern neuroimaging methods described above and will be used to illustrate some general principles. A simple imaging experiment to imagine is measurement of the distribution of brain activity during an eyes-open and an eyes-closed state. A comparison of brain activities recorded in each of the two states identifies areas of the brain in which activity is specifically associated with vision. When early sensory processing is the object of study this comparative approach is relatively free of assumptions. When more complex cognitive functions are studied more sophisticated experiments and analyses must be used.

The visual world is mapped from retina to cortex

The visual world depends on patterns of light hitting the retina. The evoked retinal signals are transmitted to the visual cortex in a point to point manner. Signals coming from adjacent patches of retina and hence adjacent parts of the visual field are mapped onto adjacent patches of cortex, a fact that is also deduced from studies of patients with focal lesions of the visual cortex. This retinotopic organization of primary visual cortex (V1) has been clearly confirmed with functional scanning in normal humans. Activity recorded in the brain with peripheral visual targets can be compared with that recorded with central presentation. Each quadrant of the visual field is located in the opposite cerebral hemisphere and quadrant of the visual cortex. The fovea is represented at the pole of the occipital cortex and peripheral vision activates more anterior parts of the calcarine cortex. One can calculate from such data the magnification factor, i.e. the length of cortex that maps a given 'length' of the visual field, and also the borders between specialized extrastriate visual regions.

The extrastriate occipital cortex receives multiple parallel outputs from area V1. This cortex is functionally heterogeneous, different parts activate in association with different aspects of visual perception (for example form, colour, movement, and face recognition). Area V5 is an extrastriate area in which activity is associated with visually perceived motion. The brains of individuals vary one from another quite markedly, not only in shape but also in the disposition of the gyri and sulci of parts of the cortex. However, accurate alignment of functional and anatomical images is a trivial issue with the use of modern computers. It is possible to show precise relationships between structure and function despite considerable individual variability of the normal anatomy of the occipital cortex. V5 is always found in a circumscribed part of the occipital lobe at the junction with the temporal lobe in the angle formed by two occipital gyri—the inferior occipital and the ascending limb of the inferior temporal. This anatomical site is relatively developed in infants with heavy myelination of the associated white matter fibres. In summary, there is a remarkable correlation between developmental factors, functional specialization, and anatomical location, despite considerable variability in the absolute spatial location of the anatomical structure between different individuals. The heavy myelination that is characteristic of area V5 can be demonstrated by high-resolution anatomical magnetic resonance imaging, as can the stria of Gennari, a unique structural characteristic of primary visual cortex (V1).

Activity in V5 occurs with perceived visual motion, whether that motion is real or illusory. One area of extrastriate cortex (V3) shows equivalent activity when real or illusory objects are perceived. Schizophrenic patients with visual delusions show activation of extrastriate areas that determine the content of their delusions. This evidence suggests that the visual brain is constructing an intrerpretation of the visual scene from the information provided. Sometimes that information is appropriate to reality, at other times it has a configuration that, for unknown reasons, elicits activity in an unexpected specialized visual area. The consequent illusory perception is congruent with that experienced when the area is activated by real stimuli. The Kanizsa triangle is an example of a normal visual illusion of this type for which a partial explanation can be proposed. The perception of an apparent triangle in front of a solid body can be ascribed to the fact that in normal visual life we expect to see objects hidden by others that lie in front of them. The triangle illusion is a reflection of this phenomenon. Similarly, activation of the visual motion area (V5) is seen during the waterfall illusion in which looking at a waterfall and looking away results in a temporary illusion of continuing motion. The stimulus–response characteristic of the visual processing machinery is determined in part by genes and in part by experience. At times the experiential component results in a conflict with reality and

hence an illusion.

Sometimes two perceptual solutions seem equally likely to the brain, as in the case of ambiguous or bistable figures. These figures can be interpreted in one of two ways. The alternatives flip in a deterministic fashion described by a gamma function so that as long as fixation is maintained conscious control over flip frequency is minimal. Studies with event-related functional magnetic resonance imaging, a new technical development that permits examination of changes in the blood oxygen level-dependent signal due to transient neural or perceptual events, has led to investigation of the mechanisms underlying this phenomenon. A perceptual 'flip' results in a transient activation of extrastriate visual areas (amongst other neocortical sites). At the same time there is a transient deactivation of the pulvinar of the thalamus and V1. This result suggests a subcortical–cortical perceptual system in which the thalamus maintains perceptual stability and the cortex effects a reinterpretation of the perceptual content when the stabilizing influence of the thalamus wanes. The importance of the functionally specialized modules to perceptual content can also be demonstrated non-invasively by temporary, localized, functional lesions using transcranial magnetic stimulation. Thus the perception of visual motion can be temporarily disturbed by a shock at an appropriate time after a moving stimulus excites the retina.

Patients with lesions at functionally specialized sites have syndromes of loss of function and provide additional information about the organization of the visual system.. Thus lesions in the lingual gyrus at the site of V4 lead to the syndrome of achromatopsia (cortical colour blindness). Lesions in the V1 cortex provide a substrate for examining the function of retinocortical pathways that access extrastriate cortex without passage through and processing in V1. Up to 10 per cent of retinofugal fibres are of this type. A patient with a V1 lesion has been described who shows residual perception of high contrast, rapidly moving stimuli in his blind hemifield. This is associated with activation of V5, but not V1, which is destroyed. This finding raises issues about just how much cortex is required to produce a conscious experience and whether consciousness is itself organized in a modular fashion. The importance of such 'minor' pathways has not been well understood. In normal subjects, event-related electrical potential mapping in response to a perceptible moving visual stimulus shows a response in area V5 that preceeds the response in V1 by up to 40 ms. As all specialized areas that send projections to another area receive them from it in return, the conditions are established by which preprocessing of a salient visual motion stimulus in V5 might prime V1 to receive the main neural volley from the same stimulus—a potential feedforward regulatory system.

Beyond the extrastriate cortex

The awareness of the position of an object and knowledge of its physical qualities, leading to recognition, are two visual cognitive functions that depend, at least in part, on a recognition of the object's shape, colour, and direction of motion. Imaging studies suggest that the pathways activated in association with these two attributes of objects overlap substantially, but there is also some segregation relevant to each attribute in brain areas in front of the occipital cortex. Activation of posterior parts of the inferior temporal lobes occurs when objects are recognized, for example to be named. Identification of an object's position in space preferentially activates posterior parts of the parietal lobe. A third pathway, in which activity is associated with visually guided reaching for objects, has been demonstrated in the parietal lobes between those areas activated by recognition and those by awareness of position. The recognition of further pathways is to be expected because, in general, integration of visual signals with behaviour occurs at multiple anatomical levels in the human brain. Each specialized brain area that has connections to another specialized area receives signals back. Each area sends and receives signals to and from multiple other dispersed areas and draws on signals from these areas as the behavioural context demands. Yet signal traffic is not chaotic, a remarkable and often ignored result provided by functional neuroimaging.

Synaesthesia are curious experiential phenomena in which signals of one sensory modality elicit experiences in another. The condition is probably developmental and not uncommon early in life. The most frequent manifestation is the visualization of colours whilst reading or speaking. Certain colours are associated with certain stimuli, for example the first letter of a word. The experiences are not unpleasant but bizarre and are therefore frequently unacknowledged or even denied. Such phenomena provide a paradigm for examination of the interactions between sensory modalities. In aural–colour vision synaesthetes, there is abnormal activation of cortical areas beyond V4 and other early extrastriate visual areas. In fact, activity in V4 may be diminished in association with synaesthesia. Another situation in which crossmodality interactions occur is in blind Braille readers. If blindness is congenital, Braille reading is always more proficient than if it is learned after acquired blindness. Touch stimulation in Braille readers elicits visual cortex activation. However, this phenomenon involves V1 only in people with acquired blindness. It is therefore equally plausible that V1 is recruited for touch processing or that in a primed, previously 'seeing', V1 activity may be due to imagery of letters read through the touch sense. Such people can also provide important information about postperceptual processing. For example, sighted people reading visually, blind people reading with Braille, and blind people hearing spoken words all activate a posterior inferior temporal region implicating it in a supramodal function that involves word processing irrespective of input modality.

Conclusion

The brain is organized according to relatively well-ordered principles. Responses are reproducible and common to most humans. The correlation of behaviour, anatomy, and physiology promises much for an understanding of normal brain function and also for understanding better the symptoms of cerebral disease. Functional neuroimaging and advances in computerized analysis of structural images are breakthroughs for the cognitive neurosciences. It is now possible to analyse thoughts, percepts, actions, and emotions at the level of neuronal populations. Brain activity can be followed over time and in different contexts permitting the study of recovery, attention, and pharmacological modulation of brain function. New methods for measuring connection strengths between brain areas and their modification under different conditions add further opportunities for expanding knowledge as to how the human brain works in health and disease.

24.4 Investigation of central motor pathways: magnetic brain stimulation

K. R. Mills

The ability to stimulate percutaneously and without pain the central nervous system of awake humans has opened up new areas for neurophysiological investigation both in terms of the early diagnosis of neurological disease and the further understanding of normal and abnormal motor control. Magnetic stimulators are now available that are capable of exciting both upper and lower limb areas of the motor cortex, as well as cranial nerves, motor roots, and deeply sited peripheral nerves.

Magnetic stimulators

The magnetic stimulator is an essentially simple device; a brief pulse of electric current is passed through a coil which then generates an intense magnetic field permeating unattenuated into the surrounding media. Any electrical conductor, such as the brain, in the vicinity of the coil will have currents induced within it; these induced currents are capable of exciting cerebral neurones. Coils are placed on the scalp and may be plane circular, figure of eight, or double cone in geometry, the last being especially effective in exciting leg areas of the motor cortex. Some magnetic stimulators produce a predominantly monophasic field pulse, others produce multiphasic pulses; with the former, the side of the coil next to the scalp determines which hemisphere is predominantly excited, whereas with the latter both hemispheres are about equally excited.

Physiology

If a single anodal shock is applied to the exposed cortex of a monkey and recordings are made from the pyramidal tract, it is seen that, if stimulus intensity is sufficient, an initial wave produced by direct activation of pyramidal tract neurones (the D wave) is followed by a variable number of other waves produced by indirect trans-synaptic activation (I waves) of the same pyramidal neurones. In humans a single weak stimulus to the scalp probably excites pyramidal tract cells trans-synaptically; stronger stimuli may excite the cells directly. The effect of a single stimulus is to cause a high frequency (500 to 1000 Hz) burst of impulses to descend in the fastest fibres of the pyramidal tract; the spinal motoneurones are engaged by these impulses and if their excitability is high enough and there is sufficient temporal and spatial summation, then the motoneurones fire, causing a muscle contraction. There is considerable convergence and divergence of pyramidal tract fibres within motoneurone pools; single spinal motoneurones receive many corticospinal inputs and, conversely, single pyramidal tract fibres branch to supply many spinal motoneurones. Intrinsic hand muscles are the most easily excited from brain stimulation but all voluntary muscles appear to be accessible from cortical stimulation. The amplitude of response of a muscle depends on the intensity of the stimulus, to a lesser extent on coil placement on the scalp, but most potently on the degree of voluntary preactivation of the muscle. Thus the amplitude of response of an intrinsic hand muscle may be 20 to 30 times greater if the subject performs a gentle (5 to 10 per cent maximum) voluntary contraction of the muscle. This facilitation is probably due to both cortical and spinal cord mechanisms, voluntary action increasing the effectiveness of the stimulus at the cortex at the same time as the excitability of spinal motoneurones is increased by other pathways. The latter mechanism predominates in intrinsic hand muscles. Clearly, many factors, including mental set, affect the size of muscle response to the stimulus and it should be emphasized that this phenomenon of response variability contrasts with the identical and reproducible responses obtained from maximal electrical peripheral nerve shocks; central motor conduction studies should not be regarded simply as an extension of nerve conduction measurements.

Single scalp shocks also bring into play inhibitory mechanisms: if a subject maintains a steady voluntary muscle contraction, the initial excitation caused by the stimulus is followed by a silent period. The mechanisms underlying this are still unclear but probably involve inhibition at both cortical and spinal levels.

Safety of magnetic stimulation

A number of studies have looked at the acute effects of magnetic stimuli on animals. It has been shown that magnetic stimuli have little detectable effect on the heart rate, arterial blood pressure, or cerebral blood flow in cats. Magnetic brain stimulation has no acute effects on the human electroencephalogram or on the performance of simple cognitive tests. There have currently been no reports of adverse effects in healthy human subjects, but clearly, workers in the field should remain vigilant, especially for long-term effects.

It has been calculated that the total amount of power dissipated in the brain during magnetic stimulation is 1.8 μJ/cm ^{3}per stimulus and at the maximal rate of stimulation of 0.3 Hz, the average power dissipation is 53 μW, some five orders of magnitude below the basal metabolic rate of the brain.

It was considered prudent for early users of magnetic stimulation to exclude patients who had a history of epilepsy from their studies. Since then, magnetic stimulation has actually been used to attempt to localize epileptic foci in patients with intractable seizures. However, the risks of provoking a fit are considered small since it had been shown in cats that repetitive stimuli direct to the cortex in animals that had lesions induced by penicillin were only effective at rates above 5 Hz. Despite magnetic stimulation devices being used on many thousands of patients, many of whom must have had a predilection for epilepsy, there have been only a few reports of a fit being related to single-pulse brain stimulation.

Measurement of central motor conduction time

The latency of muscle response has a central and peripheral component and a delay due to synaptic transmission in the spinal cord. There is good evidence that, at least with limb muscle, the connection from the pyramidal tract to spinal motoneurone is monosynaptic. The central component of conduction—central motor conduction time (**CMCT**)—can be estimated by subtracting from the cortex to muscle latency an estimate of the peripheral conduction time obtained either from F wave measurement (see Chapter 24.2) or from responses evoked by root stimulation. In healthy subjects, the mean latency (± standard deviation) of responses in intrinsic hand muscle is 19.7 ± 1.2 ms and the CMCT is 6.1 ± 0.9 ms. The amplitude of responses from brain stimulation is usually compared with that obtained from maximal peripheral nerve stimulation; again there is great variability, but in healthy subjects the response from cortical stimuli is usually at least 15 per cent of that from nerve stimulation. Since many factors can influence these values, each laboratory should develop its own normative database.

Motor roots may be excited by both electrical and magnetic stimulators. The former method is preferable since it is not possible to obtain maximal responses in all healthy subjects with magnetic coils, even with optimal coil geometry, coil orientation, and coil position. Both devices activate motor roots at or just outside the intervertebral foramina and so peripheral conduction time estimated by this method omits conduction in the small segment of motor root within the spinal canal and CMCT is slightly overestimated. The method must be used, however, if F waves are unobtainable.

Compound responses from muscle may be recorded with surface electrodes, or single motor unit responses may be recorded with needle electrodes; the former method is used clinically, the latter is useful in research. A number of parameters of the surface-recorded response are useful: the maximum amplitude, the onset latency with the muscle relaxed or contracted, the threshold for evoking a response, and the variability in latency or amplitude in a series of responses.

Prolongation of CMCT has been reported in many conditions and is not specific. Delay can be produced by a variety of pathological processes: demyelination of central fibres can lead to slowing of impulse propagation in the central motor pathway; desynchronization of descending impulses can lead to loss of temporal summation at the motoneurone and delay in its firing; and loss of corticospinal axons can lead to impairment of spatial summation at motoneurones and can again

delay firing.

Multiple sclerosis

In multiple sclerosis, CMCT is prolonged in about 70 per cent of cases when there are clear clinical signs of a pyramidal lesion in the particular limb (Fig. 1). The delay in some cases is very considerable, CMCT may be up to five times longer than in controls. It is likely that, in these cases, demyelination of central fibres is the mechanism leading to delay. In other cases, delay is more modest, only a few milliseconds, and the mechanism is less certain. Abnormal central motor conduction appears to correlate most closely with exaggerated reflexes and spasticity rather than with weakness or cerebellar signs in the limb. Abnormal CMCT from leg areas of motor cortex also correlates with the finding of extensor plantar responses.

Fig. 1 Slowing of central motor conduction in multiple sclerosis. Compound muscle action potentials are recorded with surface electrodes over the left and right abductor digiti minimi muscles. Stimuli are given to the ulnar nerve at the wrist (left), the C7/T1 motor roots (middle), and the motor cortex (right). Onset latencies are shown and the variability of responses from cortical stimulation can be seen. On the left CMCT is 7.4 ms, but on the right is prolonged at 13.9 ms.

Central motor conduction can be abnormal, however, even in the absence of clinical signs. In a large series, it was found that central conduction was abnormal in 20 per cent of cases of multiple sclerosis with no motor signs in the particular limb. The technique can thus be used as a screening test for multiple sclerosis, although it compares unfavourably with visual evoked potentials, which have a higher rate of abnormality in the absence of clinical signs. This may merely reflect the greater accuracy with which the motor system can be examined clinically. Central motor studies may also be helpful in deciding on the importance of equivocal motor signs, such as mild impairment of fine finger movements.

Motor neurone disease

In motor neurone disease, the most common abnormality is a raised threshold for excitation of the motor cortex, although in early cases the threshold may be reduced. In many cases responses cannot be obtained even with the strongest stimuli applied in optimal conditions. CMCT may be prolonged, but usually only modestly, and responses are often reduced in amplitude in comparison with responses evoked by maximal nerve stimulation. The test can be used to confirm an upper motor neurone component to weakness when lower motor neurone signs predominate or for detecting an upper motor neurone lesion in a limb without clinical signs.

Cerebrovascular disease

In stroke, responses in an affected limb may be normal, delayed, or absent, with abnormality grossly paralleling the clinical abnormality. Central motor conduction studies have been used to predict outcome of stroke; if performed within the first 48 h after the ictus, a poor outcome at 6 months is predicted by absent responses and a favourable outcome by normal responses. Whether the prediction is superior to that made purely on clinical grounds is uncertain, but at least the method is quantitative and can be used serially to follow recovery.

Movement disorders

Most studies have shown central motor conduction to be normal in Parkinson's disease, multiple system atrophy, Wilson's disease, Huntington's disease (including at-risk relatives), dystonia, and progressive supranuclear palsy. In some cases of Wilson's disease, central conduction delays have been found. In all these conditions, however, there may be subtle changes in motor cortex excitability detectable as a change in threshold or an abnormal inhibitory response to appropriately timed pairs of cortical stimuli.

Degenerative neurological diseases

A number of rarer degenerative diseases have been investigated with the technique: Friedreich's ataxia often shows delayed and dispersed responses, as does early-onset cerebellar ataxia with retained reflexes, the severity of the abnormalities reflecting disease duration. In late-onset cerebellar degeneration on the other hand, the responses are normal in 62 per cent of cases. In hereditary spastic paraparesis and tropical spastic paraparesis, responses from upper limb muscles are usually normal, whereas those from the lower limbs are delayed or absent. Abnormalities of central motor conduction have also been described in some cases of hereditary motor and sensory neuropathy types I and II, the abnormalities being found especially in those patients with additional upper motor neurone signs. Central motor conduction abnormalities have also been described in a family with hereditary motor and sensory neuropathy with pyramidal signs (HMSN type V).

Spinal cord lesions

Magnetic brain stimulation has been used to assess the completeness of spinal cord injury. A variety of facilitating techniques must be used; the modulation of flexion reflexes by brain stimuli has been shown to be useful in establishing whether injury is complete; in 4 of 26 patients evidence of incomplete lesions was found in patients with clinically complete spinal cord injuries. In compressive myelopathy, by recording from a variety of upper limb muscles, CMCT can be used to localize more accurately the compressed cord segment.

Paediatric applications

The central conduction time in a group of 457 normal subjects between the ages of 32 weeks and 55 years has been determined. It was found that central conduction time decreases rapidly over the first 2 years of life and then remains constant at the adult value. In contrast, peripheral conduction increases in proportion to arm length after the age of 5 years. It is suggested that this constant central delay could be useful during the acquisition of motor skills. Central motor conduction has been studied in a range of neurological diseases in children. For example, in 13 of 20 children with an upper motor neurone syndrome of varied aetiology, the central conduction time was abnormal, but magnetic resonance imaging and/or computed tomography scans showed focal abnormalities in only seven. In 15 children with extrapyramidal syndromes, the central conduction time was normal.

Use of brain stimulation for neurosurgical monitoring

Although somatosensory motoring has been shown to be of use during neurosurgical procedures to alert the surgeon of the possibility of cord damage, the use of motor monitoring is far more relevant since paraplegia is one of the most feared, although rare, outcomes of surgery near the cord. Electrical brain stimulation and recording from the cord by epidural electrodes has been achieved; responses consist of a series of waves analogous to the D and I waves recordable in primates. Magnetic stimulation appears to produce I waves but the responses are very sensitive to the depth of anaesthetic agents, especially nitrous oxide. If the aim of monitoring is merely to stimulate the motor cortex, there seems little to be gained by using magnetic stimuli in favour of the electrical method since the pain of the

procedure is not a factor.

Conclusion

Non-invasive magnetic brain stimulation has shown itself to be a powerful technique in the diagnosis and prognosis of disorders of the central motor system, as well as providing new insights into the normal control of human voluntary movement. It can be used serially to monitor progress or the effects of drugs, can be used safely in neonates and children, and can be used to demonstrate short- or long-term plasticity in the human nervous system after injury.

24.5 Imaging in neurological diseases

Andrew J. Molyneux and Philip Anslow

Introduction

The modern imaging techniques of X-ray computed tomography (**CT**) and magnetic resonance imaging (**MRI**) for the demonstration of structural neurological disease have developed rapidly over the last 20 years. They have done more than any other single development to revolutionize the diagnosis and treatment of structural neurological disease. More recently, a variety of functional imaging techniques have been developed that enable functional and biochemical information to be obtained from the living brain.

Current techniques for neuroimaging

Computed tomography (CT)

X-ray computed tomography was developed by the British scientist and engineer Godfrey Hounsfield during the early 1970s. CT was the first technique to provide non-invasive and cross-sectional images of the brain. It was introduced into clinical usage at the Atkinson Morley Hospital in Wimbledon, London, in 1972 and results were published in 1973. This was the start of a complete revolution in radiological imaging, for which Hounsfield received the Nobel prize for medicine in 1979.

CT rapidly became the mainstay of the diagnosis of structural brain disease until the advent of magnetic resonance imaging (MRI) into widespread clinical use during the late 1980s and early 1990s. However, CT remains an extremely valuable and essential tool, particularly in the acute situation and in countries and regions where the cost of MRI systems is prohibitively expensive.

CT produces a series of cross-sectional images, usually in the axial plane (hence the acronym CAT scan, standing for computed axial tomography). During exposure to an X-ray beam, a detector array spins around the patient and measures the absorption coefficients of tissues within the beam. It is the different coefficients that provide contrast.

Magnetic resonance imaging (MRI)

Magnetic resonance imaging is a fundamentally different method of obtaining images. It relies on a powerful static magnetic field and the various properties of the protons (hydrogen ions) in the different tissues. When a strong magnetic field is subjected to certain radio waves of a specific frequency (radiofrequency) the protons will resonate at an exact frequency that depends on the field strength of the magnet. The radio signal emitted back by the protons when the radiofrequency is switched off can be detected in a receiver coil and a detailed image built up. The resolution of modern MRI scanners is extremely high, as is the sensitivity of the images obtained for the detection of intracranial anatomy and pathology.

Many different radio-pulse sequences are of use in MRI, which are determined by the way the radio signals are timed. They detect different aspects of tissue properties by what is called 'the relaxation times of the protons'; times that will vary according to the proton-containing tissue and the relative mobility of the water molecules. The most commonly used sequences are what are termed '*T*1-weighted and *T*2-weighted sequences'. The appearances of these scans are quite different: for example, cerebrospinal fluid (**CSF**) is white on *T*2 and dark on *T*1 images (Fig. 1 and Fig. 2). Some tissues such as fat and some blood breakdown products (for instance, methaemoglobin) will appear bright on *T*1- and *T*2-weighted images.

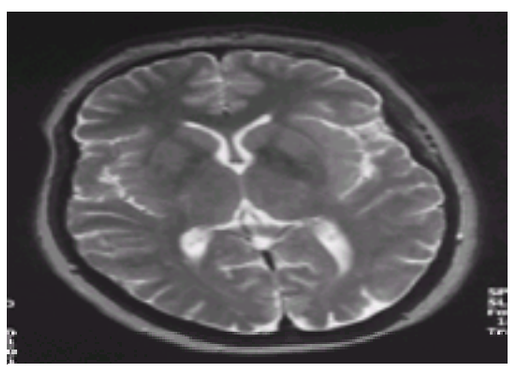

Fig. 1 Normal axial *T*2-weighted image of a brain at the level of the ventricular system. Note that the cerebrospinal fluid is white, the white matter is dark, and the grey matter is lighter than the white matter. This is the most commonly used MRI sequence and it is usually the most sensitive in the detection of pathological processes.

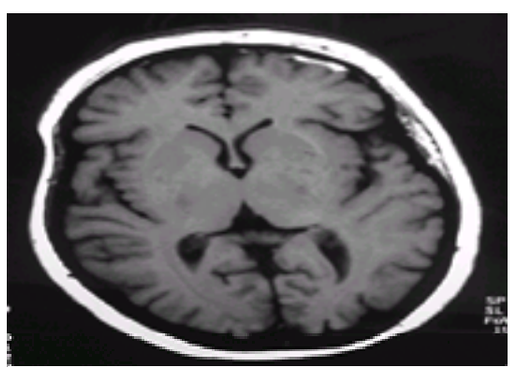

Fig. 2 Axial *T*1-weighted unenhanced MRI image at the similar level of the ventricles as in Fig. 1, showing the CSF dark and the white matter lighter than the grey

matter.

Contrast enhancement in brain imaging

Intravenous contrast in brain imaging is frequently used to determine the vascularity of structures and whether the blood–brain barrier is intact. It will show the extent and patterns of enhancement in tumours, infarcts, and inflammatory lesions. For CT scanning, the same iodinated contrast agents that are used in general vascular imaging are used. In MRI, gadolinium-labelled compounds, which shorten the *T*1 relaxation time, are used. These provide extremely useful information and show the same patterns of enhancement as the iodinated contrast media used for CT scanning, although the sensitivity of MRI contrast agents are significantly greater.

Cerebral angiography

This is used to demonstrate the intra- and extracerebral vessels. The procedure is nearly always performed by transfemoral catheterization of the neck vessels. Before the introduction of CT it was the main means of diagnosing intracranial pathology, particularly of masses and stroke-causing lesions such as vessel occlusions or haemorrhages. The main indication now for angiography is intracranial haemorrhage or suspected extracranial carotid or vertebral stenosis. Non-invasive methods, such as Doppler ultrasound of the neck vessels and magnetic resonance angiographic imaging (which does not require contrast media), has reduced the number of patients requiring invasive intra-arterial angiography, particularly for suspected ischaemic cerebrovascular disease.

Other imaging techniques including functional imaging

Although these are used less frequently, nuclear medicine studies using radioactive labelled isotopes—generally with technetium-99m and **HMPAO** (hexamethylpropylene amine oxide) as the ligand—and a gamma camera can be used to produce perfusion imaging scans of the brain. This technique is known as single-photon computed tomography (**SPECT**). Positron emission tomography (**PET**) scanning requires a cyclotron to produce the very short-lived isotopes of carbon and oxygen, and is primarily used as a research tool for investigation of the functional imaging of the brain.

Functional MRI and spectroscopy

High-field MRI 1.5 tesla or greater, up to 4 tesla, magnetic fields can also be used to provide functional information on brain function and biochemistry (spectroscopy from either hydrogen or phosphorous nuclei). These techniques are not yet in routine clinical use.

Imaging of common neurological diseases

Cerebrovascular disease and stroke

The most frequent neurological presentation is that of acute stroke. Patients presenting with a sudden onset of neurological deficit should be deemed to have suffered a vascular event until proved otherwise. In practice the clinical diagnosis of stroke is very accurate, provided an adequate history is available. The primary role of imaging in patients with acute stroke is to identify whether it is ischaemic or haemorrhagic in origin, or where there is doubt about the underlying pathology based on the clinical history. CT scanning provides a completely reliable way of excluding primary intracerebral haemorrhage as a cause of acute stroke, provided it is performed within about a week of onset. In ischaemic stroke, depending on the timing of the examination relative to the onset of neurological deficit, it will variably detect acute infarction.

Cerebral infarction

Early appearances

Within hours of a stroke, the CT scan may show a vague low attenuation or slight swelling and effacement of the sulci in the area of damage, or it may be normal. Standard MRI imaging may also be normal at this stage. However, certain more recently introduced MRI techniques, known as 'diffusion-weighted imaging', can show abnormalities even within less than an hour of onset that reflect alterations in the state and mobility of the protons in tissue water.

It should be emphasized that a negative CT or MRI scan in a patient with a clinical acute stroke does not mean that the patient has not had a stroke. It just means that imaging has not detected an area of infarction (Fig. 3 and Fig. 4).

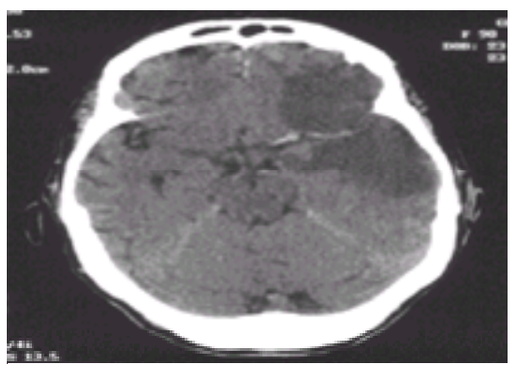

Fig. 3 CT scan showing an acute middle cerebral territory infarction within a few hours of onset of the neurological deficit. (Note the increased density in the left middle cerebral artery representing a thrombus.)

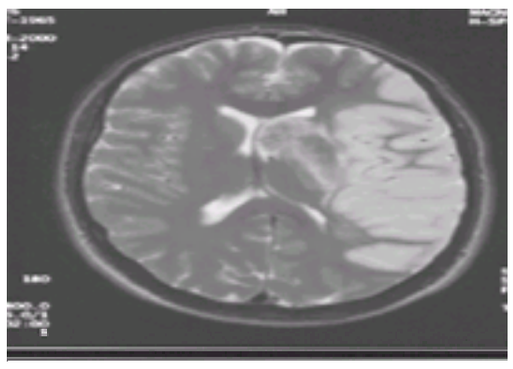

Fig. 4 *T*2-weighted MRI scan of the same patient as in Fig. 3 showing the extensive high *T*2 signal affecting grey and white matter in the left middle cerebral artery territory.

Later imaging findings

There is progressive development of a low-attenuation area on CT scanning, or a high *T*2 signal area on MRI scanning, in the area of damage. There may also be some swelling around the area, representing oedema with effacement of sulci and ventricles. It may be impossible to identify those areas that are truly infarcted and the area, which is ischaemic and may recover, called the 'ischaemic penumbra'. Over a period of a week or more the area of infarction matures with the development of a progressively better defined area of low attenuation, and loss of volume in the damaged area over time.

Intravenous contrast is frequently used when the nature of pathology in patients with cerebral infarction and its differential diagnosis from a mass lesion is in doubt. This will demonstrate increased vascularity of tissues and areas where the normal blood–brain barrier is disrupted; normal cerebral tissue will not enhance and the tight junctions of the normal blood–brain barrier will not allow contrast into the cerebral tissues. In areas of ischaemia or infarction there is diffuse cortical enhancement in ischaemic/infarcted areas. It is possible to confuse these appearances with tumours.

Intracranial haemorrhage

Primary intracranial bleeding (**PICH**) into the brain parenchyma is easily detected on CT scanning. Blood appears as an area of high attenuation on CT imaging (Fig. 5).

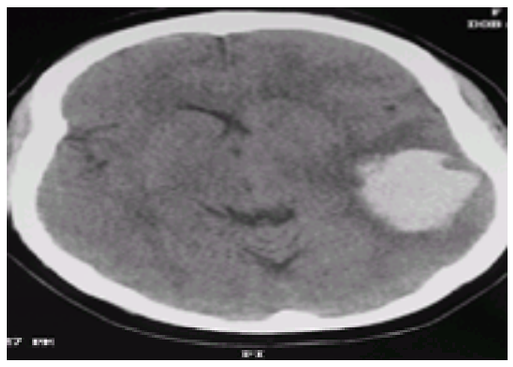

Fig. 5 CT scan of a patient with an acute stroke due to a large intracerebral haemorrhage in the left temporal lobe.

Blood in the subarachnoid space may be visible around the base of the brain as a white layer, in contrast to the normal dark outline of CSF in the basal cisterns. If a scan is carried out within 24 h of a subarachnoid haemorrhage (**SAH**) it will usually be positive for the presence of blood (about 90 per cent of the time); with a large SAH, the scan will remain positive for 3 to 4 days (Fig. 6).

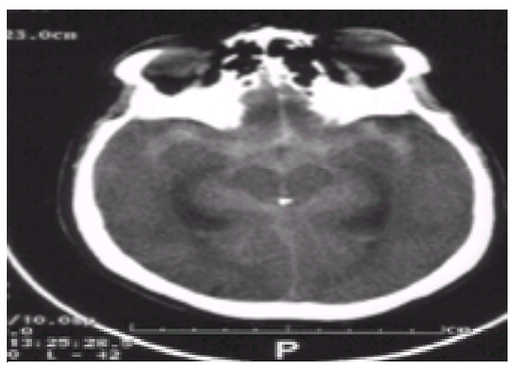

Fig. 6 CT scan of a patient with a subarachnoid haemorrhage. Note that the CSF surrounding the brainstem and in the basal cisterns is high attenuation (bright) compared with normal CSF, which on CT would be dark.

However, the lack of visible blood on CT scanning does not exclude the diagnosis of a subarachnoid haemorrhage. Lumbar puncture is essential if this diagnosis is suspected and if CT is negative or equivocal. The key clinical differential diagnosis is of acute meningitis or a very small subarachnoid haemorrhage undetectable on CT, which may result from rupture of an intracranial aneurysm.

After an intracranial haemorrhage, a decision must be made whether to investigate patients in more detail for the presence of an underlying lesion responsible for the haemorrhage, such as an intracranial aneurysm or vascular malformation. Selection of which patients should undergo cerebral angiography is sometimes difficult. However, all patients under about 50 years of age with primary intracranial bleeding but without a typical hypertensive bleed should probably undergo cerebral angiography to search for an underlying vascular malformation. All patients who survive a primary subarachnoid haemorrhage and who are in good condition should undergo cerebral angiography to detect the presence of an berry aneurysm that may be responsible for the haemorrhage. Recently ruptured aneurysms have a high likelihood of re-bleeding, as much as 30 per cent in the first 4 weeks after the haemorrhage. Without treatment there is a 50 per cent mortality by 6 months. These lesions should be detected and treated if possible, either by surgical clipping or the newer endovascular techniques using detachable platinum coils (Fig. 7 and Fig. 8). A recent large multicentre randomized trial has reported improved 1 year outcomes following coil treatment compared with surgical clipping.

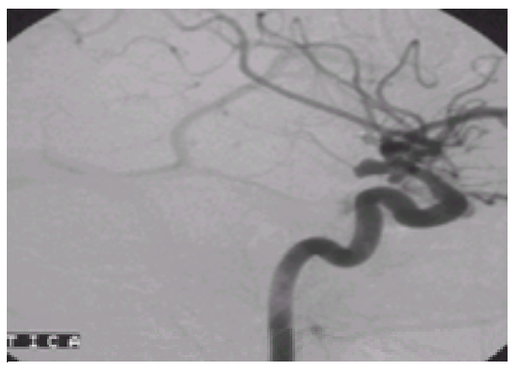

Fig. 7 Digital subtraction cerebral angiogram showing two aneurysms arising from the internal carotid artery that had recently ruptured.

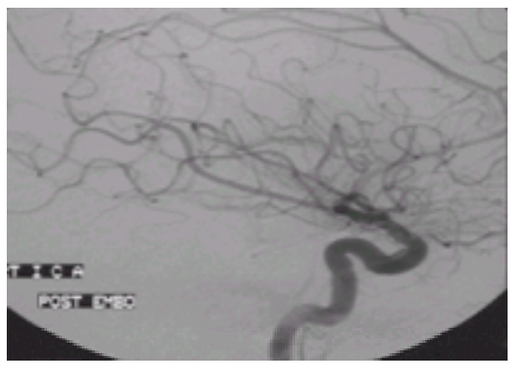

Fig. 8 Digital subtraction cerebral angiogram following placement of detachable platinum coils in the aneurysm to occlude the flow and prevent re-bleeding.

Other vascular diseases

Cerebral venous sinus thrombosis

This uncommon, potentially fatal, condition presents with severe headache, confusion, variable neurological deficits, and sometimes seizures. Since it can be difficult to detect on CT scanning, the diagnosis is best made on MRI scanning, where a lack of flow void is seen on some sequences (*T*2-weighted) and a high signal on *T*1-weighted sequences is seen in affected dural sinuses. Flow-sensitive MRI sequences demonstrate the obstructed sinus well. Anticoagulation treatment is urgently required since progression of the thrombosis can lead to intracerebral haemorrhage and fatal venous infarction (Fig. 9 and Fig. 10).

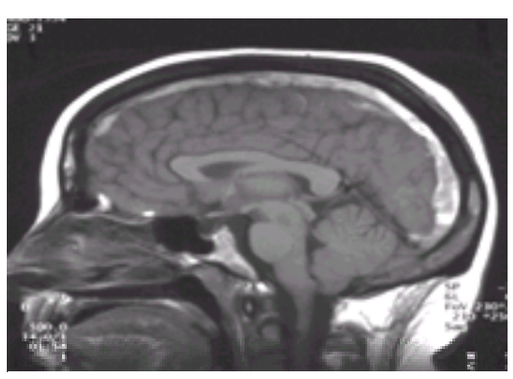

Fig. 9 Sagittal *T*1-weighted MRI scan showing a high signal in the superior sagittal sinus representing an extensive clot throughout the sinus. This 30-year-old woman presented with severe headaches, a depressed level of consciousness, and papilloedema.

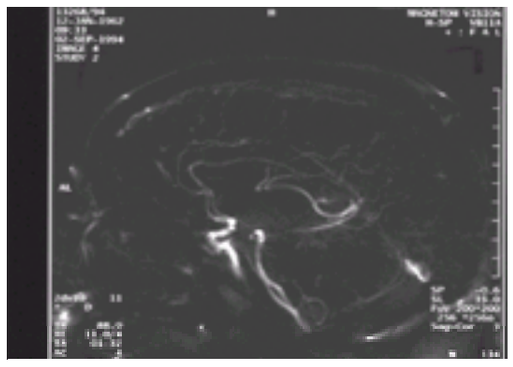

Fig. 10 Sagittal magnetic resonance venogram image showing the lack of flow in the superior sagittal sinus. This sequence is sensitive to flow and is useful in demonstrating whether a venous sinus or artery is blocked, if it is unclear from the normal sequences.

Inflammatory diseases of the nervous system

Multiple sclerosis

The most common neurological disease after stroke is multiple sclerosis. Imaging plays a crucial role in the diagnosis of this condition. However, it is important to understand that MRI alone cannot provide the diagnosis. The investigation must be placed in the context of the clinical presentation and the history and findings on neurological examination.

When patients present with symptoms of spinal cord disease, MRI of the brain and spine is indicated. The whole spinal cord is imaged to ensure that no spinal cord compressive lesion is responsible for the neurological condition. An inflammatory plaque will be seen in the spinal cord, particularly in the cervical cord, in a number of cases (Fig. 11); although failure to identify such a lesion does not mean that one is not present. Current imaging will not detect all spinal or indeed all brain lesions. However, imaging of the brain in patients with a spinal cord lesion is helpful in determining the presence of further lesions in the brain, thereby indicating a multifocal pathology. The difficulty comes in older patients over 45 years of age, where the frequency of incidental lesions in the brain presumed to be due to age-related vascular pathology becomes much more common. The pattern and extent of the white-matter lesions in patients with multiple sclerosis often characteristically affect the corpus callosum and deep white matter. However, it has again to be emphasized that the diagnosis of multiple sclerosis must not be based purely on imaging findings, attacks must be disseminated in time as well as location in the nervous system. An incorrect diagnostic label has profound consequences for the patient (Fig. 12 and Fig. 13).

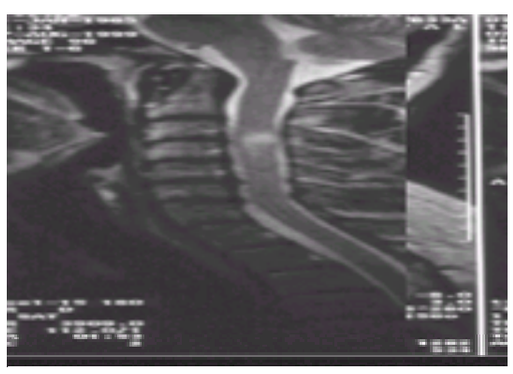

Fig. 11 Sagittal *T*2-weighted image of the cervical cord showing a high-signal lesion lying at the C3 level with some associated swelling of the cord. This is typical for

acute demyelination.

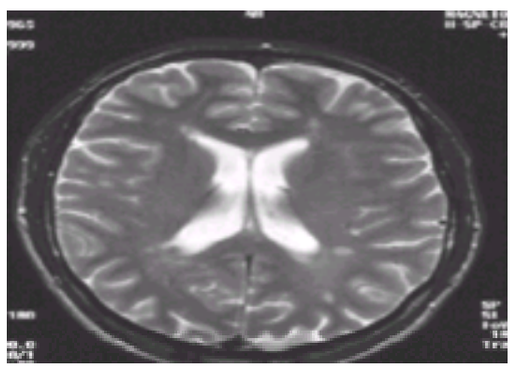

Fig. 12 Axial *T*2-weighted MRI showing high-signal lesions in the white matter around the ventricles and in both hemispheres.

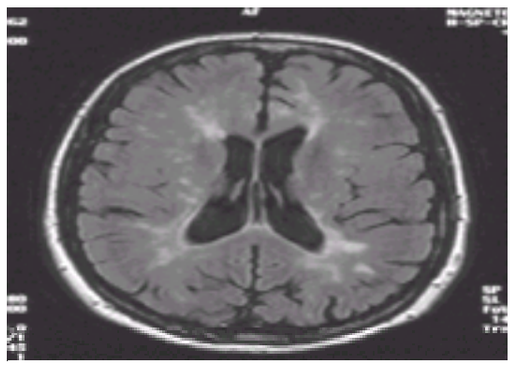

Fig. 13 This is known as a 'Flair sequence'. It detects lesions that give a high *T*2 signal but suppresses the signal from the CSF in the ventricles, so that lesions adjacent to the ventricles are more evident.

Neoplasms

Primary intracranial tumours

Primary intracranial tumours can be divided into those arising outside the brain and those arising in the cerebral substance (intra-axial or extra-axial). The range of pathology of the two locations is fundamentally different, as is often the prognosis. The primary objective of neuroimaging is to establish whether a mass lesion is present and to determine whether the lesion is intra- or extra-axial.

Extrinsic brain tumours

The most common tumours arising from structures outside the brain are meningiomas and acoustic schwannomas arising from the VIIIth nerve (frequently called 'acoustic neuroma'). Both these tumours are usually benign and present with symptoms of local pressure: VIIIth cranial nerve tumours can produce sensorineural deafness and/or sometimes dizziness, while meningiomas over the cerebral convexity may cause seizures.

The imaging characteristics of meningiomas and acoustic neuromas are similar. CT scans usually show a slight hyperdense mass causing local displacement of cerebral tissue. Masses generally enhance uniformly following the administration of intravenous contrast, although they may occasionally contain areas of low attenuation that may represent necrosis or occasionally cyst formation within the tumour (Fig. 14 and Fig. 15).

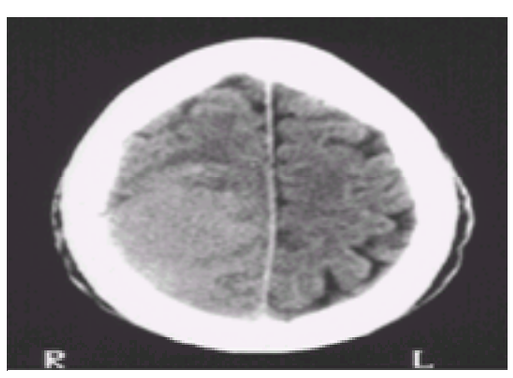

Fig. 14 Typical appearance of a meningioma. CT scan without contrast showing a high-attenuation mass lying over the surface of the brain.

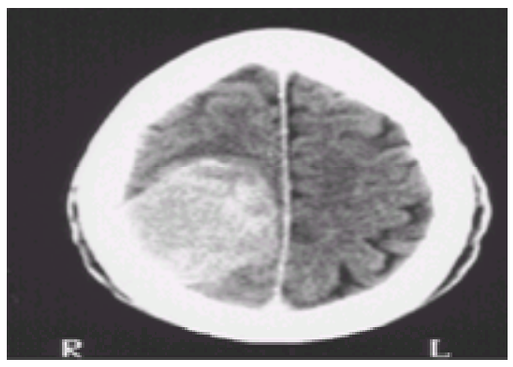

Fig. 15 CT scan after intravenous contrast showing the uniform enhancement of the mass lying over the surface of the brain.

Although MRI shows lesions that give a uniform intermediate signal on *T*1 and *T*2-weighted sequences, gadolinium administration yields uniform similar but intensely enhanced images (Fig. 16). Differentiation between intrinsic and extrinsic lesions is usually easier on MRI than on CT scanning because of the multiplanar capability

of MRI compared with CT. MRI is also superior for surgical planning purposes, to establish the relationship of the tumour to adjacent structures such as the venous sinuses or the skull base.

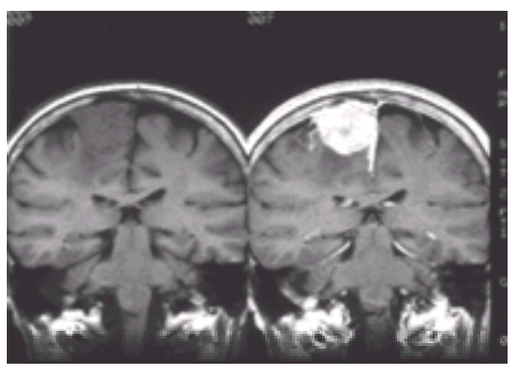

Fig. 16 Coronal *T*1-weighted MRI scan showing the typical appearances of a meningioma before and after intravenous gadolinium.

Screening for acoustic schwannomas

The most frequent presentation of an acoustic schwannoma is sensorineural hearing loss, but only a small percentage of patients with these symptoms will have an acoustic neuroma. Nevertheless, such patients should be screened to exclude the presence of a tumour. This is best achieved by a limited MRI scan, either a high-resolution *T*2-weighted or a 3D sequence. A modern MRI scanner can perform such a scan in less than 15 min.

Intrinsic cerebral tumours

When a mass lesion arises from the brain substance, the range of tissues of origin is completely different. Most tumours arise from glial cells and are therefore classified as gliomas in broad terms. However, the range of biological behaviour of these tumours is very wide. Similarly, the imaging findings can vary greatly, reflecting this biological behaviour. The most common single brain tumour is the malignant glioma or glioblastoma multiforme. These tumours are also referred to as high-grade gliomas.

Glioblastoma multiforme

These tumours show widespread infiltration and a mass effect on CT and MRI, with a high *T*2 signal on MRI and a low attenuation on CT. The distinction between oedema and tumour infiltration may be difficult on imaging grounds.

However, the pattern of glioblastoma multiforme is usually very characteristic on imaging, with extensive enhancement following contrast on both CT and MRI scanning. Irregular margins of low-signal areas due to tumour necrosis are common. It is also common for cysts to form in association with both glioblastoma multiforme and lower grade gliomas (Fig. 17). Figure 18, Figure 19, and Figure 20 show the MRI appearances of a glioblastoma.

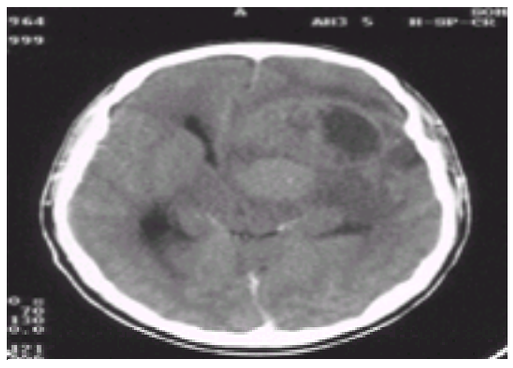

Fig. 17 Contrast-enhanced CT scan showing a large, deeply situated mass in the left hemisphere, with considerable enhancement postcontrast and a cystic or necrotic component with a low-attenuation area. This lesion was confirmed as a glioblastoma multiforme.

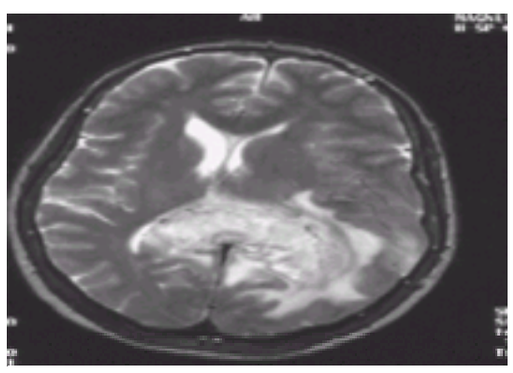

Fig. 18 Axial *T*2-weighted image of a large glioblastoma involving the corpus callosum.

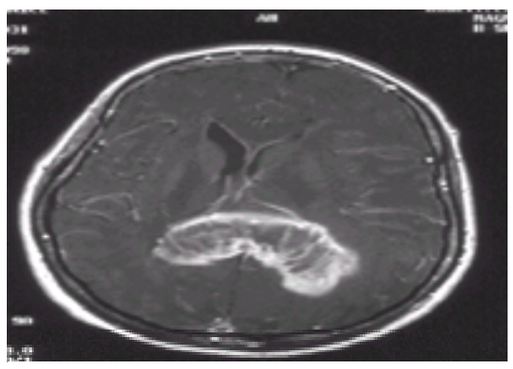

Fig. 19 Contrast-enhanced axial *T*1-weighted MRI image of glioblastoma showing marked irregular contrast enhancement of the margins of the tumour, with lack of central enhancement reflecting the extensive necrosis that is often a feature of these tumours.

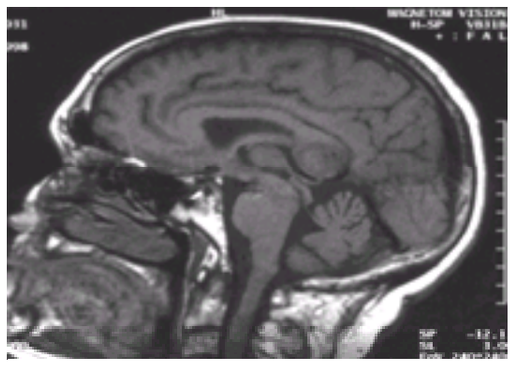

Fig. 20 Sagittal *T*1-weighted image without contrast showing the marked enlargement of the splenium of the corpus callosum depicted in the same patient as Fig. 18 and Fig. 19.

Astrocytoma

These tumours are less aggressive than glioblastoma multiforme and range from benign lesions, which may remain stable for many years, to aggressive malignant lesions. Astrocytomas often form cysts and are seen in children as what are termed 'pilocytic astrocytomas'. These are often benign. The imaging findings show a diffuse mass effect on CT and MRI, with low attenuation on CT and on *T*1-weighted MRI sequences but a high signal on *T*2-weighted MRI. Enhancement is very variable; sometimes there is considerable enhancement in pilocytic astrocytoma in children but often little in the way of enhancement in many low-grade astrocytomas in adults (Fig. 21).

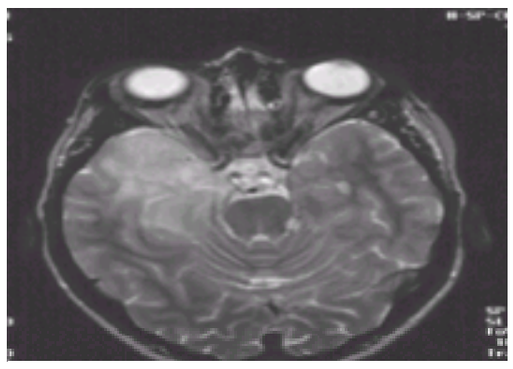

Fig. 21 Axial *T*2-weighted MRI showing a diffuse high-signal lesion in the right temporal lobe with a diffuse mass effect and sulcal effacement. These are typical appearances for a low-grade glioma. Although the differential diagnosis includes herpes encephalitis, the clinical presentation is completely different.

Oligodendroglioma

These tumours are the most benign of the intrinsic cerebral tumours. They often present with seizures rather than neurological deficit. Their radiological hallmark is calcification, best detected on CT scanning. Calcification may be invisible on MRI. The time course of these tumours may be very long, often evolving over 10 to 20 years. Oligodendrogliomas may remain static for long periods (Fig. 22 and Fig. 23).

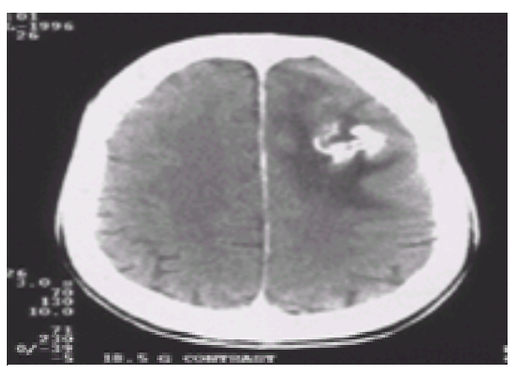

Fig. 22 CT scan of a partially calcified oligodendroglioma in the left frontal lobe.

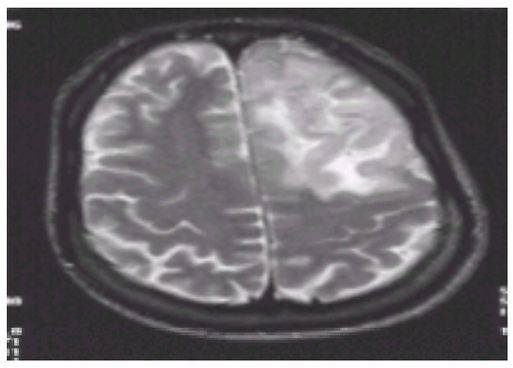

Fig. 23 MRI scan of the same pathology as in Fig. 22 with a diffuse high signal throughout the left frontal lobe.

Posterior fossa tumours

Intrinsic posterior fossa tumours are the most common intracranial tumours in children. The most common lesion is a medulloblastoma (Fig. 24). These usually arise in or near the midline posterior fossa in relation to the cerebellar vermis, they account for about 75 per cent of posterior fossa tumours in children. Other tumours commonly encountered are ependymomas and pilocytic astrocytomas, both of which have a better prognosis than medulloblastomas. Medulloblastomas and ependymomas commonly metastasize down the spinal canal, producing what are known as 'drop metastases' to the lumbar or sacral region.

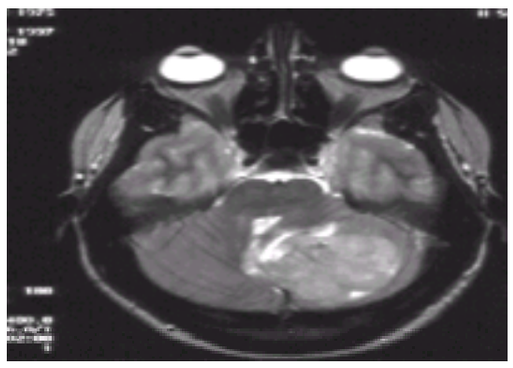

Fig. 24 Large medulloblastoma in the left cerebellar hemisphere demonstrated on *T*2-weighted MRI causing severe compression of the fourth ventricle.

Other intracranial tumours

Colloid cyst

This is a very characteristic benign lesion that arises at the foramen of Munro and causes obstructive hydrocephalus. Colloid cysts are usually readily detectable on CT and MRI and absolutely characteristic in their position, though the attenuation and signal characteristics can vary quite widely (Fig. 25).

Fig. 25 CT scan showing the typical appearance of a colloid cyst arising at the foramen of Munro.

Pituitary region tumours

MRI is the investigation of choice for suspected pituitary lesions. CT is a second best imaging modality.

These tumours, which arise outside the brain itself, are associated with a characteristic range of pathology. The most common lesion is a non-functioning pituitary adenoma, followed by hormonally active tumours, namely Cushing's disease (producing ACTH), prolactinomas, growth-hormone-secreting tumours (acromegaly). All these have similar characteristics, but their size varies widely: ACTH-secreting adenoma are usually very small and may not be detectable even on high-quality MRI imaging. Non-functioning adenomas tend to present late, often with visual loss and/or pituitary failure due to the large size and optic chiasmal compression (Fig. 26 and Fig. 27).

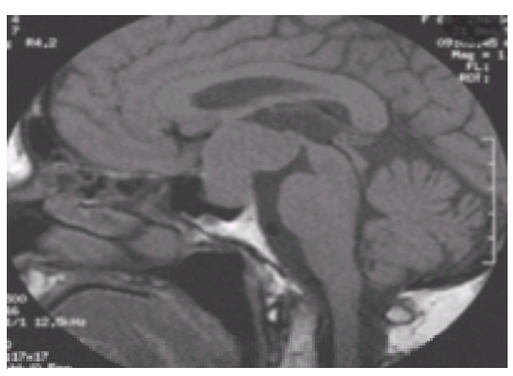

Fig. 26 Sagittal *T*1-weighted MRI showing a large pituitary adenoma extending into the suprasellar cistern.

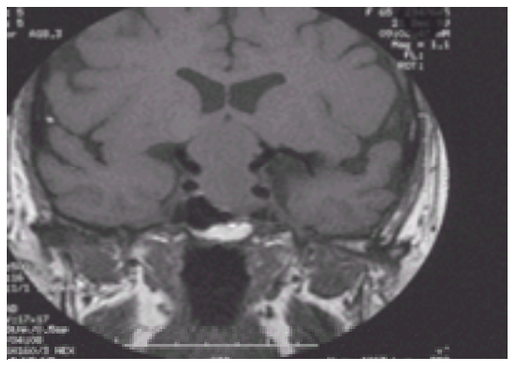

Fig. 27 Coronal *T*1-weighted MRI showing a large pituitary adenoma extending into the suprasellar cistern.

Craniopharyngioma

This specific benign tumour arises in the hypothalamic region usually in young patients, and presents with either visual loss and/or pituitary failure. The characteristic findings on CT are calcification, which may also be seen on plain skull films. There is often a cystic as well as a solid component to the lesion.

Brainstem gliomas

These relatively uncommon tumours occur at a relatively young age. However, because of their location there is no prospect of any surgical approach and if any treatment is appropriate, it is usually radiotherapy. Brainstem gliomas may vary widely in their aggressiveness, from rapidly progressive lesions behaving like glioblastomas to indolent lesions that may remain static for many years (Fig. 28).

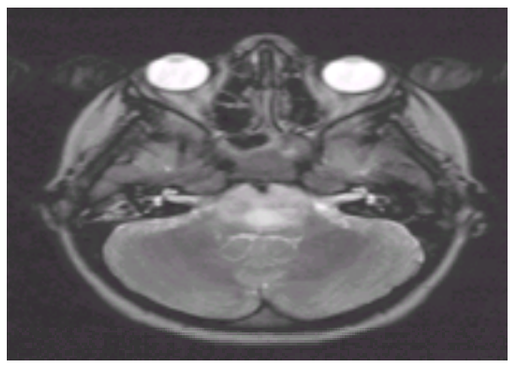

Fig. 28 Brainstem glioma shown on axial *T*2-weighted MRI with a diffuse high signal within the pons causing a local mass effect.

Secondary cerebral tumours

These are amongst the most common intracranial tumours and may be the presenting feature in some patients. Lung, breast, and gastrointestinal tumours as well as melanomas especially metastasize to the brain.

Secondary tumours may be solitary or multiple and are fairly characteristic on the imaging, with intracranial masses surrounded by oedema and frequently with enhancement after intravenous contrast (Fig. 29). The differential diagnosis of multiple ring-enhancing lesions in the brain is between cerebral metastases and abscesses. Sometimes this distinction cannot be made on imaging grounds and other evidence of the underlying cause must be sought; if necessary, biopsy or aspiration may be required.

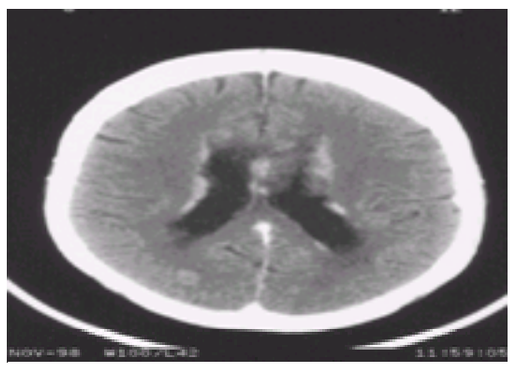

Fig. 29 Enhanced CT of a brain showing extensive secondary deposits around the cerebral ventricles from an oat-cell carcinoma of the bronchus.

Meningeal deposits of primary or secondary tumours are relatively uncommon, but they do occur and may be difficult to detect. MRI with gadolinium enhancement is the most sensitive detection method if the cerebrospinal fluid examination is negative for abnormal cells.

Intracranial infections

Although intracranial infections are less common than tumours, it is vitally important that they be detected as urgent and definitive diagnosis and treatment is essential to their effective management.

Bacterial infections

Pyogenic brain abscesses may be single or multiple. In the early stage they may not be particularly well defined, but by the time they present for scanning they often show a characteristic ring-enhancing mass surrounded by oedema (Fig. 30). If a pyogenic abscess is suspected then burr-hole aspiration is mandatory to establish the diagnosis and to drain the abscess. Abscesses may be seen at various stages of evolution if associated with a septicaemic illness. The source is either due to blood spread, or direct spread from the infection in the paranasal sinuses or the mastoid.

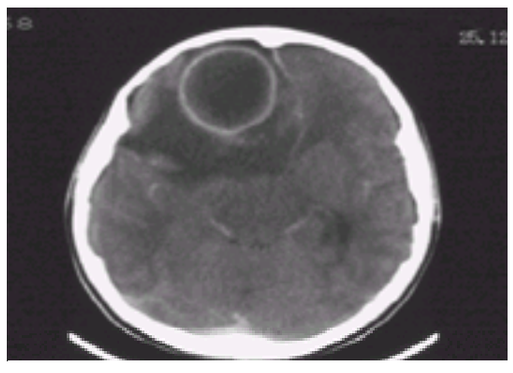

Fig. 30 Enhanced CT scan showing a large ring-enhancing frontal mass due to a pyogenic abscess. The differential diagnosis for these appearances is from a metastasis, or a glioma can occasionally appear similar.

Meningitis is not usually diagnosed by CT or MRI and lumbar puncture remains the method of choice. If imaging is performed, however, it may show a mild communicating hydrocephalus and enhancement of the meninges following intravenous contrast. Note that mild communicating hydrocephalus is not a contraindication to lumbar puncture (see below).

Subdural empyema

This is rare, but important, intracranial infection due to spread from a paranasal sinus infection. Pus accumulates in the subdural space causing a spreading cortical thrombophlebitis. Empyema is usually due to the anaerobic bacterium, *Streptococcus milleri*. Such abscesses are rapidly fatal if they are not treated aggressively with antibiotics and neurosurgical drainage. CT findings are those of a thin subdural collection of fluid, which spreads over the surface, and often alongside the falx. MRI is more sensitive in the detection of the small subdural collections, but it is unnecessary if the diagnosis is clear on CT scans (Fig. 31).

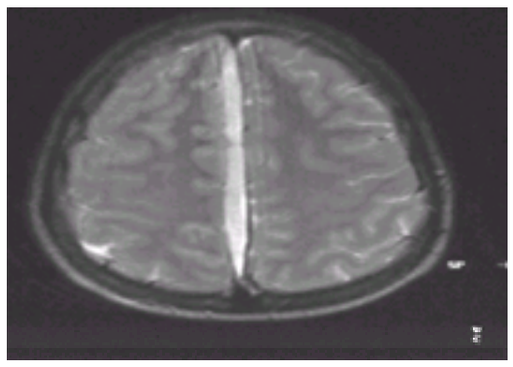

Fig. 31 Axial *T*2-weighted MRI showing a collection of fluid alongside the falx in a patient with a large subdural empyema.

The underlying brain appears swollen and tight with the sulci obliterated, it will show moderate meningeal enhancement following intravenous contrast.

Tuberculosis

This may manifest itself as either abscesses or granulomas in the brain or a basal meningitis. If the meninges are involved there is almost invariably a degree of hydrocephalus.

Viral encephalitis

The most common cerebral viral infection is herpes simplex encephalitis (**HSE**). The imaging findings are often fairly typical, though CT scan changes may be very subtle during the early phase. CT scans show a mild swelling in the temporal region and diffuse low attenuation, as the focus of the pathology in HSE lies in the hippocampal region and medial temporal structures. MRI detects the disease more accurately and earlier and is the investigation of choice. When the disease is advanced or only partially treated it can present with a quite marked mass effect and irregular enhancement simulating an aggressive tumour.

Hydrocephalus

An understanding of hydrocephalus and its two main types is important to knowing whether it is 'safe to carry out a lumbar puncture' in a patient or not.

Obstructive or non-communicating hydrocephalus

This is the term given to enlargement of the ventricles caused by an obstruction, usually a mass lesion in the cerebrospinal fluid pathways within the brain (that is, between where the CSF is produced from the choroid plexus in the lateral ventricles and the outflow from the fourth ventricle). It is usually caused by a tumour pressing on the CSF pathways.

Communicating hydrocephalus

If cerebrospinal fluid escapes from the fourth ventricle but there is disturbance of flow around the basal cisterns over the cortex, or there is a failure of absorption of CSF, this is termed 'communicating hydrocephalus'. Communicating hydrocephalus occurs most commonly with a subarachnoid haemorrhage or meningitis and usually does not require treatment. However, because cerebrospinal fluid escapes from the fourth ventricle and circulates round the spinal CSF spaces, it means that it is safe to perform a lumbar puncture to measure and, if appropriate, lower CSF pressure. Lumbar puncture or drainage may also relieve intracranial pressure after a subarachnoid haemorrhage.

Congenital anomalies and paediatric imaging

Any detailed discussion of this subject is beyond the scope of this chapter, and the reader is directed to a specialist text such as Scott, Atlas.

Where available, MRI is the investigation of choice in infants and children presenting with suspected congenital anomalies of the brain. It provides the most information and avoids exposure of young patients to ionizing radiation. The main drawback in this age group is the need for sedation or anaesthesia. The most common indication for imaging in such patients is developmental delay or seizure disorders. It also plays a vital role in the imaging of a suspected, neonatal, hypoxic ischaemic insult and in elucidating the cause of cerebral palsy. CT is a reasonable alternative, but cannot be relied to detect all relevant pathology, particularly in hypoxic ischaemic injury.

A wide variety of congenital anomalies are possible. These range from minor abnormalities of neuronal migration, or localized areas of dysplastic cortex, to major anomalies of the whole brain and encephaloceles where there is an associated defect of the skull or spine such as a spina bifida. The most frequent is the Chiari malformation of the posterior fossa associated with cerebellar ectopia, the cerebellar tonsils lie below the foramen magnum.

Summary

Modern imaging techniques have revolutionized the diagnosis of neurological disease in the last 20 years. The techniques are likely to become more sophisticated and accurate with further extension into functional imaging techniques, both with magnetic resonance and nuclear medicine single-photon emission tomography (SPECT) and positron emission tomography (PET).

The contribution of these techniques to the efficient and effective diagnosis of intracranial and spinal pathology, together with the ability to effectively exclude structural disease, has had a huge impact on clinical practice. The development of interventional neuroradiological techniques for the treatment of vascular disease in the brain, particularly the endovascular coil treatment for intracranial aneurysms, may soon represent a further revolution in the management of patients with subarachnoid haemorrhages and intracranial aneurysms.

24.6.1 Inherited disorders

P. K. Thomas

There are many genetically determined neurological disorders, and other multifactorial disorders in which a genetic component can be detected. Inherited movement disorders, disorders of the peripheral nerves and muscles, and those aminoacidurias that are associated with neurological involvement are considered elsewhere, as is the question of genetic factors in the aetiology of conditions such as developmental abnormalities of the nervous system, epilepsy, migraine, Alzheimer's disease, and multiple sclerosis.

Hereditary ataxias

The classification of the hereditary ataxias remains a matter of controversy. A spinocerebellar degeneration may develop in disorders with a known metabolic basis. This category includes abetalipoproteinaemia (see Section 11), ataxia telangiectasia, and xeroderma pigmentosum (see Section 23). In general, the inherited cerebellar and spinocerebellar degenerations can be divided into examples having an early onset (under the age of 25 years), which are usually of autosomal recessive inheritance and of which Friedreich's ataxia is the commonest example, and the later onset cases of cerebellar degeneration that are most often dominantly inherited.

Early onset hereditary ataxias

Friedreich's ataxia

This disorder is an example of a spinocerebellar degeneration and is dominated by progressive ataxia with an onset in childhood or adolescence. The condition is inherited as an autosomal recessive trait and affects males and females approximately equally. The gene responsible has been localized to chromosome 9q13–q21 and is due to a trinucleotide repeat in a non-coding region of the gene for frataxin, a mitochondrial protein. Degeneration of the larger dorsal root ganglion cells occurs with consequent loss of the larger myelinated fibres in the peripheral nerves and degeneration in the dorsal columns. Degeneration is also evident in Clarke's column, in the spinocerebellar tracts, and in the corticospinal pathways. There is variable loss of Purkinje cells in the cerebellum.

The average age of onset is 11 to 12 years, but cases of later onset may occur. The initial symptom is almost invariably ataxia of gait, although foot or spinal deformity may antedate this. At first it is noted that the child walks awkwardly with a tendency to stumble and fall readily; in cases of early onset, walking may never have been normal. As the disease progresses, the gait slowly becomes more irregular and clumsy. The patient walks on a broad base and tends to lurch from side to side. Involvement of the upper limbs develops later, at first giving rise to clumsiness of fine movements, subsequently for all movements. A coarse intention tremor becomes obvious. The trunk is also affected, leading to oscillation of the body when standing or sitting unsupported. A regular tremor of the head (titubation) occasionally appears. Nystagmus is present in about one-quarter of the cases. Dysarthria of cerebellar type develops and may become severe enough to make speech almost unintelligible.

Initially weakness is not obtrusive, but this develops as the disease advances, beginning in the legs and later involving the upper limbs. It results from degeneration in the corticospinal pathways and tends to vary in severity between cases. The plantar responses become extensor, but tone is not usually increased because of the accompanying disturbance of the afferent fibres from muscle spindles. There may be mild wasting of the anterior tibial and small hand muscles related to loss of anterior horn cells. Bladder and bowel function is usually unaffected.

Loss of the larger dorsal root ganglion cells leads to impairment of the sense of joint position, vibration, and to some extent of touch–pressure sensibility, initially distally in the limbs. The impairment of proprioception superimposes a sensory element on the cerebellar ataxia. The tendon reflexes are depressed or absent.

Apart from occasional nystagmus, the ocular movements are usually intact. The pupils are unaffected. Optic atrophy is present in about one-third of cases and 10 per cent of cases develop sensorineural deafness with particular difficulty in speech discrimination.

Associated skeletal deformities are common, in particular foot deformities (pes cavus and pes equinovarus) and kyphoscoliosis. Contractures of the knees may develop in the later stages. Electrocardiography demonstrates widespread T-wave inversion and ventricular hypertrophy in nearly 70 per cent of patients. Echocardiography may suggest the presence of hypertrophic obstructive cardiomyopathy, but these findings are not specific and the ECG is a more sensitive investigation for the detection of cardiomyopathy. The ECG changes are present early in the disease and tend not to be associated with symptoms. Cardiac failure occurs late and is usually precipitated by supraventricular arrhythmias.

Although progressive dementia is not a feature of the disease, reduced intelligence is present in some cases. There is an increased incidence of diabetes mellitus in Friedreich's ataxia (10 per cent).

The disease is slowly progressive, the average age of death being in the latter part of the fourth decade. The foot and spinal deformities may require orthopaedic

correction. Ultimately patients become bedridden. Death is usually from an intercurrent infection or cardiac failure.

Later onset hereditary ataxias (ADCA)

Autosomal dominant cerebellar ataxia

This comprises the main group of disorders within the adult onset hereditary ataxias. The age of onset usually ranges from the third to the fifth decades. Clinically, these disorders can be divided into three categories. Autosomal dominant cerebellar ataxia (ADCA) type I consists of a multisystem disorder with varying combinations of cerebellar ataxia, dementia, optic atrophy, disturbances of eye movement, pyramidal and extrapyramidal features, and peripheral neuropathy. Autosomal dominant cerebellar ataxia type II consists of these features plus pigmentary macular degeneration. Autosomal dominant cerebellar ataxia type III is a relatively pure cerebellar degeneration. Molecular genetic studies have identified a number of different mutations underlying autosomal dominant cerebellar ataxia, designated spinocerebellar ataxia, at present running from spinocerebellar ataxia 1 to spinocerebellar ataxia 7. Amongst these, spinocerebellar ataxia 1 to 4 and spinocerebellar ataxia 6 correspond to autosomal dominant cerebellar ataxia type I, spinocerebellar ataxia 5 (Lincoln ataxia) to autosomal dominant cerebellar ataxia type III, and spinocerebellar ataxia 7 to autosomal dominant cerebellar ataxia type II. Spinocerebellar ataxia 3 is Machado–Joseph disease. A number of these disorders (spinocerebellar ataxias (SCA) 1, 2, 3, 6, and 7) have been shown to be the result of unstable CAG (cytosine–adenine–guanine) trinucleotide repeats.

The category of Marie's delayed cerebellar atrophy was introduced to describe cases of hereditary ataxia with a later onset than Friedreich's ataxia in which the symptoms develop during the third or fourth decades of life or later. It is clear that Marie collected together a heterogeneous group of disorders, but his description served to emphasize the broad subdivision of the hereditary ataxias into the early and later onset groups. Cerebellar degeneration may be a feature in mitochondrial encephalomyopathies. Many instances of late onset cerebellar ataxia, particularly those without ophthalmoplegia or optic atrophy, are probably non-genetic.

Familial episodic ataxia

This comprises two disorders—episodic ataxia 1 mapping to chromosome 12p13 and episodic ataxia 2 mapping to chromosome 19p13. Both involve transient attacks of ataxia together in some cases with paroxysmal kinesogenic choreoathetosis which lasts for seconds to minutes in episodic ataxia 1 and minutes to hours in episodic ataxia 2. Chronic ataxia may develop in episodic ataxia 2. Episodic ataxia 1 has been shown to be due to mutations in K^+ channel genes. In both forms the attacks respond to acetazolamide.

Hereditary spastic paraplegia

Hereditary spastic paraplegia can be subdivided into a 'pure' form (Strümpell's disease) and others in which a variety of other features coexist, some of which are due to mitochondrial dysfunction. Strümpell's disease is genetically heterogeneous. It may display either autosomal dominant inheritance with mutations on chromosomes 14q and 15q or autosomal recessive inheritance. It may present during childhood or even with delayed motor development in infancy; in other cases the onset does not occur until adult life. It gives rise to difficulty in walking because of weakness and spasticity in the legs. The tendon reflexes are exaggerated and the plantar responses are extensor. Foot deformity may be present in cases of early onset. Some patients show a mild degree of cerebellar ataxia and sensory impairment in the legs of posterior column type. The disease progresses slowly and may later affect the upper limbs. Precipitancy of micturition or urinary incontinence may occur. Pathologically there is degeneration of the corticospinal pathways in the lateral columns of the spinal cord and some fibre loss in the gracile fasciculi. An X-linked form of hereditary spastic paraplegia also exists, related to mutations in the gene for proteolipid protein. It is allelic with Pelizaeus–Merzbacher disease.

Severe spasticity, if present, may be alleviated to some extent by oral baclofen or dantrolene. Continuous intrathecal administration of baclofen by an infusion pump is helpful in selected cases. The precipitancy of micturition may be improved by oxybutynin. Surgical correction of foot deformities is sometimes required.

Genetically distinct disorders in which a spastic paraplegia is associated with other clinical features include the Sjögren–Larsson syndrome, a recessively inherited condition which combines congenital ichthyosis and oligophrenia with a childhood onset spastic paraplegia, and the dominantly inherited disorder in which the paraplegia is associated with distal amyotrophy in the limbs resembling peroneal muscular atrophy. Hereditary spastic paraplegia can represent a mitochondrial disorder affecting the gene for paraplegin.

Disorders of lipid metabolism (see alsoSection 11)

Neurolipidoses

The lipidoses constitute a group of disorders characterized by the intracellular accumulation of a variety of different lipids. Some predominantly involve the nervous system; others primarily affect the reticuloendothelial system, but may also involve nervous tissue. They may be classified in terms of the particular lipid that is stored.

Niemann–Pick disease

This consists of a group of recessively inherited disorders in which there is an accumulation of lipid in 'foam cells' in the reticuloendothelial system. Types A and B, due to mutations on chromosomes p15.1–15.4, are the result of acid sphingomyelinase deficiency resulting in accumulation of sphingomyelin. Types C and D are related to a defect in the intracellular homeostasis of unesterified cholesterol. In type A, progressive mental deterioration and spastic paralysis in association with hepatosplenomegaly appear in the first 6 months of life, leading to death before the age of 3 years. Cherry-red spots are present at the maculae in 50 per cent of cases. Type B does not affect the nervous system. Types C and D resemble type A but the storage material consists of cholesterol and neutral lipids. Sphingomyelinase activity is normal.

Glucosyl ceramide lipidosis (Gaucher's disease)

Three variants exist, all recessively inherited, characterized by hepatosplenomegaly related to the accumulation of glucosyl ceramide in histiocytes as a consequence of a deficiency of the enzyme glucocerebrosidase. The type I adult onset form does not usually affect the nervous system but types II and III, with an infantile and juvenile onset respectively, and a more rapid progression, display widespread cerebral involvement.

Gangliosidoses

These comprise a group of recessively inherited disorders in which there is a combination of progressive dementia, epilepsy, and visual failure. They are related to defective ganglioside degradation. Several GM_1 gangliosidoses exist and are the result of an inherited deficiency of acid b-galactosidase. In the infantile form, which maps to chromosome 3p14.3, there is a generalized storage of GM_1 ganglioside affecting the brain, the viscera, and the skeleton. The onset is at birth or in early infancy, and initially is manifested by a failure to thrive and by hepatosplenomegaly. Later, mental and motor deterioration become evident, and a cherry-red spot may be present at the macula, related to retinal degeneration. Skeletal abnormalities, including abnormal facial features, have led to the condition being referred to as the 'pseudo Hurler syndrome'. Death takes place before the age of 3 years. A juvenile onset variant also exists.

The GM_2 gangliosidoses involve the storage of GM_2 gangliosides, which are largely confined to the nervous system. In the type 1 variety (Tay–Sachs disease), the disorder usually begins within the first 6 months of life. It is encountered most frequently in Ashkenazi Jews. Initially there is retardation of development which is followed by progressive dementia, hypotonic weakness, and blindness. There is a cherry-red spot at the macula. Later, seizures occur and terminally generalized spasticity develops. Death generally takes place in the fourth year of life. The disorder is related to an inherited deficiency of hexosaminidase A and the gene has been localized to chromosome 15q23–q24. Carrier detection is possible by a serum assay, and mass screening programmes have been undertaken in some countries. Antenatal diagnosis by amniocentesis is also possible. There is no specific therapy. The type 2 form (Sandhoff's disease) is similar clinically but involves a combined deficiency of hexosaminidase A and B. A form with juvenile onset also exists, as do phenotypes presenting as spinal muscular atrophy, spinocerebellar degeneration, or as a dystonic syndrome. The gene is localized on chromosome 5q13.

Neuronal ceroid lipofuscinosis

Under this heading are grouped a number of rare disorders in which retinal degeneration, progressive dementia, epilepsy, spasticity, and ataxia occur in various

combinations. The age of onset may be infantile (Santavuori), late infantile (Jansky–Bielschowsky), juvenile (Spielmeyer–Vogt or Batten), or adult (Kufs). There is neuronal storage of lipopigment, but the molecular basis for these disorders has not been established. The infantile, late infantile, and juvenile forms are all of autosomal recessive inheritance. The infantile, late infantile, and juvenile forms map to chromosome 1p, 11p, and 16p respectively.

Leucodystrophies

These disorders are characterized by a diffuse disintegration of white matter in the central nervous system and sometimes also by segmental demyelination in the peripheral nerves. The cell bodies of the neurones are generally spared, although both myelin sheaths and axons show destruction in the white matter lesions.

Metachromatic leucodystrophy (sulphatide lipidosis)

The most common variant is the late infantile type which usually begins in the third year of life with weakness and ataxia in the limbs. Subsequently a progressive dementia supervenes, seizures may occur, and in some instances optic atrophy develops. The tendon reflexes may be depressed or absent in those patients in whom peripheral nerve involvement is prominent. Nerve conduction velocity is reduced. Death sometimes occurs after a course of a few months, but occasionally after as long as 5 or 6 years. Terminally the affected children are demented, with a spastic tetraplegia, and are often blind.

The term metachromatic leucodystrophy is derived from the presence of galactosyl sulphatide in the affected tissues. This stains metachromatically with dyes such as cresyl violet and toluidine blue. It may be demonstrated within cells in fresh specimens of urine and also within Schwann cells and macrophages in biopsies of the peripheral nerves or rectal wall. The disorder, which maps to chromosome 22q13–13qter, is inherited in an autosomal recessive manner, and is due to a deficiency of aryl sulphatase A. This can be demonstrated by assay on leucocytes.

Juvenile and adult onset forms of metachromatic leucodystrophy are also encountered, but are rare. Prenatal diagnosis by amniocentesis and assay of aryl sulphatase activity on cultured amniotic fibroblasts is possible in both the late infantile and juvenile forms. Variants related to multiple sulphatase deficiency and to deficiency of activator protein also occur.

Globoid cell leucodystrophy (Krabbe's disease)

This derives its title from the presence of large multinucleate cells containing galactosylceramide in areas of white matter damage. The condition begins at the age of 3 or 4 months as a failure to thrive. Developmental regression then becomes evident and the tendon reflexes are lost. As the disease advances, generalized hypertonus appears, together with various types of seizure, and optic atrophy. Death often occurs in the first year of life or it may be delayed into the second year. There are also rare late onset cases.

The peripheral nerves are affected, biopsies showing segmental demyelination and inclusions within Schwann cells. Nerve conduction velocity is reduced. This can be helpful diagnostically in suspected cases

The disorder is inherited in an autosomal recessive manner and is due to a deficiency of galactosylceramide b-galactosidase. It maps to chromosome 14q21–q31. This may be demonstrated by assays on leucocytes or serum.

Adrenoleucodystrophy and adrenomyeloneuropathy (see Chapter 24.10)

These are a group of conditions that give rise to widespread demyelination in the brain with an onset during childhood, and cases of adrenoleucodystrophy can be separated by virtue of X-linked inheritance and associated adrenal insufficiency with features resembling those of Addison's disease. The disorder maps to chromosome Xq28. The affected boys exhibit a progressive illness characterized by the development of dementia, cortical blindness, ataxia, and spastic weakness in the limbs. A myeloneuropathy is sometimes the presenting deficit, or other phenotypes. Manifesting female carriers may show a mild spastic paraparesis or adrenal insufficiency.

Other rare demyelinating conditions

Pelizaeus–Merzbacher disease is an X-linked recessive disease that appears in early infancy. It maps to chromosome Xq22. Affected males develop ataxia and spasticity. It is due to the defective production of proteolipid protein in central myelin. Canavan's disease also develops in early infancy, is of autosomal recessive inheritance, and gives rise to progressive mental deterioration and megalencephaly associated with spongy degeneration of the white matter. It is related to a deficiency of aspartoacylase. Affected children show excessive urinary excretion of *N*-acetylaspartic acid. Prenatal diagnosis is possible.

Fabry's disease (a-galactosidase A deficiency) (see also Section 11)

This condition, otherwise known as angiokeratoma corporis diffusum, is an inborn error of glycosphingolipid metabolism. Neutral glycosphingolipids are deposited in various tissues as a consequence of a deficiency of the enzyme a-galactosidase A. The disorder is inherited in an X-linked recessive manner and maps to chromosome Xq21.33–q22. Affected hemizygous males develop a mild peripheral neuropathy which is manifested by the occurrence of severe pains in the extremities, often beginning in childhood. Cerebrovascular lesions also occur, either cerebral infarction or haemorrhage. Non-neurological features include corneal opacification, punctate angiectatic lesions over the lower trunk, buttocks, and upper legs, and cardiac and renal lesions. Heterozygous females may display mild manifestations, most usually corneal opacification.

Hereditary lipoprotein deficiency (see also Section 11)

The occurrence of peripheral neuropathy in hereditary high-density lipoprotein deficiency (Tangier disease) is discussed in Section 11. Hereditary abetalipoproteinaemia (Bassen–Kornzweig disease) is a recessively inherited disorder mapping to chromosome 2p24, in which a spinocerebellar degeneration may develop with features that bear some resemblance to Friedreich's ataxia. Other manifestations of this uncommon disorder include intestinal malabsorption, pigmentary retinopathy, and the presence of acanthocytes in the peripheral blood (see Section 22). In addition to the absence of serum low-density lipoproteins, the serum cholesterol level is substantially reduced. There is evidence that the development of the neurological lesions may be prevented by the administration of vitamin E orally, the absorption of which from the gut is impaired. A spinocerebellar degeneration has also been described in individuals homozygous for hereditary hypobetalipoproteinaemia, a genetically separate condition.

Isolated vitamin E deficiency

A spinocerebellar syndrome resembling Friedreich's ataxia has been described in recent years due to vitamin E deficiency in the absence of generalized fat malabsorption. Titubatory head tremor is a particular feature. The disorder is of autosomal recessive inheritance, maps to chromosome 8q13.1–13.3, and is due to a deficiency of an a-tocopherol carrier protein. Treatment is by vitamin E replacement.

Neurocutaneous syndromes

This category encompasses a number of disorders in which a variety of neurological disturbances are associated with cutaneous abnormalities.

Neurofibromatosis

Two major forms of this disorder exist. Both are of autosomal dominant inheritance. The gene for neurofibromatosis type 1 (von Recklinghausen's disease) is on the proximal long arm of chromosome 17 at q11.2. The gene product neurofibromin is a member of the GTPase activating family of proteins. The disorder has a wide range of manifestations, the most constant of which are focal areas of hyperpigmentation (*café au lait* spots), multiple neurofibromas, and Lisch nodules on the iris. Six or more *café au lait* spots are necessary for them to be considered abnormal. Axillary and inguinal freckling is frequent. The cutaneous fibromas are of varying dimensions and can be extremely numerous. At times, giant plexiform neuromas develop in which there is extensive subcutaneous overgrowth of neurofibromatous tissue. Massive mediastinal, pelvic, or retroabdominal plexiform neurofibromas can occur, as well as cervical paraspinal tumours and astrocytomas of the optic nerve,

cerebellum, or brainstem. Malignant change occurs in a small proportion of peripheral neurofibromas. Mental retardation due to diffuse cortical dysgenesis is encountered in at least 10 per cent of patients. Other manifestations include congenital glaucoma, phaeochromocytoma, spinal deformity, pathological fractures of limb bones with malunion and pseudoarthrosis, and local gigantism of a limb. The neurofibromas are composed of proliferated Schwann cells and fibroblasts in a collagenous matrix through which course nerve fibres in an irregular manner.

Most cases of neurofibromatosis type 1 require no treatment. Neurofibromas causing pressure symptoms may necessitate excision and others may merit removal for cosmetic reasons. Rapid expansion of a tumour, the development of pain, and loss of neural function, will suggest malignant change. This most often occurs during adolescence or in young adults. The development of hypertension will require investigation for phaeochromocytoma, and spinal deformity may need orthopaedic attention.

The gene for neurofibromatosis type 2 (central neurofibromatosis) has been mapped to chromosome 22q12.2. The gene product merlin has homology with proteins at the plasma membrane/cytoskeleton interface. This disorder is characterized in particular by bilateral acoustic neurinomas (Fig. 1) but tumours may occur on other cranial nerves or spinal roots and also paraspinally. Meningiomas and gliomas may develop. A further feature is the occurrence of juvenile posterior subcapsular lenticular opacities.

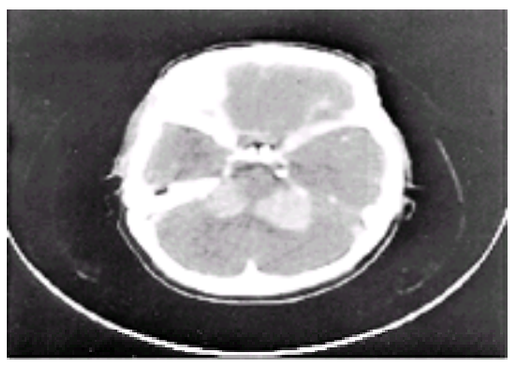

Fig. 1 Computed tomography scan showing bilateral acoustic neurinomas in a patient with neurofibromatosis type 2. She also had an astrocytoma of the thoracic spinal cord.

Segmental neurofibromatosis affecting a restricted area of the body may be due to somatic mutation.

Tuberous sclerosis (Bourneville's disease, epiloia)

The features of this condition are mental retardation, infantile spasms, epilepsy, and the occurrence of retinal hamartomata and characteristic skin lesions. The disorder is dominantly inherited, but may be transmitted by individuals who are asymptomatic and who show only minimal clinical evidence of the disease. Isolated cases are frequent, comprising as many as 80 or 90 per cent of index cases. Many of them probably represent new mutations: others are transmitted by gene carriers with trivial manifestations. Genetic heterogeneity has now been established, with separate loci on chromosomes 9q34 (*TSC1*) and 16p13.3 (*TSC2*). The gene *TSC2*, which has a more severe phenotype, has been identified and its product, called tuberin, has the structure of a GTPase activating protein.

The earliest cutaneous lesions are irregular foliate areas of depigmentation over the trunk. These patches are readily identified when viewed under ultraviolet illumination using a Woods lamp. Facial angiofibromas ('adenoma sebaceum') are a second type of skin lesion which develop over the cheeks in a 'butterfly' distribution and on the forehead (Fig. 2) with multiple small warty elevations. Finally, a 'shagreen patch' may be present over the lower back. This consists of an area of elevated roughened skin with a yellowish tinge which has been likened to shark skin.

Fig. 2 Adenoma sebaceum in a patient with tuberous sclerosis.

The cerebral changes give rise to mental retardation which is evident in early life and which may be static or involve a slowly progressive cognitive decline, often complicated by behavioural disorder. Infantile spasms or epilepsy with recurrent generalized or focal seizures may occur in association with mental retardation or in individuals of normal intelligence. The cerebral lesions, which are demonstrable by computed tomography or magnetic resonance imaging, are typified by nodular or tuberous masses composed of proliferated glial cells and enlarged distorted neurones. They may become calcified. They are found scattered throughout the cerebral cortex and also extend into the ventricles to produce an appearance that was considered to resemble 'candle guttering' when seen in pneumoencephalograms. Gliomas sometimes arise in these lesions.

Retinal tumours, termed phakomas, may be present, and cardiac rhabdomyomas occasionally arise as well as hamartomas of the lungs and kidneys. Polycystic disease of the kidneys may also be associated.

Treatment consists of control of the epilepsy and the management of the mental retardation and behavioural disorder. Many of the more severe cases require institutionalization.

Cerebelloretinal haemangioblastosis (von Hippel–Lindau disease)

This condition comprises the occurrence of vascular tumours in the retina and within the central nervous system, most commonly in the cerebellum and spinal cord. The inheritance is autosomal dominant in pattern. The disorder maps to chromosome 3p25–26.

The retinal lesions consist of angiomatous vascular malformations. The cerebellar lesion is a haemangioblastoma, often cystic, which may slowly expand and present with features of a cerebellar tumour. It may require surgical treatment. Such tumours may be associated with polycythaemia, related to the production of erythropoietin or a similar substance by the tumour. Haemangioblastomas may occur in the spinal cord and rarely in the cerebral hemispheres, as may renal cell tumours and renal and pancreatic cysts. Regular screening for renal tumours in patients and relatives at risk is an important aspect of management.

Ataxia telangiectasia (Louis–Bar syndrome)

The inclusion of this disorder with the neurocutaneous syndromes depends upon the coincidence of a progressive cerebellar degeneration with cutaneous vascular lesions. The inheritance is of autosomal recessive type and the gene is localized on chromosome 11q22.3–q23.1. Ataxia begins in early childhood and choreoathetosis and oculomotor apraxia appear later. Telangiectasia of the conjunctivae is present as a relatively early feature and later becomes evident in the pinnae, over the face, and in the limb flexures. Some patients show an immunoglobulin deficiency and recurrent infections, or the development of malignancies may complicate the clinical picture. Defective DNA repair after irradiation with X-rays is demonstrable in cultured skin fibroblasts. Affected children usually become unable to walk by the age of 12 years and death occurs during the second or sometimes the third decade of life.

Hereditary myoclonic epilepsies (see alsoChapter 24.10)

A number of conditions exist in which generalized epileptic seizures and myoclonus are associated with a progressive degenerative neurological disorder occurring on a genetic basis.

Lafora body disease

This is the most clearly defined form of progressive myoclonic epilepsy. It consists of a combination of major seizures, myoclonus, and progressive dementia with an onset in late childhood or early adolescence, with death usually occurring before adult life is reached. Cerebellar signs may appear later in the illness. The condition is characterized by the presence of intracellular inclusion bodies found most consistently in neurones of the cerebral cortex and in the cerebellar dentate nuclei. They are also detectable in the liver, axillary sweat gland, and in skeletal muscles, all of which are convenient sites for biopsy in order to establish the diagnosis. These Lafora bodies are composed of a polyglucosan. The disorder is caused by an autosomal recessive gene, mapping to 6q23–25. Treatment is directed towards control of the epilepsy.

Progressive myoclonic ataxia (Ramsay Hunt syndrome)

This is a heterogeneous group, the best characterized form being Unverricht–Lundborg disease or 'Baltic myoclonus'. Stimulus-sensitive myoclonus develops from the age of 6 to 15 years, associated with mild mental retardation, followed later by dysarthria and ataxia. The disorder is of autosomal dominant inheritance. The gene maps to chromosome 21q22.3 and encodes for cystatin B, a cysteine protease inhibitor.

Mitochondrial encephalomyopathy

Myoclonus and ataxia, along with other features, may occur in mitochondrial disorders.

Sialidosis

The cherry-red spot–myoclonus syndrome consists of two autosomal recessive disorders (types I and II) with an onset in late childhood, adolescence, or early adult life that combine action myoclonus with mental retardation, ataxia, cherry-red spots at the maculae, and cataracts. Both types I and II are related to a deficiency of sialidase. Type II is associated with dysmorphic features.

The myoclonus in these inherited disorders may respond to combination treatment with clonazepam and piracetam.

Hereditary spinal muscular atrophies

The hereditary spinal muscular atrophies constitute a group of disorders that involve a selective degeneration of anterior horn cells and sometimes also of the motor nuclei of the lower cranial nerves. They can be classified in terms of the pattern of involvement and the age of onset. Only the more common varieties will be described.

Hereditary proximal spinal muscular atrophy

Acute infantile spinal muscular atrophy (Werdnig–Hoffmann disease) almost always begins within the first year of life. It may have a prenatal onset and is one cause of the 'rag doll' child syndrome of hypotonic muscle weakness in infancy. Progressive proximal muscular weakness and wasting, later becoming generalized and involving the bulbar musculature, usually leads to death before the age of 4 years. Cases with prolonged survival also occur (chronic childhood form). In hereditary juvenile proximal spinal muscular atrophy (Kugelberg–Welander disease) the onset is during childhood after the age of 2 years or as late as adolescence. The involvement of the proximal limb and trunk musculature mimics limb girdle muscular dystrophy, but fasciculation may be observed. The course is relatively benign, but progressive disability in adult life occurs in some cases; others remain relatively mildly affected. All three forms are of autosomal recessive inheritance and have been mapped to chromosome 5q12.2–q13.3. They appear to be due to allelic genes.

X-linked bulbospinal neuronopathy

This disorder, otherwise known as Kennedy's syndrome, consists of the development, commonly in the third or fourth decades, of progressive limb weakness and, later, a bulbar palsy. Contraction fasciculation of the facial muscles is usually present. Muscle cramps and upper limb postural tremor are often evident from early adult life. About 50 per cent of cases show gynaecomastia and some have diabetes mellitus. The disorder is due to a trinucleotide repeat expansion within the androgen receptor gene on the proximal long arm of the X chromosome at Xq21.3–q22.

Other miscellaneous disorders

A wide variety of other rare inherited conditions exist, of which the following deserve brief mention.

Hereditary optic neuropathy

Dominantly inherited juvenile optic neuropathy

This disorder gives rise to the insidious bilateral onset of optic atrophy during childhood with either mild or severe loss of vision. A central or centrocaecal scotoma may be detected. Electroretinography and visual evoked potentials demonstrate no loss of retinal receptors and suggest that the lesion affects retinal neuronal elements. There are no associated neurological abnormalities.

Leber's hereditary optic neuropathy

This disorder typically gives rise to acute or subacute bilateral visual loss in males between the ages of 18 and 30 years, although earlier and later ages of onset may be encountered. It may remain monocular for months or years. Initially there is enlargement of the blind spot and later this increases to involve central vision, producing a large centrocaecal scotoma. In the acute phase there is swelling in the nerve fibre layer around the optic disc with tortuous retinal arterioles and peripapillary telangiectasias. Later the disc becomes atrophic. In affected females the age of onset tends to be later and a multiple sclerosis-like syndrome may develop (Harding's syndrome). The disease is only transmitted by females and has recently been shown to be due to mutations of mitochondrial DNA.

Mucopolysaccharidoses (see also Section 11)

The mucopolysaccharidoses constitute a group of disorders related to deficiencies of specific lysosomal enzymes, involving an accumulation in various tissues of acid mucopolysaccharides and gangliosides, and the presence of mucopolysaccharides in the urine. In both the recessively inherited Hurler's syndrome and the X-linked recessive Hunter's syndrome, the skeletal and other manifestations may be accompanied by mental retardation and pigmentary retinal degeneration. Spastic weakness in the limbs may develop in Hurler's syndrome. Mental retardation is also seen in the recessively inherited Sanfilippo's syndrome. Entrapment neuropathies

are a feature in some forms, related to the skeletal changes.

Subacute necrotizing encephalopathy (Leigh's syndrome)

Typically this label is applicable to a fatal encephalopathy that develops during the first 2 years of life with variable combinations of mental retardation, seizures, optic atrophy, cerebellar ataxia, and central respiratory failure associated with lactic acidosis. Pathologically there are necrotic lesions in the brainstem and a prominence of small blood vessels. Haemorrhage does not occur. The distribution of the lesions bears some resemblance to Wernicke's encephalopathy. Later onset cases with similar pathological changes occur. The disorder is genetically heterogeneous **,** but may be related to mutations in mitochondrial DNA leading to a deficiency of cytochrome oxidase. Pyruvate dehydrogenase and pyruvate decarboxylase deficiency may also be responsible.

Progressive neuronal degeneration of childhood with liver disease (Alpers–Huttenlocher syndrome)

This disorder, which is probably of autosomal recessive inheritance, begins at 3 to 15 months of age with developmental delay and failure to thrive. Recurrent vomiting and hypotonia are common, followed by intractable seizures. Death occurs at 10 to 90 months. Pathologically there is extensive neuronal loss and astrocytosis, particularly in the cerebral cortex, and fatty degeneration, cell loss, and fibrosis in the liver. An unidentified biochemical defect is assumed.

Infantile neuroaxonal dystrophy (Seitelberger's disease)

This is a rare, probably recessive condition that develops between the ages of 1 and 3 years and gives rise to progressive motor weakness from both upper and lower motor neurone deficits. It maps to chromosome 22q13–qter. Optic atrophy also occurs and death usually ensues before the end of the first decade. Degenerative changes are present in the brain and the spinal cord, the most striking feature of which is the occurrence of large axonal swellings in the grey matter of the brain and spinal cord.

Menkes' syndrome ('kinky' or 'steely' hair)

Menkes' syndrome is an X-linked recessive disorder in which developmental regression begins within a few months of birth. The gene locus is at Xq12–q13. Muscle hypotonus or hypertonus and seizures appear and are associated with abnormal hair. The scalp hair is sparse, stubbly, and greyish in colour. When examined under magnification, the hairs are seen to be twisted and display partial breaks. The serum copper and caeruloplasmin levels are low and the condition probably results from defective absorption of copper from the gut. Prenatal diagnosis is possible.

Lesch–Nyhan syndrome

This is an X-linked recessive disorder (see also Chapter 24.10 and Section 11) related to the absence of an enzyme of purine metabolism, hypoxanthine–guanine phosphoribosyl transferase. It maps to chromosome Xq25–q27.2. The salient features are overproduction of uric acid and consequent hyperuricaemia which are associated with various behavioural and neurological manifestations, including mental retardation, self-mutilation, choreoathetosis, pyramidal signs, and spasticity in the limbs. The neurological abnormalities develop in childhood and death usually occurs in the second or third decade from renal failure. Allopurinol may reduce some of the non-neurological consequences of the hyperuricaemia, but no treatment influences the neurological abnormalities, the mechanism of which is not understood. Prenatal diagnosis and carrier detection are available.

Cockayne's syndrome

This is of autosomal recessive inheritance and consists of the development in childhood of dwarfism, microcephaly, progeria, mental retardation, cataract, pigmentary retinopathy, and ataxia. There is cutaneous sensitivity to ultraviolet light. The cerebral changes are those of a leucodystrophy. A demyelinating neuropathy coexists.

24.6.2 Neurogenetics

Nicholas Wood

Introduction

There has been dramatic improvement in our understanding of inherited neurological disease. It is clearly impossible to be comprehensive here, and a few examples have been chosen to illustrate some of these major developments. The genetics of movement disorders, especially Huntington's disease, are discussed in the context of identified genes causing neurological disease. However, the greatest challenge of the next few years will be to identify the genetic factors and environmental interactions involved in complex disorders such as Parkinson's disease.

Table 1 shows a much wider range of disorders. The rapid progress in this area, however, means that it cannot be comprehensive or up to date and current research publications should be consulted for the latest information.

Huntington's disease

This is one of the most common hereditary movement disorders with a prevalence of approximately 1 in 20 000. Onset is usually between the fourth and sixth decades, but onset in childhood and old age can also be seen. The initial mental and cognitive signs may be very subtle and progress insidiously. Family members often report a change in personality, a coarsening of sensitivities, and the expression of new, often antisocial, behaviours. Usually in parallel, but often not even noticed by the relatives, is the onset of choreic movements. These may start as a slight fidgetiness before semi-purposeful jerky movements develop.

As the disease progresses, dementia becomes more pronounced and the chorea more extreme; this may eventually upset balance and resemble an ataxic disorder. Finally, immobility occurs. The mean time from onset to death is approximately 15 years.

Huntington's disease may present with a parkinsonian syndrome and occasionally epilepsy, especially if the onset is early (under 20 years). Later onset may produce a predominant choreic illness with little cognitive disturbance. Before the identification of the gene it had been noted that age of onset and decreased severity increased in successive generations. This 'anticipation' was initially ascribed to bias but there is now a molecular explanation, which is discussed below.

There is no disease-modifying treatment currently available, but controlled trials are now being undertaken. These are largely based on findings from transgenic animals. Choreic movements may be controlled by sulpiride or tetrabenazine, but often patients prefer chorea to the parkinsonism that can result from this medication. Psychiatric disturbances should be treated as appropriate.

Genetics

The disease is autosomal dominant and therefore offspring are at a 50 per cent risk of inheriting the mutant allele. It is highly penetrant and very seldom are gene carriers ultimately unaffected. The gene was cloned in 1993 and was shown to be due to an expanded CAG repeat in exon 1 of a novel gene, subsequently called Huntingtin. The role of the protein is still unknown but progress has been made in evaluating the role of this abnormal CAG triplet repeat. This is in part because the same mutation is found in a group of neurodegenerative diseases (see Table 2). These diseases not only differ in their clinical features but the genes and proteins have very little in common other than this abnormal repeat. The codon CAG encodes glutamine and the term polyglutamine disorders has been coined. All the CAG repeat disorders so far described are the result of a relatively modest expansion within the coding region of the affected gene. Although the exact number of repeats on both the normal and the abnormal allele varies between the different diseases, the normal range of repeats is in the 20s, whereas for the disease-carrying allele, it tends to be over 40. All of these diseases are predominantly adult-onset neurodegenerative disorders, and most show evidence of anticipation. This is particularly seen with paternal transmission. The exact function of the polyglutamine tract remains unknown, but the repeat length is a major determinant of age of onset and probably also partly determines severity. Recent transgenic animal and cell culture studies strongly support the hypothesis of a gain of function for the allele harbouring the CAG expansion. It is unknown how the neuronal specificity of this disorder is brought about as both wild-type and mutant proteins are widely expressed. Moreover, the common link between an expanded polyglutamine tract and toxicity is unknown. There are at least 14 other proteins that interact with Huntingtin. An insight into the toxic pathway has emerged recently since mice transgenic for exon 1 of the human Huntingtin gene carrying over 100 CAG repeats developed abundant intranuclear inclusions. These pathological changes predated the neurological phenotype. Similar findings are reported in several of the other CAG repeat disorders. Identification of a common downstream pathway which could be manipulated by inhibitory drugs might offer the hope of improving the outcome from these disorders.

Dentatorubropallidoluysian atrophy

This is a dominant disorder reported mainly in Japanese families but is found worldwide. It has a variable phenotype including various combinations of ataxia, dystonia, myoclonus, other types of seizure, dementia, and parkinsonism. It may also closely resemble Huntington's disease. Onset ranges from late childhood to late adult life. The pathological features are incorporated in the name of the disease. This disorder was mapped to chromosome 12p in Japan, and the disease mutation is another expanded CAG repeat. The same mutation has now been described in other populations, but the disease is much less frequent than Huntington's disease outside Japan.

Parkinson's disease

There are several akinetic rigid syndromes with a clearly defined genetic basis (see Table 3). Many are of childhood onset and have additional neurological features. Nevertheless, as the table illustrates, there is a growing list of adult-onset disorders in which parkinsonism may be the presenting feature, in many cases the diagnosis can be confirmed by DNA testing techniques. However, these disorders account for only a small minority of cases of adult-onset parkinsonism, and in the remainder the role of genetic factors is less clear-cut.

Parkinson's disease is a common neurodegenerative disorder among the elderly. In Europe the overall age-standardized prevalence for Parkinson's disease in subjects of 55 years or older is 1.6 per 100, with an increasing frequency up to 4.3 per cent in those aged 85 years and over. Despite intensive efforts, the cause of Parkinson's disease remains largely unknown and treatment is symptomatic with only temporary results. However, there is increasing evidence that genetic factors play an important role in the aetiology of Parkinson's disease. Familial clustering of Parkinson's disease has been reported in many studies. Classic linkage and positional cloning strategies have identified a number of genes and loci responsible for mendelian Parkinson's disease (see Table 3). The a-synuclein gene was the first identified gene in autosomal dominant Parkinson's disease. Since then, a mutation in UCH-L1 and two loci 2p13 and 4p14–16.3 have been implicated in

autosomal dominantly inherited Parkinson's disease.

Juvenile Parkinson's disease

This condition differs from Parkinson's disease not only in the age of onset, but also the classic triad of signs (bradykinesia, rigidity, and tremor) is relatively mild, whereas there is more prominent dystonia, postural instability, and hyperreflexia. Additional features include: (i) early onset, typically before the age of 40; (ii) dystonia at onset; (iii) diurnal fluctuations; (iv) slow disease progression; and (v) early and severe levodopa-induced dyskinesias. A gene for autosomal recessive juvenile Parkinson's disease has recently been linked to chromosome 6q25.2–27 and designated *PARK2*. Pathological examination has shown a massive loss of dopaminergic neurones in the pars compacta of the substantia nigra, in the absence of Lewy bodies, the histopathological hallmark of classic Parkinson's disease. A novel gene designated parkin, in which homozygous exon deletions were detected in four Japanese families with autosomal recessive juvenile Parkinson's disease, has been described. The parkin protein is composed of 465 amino acids, shows moderate homology to ubiquitin at the amino terminus, and contains a RING-finger motif at the carboxy terminus, and it has been shown that it has ubiquitin ligase activity. Subsequently, it has been shown that among the patients with isolated Parkinson's disease, mutations were detected in 77 per cent with onset at 20 years or earlier, but they were much more rare in later onset disease accounting for 3 per cent with onset at over 30 years. Multiple mutations have now been described in this gene and it is numerically the most important locus hitherto described for Parkinson's disease.

Very recently two other autosomal recessive loci have been identified (PARK6 and 7).

Other parkinsonian syndromes

There are a number of syndromes incorporating both parkinsonism and additional features. These are summarized in Table 3. Some of the more recent developments are discussed in more detail here.

Chromosome 17-linked tauopathies

There are a number of diseases consisting of parkinsonism complicated by a variety of features, especially cognitive impairment, see Table 3. Recently the genetic mechanisms underlying chromosome 17-linked parkinsonism dementia have been defined. Mutations of the *tau* exon 10 splice site and coding mutations in *tau* have been described which are predicted to lead to an increase in the transcription of four repeat tau isoforms or a disruption of microtubule binding, respectively. This is consistent with the predominant deposition of four repeat tau isoforms in these types of neurodegeneration.

Other tauopathies

Progressive supranuclear palsy and corticobasal degeneration

Progressive supranuclear palsy is a neurodegenerative condition which affects the brainstem and basal ganglia. It is frequently misdiagnosed, most commonly as Parkinson's disease. Patients present with disturbance of balance, a disorder of vertical gaze, and parkinsonism not resposive to levodopa. They usually develop progressive dysphagia and dysarthria leading to death from the complications of immobility and aspiration. Its prevalence is estimated at 1.4 per 100 000 with a median survival of 9 years, but a pathological study showed that 20 per cent of clinically diagnosed cases of Parkinson's disease had alternative pathological diagnoses and progressive supranuclear palsy accounted for about 6 per cent. Treatment for progressive supranuclear palsy remains largely supportive.

Progressive supranuclear palsy is also a tauopathy characterized by deposition of the four-repeat isoform of tau. Analysis of sporadic cases of progressive supranuclear palsy has demonstrated that one allele (A0) of an intronic polymorphism within the *tau* gene occurs more frequently in patients with progressive supranuclear palsy than controls. It appears that this allele increases the risk of developing progressive supranuclear palsy, but is in itself neither necessary nor sufficient to cause the disease. Interestingly this allele (Ao) and its associate haplotype (H1) is also known to be associated with increased risk of developing corticobasal degeneration, another tauopathy. The link between a genetic predisposition to progressive supranuclear palsy and the differential isoform expression of the *tau* gene may be the key to explaining the pathogenesis of these conditions.

Dystonias

Primary torsion dystonia is a clinically and genetically heterogeneous movement disorder. It is characterized by involuntary muscle spasms causing twisting and repetitive movements and postures, and is distinguished from secondary dystonia by the absence of causative exogenous factors (such as drugs, trauma) or other neurological disorders.

Early-onset dystonia (before 28 years) is the most severe and common form of hereditary primary torsion dystonia. It usually begins in a limb and spreads to other limbs within a few years, usually sparing craniocervical muscles. Most cases of early-onset dystonia are caused by an autosomal dominant gene with reduced penetrance (*DYT1*), on human chromosome 9q34. The *DYT1*-associated phenotype is similar in all ethnic communities, with highest prevalence in the Ashkenazi Jewish population. Recently, a 3-base pair (GAG) deletion in the coding sequence of the *DYT1* gene was found in all affected individuals and obligate gene carriers with 9q34-linked primary torsion dystonia, both in the Jewish and non-Jewish populations. About two-thirds of patients with early-onset dystonia carry the *DYT1* 3-base pair deletion. *De novo* GAG deletions in the *DYT1* gene can also occur rarely.

Dopa-responsive dystonia

In classic cases, the disease manifests in early childhood with walking difficulties due to dystonia of the lower limbs. Some 'parkinsonian' features such as reduced facial expression or slowing of fine finger movements frequently accompany the dystonia. Although rare, patients respond very well to small doses of levodopa without the later motor fluctuations seen in Parkinson's disease, suggesting that dopamine biosynthesis may be disturbed. This has implicated the biochemical pathway producing dopamine. Two different genes have been implicated in this disorder, both of which disrupt dopamine production. Most commonly, heterozygote mutations of the GTP cyclohydrolase I gene are found. This is the rate-limiting enzyme in the synthesis of tetrahydrobiopterin. Tetrahydrobiopterin is an essential cofactor for tyrosine hydroxylase, the rate-limiting enzyme in the synthesis of dopamine. Reduced levels of tetrahydrobiopterin lead to the dopamine-deficit syndrome, dopa-responsive dystonia, because of reduced tyrosine hydroxylase activity. The second, much less common, genetic abnormality is due to recessive mutations in tyrosine hydroxylase itself.

Other genes associated with dystonic syndromes are summarized in Table 1.

Paroxysmal movement disorders

Paroxysmal dyskinesias are rare movement disorders that are currently classified into three groups: paroxysmal non-kinesigenic dyskinesia, paroxysmal kinesigenic dyskinesia, and paroxysmal exercise-induced dyskinesia.

Paroxysmal non-kinesigenic dyskinesia (formerly termed paroxysmal dystonic choreoathetosis) is distinguished by attacks, mainly choreoathetotic, lasting from 5 min to 4 h, which are usually precipitated by alcohol, fatigue, coffee, tea, or excitement, but not by sudden movement. Between attacks, neurological examination is usually normal. This disorder is usually inherited in an autosomal dominant fashion, and sporadic cases are rare. It has been linked to a 4 cM area on chromosome 2q33–35, but the responsible gene has not yet been identified.

In paroxysmal kinesigenic dyskinesia, typically the paroxysms consist of dystonic posturing and choreoathetotic or ballistic movements. All attacks are brief (usually less than 2 min) and are precipitated by sudden movements. Frequency may be as high as 100 attacks each day. Patients with this disorder usually respond to anticonvulsants. Linkage of this disorder to chromosome 16 has recently been described, but no genes have yet been cloned.

In paroxysmal exercise-induced dyskinesia, attacks are mainly dystonic and in most cases predominantly involve the legs. They are precipitated by exercise and are not brought on by sudden movements. Response to medication is generally poor. Recently, a novel autosomal recessive syndrome characterized by rolandic epilepsy, paroxysmal exercise-induced dyskinesia, and writer's cramp has been linked to a region on chromosome 16. There appears to be at least two genes causing

paroxysmal movement disorders on chromosome 16.

These disorders with their overlap with other paroxysmal movement disorders, epilepsy, and some response to anticonvulsant medication implicate an ion channel disorder.

The ataxias

The clinical features of the inherited ataxias are described in Chapter 24.6.1. Inherited ataxic disorders can be divided according to their mode of inheritance. Most autosomal recessive disorders are of early onset (less than 20 years), and autosomal dominant disorders are usually of later onset (over 20 years). X-linked inheritance of ataxia is exceedingly rare.

Autosomal recessive ataxias

Friedreich's ataxia

Friedreich's ataxia is the most common of the autosomal recessive ataxias and accounts for at least 50 per cent of cases of hereditary ataxia in most large series reported from Europe and the United States. The prevalence of the disease in these regions is similar, between 1 and 2 per 100 000.

Cloning of the gene showed that the predominant mutation was a trinucleotide repeat (GAA) in intron 1. Expansion of both alleles was found in over 96 per cent of patients and the remaining alleles carry point mutations. To date no cases have been reported of two point mutations in a singe case, therefore the absence of a least one expansion is very strong evidence against the diagnosis of Friedreich's ataxia. This has permitted the introduction of a specific and sensitive diagnostic test, as it is a relatively simple matter to measure the repeat size. On normal chromosomes the number of GAA repeats varies from 7 to 22 units, whereas on disease chromosomes, the range is anything from around 100 to 2000 repeats. The number of repeats is a determinant of age of onset and therefore to some degree influences the severity.

The exact mechanism of action of this repeat in intron 1 is not known, but it is possible that this huge expansion disrupts normal splicesome binding and therefore exon 1 is not spliced correctly to exon 2. This results in a reduction in mRNA and protein levels accordingly.

Other autosomal recessive ataxias

The other early-onset ataxias listed in Table 4 are rare.

Autosomal dominant cerebellar ataxias

The autosomal dominant cerebellar ataxias are a clinically and genetically complex group of neurodegenerative disorders divided into three types (see Chapter 24.6.1). Type I is characterized by a progressive cerebellar ataxia and is variably associated with other extracerebellar neurological features such as ophthalmoplegia, optic atrophy, peripheral neuropathy, and pyramidal and extrapyramidal signs. The presence and severity of these signs is, in part, dependent on the duration of the disease. Mild or moderate dementia may occur, but it is usually not a prominent early feature. Type II is clinically distinguished from type I by the presence of pigmentary macular dystrophy, whereas type III is a relatively 'pure' cerebellar syndrome and generally starts at a later age. This clinical classification is still useful, despite the tremendous improvements in our understanding of the genetic basis, because it provides a framework which can be used in the clinic and helps direct the genetic evaluation.

Molecular genetics of the autosomal dominant cerebellar ataxias

The classification of the autosomal dominant cerebellar ataxias is potentially confusing. The progress in our understanding of the genes and mutations has led to an additional classification system, but luckily there are many common features between these disorders. The first autosomal dominant cerebellar ataxia to be linked (to chromosome 6p) was labelled spinocerebellar ataxia type 1 (**SCA1**). Thereafter, each new locus was given a subsequent SCA number; SCA2 to chromosome 12q, and so on. At the time of writing there are currently 13 SCA loci. Of these, mutations have been identified definitively for SCA 1, 2, 3, 6, 7, and 12. SCA 12 has only been described in two families to date. The others have all been described in many different populations. They are all caused by an expansion of an exonic CAG repeat. The resultant proteins all possess an expanded polyglutamine tract and there are now at least eight conditions caused by these expansions. This common mutational scheme is discussed above with reference to Huntington's disease.

Autosomal dominant periodic ataxia

Autosomal dominant periodic ataxia is characterized by the childhood or adolescent onset of attacks of ataxia, dysarthria, vertigo, and nystagmus. Not all patients have affected relatives. There are at least two forms of this disorder.

Episodic ataxia type 1

The attacks tend to be relatively brief (minutes and occasionally hours) and clinically and electrophysiologically myokymia may be seen. Mutations in a potassium channel have been found. These patients may benefit from acetazolamide, and phenytoin has also been reported to be useful. Patients tend to be neurologically normal between the attacks.

Episodic ataxia type 2

The attacks tend to be longer, lasting hours or even days. They are usually associated with vertigo and consequent nausea and vomiting. They tend to be more severe in childhood with associated drowsiness, headache, and fever. Although when the disease first begins the patients are well between attacks, an interictal nystagmus can be seen. As the years pass, a slowly progressive ataxia is seen. MRI may reveal cerebellar atrophy. These patients tend to respond better to acetazolamide therapy than patients with episodic ataxia type 1. Mutations in a calcium channel gene on chromosome 19q have been demonstrated. Other mutations in this gene have been described in families with familial hemiplegic migraine and a form of dominant ataxia (SCA6), that is, they are allelic.

24.7 Lumbar puncture

Robert A. Fishman

Indications

Lumbar puncture should be performed only after clinical evaluation of the patient and consideration of the potential value and hazards of the procedure. The cerebrospinal fluid findings are important in the differential diagnosis of the gamut of central nervous system infections, meningitis, and encephalitis, as well as subarachnoid haemorrhage, confusional states, acute stroke, status epilepticus, meningeal malignancies, demyelinating diseases, and central nervous system vasculitis. Examination of the cerebrospinal fluid is usually necessary in patients with suspected intracranial bleeding to establish the diagnosis, although computed tomography (**CT**), when available, may be more valuable. For example, primary intracerebral haemorrhage or post-traumatic haemorrhage is often readily observed with CT making lumbar puncture an unnecessary hazard. However, in primary subarachnoid haemorrhage lumbar puncture may establish the diagnosis when CT is falsely negative. Lumbar puncture is useful to ascertain that the cerebrospinal fluid is free of blood before anticoagulant therapy for stroke is begun. (However, extensive subarachnoid bleeding is a rare complication of heparin anticoagulation, begun several hours after a traumatic bloody tap. Therefore heparin therapy should not begin for at least an hour after a bloody tap.) Lumbar puncture has limited therapeutic usefulness, for example in intrathecal therapy in meningeal malignancies and fungal meningitis.

Contraindications

Lumbar puncture is contraindicated in the presence of infection in the skin overlying the spine. A serious complication of lumbar puncture is the possibility of aggravating a pre-existing, often unrecognized, brain herniation syndrome (for example uncal, cerebellar, or cingulate herniation) associated with intracranial hypertension. This hazard is the basis for considering papilloedema to be a relative contraindication to lumbar puncture. The availability of CT has simplified the management of patients with papilloedema. If CT reveals no evidence of a mass lesion, then lumbar puncture is usually needed in the presence of papilloedema to establish the diagnosis of pseudotumour cerebri and to exclude meningeal inflammation or malignancy.

Thrombocytopenia and other bleeding diatheses predispose patients to needle induced subarachnoid, subdural, and epidural haemorrhage. Lumbar puncture should be undertaken only if urgently needed when the platelet count is depressed to about 50 000/µl or below. Platelet transfusion just before the puncture is recommended if the count is below 20 000/µl or dropping rapidly. The administration of protamine to patients on heparin and vitamin K or fresh frozen plasma to those receiving warfarin is recommended before lumbar puncture to minimize the hazard of the procedure.

Complications

Complications of lumbar puncture include worsening of brain herniation and spinal cord compression, headache, subarachnoid bleeding, diplopia, backache, and radicular symptoms. Post-lumbar puncture headache is the most common complication, occurring in about 25 per cent of patients and usually lasting 2 to 8 days. It results from low cerebrospinal fluid pressures due to persistent fluid leakage through the dural hole. Characteristically, pain is present in the upright position and is promptly relieved with a supine position. Aching of the neck and low back is common. The headaches are aggravated by cough or strain and may be associated with nausea, vomiting, or tinnitus. They are less likely if a small syletted needle is used and if multiple puncture holes are not made. The management of post-spinal headache depends upon strict bedrest in the horizontal position, adequate hydration, and simple analgesics. If conservative measure fail, the use of a 'blood patch' is indicated. The technique utilizes the epidural injection of autologous blood close to site of the dural puncture to form a thrombotic tamponade which seals the dural hole.

Cerebrospinal fluid

The cerebrospinal fluid pressure should be measured routinely. The pressure level within the right atrium is the reference level with the patient horizontal in the lateral decubitus position. The normal lumbar cerebrospinal fluid pressure ranges between 50 and 200 mmH_2O (and as high as 250 mmH_2O in very obese subjects). With the use of the clinical manometer the arterially derived pulsatile pressures are obscured but respiratory pressure waves reflecting changes in central venous pressures are visible. Low pressures are seen in dehydration, spinal subarachnoid block, following previous lumbar puncture or other cerebrospinal fluid leaks, or may be technical in origin because of faulty needle placement. Increased pressures occur with brain oedema, intracranial mass lesions, infections, acute stroke, cerebral venous occlusions, congestive heart failure, pulmonary insufficiency, and benign intracranial hypertension (pseudotumour cerebri) of diverse aetiology.

Normal cerebrospinal fluid contains no more than five lymphocytes or mononuclear cells per microlitre. A higher white cell count is pathognomonic of disease in the central nervous system or meninges. A stained smear of the sediment is needed for an accurate differential cell count. A variety of centrifugal and sedimentation techniques have been used. A pleocytosis occurs with the gamut of inflammatory disorders. The changes characteristic of the various meningitides are listed in Table 1. The heterogeneous forms of neuro-AIDS also are associated with a wide range of cellular responses. Other disorders associated with a pleocytosis include brain infarction, subarachnoid bleeding, cerebral vasculitis, acute demyelination, and brain tumours. Eosinophilia most often accompanies parasitic infections, for example cysticercosis. Cytological studies for malignant cells are rewarding with some central nervous system neoplasms.

Bloody cerebrospinal fluid due to needle trauma contains increased numbers of white cells contributed by the blood. A useful approximation to a true white cell count can be obtained by the following correction for the presence of the added blood: if the patient has a normal haemogram, subtract from the total white cell count (WBC; per µl) one white cell for each 1000 red blood cells (RBC) present. Thus, if bloody fluid contains 10 000 red cells and 100 white cell/µl, ten white cells would be accounted for by the added blood and the corrected leucocyte count would be 90/µl. If the patient's haemogram reveals significant anaemia or leucocytosis, the following formula may be used to determine more accurately the number of white cells (W) in the spinal fluid before the blood was added:

$$W = \text{blood WBC} \times \text{cerebrospinal fluid RBC/blood RBC} \times 100.$$

The presence of blood in the subarachnoid space produces a secondary inflammatory response which leads to a disproportionate increase in the number of white cells. Following an acute subarachnoid haemorrhage, this elevation in the white cell count is most marked about 48 h after onset, when meningeal signs are most striking.

To correct cerebrospinal fluid protein values for the presence of added blood due to needle trauma, subtract 0.001 g for every 1000 red blood cells. Thus, if the red cell count is 10 000/µl and the total protein is 1.1 g/l the corrected protein level would be about 1 g/l. The corrections are reliable only if the cell count and total protein are both made on the same tube of fluid.

Blood in the cerebrospinal fluid: differential diagnosis and the three-tube test

To differentiate between a traumatic spinal puncture and pre-existing subarachnoid haemorrhage, the fluid should be collected in at least three separate tubes (the

'three-tube test'). In traumatic punctures, the fluid generally clears between the first and the third collections. This is detectable with the naked eye and should be confirmed by cell count. In subarachnoid bleeding, the blood is generally evenly admixed in the three tubes. A sample of the bloody fluid should be centrifuged and the supernatant fluid compared with tap water to exclude the presence of pigment. The supernatant fluid is crystal clear if the red cell count is less than about 100 000 cells/µl. With bloody contamination of greater magnitude, plasma proteins may be sufficient to cause minimal xanthochromia; this requires enough serum to raise the cerebrospinal fluid protein concentration to about 1.5 g/l.

Following subarachnoid haemorrhage, the supernatant fluid usually remains clear for 2 to 4 h and even longer after the onset of subarachnoid bleeding. The clear supernatant fluid may mislead the physician to conclude erroneously that the observed blood is due to needle trauma in patients who have had a lumbar puncture within 4 h of aneurysmal rupture. After an especially traumatic puncture, some blood and xanthochromia may be present for as long as 2 to 5 days following the initial puncture. In pathological states associated with a cerebrospinal fluid protein greater than 1.5 g/l, and in the absence of bleeding, very faint xanthochromia may be detected. When the protein is elevated to much higher levels, as in spinal block, polyneuritis, and meningitis, the xanthochromia may be considerable. A xanthochromic fluid with a normal protein level or a minor elevation to less than 1.5 g/l usually indicates a previous subarachnoid or intracerebral haemorrhage (rarely the xanthochromia is due to severe jaundice, carotenaemia, or rifampin).

Pigments

Two major pigments derived from red cells may be observed in cerebrospinal fluid—oxyhaemoglobin and bilirubin. Methaemoglobin is only seen spectrophotometrically. Oxyhaemoglobin, released with lysis of red cells, may be detected in the supernatant fluid within 2 h of a subarachnoid hemorrhage. It reaches a maximum in about the first 36 h and gradually disappears over the next 7 to 10 days. Bilirubin, is produced *in vivo* by leptomeningeal cells following red cell haemolysis. Bilirubin is first detected about 10 h after the onset of subarachnoid bleeding. It reaches a maximum at 48 h and may persist for 2 to 4 weeks after extensive bleeding. The severity of the meningeal signs associated with subarachnoid bleeding correlates with the inflammatory response, i.e. the leucocytic pleocytosis.

Total protein

The total protein level of cerebrospinal fluid ranges between 1.5 and 5 g/l. While an elevated protein level lacks specificity, it is an index of neurological disease reflecting a pathological increase in the permeability of endothelial cells. Greatly increased protein levels, 5 g/l and above, are seen in meningitis, bloody fluids, or cord tumour with spinal block. Polyneuritis (Guillain Barre syndrome), diabetic radiculoneuropathy, and myxoedema may also increase the level to 1 to 3 g/l. Low protein levels, below 0.15 g/l, occur most often with cerebrospinal fluid leaks due to a previous lumbar puncture or traumatic dural fistula.

Immunoglobulins

Although a vast number of proteins may be measured in cerebrospinal fluid only an increase in immunoglobulins is of diagnostic importance. Such increases are indicative of an inflammatory response in the central nervous system and occur with immunological disorders, and bacterial, viral, spirochaetal, and fungal diseases. Immunoglobulin assays are most useful in the diagnosis of multiple sclerosis, other demyelinating diseases, and central nervous system vasculitis. The cerebrospinal fluid level is corrected for the entry of immunoglobulins from the serum by calculating the IgG index (see Table 1). More than one oligoclonal band in cerebrospinal fluid with gel electrophoresis (and absent in serum) is also abnormal, occurring in 90 per cent of multiple sclerosis cases and variably in the gamut of inflammatory diseases including central nervous system vasculitis.

Glucose

The concentration of glucose in cerebrospinal fluid is dependent upon the concentration in the blood. The normal range of glucose concentration in cerebrospinal fluid is between 2.5 and 4.5 mmol/l in patients with a blood glucose between 4 and 7 mmol/l, i.e. 60 to 80 per cent of the normal blood level. Cerebrospinal fluid glucose values between 2.2 and 2.5 mmol/l are usually abnormal, and values below 2.2 mmol/l invariably so. Hyperglycaemia during the 4 h prior to lumbar puncture results in a parallel increase in cerebrospinal fluid glucose. The latter approaches a maximum and the cerebrospinal fluid/blood ratio may be as low as 0.35 in the presence of a greatly elevated blood glucose level and in the absence of any neurological disease. An increase in cerebrospinal fluid glucose is of no diagnostic significance apart from reflecting hyperglycaemia within the 4 h prior to lumbar puncture. The cerebrospinal fluid glucose level is abnormally low (hypoglycorrhachia) in several diseases of the nervous system apart from hypoglycaemia. It is characteristic of acute purulent meningitis, and is a usual finding in tuberculous and fungal meningitis. It is usually normal in viral meningitis, although reduced in about 25 per cent of mumps cases, and in some cases of herpes simplex and zoster meningoencephalitis. The cerebrospinal fluid glucose is also reduced in other inflammatory meningitides including cysticercosis, amoebic meningitis (*Nagleria*), acute syphilitic meningitis, sarcoidosis, granulomatous arteritis, and other vasculitides. The glucose level is also reduced in the chemical meningitis that follows intrathecal injections, and in subarachnoid haemorrhage, usually 4 to 8 days after the bleed. The major factor responsible for the depressed glucose levels is increased anaerobic glycolysis in adjacent neural tissues and to a lesser degree by polymorphonuclear leucocytes. Thus, the decrease in the cerebrospinal fluid glucose level is accompanied by an inverse increase in the cerebrospinal fluid lactate level.

Microbiological and serological reactions

The use of appropriate stains and cultures is essential in cases of suspected infection. Tests for specific bacterial and fungal antigens (countercurrent immunoelectrophoresis) are useful in establishing a specific aetiology. DNA amplification techniques using the polymerase chain reaction have improved diagnostic sensitivity. Serological tests on cerebrospinal fluid for syphilis include the reagin antibody tests and specific treponemal antibody tests. The former are particularly useful in evaluating cerebrospinal fluid because positive results may occur even in the presence of a negative blood serology. There is no basis for applying the specific treponemal antibody tests to cerebrospinal fluid because these antibodies are derived from the plasma where they are present in greater concentration. The search continues for specific diagnostic markers in cerebrospinal fluid in the heterogeneous degenerative diseases of the central nervous system.

24.8 Disturbances of higher cerebral function

Peter Nestor and John R. Hodges

Introduction

Modern scientific study of higher cerebral function began in the late nineteenth century with the case studies of Broca and Wernicke. Their observations of language disorders associated with damage to the left hemisphere gave rise to the notion that specific mental faculties could be dissociated from each other and localized to specific regions within the cerebral hemisphere. Since that time clinicopathological and, more recently, imaging studies have established associations between specific cognitive disorders and focal brain lesions; these studies also show that some lesions do not give rise to highly specific deficits. The field of neuropsychology has offered complementary insights into this area by providing concepts of how cognitive faculties are organized.

The border between psychiatry and neurology has become less distinct; many patients with brain diseases have psychiatric symptoms, cognitive complaints are prominent in depression and schizophrenia, and a biological basis for many 'functional' psychiatric disorders is now well accepted.

Another critical area has been the study of anatomy: the finding that neocortical histology varies by region led to the development of cytoarchitectonic maps such as that of Brodmann. Brodmann's map has become a shorthand way of discussing regional specialization across the cortex. Meanwhile, anatomical studies of neural tracts have provided insights into how topographically distinct regions may interact.

Handedness and hemispheric dominance

The finding of asymmetric functions in the human cerebral cortex led to the introduction of the term hemispheric dominance. Neuroscientists often refer to cognitive processes being a function of the 'dominant' or 'non-dominant' hemisphere; when such terminology is used, the 'dominant' hemisphere is synonymous with that which underpins language function. In right handers, over 95 per cent have left hemisphere dominance: only rarely does aphasia arise from right hemisphere damage in which circumstance it is referred to as 'crossed aphasia'. In left handers, dominance is more complex and language skills are more often shared between the hemispheres although the left hemisphere is relatively dominant in about 70 per cent of individuals. While the left hemisphere usually specializes in language, the non-dominant hemisphere plays an important role in spatial cognition (with damage to the frontoparietal regions resulting in spatial neglect) and particularly in face processing (with damage to the right occipitotemporal junction producing prosopagnosia).

Primary sensory input and motor output

Motor

The primary motor area lies in the precentral gyrus, immediately rostral to the central sulcus. The body is represented 'somatotopically' along the precentral gyrus; the lower limb at the superomedial, and the face at the inferolateral extremity with the upper limb in between. This is of clinical importance as the vascular supply of the superomedial region is from the anterior cerebral artery whilst the rest of the motor cortex is from the middle cerebral artery. Thus middle cerebral artery territory infarction will affect face and upper limb with relative sparing of the lower limb, and the converse will be the case with anterior cerebral territory occlusions.

Vision

After passing from the retina, via optic nerves and tracts to the lateral geniculate body of the thalamus, visual information passes to the striate cortex of the occipital lobes (primary visual cortex) through the optic radiations (see Chapter 24.11). As images presented to the right visual field are represented on the left retina and conveyed to the left occipital lobe, a lesion of the latter will cause a right homonymous hemianopia (and vice versa for right occipital lesions). Fibres in each optic radiation separate such that input from the superior half of the retina (inferior visual field) runs from lateral geniculate to the striate cortex via parietal white matter whilst that from the inferior retina (superior visual field) loops down into the temporal lobe. Consequently, a lesion of the parietal lobe can cause a contralesional inferior quadrantanopic field defect whilst a temporal lobe lesion can cause a contralesional superior quadrantanopia. Large temporoparietal lesions (for example due to middle cerebral artery occlusion) may also cause homonymous hemianopia which may be distinguished from that due to an occipital lesion by preservation of opticokinetic nystagmus in the latter but not the former.

Bilateral lesions to the primary visual cortex lead to 'cortical blindness' in which vision is lost, but unlike blindness secondary to retinal or optic nerve diseases, pupillary reflexes are preserved. Some cortically blind individuals deny they have any visual disorder at all (namely visual anosagnosia)—a condition known as Anton's syndrome. These cases tend to have more extensive lesions involving both striate and adjacent visual association cortices.

Somatosensory

The primary somatosensory cortex occupies the post-central gyrus of the parietal lobe with a somatotopic representation of the body analogous to that of the primary motor area. Sensory deficits due to lesions of the thalamus, or lower components of the sensory system, cause gross abnormalities in the appreciation of touch, pinprick, temperature, and other sensations, and must be excluded before comment can be made on higher sensory function. Parietal lesions cause specific impairment of 'discriminative' sensation, including joint position sense and two-point discrimination. Parietal drift (the patient is asked, with eyes closed, to maintain the upper limbs outstretched in front of the trunk at 90°) is a sign of impairment of the former ability. It is considered specific for a contralateral parietal lesion when the drift is upward, as a downwards drift may also be a consequence of subtle motor weakness. The normal separation distance at which one can discriminate one point from two varies according to body region: fingertips 3 mm, palm 1 cm, and body surface 4 to 7 cm.

Other signs of parietal sensory impairment are an inability to name numbers traced on the palm of the hand (agraphaesthesia), and an inability to name small objects (such as keys and coins) placed in the patient's hand (astereognosis). Obviously there is potential to confuse true astereognosis with a more general deficit of object naming such as due to loss of semantic knowledge or aphasia (see below). However, ambiguous results on parietal sensory testing can largely be avoided if the examiner adopts a methodical approach of: (i) excluding a lesion below the parietal lobe by establishing that the patient can appreciate, for instance, a pinprick or light touch; and (ii) examining from the suspected normal to abnormal side to exclude a more general impairment of cognitive faculties.

Auditory

Auditory information coming from the cochlear nuclei via the inferior colliculus and the medial geniculate nucleus of the thalamus travels to the primary auditory cortex (Heschl's gyrus) in the posterosuperior temporal lobe. Clinically apparent cortical hearing impairment is uncommon due to the bilateral representation of auditory material from each ear by the cerebral cortex. Bilateral lesions of this area (as a result of strokes, prolonged hypotension, or carbon monoxide poisoning) will cause 'cortical deafness', a rare disorder manifest by inability to understand spoken language or recognize sounds although presence or absence of noise can be determined. Unlike Wernicke's aphasia (see below), subjects can understand written text and their language output is normal.

Cognitive domains

Beyond the primary sensory and motor cortices, the neocortex is made up of unimodal and heteromodal association areas. Unimodal association cortices lie adjacent to their respective primary modality while heteromodal association cortex is found in the prefrontal and temporoparietal regions. Moving from primary through unimodal to heteromodal association cortex, the linkage of topographical region to specific functional attribute becomes progressively less tightly defined. Heteromodal association cortices, as the name implies, receive inputs from multiple unimodal areas but also from non-neocortical areas. Anatomically, as the neocortex approaches the diencephalon, upon which the cerebral hemispheres sit, it transforms into a histologically distinct area: the limbic system. These areas also have critical roles in cognition, particularly in the domains of memory and emotion and have reciprocal projections with heteromodal association cortices.

Other brain regions which have important modulatory roles on cognition include: (i) the basal forebrain nuclei, which contain cholinergic neurones that project extensively to limbic and neocortical regions and are known to be important to the successful encoding of memory; (ii) the basal ganglia, which have reciprocal links to frontal association cortices and have important modulatory roles relating particularly to attention and speed of cognitive processing; and (iii) brainstem reticular formation nuclei which project into the hemispheres via the thalami: the most clearly defined role for these projections being at the level of arousal.

Although the remainder of this section discusses various disorders of higher mental function individually, one should not view these specific deficits as a random and independent collection of phenomena. It cannot be overemphasized that one should always follow a logical sequence in assessing cognitive function so as to avoid false-positive diagnoses due to sequential effects. For example, tests of executive function that utilize analysis of complex verbal material would be beyond the grasp of a patient with Wernicke's aphasia due to the fundamental disorder of language comprehension without needing to implicate frontal lobe damage. Likewise, a patient with an acute delirium may be unable to perform even the most basic memory tasks as a consequence of their attention deficit and therefore ought not to be labelled amnesic. Therefore, regardless of the suspected disorder, one should always bear the following sequence in mind: (i) ensure adequate attention to undergo further testing; (ii) as almost all tests are going to be presented with verbal instruction, assess language comprehension; and (iii) as tests of executive function and praxis often require adequate levels of function in all other cognitive domains, these should be left to last. In summary, always ask 'can this apparent disorder be explained in terms of a more elemental deficit?'

Attention

The ability to attend to a specific sensory stimulus, such as a human voice or passage of text, and to maintain attention is an obligatory first step to any further cognitive processing. Humans are continuously bombarded with sensory stimuli from both within and between individual sensory input modalities; loss of ability to focus and sustain attention (or alternatively, block out irrelevant 'noise') renders the individual incapable of following a specific sensory stimulus (such as a conversation) and at the same time vulnerable to random irrelevant environmental stimuli. Although disorders of the frontal lobes, basal ganglia, and ascending reticular formation are associated with poor attention, it is overly simplistic to consider attention as a localizable brain function. The commonest causes of acute attention failure are diffuse brain insults such as a metabolic encephalopathy or closed head injury; breakdown in attentional processing is the central deficit in delirium or acute confusional states, the main features of which are summarized in Table 1.

Digit span is one of the most simple methods of assessing attention, especially in the backwards condition; normal subjects have a forward span of at least six digits and a reverse span one or two digits less. The digits must be presented as individual items (read the string to be repeated at a rate of one digit per second). A common pitfall is to cluster digits as one does when reciting telephone numbers. This inflates span as each cluster becomes an individual item: compare repeating 6953–8127 with 6 … 9 … 5 … 3 … 8 … 1 … 2 … 7. Ability to persevere at a given task is another way of considering attention; this can be tested by asking the patient to recite the months of the year in reverse order.

Orientation is heavily dependent upon attention and is assessed by questions of time and place. Testing personal orientation adds little, as only profoundly aphasic or hysterical patients are unable to relate their own name. A recent onset of profound disorientation and attention deficit is typical of a delirium. It should be noted that many patients with episodic memory problems (such as early Alzheimer's disease) remain well orientated.

Language and related disorders

Numerous terms are in use to describe aphasic syndromes, although some serve more to confuse than enlighten. The terms 'expressive' and 'receptive' particularly seem to mislead: on the one hand all patients with aphasia have some form of difficulty 'expressing' themselves, and on the other hand 'receptive' aphasia is often, erroneously, taken to mean that patients have difficulty only with incoming language, but can produce their own language perfectly well. Less ambiguous terms for the two principal divisions of aphasia are 'non-fluent' and 'fluent', which correspond in classic aphasia nomenclature to Broca's and Wernicke's aphasia. The classic aphasia syndromes are, however, rarely seen in the acute stages after stroke and do not characterize the language deficits found in the dementias. A better approach is therefore to consider language fluency and paraphasias in spontaneous conversation, comprehension, naming, and repetition.

Examining patients with aphasia

Fluency and paraphasic errors

Speech can be described as fluent if the patient is able to produce some well-formed sentences or phrases even if empty or anomic (such as 'Oh you know, the thing you put the stuff in when you're going somewhere and …'). Non-fluent language, in contrast, is a consequence of breakdown of the language production and syntactic (grammatical) aspects of language and is the hallmark of damage to Broca's area and the insula. Output is laboured or 'telegraphic', with often as few as two or three words per minute; in spite of which they can convey meaning fairly successfully, for example 'I … go … hospital'.

Paraphasic errors are substitutions of a correct word for one related in sound or meaning. The former, known as phonological or phonemic paraphasias, involve the substitution of related sound fragments ('phonemes') such as 'dobble' for 'bottle'. Semantic paraphasic errors involve substitution of words of related meaning; the substituted word is typically a higher frequency example of the same semantic category (such as 'dog' for 'fox') or else of a superordinate category (such as 'animal' for 'fox'). In more extreme circumstances, paraphasic substitutions may not be words at all ('neologisms'); fluent output with virtually continuous neologisms is an utterly incomprehensible state sometimes referred to as jargon aphasia. Patients with lesions to Wernicke's area invariably make a mixture of phonemic and semantic errors. Semantic errors are also very common in Alzheimer's disease and semantic dementia. In Broca's aphasia, phonological errors predominate.

Comprehension

Some degree of impairment of language comprehension can be detected in both fluent and non-fluent aphasia. Patients with fluent aphasia have more overtly impaired comprehension of word meaning (for example ordinary nouns). In mild cases this can be demonstrated with semantically complex language tasks (such as 'Can you point to a source of artificial illumination?') or by defining uncommon words (such as 'What is an aubergine, accordion etc.'). Comprehension of single nouns is preserved in patients with non-fluent aphasia, but comprehension—in addition to production—of complex grammar is impaired. This can be tested with reversible passive sentences (such as 'The lion was eaten by the tiger, who survived?') or by asking the patient to obey syntactically complex commands (such as 'Touch the keys after touching the book').

Anomia

Naming is a complex task that requires the integrity of three basic processes: visual analysis, semantic knowledge (see Memory, below), and word production

(phonology). Virtually all patients with aphasia are anomic when tested using items of low familiarity and late age of acquisition. The type of naming error and the ability to circumvent the deficit varies, however, according to the locus of damage. Patients with visuoperceptive deficits that produce visual errors (a 'head' for a 'mushroom' etc.) have retained tactile naming and can give correct responses when asked to put a name to a description ('What do we call the large grey African animal with a trunk?').

A breakdown in the central semantic process causes impairment in naming from all modalities, while phonological deficits produce phonological errors regardless of the mode of input.

Repetition

Lesions involving any of the peri-Sylvian language structures are almost always associated with impaired repetition, although this may not be apparent unless multisyllabic words ('caterpillar', 'fundamental' etc.) and phrases ('no ifs, ands, or buts') are tested. Certain aphasic syndromes (see below) show either disproportionate impairment or preservation of repetition.

Aphasic syndromes

Broca's aphasia

This classic form of non-fluent aphasia is characterized by grossly distorted speech output with impaired production and comprehension of syntax. Phonological paraphasias are common and there is impaired repetition of phrases. It is associated with lesions to the left ventrolateral frontal lobe (Broca's area); owing to its close proximity to the motor cortex, when focal lesions (such as stroke or tumour) cause a Broca's aphasia it is typically associated with a right hemiparesis. The distortion of language output, often described as speech apraxia, is thought to relate to concurrent damage to structures within the insula, which is almost always affected.

Wernicke's aphasia

In Wernicke's aphasia there is fluent although vacuous output with a mixture of semantic and phonological paraphasic errors and often neologisms. There is also impaired comprehension of word meanings and impaired repetition. In contrast to the fundamental loss of word meaning seen in patients with semantic dementia and destruction of the left inferior temporal lobe after herpes simplex encephalitis, patients with Wernicke's aphasia have breakdown in the mapping between speech and meaning systems. Lesions localize to the posterior portion of the left superior temporal gyrus—known as Wernicke's area. As this area overlies the optic radiation, the commonest neighbourhood sign is a right homonymous hemianopia.

Conduction aphasia

This form of aphasia, as the name implies, is due to a disconnection of the two principle language areas. Comprehension is relatively preserved and output is fluent although phonemic paraphasias occur. The striking abnormality is an impairment of repetition even for single syllable words such that attempts at repeating are laboured and contain phonemic errors. Likewise, naming produces phonemic errors even for high frequency items (such as for 'cup': 'cah … cahb … cub' etc.). Lesions producing conduction aphasia occur in the region of the supramarginal gyrus, and particularly, the underlying arcuate fasciculus, the tract linking the anterior and posterior language areas.

Global aphasia

In this devastating form of aphasia there is derangement of all aspects of language; patients with global aphasia are non-fluent and have impaired word comprehension, repetition, and naming. Language output is restricted to infrequent unintelligible noises or, at best, a single word or clichéd phrase. As the blood supply to both language areas is from the middle cerebral artery, global aphasia is not uncommon secondary to proximal occlusion of this vessel. Consequently these patients are usually also hemiplegic and hemianopic.

Atypical aphasias and the dementias

The term 'transcortical aphasia' is a legacy of an abandoned neural explanation for a distinct category of aphasia. Although the term is meaningless in its originally coined anatomical sense, it is still sometimes used to describe a distinct syndrome in which a patient with aphasia shows preservation of repetition. Patients with so-called transcortical sensory aphasia are fluent and show profound impairment in word comprehension with preserved repetition; this syndrome is also referred to as amnesic aphasia reflecting the loss of word meaning. It is seen in semantic dementia (the temporal lobe variant of frontotemporal dementia or Pick's disease) and advanced Alzheimer's disease. Earlier in Alzheimer's disease impaired naming with intact fluency and word comprehension (sometimes called anomic aphasia) is commonly seen. Impairment in language output with preserved repetition, transcortical motor aphasia, is most often associated with dorsomedial frontal lesions that involve the supplementary motor area.

Dyslexia

Patients with aphasia show dyslexic difficulties in keeping with their type of aphasia, thus those with fluent aphasia will struggle to understand the meaning of words in printed form, while those with non-fluent aphasia have trouble with grammatical aspects or reading (particularly word endings: -ed, -ing etc.). Within acquired dyslexia, however, dissociations have been defined for reading single words, these syndromes are known as deep and surface dyslexia.

Deep dyslexia and surface dyslexia

There may be a dissociation between ability to read orthographically regular (pronounced as they are spelt) words such as mint, flint, and hat, and irregular words such as pint, cellist, and island. Difficulty reading the latter type is known as surface dyslexia and is one of the hallmarks of semantic dementia; for an irregular word such as 'pint' or 'yacht' to be read correctly, the reader must access knowledge of the word meaning as the graphical representation of the word alone (that is, its 'surface' structure) will not lead to correct pronunciation. If the semantic knowledge base (located in the dominant temporal lobe) breaks down, then the word can only be pronounced according to the rules of graphical to phonological translation and thus 'pint' will be pronounced like 'mint' (known as a 'regularization' error); in other words, analogous to how a normal person would pronounce a non-word, such as 'rint'.

A complimentary syndrome is that of deep dyslexia in which patients produce semantic paralexias when reading (reading 'prison' for 'gaol' or 'beer' for 'pint'), are unable to read non-words, and have greater difficulty with abstract than concrete words. This, simplistically, is thought to represent a loss of the grapheme to phoneme route with intact semantic knowledge (that is,. its 'deep' meaning). Deep dyslexia is typically seen in patients with extensive left hemisphere lesions and global aphasia.

Alexia without agraphia

This syndrome represents a classic disconnection syndrome of visual input from language areas due to a lesion in the left occipital lobe and adjacent splenium (disrupting input form the right occipital lobe); as such, although the right occipital cortex is capable of registering text, the information cannot be decoded by the language hemisphere. Patients are not aphasic and can write normally, they cannot read but can say words spelt out loud to them. Visual field testing shows a right homonymous hemianopia. Patients rapidly relearn how to read by identifying individual letters and reconstructing words by a laborious and slow letter-by-letter reading strategy.

Agraphia

Various acquired disorders of writing occur as homologues of other cognitive deficits. For instance, patients with aphasia make writing errors consistent with their aphasic syndrome (for example patients with a Broca's aphasia will make errors in writing syntax), deep and surface dysgraphia give rise to similar errors as deep and surface dyslexia, and ideomotor apraxia (see below) will cause a disorder in motor execution such that writing will be of poor quality.

Visuospatial and perceptual disorders

The regions of the brain concerned with the higher order analysis of visual information can be divided into a dorsal (occipitoparietal) pathway concerned with spatial information and preparation for reaching, and a ventral (occipitotemporal) pathway concerned with identifying visual stimuli. In other words, the dorsal stream is involved in 'where?' and 'how?' and the ventral with 'what?' information for a given visual stimulus. Some of the most striking neuropsychological syndromes are seen following selective damage to one stream.

The dorsal stream and Balint's syndrome

Constructional apraxia, an inability to draw or copy line drawings such as wire cubes and clock faces, is a common finding in parietal pathology, particularly with right-sided lesions. More severe breakdown in spatial cognition causing individuals to misreach for visually guided targets, to trip on steps, or collide with furniture when walking is seen with bilateral parietal diseases (such as watershed infarction, the biparietal variant of Alzheimer's disease, and venous sinus thrombosis) and results clinically in Balint's syndrome; the features of which are simultanagnosia, optic ataxia, and ocular apraxia. Simultanagnosia is the inability to integrate and make sense of an overall visual scene in spite of preservation in the ability to identify individual elements. Such patients are relatively better at identifying small objects; this can also be demonstrated by an inability to read vertically printed words although they can be read when printed normally. Ocular apraxia describes the inability to direct gaze to a novel visual stimulus, while optic ataxia is the inability to reach accurately for a visually guided target.

Spatial neglect

Although considered under the visuospatial heading, spatial neglect is really a cross-modality disorder that typically involves the neglect of all sensory information (visual, tactile, auditory) from the side contralateral to the lesion. Chronic neglect virtually only occurs in the context of right parietal lobe damage. Right hemispatial neglect following an acute left parietal lesion can occur, but is usually less severe and tends to resolve within days. In addition to being a cross-modality disorder it is not correct to define a 'hemispatial field' in purely retinotopic terms. For instance, if a patient who exhibits neglect on visual field testing has the body turned to face the neglected extrapersonal hemispace (with head and eyes fixed in the original position), then the neglected space is reduced.

Visual neglect is best tested by cancellation (crossing off 'A's on a sheet of paper containing randomly arranged letters), drawing (clock, house, flower), or line bisection tasks. Patients with severe visual neglect may even appear to be hemianopic. A milder form of neglect can be elicited by 'sensory extinction' of the neglected side during bilateral sensory (visual and somatosensory at the bedside, although auditory neglect can be demonstrated experimentally) stimulation. Patients often have associated hemiparesis, although as part of their neglect syndrome they may deny this impairment—a phenomenon known as anosagnosia. When presented with the hemiparetic limb they may even deny that it is their own.

The ventral stream

Lesions to the occipitotemporal pathway give rise to difficulty recognizing visual stimuli that is not a consequence of being unable to appreciate where an object is in space as is the case in simultanagnosia. This deficit is known as visual object agnosia and has been divided further into aperceptual and associative varieties. In aperceptual agnosia, basic aspects of vision (acuity, fields, and contrast sensitivity) are intact, but patients cannot identify, or match identical, objects and have grave difficulty copying line drawings, although knowledge of these objects is intact if tested using other inputs such as describing from name. In contrast, associative agnosia describes a state where loss of object knowledge occurs such that although patients can copy line drawings well and match perceptually identical pictures, they cannot match non-perceptually identical images such as different angles of the same face or, for instance, tell that two different types of clock are both clocks. Associative agnosia is a cross-modality disorder such that knowledge of objects is impaired in non-visual modalities—in other words one component of generalized failure of semantic knowledge (see below). Differentiating these agnosias requires the use of test material only found in neuropsychology laboratories. One component of object knowledge is colour, loss of which (achromatopsia) usually accompanies occipitotemporal lesions and is more accessible to bedside evaluation.

A restricted form of impaired object recognition relates to faces. Known as prosopagnosia, the subject can no longer recognize previously familiar faces but can recognize their voices and have access to knowledge from their names. Usually bilateral lesions of the inferior occipitotemporal junction are responsible, although cases with lesions restricted to just the right side have been described.

Memory

Memory is divided by researchers into implicit and explicit subtypes (also known as non-declarative and declarative, respectively). Implicit memory refers to unconscious memory systems such as that responsible for conditioning as well as memory for motor tasks such hitting a golf ball or playing a piece of music 'by heart'. Explicit memory, in contrast, refers to consciously apprehended emory and is further divided into episodic and semantic memory. In clinical terms, when one refers to memory, it is only the explicit type of memory which is considered. When assessing memory complaints it is useful to apply a theoretically motivated approach to analysing symptoms according to the subcomponent of memory involved. In broad terms, memory subtypes can be considered under the following headings.

Working memory

Working memory refers to the amount of information that can be held by the brain 'on-line' (such as reading a phone number then holding it as the object of one's attention until the number can be dialled, or solving mathematical problems in the head); in the absence of rehearsal, when the focus of one's attention has moved to a novel topic for more than a few seconds, such items are lost. Working memory is also referred to as 'short-term' memory by psychologists, although this latter term is often used by patients and their doctors to describe recently acquired episodic memory (see below); it also involves aspects of attention (see above) so, to avoid confusion, the term 'working memory' is preferable. Slips of working memory are often erroneously seen by patients as the harbinger of dementia and thus these individuals are commonly referred to memory clinics: these lapses of attention (such as forgetting why you opened the refrigerator door or went into the study, or immediately forgetting a new telephone number) are common everyday symptoms which are increased with anxiety, depression, and also occur more commonly with advancing age. Complaints of this type are also common after head injury and in basal ganglia disorders.

Semantic memory

Semantic memory refers to the brain's knowledge store of, for example, objects and word meanings; it is also the term applied to knowledge of facts, such as that Paris is the capital of France, canaries are small yellow birds kept as pets, or that Ronald Reagan was a president of the United States. The inferolateral and polar regions of the temporal lobes (left for word and object meanings, right for face knowledge) are particularly critical to supporting semantic knowledge. Loss of memory for words is the usual complaint in patients with a primary disorder of semantic memory such as semantic dementia (also known as progressive fluent aphasia) and after herpes simplex virus encephalitis. However, it is important to distinguish between the occasional word finding lapse, usually for proper nouns, which occurs normally (especially in later life), and the relentlessly progressive loss of vocabulary, which occurs in association with left temporal lobe pathology. Low frequency words are the most vulnerable and patients with semantic dementia often have some insight into this problem in the early stages. For instance, a carpenter may complain that he can no longer remember the names of tools. Alzheimer's sufferers show a similar phenomenon, although it is usually overshadowed by their profound episodic memory deficit.

Breakdown in semantic memory manifests as inability to name objects or drawings with the production of broad superordinate responses (such as 'animal' for 'elephant') and the inability to define the meaning of words. Category fluency (the ability to generate exemplars from a given semantic category such as types of animals or kitchen utensils or birds) is another sensitive measure of semantic memory. Knowledge of famous people can be tested by identifying photographs and names or asking the patient to list prime ministers in chronological order.

Episodic memory

Episodic memory refers to the event-based memories unique to each individual, in other words our recollection of personally experienced episodes (indeed, it is sometimes termed 'autobiographical' memory). Difficulty with the acquisition of new event-based memories (such as inability to recall details of a television programme or conversation with a friend despite good attention at the time) is the hallmark of early Alzheimer's disease and other causes of the amnesic syndrome (Table 2). Lesions that give rise to amnesia involve the limbic system of the brain (especially the hippocampi and their connections; Fig. 1). Although bilateral involvement is usually required to cause a full-blown amnesic syndrome, neuropsychological testing can often reveal a selective deficit in verbal or non-verbal

memory in cases of left- or right-sided damage, respectively. Retrograde memory (established prior to the amnesic insult) is typically better than anterograde (established any time after) in amnesic syndromes and within retrograde memory, very remote memory is classically (although not universally) better preserved than recent memory.

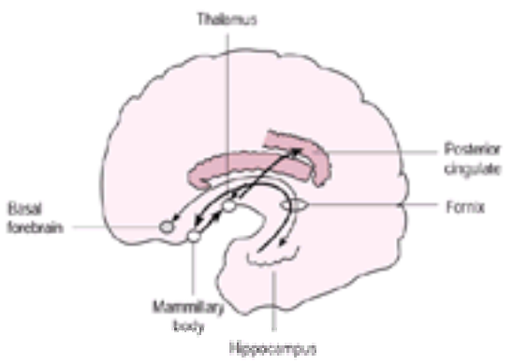

Fig. 1 Principal connections of structures critical to sustaining human memory.

On examination, patients with amnesia have a striking inability to relate anecdotes from their recent life, although in cases of basal forebrain amnesia they may offer confabulations. Amnesia can be assessed in the clinic by asking the patient to learn some information such as a new name and address; patients with amnesic syndromes (including early Alzheimer's disease) typically repeat a name and address perfectly after two to three trials, but show very rapid forgetting and recall little or nothing after a delay of a few minutes of a distracting task.

Amnesia may occur as a temporary state as is seen with transient global amnesia, in which there is a sudden onset of severe amnesia that lasts several hours before resolution; afterwards the patient, characteristically elderly, is left with an islet of amnesia for the hours of the episode. Transient global amnesia typically occurs as a solitary episode; recurrent attacks of self-limiting amnesia occasionally occur as a consequence of epileptic activity, hence the term transient epileptic amnesia.

Apraxia

Apraxia is defined as a loss of ability to carry out skilled motor tasks that cannot be explained in terms of an elementary disorder of motor control (weakness or ataxia), primary sensory disturbance, or a global impairment of cognition. In the early twentieth century Leipmann distinguished three types of apraxia—limb-kinetic, ideomotor, and ideational—and although these terms have suffered from a lack of universally accepted definition they are still widely used today. In an attempt to clear up ambiguity, the terms 'production' and 'conceptual' apraxia are also now used to indicate ideomotor and ideational apraxia according to the definitions below.

Limb-kinetic apraxia refers to the loss of fine motor dexterity that can be seen, for instance, with mild pyramidal lesions (such as after recovery from stroke). In spite of apparently good strength and co-ordination, the subject cannot manage tasks requiring fine motor control such as tying a shoelace or buttoning a shirt. As such, according to the above definition, this is not a 'true' apraxia but rather an artefact of the insensitivity of bedside tests of the motor system: in other words a primary motor deficit is only unmasked by tasks more demanding than routine tests of power and co-ordination.

Ideomotor (production) apraxia refers to the inability to execute the motor programme for a given task (the temporal and spatial organization of movement) in spite of adequate comprehension, as demonstrated, for instance, by the ability to describe the correct execution of the task (such as sharpening a pencil: 'you put the pointed end of the pencil into the hole then turn it') or to identify correctly a task when done by someone else. Patients with ideomotor apraxia also have problems performing meaningless (non-symbolic) gestures.

Ideational (conceptual) apraxia, in contrast, is a loss of knowledge of actions: there is an inability to either perform or recognize a given motor task. There is also an inability to match tools correctly to their actions, thus a subject may select a screwdriver to hammer a nail. Unlike patients with ideomotor apraxia, they do not show disorders of the spatial and temporal aspects of action and thus their tool use, although incorrect, is fluent.

To screen for apraxia, patients should be asked to perform skilled motor tasks to verbal instruction or to imitation including both meaningful and meaningless gestures. If deficits are uncovered, tests such as correctly identifying mimes performed by the examiner and matching tools to functions should be given. Subtle disorders of praxis may be evident only with low frequency tasks (such as using a vegetable peeler or a pencil sharpener as opposed to a knife or a hairbrush). When asked to pantomime an action (such as hair combing or brushing teeth), 'body part as tool' errors are often cited as evidence for apraxia: the patient uses his or her hand as the tool (for example rubbing an extended index finger over the teeth as a toothbrush). It is, however, not uncommon for normal subjects to make these 'body part as tool' errors when asked to perform such tasks, hence it is essential when this type of error is committed to draw it to the subject's attention and reinstruct them accordingly. Normal subjects are able to correct these errors, whilst those with apraxia cannot.

In terms of the neural substrate for production (ideomotor) apraxia, the overwhelming majority of cases follow damage to the left (dominant) hemisphere. More specifically, there is evidence that a motor system incorporating the superior parietal lobule (Brodmann areas 5 and 7) and the premotor area of the left frontal lobe is particularly critical to the temporal and spatial organization of motor programmes. Conceptual apraxia is also indicative of left hemisphere dysfunction in most cases, although whether a more specific site can be identified is contentious. It is also important where a conceptual apraxia is suspected to ensure it is not just one manifestation of a more generalized breakdown of semantic knowledge (see Memory, above)

Buccofacial apraxia represents a specific form of apraxia in which patients are unable to perform tasks such as licking lips or blowing out matches to command. It is particularly associated with non-fluent aphasia, presumably as the motor programming of articulation and non-linguistic buccofacial movements share a common pathway.

Personality and behavioural change

So far, disorders of higher mental function have been considered in quite discrete terms, both in the sense of the cognitive deficit and the cerebral location. Alterations in complex behaviour, personality, and social comportment, however, cannot be so simply defined, but are broadly associated with frontal or anterior temporal lobe pathology. The key to identifying such disorders is the presence of a sustained change from a previous state (thus differing from a lifelong eccentric personality) which cannot be explained by a primary psychiatric diagnosis. The only reliable way to confirm such changes is by taking a separate history from a spouse or other close personal acquaintance with knowledge of the patient's premorbid personality.

Prefrontal syndromes

The prefrontal cortex comprises that part of the frontal lobe rostral to the premotor area; it is classified as heteromodal association cortex and receives extensive inputs from unimodal association areas posterior to the central sulcus. The frontal lobes also have loop projections running to the basal ganglia, then the thalamus, and back to the frontal lobes. Thus lesions along this loop (as seen in conditions such as Huntington's disease or progressive supranuclear palsy) may also share deficits in common with primary frontal lobe disorders. Anatomically, the prefrontal cortex can be divided into dorsolateral, orbital, and medial surfaces; although in many cases damage will not be restricted to just one of these regions, they provide a useful framework for considering prefrontal functions. Broadly, lesions to the dorsolateral surface are responsible for the frontal 'dysexecutive' syndrome, to the orbital surface for the classic frontal behavioural syndrome, and to the medial surface (anterior cingulate) for a profound amotivational state.

The dysexecutive syndrome

The term 'executive' refers to aspects of higher-order brain function, such as problem solving, reasoning, and mental abstraction, which rely upon the dorsolateral prefrontal lobes. It is also associated with impulsivity, susceptibility to distraction, and failure to persevere with the task at hand. Various methods are available to

measure these phenomena although no single test offers foolproof sensitivity in this domain, so one should apply as many as ossible if the index of suspicion is high.

The combination of letter- and category-based verbal fluency provides much useful information. In letter fluency, the patient is asked to generate as many words as they can think of beginning with a given letter in 1 min. They are instructed not to use proper nouns and not to just change the endings to create new exemplars ('go, goes, going' etc.). Neuropsychologists typically use the letters F, A, and S for this test, so it is best to choose another letter if it is likely that patients are also going to have a formal neuropsychological assessment. In category fluency, patients are asked to produce as many exemplars as possible from a given category in 1 min. Normal subjects usually generate 15 or more words on letter fluency and do slightly better on the 'animal' category. Patients with executive deficits secondary to frontal (or the subcortical loop) pathology show an exaggeration of this relationship, doing poorly on category fluency but even worse on letter fluency (patients with semantic impairments related to temporal lobe diseases such as semantic dementia and Alzheimer's disease typically show the reverse pattern of relatively worse performance on category fluency).

The 'go–no go' test offers a way of assessing impulsivity: the patient is asked to tap the desk once if the examiner does so, but if the examiner taps twice, he should not tap at all. Patients with frontal pathology are often unable to stop themselves from tapping in both conditions. Failure to abstract meaning from proverbs ('What does “too many cooks spoil the broth” mean') is a common test but is influenced by background intellectual ability and is culture bound. The so-called 'cognitive estimates' test is also useful ('What is the height of the post-office tower in London?' or 'How fast does a racehorse gallop?'), as are 'differences and similarities' ('What's the difference between a child and a dwarf?' or 'In what way are a sculpture and a piece of music similar?'). Finally, the susceptibility to irrelevant stimuli mean that the tests of attention discussed above may also be impaired.

Orbitofrontal syndrome

The striking changes in behaviour seen in patients with prefrontal lesions relate particularly to orbital (or ventral) surface damage. Although devastating in their effects on social function, such lesions are notoriously difficult to detect using standard psychometric tests. Patients lack empathy and emotional warmth: for instance, if confronted with something as serious as the admission to hospital of their spouse, their primary concern may be that their mealtime routine will be disturbed. They are disinhibited and oblivious to social mores such that they may be overly familiar with strangers, disregard personal space, and make inappropriate (often of a sexual nature) comments or gestures. They often make rash and irresponsible decisions such as spending money above their means. They may develop stereotyped and ritualistic behaviours such as insisting on always taking a particular route when shopping or repetitively closing doors in the home: these behaviours can be so severe as to constitute a secondary obsessive–compulsive disorder syndrome.

A useful clue is often the presence of a change in eating behaviour. Patients may become fixated on one dish; often they develop a preference for sweet foods. A lack of normal satiety means that they may overeat, often with secondary weight gain.

Imitation and utilization behaviour are dramatic phenomena related to orbital frontal lobe damage. The patient with imitation behaviour unconsciously mimics the examiner's posture and mannerisms regardless of how absurd they are: raising an arm in the air, placing a leg on the desk, or sitting on the floor. Utilization behaviour is even more striking: patients will use any object placed in their grasp. The classic example is the patient offered multiple pairs of spectacles who attempts to wear them all, one on top of another.

Amotivational states

Medial frontal lesions are particularly associated with apathy. Patients lack spontaneity, they will not initiate conversation although can reply to specific questions. Likewise, if left to their own devices, they may not spontaneously move, preferring to sit in a chair staring blankly into space. This apathy has also been termed abulia in the past, in its most extreme form where the individual lies motionless with no speech the term akinetic-mutism has also been applied. The catatonic phenomenon of maintaining postures when the limbs are moved by the examiner may also be seen. Patients with depression also show marked apathy, although it is accompanied by both the biological features of depression (anorexia, diurnal variation etc.) and internal symptoms of mood disturbance (pessimism, suicidal thoughts, anhedonia etc.).

Temporal lobe syndromes

In addition to the cognitive deficits that can occur with temporal lobe lesions such as amnesia and loss of semantic knowledge, behavioural distrubances can also occur. The most severe, secondary to bilateral anterior temporal damage (including the amygdala), is the Klüver–Bucy syndrome, which comprises three characteristic features: placidity, even in threatening situations, indiscriminant hypersexuality, and oral exploration of objects. Other behaviours have been described in temporal lobe dysfunction, particularly, although not exclusively, in association with interictal temporal lobe epilepsy. These include preoccupation with religious or philosophical issues and a tendency to excessive writing.

24.9 Brainstem syndromes

David Bates

Most of the brainstem syndromes involving both the long tracts of the brainstem and the cranial nerve nuclei occur due to vertebrobasilar ischaemia but were originally described in relation to tumours and other non-vascular disorders. Vascular disorders by their very character often have a rostrocaudal and patchy localization rather than the simplified transverse localization that is usually demonstrated in diagrams. It may not always be possible to identify the cause of specific symptoms and signs in an individual patient and therefore the diagnosis of vascular disorders in the brainstem is more profitably identified by knowledge of brainstem anatomy.

The classic presentation of brainstem syndromes, including the long tracts and deficits of cranial nerve nuclei, commonly causes crossed cranial nerve and motor or sensory long tract deficits; the cranial nerve palsy is ipsilateral to the lesion and the long tract signs contralateral. It is important to assess the.extracranial vascular supply to the posterior circulation, especially to listen for bruits over the subclavian vessels and to record the pulse and blood pressure in both upper limbs, remembering that the vertebral arteries arise from the subclavian vessels. Apart from the crossed cranial nerve and long tract deficits, there may be ataxia, vertigo, the presence of an internuclear ophthalmoplegia and unreactive pupils, the symptoms of diplopia and oscillopsia, and the finding of nystagmus or ocular paresis.

The circulation to the brainstem is supplied by the vertebral arteries, which are the main arteries to the medulla, then the basilar artery, which supplies the pons and midbrain. The vertebral arteries are frequently asymmetrical and commonly give rise to the large posterior inferior cerebellar arteries shortly before they join to form the basilar. The vertebral arteries are susceptible to trauma within the cervical spine, but the most common lesions affecting the vertebral arteries are dissection, which is probably under-recognized, or thrombosis.

The basilar artery supplies branches which may be described as paramedian, supplying the area of the pons close to the mid-line, the short circumferential which supply the lateral two-thirds of the pons, the long circumferential which are the superior and anterior inferior cerebellar arteries, and several interpeduncular branches which arise at the bifurcation of the basilar artery and supply the sub-thalamic and high midbrain regions.

The brainstem syndromes

Thalamic syndrome

Sometimes spontaneously but commonly following a recognized hemiplegic and hemianaesthetic stroke, the patient develops altered sensation in a hemisensory distribution together with unpleasant dysaesthetic burning pain (thalamic pain). The pain may be worsened by stimulation and is associated with hemianaesthesia, sometimes proprioceptive loss, and some evidence of hemiparesis. Anatomically the lesion is usually in the ventroposteriolateral nucleus of the thalamus and is commonly caused either by a vascular event or by a tumour. The investigations required are imaging and therapy is with centrally acting analgesic agents.

Tectal deafness

There is a rare syndrome associated with damage at the level of the inferior colliculi, either due to neoplasia or vascular lesions resulting in bilateral deafness and sometimes associated difficulty in co-ordination, weakness, and vertigo. The condition must be differentiated from conductive bilateral hearing loss, cochlear disorders, bilateral eighth nerve lesions, and pure word deafness. The lesion can be identified by brain imaging.

Thalamic stroke syndrome

Lesions affecting the thalamus are commonly vascular and arise from infarction within the distribution of the posterior communicating artery, the basilar and the anterior and posterior choroidal arteries. There is usually hemiparesis with hemianopia, hemianaesthesia, and sometimes hemiataxia. There is often confusion, disorientation, and there may be language disturbance. On occasion there may be vertical-gaze ophthalmoplegia, loss of pupillary reflexes, and an inability to converge the eyes. There may also be memory impairment and on occasions visual perceptual disturbances are recorded.

Midbrain syndromes

Damage to areas of the midbrain is characterized by long tract signs contralateral to the lesion with defects of the third and fourth cranial nerves ipsilaterally. They can been seen with lesions in the brainstem or as the evolution of symptoms of rostrocaudal deterioration associated with supratentorial brain swelling (Fig. 1 and Fig. 2). They are characterized by ipsilateral third and fourth cranial nerve palsies together with contralateral hemiparesis, loss of vibration, propriception, and stereognosis, contralateral loss of pain and temperature, and an ipsilateral Horner's syndrome. Ataxia may occur and there can be eyelid ptosis, diplopia, supranuclear horizontal-gaze paresis, and an internuclear ophthalmoplegia. The association of an ipsilateral oculomotor palsy with a crossed hemiplegia due to a lesion at the base of the midbrain is called a Weber syndrome. Claude syndrome causes an ipsilateral oculomotor palsy with contralateral cerebellar ataxia and tremor and is due to a lesion in the tegmentum of the midbrain involving the red nucleus and the third nerve nucleus. Benedikt's syndrome also involves the tegmentum of the midbrain resulting in an oculomotor palsy with contralateral cerebellar ataxia, tremor, and corticospinal signs and can be regarded as a combination of Claude and Weber's syndrome. Nothnagel syndrome occurs with unilateral or bilateral involvement of the third nerve nucleus together with the superior cerebellar peduncles and causes bilateral ptosis, paralysis of gaze, and cerebellar ataxia.

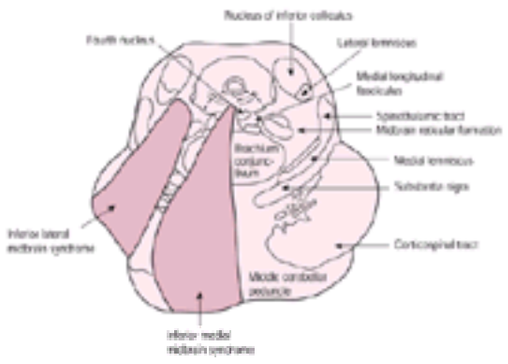

Fig. 2 Midbrain at the inferior colliculus level showing the medial and lateral territories involved with ischaemic stroke syndromes in this area. (Reprinted with permission from DeArmond SI, Fusco MM, Dewey MM, 1976, *Structure of the human brain*, 2nd edn. Oxford University Press, New York.)

Damage in the region of the dorsal midbrain results in the Parinaud syndrome in which there is paralysis of upward gaze due to damage to the supranuclear mechanisms for upward gaze, loss of accommodation, and fixed pupils. Although this may be seen with ischaemic lesions, it is more commonly seen with pineal tumours.

Pontine syndromes

Lesions in the pons and medulla are commonly identified as involving either the medial or the lateral aspect of the brainstem, depending upon whether the paramedian or short circumferential vessels from the basilar have been involved. In the pons the following three levels of damage can be detected and the basal syndrome can occur at any level.

Superior pontine syndrome

The medial superior pontine syndrome results in ipsilateral cerebellar ataxia, internuclear ophthalmoplegia, and palatal and pharyngeal myoclonus with contralateral paralysis of face, arm, and leg and sometimes loss of sensation contralaterally. The lateral superior syndrome causes ataxia of limbs and gait with dizziness, nausea, and vomiting; there is horizontal nystagmus, paresis of conjugate gaze towards the side of the lesion, loss of optokinetic nystagmus, and sometimes skew deviation of the eyes. There may also be an ipsilateral Horner's syndrome and there is contralateral loss of pain and thermal sensation on the face and limbs with impaired touch, vibration, and position sense (Fig. 3).

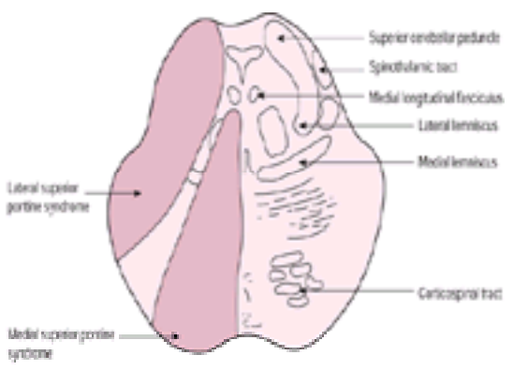

Fig. 3 Superior pontine level, showing the medial and lateral territories involved with occlusive stroke in this region. (Reprinted with permission from Adams RD, Victor M, 1993, *Principles of neurology*, 5th edn. McGraw-Hill, New York.)

The mid-pontine syndrome

The medial, mid-pontine syndrome causes ipsilateral ataxia of the limbs and gait with contralateral paralysis of the face, arm, and leg, deviation of the eyes away from the lesion, and variably impaired sensation contralaterally. The lateral syndrome at this level causes ataxia of the limbs on the side of the lesion together with paralysis of the muscles of mastication and impaired sensation over the face on the same side due to damage to the fifth nerve (Fig. 4 and Fig. 5).

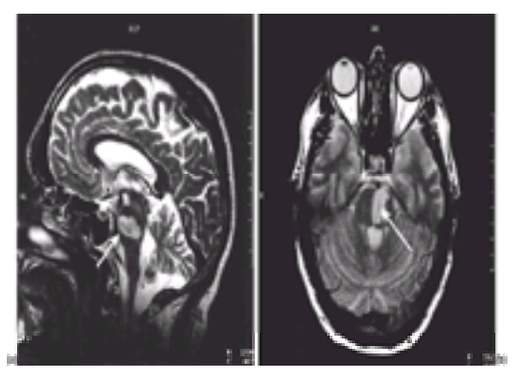

Fig. 5 MRI scan of a mid-pontine infarction.

The inferior pontine syndrome

The medial syndrome causes paralysis of conjugate gaze to the side of the lesion, nystagmus, ataxia of limbs on the same side, and double vision on gaze to that side. Contralaterally there is paralysis of the face, arm, and leg with impaired touch and proprioception over the opposite side of the body. The lateral syndrome involves ipsilateral, horizontal, and vertical nystagmus with vertigo and nausea, ipsilateral facial paralysis, paralysis of conjugate gaze to the side of the lesion, deafness, tinnitus, and ataxia on the side of the lesion with impaired sensation of the face on that side. On the opposite side there is impaired sensation over half of the body (Fig. 6).

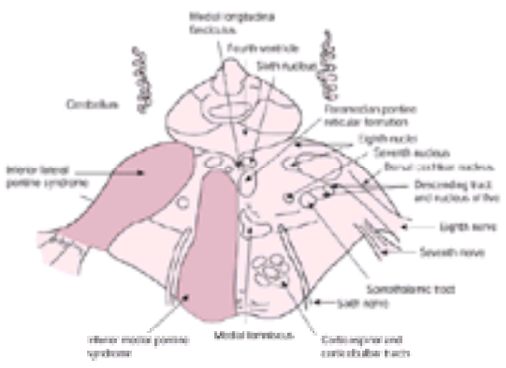

Fig. 6 Inferior pons at the level of the sixth nerve nucleus, showing the medial and lateral territories involved with occlusive stroke in this area. (Reprinted with permission from Adams RD, Victor M, 1993, *Principles of neurology*, 5th edn. McGraw-Hill, New York.)

Basal pontine syndrome (locked in syndrome)

Bilateral lesions of the paramedian vessels from the basilar, commonly seen in patients with hypertension, result in infarction of the basis pontis causing quadriplegia with loss of the ability to speak. The ascending reticular activating system is intact and consciousness is therefore preserved. Vertical eye movements and eye closure are all that are possible and under voluntary control in the 'locked-in syndrome'.

Pseudobulbar palsy

Bilateral lesions of the long descending tracts in the brainstem can result in pseudobulbar palsy, although this condition is more commonly seen with lesions higher in the cerebrum. The symptoms are those of spastic dysarthria, dysphagia, bilateral facial weakness with quadriparesis, and emotional lability.

Medullary syndromes

The medial medullary syndrome may occur with occlusion of the vertebral artery or a branch of the lower basilar artery; it causes paralysis and atrophy of the tongue on the side of the lesion with contralateral paralysis of the arm and leg but sparing the face and impaired tactile proprioceptive sensation over the contralateral half of the body. The lateral medullary syndrome occurs most commonly with dissection or occlusion of the vertebral artery, resulting in ischaemia into the posterior, inferior cerebellar artery; this causes pain, numbness, impaired sensation of the ipsilateral half of the face with ataxia of limbs on that side, the symptoms of vertigo and nausea, double vision, and oscillopsia, and the signs of nystagmus. There is an ipsilateral Horner's syndrome, often dysphagia with paralysis of the vocal cord ipsilaterally, and loss of sensation on the arm, trunk, and leg. There is contralateral impaired pain and thermal sensation over half the body and possibly the face (Fig. 7).

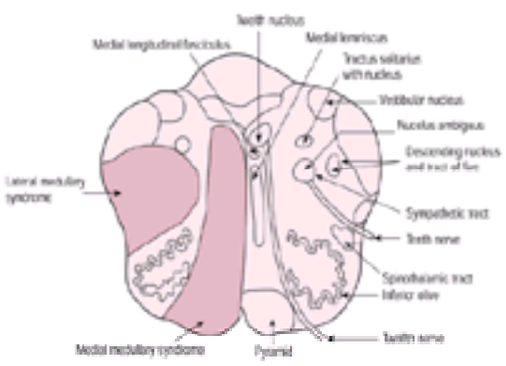

Fig. 7 Cross-section of medulla at the level of the inferior olivary complex, showing the medial and the more common lateral territory involved with ischaemic stroke in this brainstem site. (Reprinted with permission from Adams RD, Victor M, 1993, *Principles of neurology*, 5th edn. McGraw-Hill, New York.)

A syndrome involving ipsilateral seventh and sixth nerve palsies with a contralateral hemiplegia is called the Millard–Gubler syndrome; the involvement of the tenth cranial nerve causing paralysis of the soft palate and vocal cord with contralateral hemianaesthesia is termed the Avellis syndrome and is due to a lesion in the tegmentum of the medulla. The lateral medullary syndrome is eponymously called the Wallenberg syndrome.

Investigations and treatment

The clinical identification of lesions lying within the brainstem by a combination of cranial nerve and long tract signs, though important is only the beginning of diagnosis. Such syndromes commonly occur with ischaemic lesions within the brainstem but can also be seen with neoplasia, demyelination, and infective and hamartomatous lesions. The identification of a brainstem syndrome makes imaging, ideally with MRI rather than CT, obligatory and only then, and possibly following other investigations to identify systemic abnormality or cerebrospinal fluid changes, can appropriate therapy be introduced. Vascular lesions within the brainstem often carry a remarkably good prognosis, but if the syndrome appears to be evolving, the possibility of anticoagulation must be considered. In those lesions in which damage affects the medulla it may be important to protect the airway and avoid aspiration during the early phases of the illness.

24.10 Subcortical structures—the cerebellum, thalamus, and basal ganglia

N. P. Quinn

The cerebellum

Structure and function

The cerebellum occupies the greater part of the posterior fossa, reaching from the tentorium rostrally to the foramen magnum caudally, and lying dorsal to the lower pons and medulla, from which it is separated by the fourth ventricle. Its blood supply is derived from posterior circulation via the superior, anterior inferior, and posterior inferior cerebellar arteries. The cerebellum can be divided into cortex, intrinsic nuclei, and interposed white matter (medullary substance). The cortex comprises three cell layers—from the surface inwards these are the molecular layer (3), the Purkinje cell layer (2), and the granular cell layer (1). The only output cells of the cortex are the Purkinje cells. Inputs to the cerebellar cortex comprise either climbing or mossy fibres. The former synapse directly with Purkinje cells. The latter synapse with granule cells in layer 3, whose axons ascend to layer 1 where they form parallel fibres which synapse with Purkinje cell dendrites ascending from layer 2.

The cerebellum can also be divided into: archicerebellum (flocculonodular lobe), with largely vestibular inputs; palaeocerebellum (anterior lobe), with largely spinal cord inputs; and neocerebellum (posterior, largest lobe), with largely pontine inputs from cerebral cortex. Yet another way of dividing the cerebellum is into functional 'units' as follows: the vermal zone, comprising the fastigial nuclei and the midline unpaired portion of cerebellum, projects to vestibular nuclei and controls mainly axial posture, tone and balance, and locomotion; the paravermal zones, comprising the globose and emboliform nuclei and corresponding cerebellar cortex, project via the contralateral red nucleus and other nuclei of the reticular formation to influence ipsilateral limb tone; and the lateral zones, comprising the dentate nuclei and lateral cerebellar cortex, project via contralateral thalamus on to motor cortex to effect ipsilateral motor co-ordination.

The integrating function of cerebellum is evident from the fact that afferent fibres (Fig. 1) heavily outnumber efferent ones by about 40 to 1. Connections travel in three cerebellar peduncles, the lower two mainly afferent and the upper one efferent: the inferior cerebellar peduncle (restiform body) carries spino-, vestibulo-, and olivocerebellar fibres and input from other medullary ('precerebellar') nuclei; the middle cerebellar peduncle (brachium pontis) carries major afferent fibres from the pontine nuclei responsible for relaying and integrating a large input from all areas of the cerebral cortex; the superior cerebellar peduncle (brachium conjunctivum) contains a few afferent spinocerebellar fibres, but most of its bulk comprises cerebellar efferent fibres which originate in the intrinsic cerebellar nuclei and stream up to the contralateral red nucleus, or through it to the thalamus, to influence heavily thalamocortical, and then corticospinal, input. Other cerebellar efferents go to vestibular nuclei and to nuclei in the pontine and medullary reticular formation. These brainstem efferents provide access to the rubrospinal, vestibulospinal, and reticulospinal tracts.

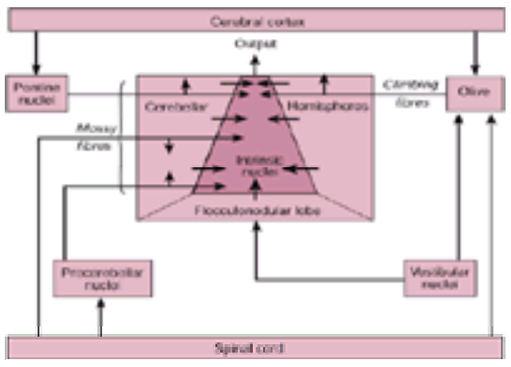

Fig. 1 A simplified diagram showing the principal afferents to cerebellar cortex and to intrinsic cerebellar nuclei. Both mossy (left) and climbing (right) fibre inputs project to both cortex and intrinsic nuclei.

Clinical aspects

There are several theories on the main functions of the cerebellum. Thus it may work as a timing device to control the duration and latency of muscle activities, it may act as a learning device to lay down circuitry for repeating previously performed movements, and it may act as a co-ordinator to harmonize and correctly scale the contribution of several brain areas to an intended movement.

The symptoms and signs resulting from lesions of the cerebellum or its pathways in humans have been based on observations in trauma (particularly gunshot wounds), tumour, stroke, and degenerative and demyelinating diseases.

Midline vermal lesions cause truncal ataxia, often in the absence of limb ataxia. The gait is wide based and particularly precarious on turning or on heel–toe walking. Patients may be unsteady for many reasons, only one of which is ataxia, so the former term is preferable where any doubt exists. Unilateral cerebellar hemispheric lesions cause deviation or falling to the ipsilateral side. Unlike a sensory ataxia, cerebellar ataxia is not made worse by shutting the eyes. Generally, ataxic patients have more problem going down, and those with weakness going up, stairs.

Disease of cerebellar hemispheres or outflow tracts often causes limb ataxia, which is in fact an amalgam of several components. First, there may be dysmetria (misreaching, or past-pointing) evident in the arms on the finger–nose test or in the legs when the heel is first brought to the opposite kneecap. Second, there is the breakdown in force, rate, and rhythm known as dysdiadochokinesia. This can best be sought by asking patients to tap gently, regularly, and rapidly on your hand or a table with their fingers. This breakdown of smooth repetitive movements can even be detected by feel or by sound ('listening to the cerebellum'). The third element is intention tremor. Many individuals claimed to have intention tremor do not actually have it, the principal error being to use this term to describe a tremor that simply appears or worsens terminally. Thus, many postural tremors are positionally dependent, and some are only seen when the hands are in a given posture, particularly either outstretched or held in front of the nose. Other non-cerebellar tremors may be present, or appear only during action (action or kinetic tremor). Only if additional signs of cerebellar dysfunction considered above are also present, is it reasonable to use the term intention tremor. Such tremor should augment throughout a movement from inception to completion. A particular form of tremor may be produced by lesions strategically placed in a small area between cerebellum, midbrain, and subthalamus. This tremor has been variously called Holmes', rubral, midbrain, or peduncular tremor, and combines a tremor at rest with a tremor on posture and an intention tremor on movement. Cerebellar lesions may also cause the 'rebound phenomenon' resulting from impaired damping of limbs when suddenly a load is removed or a displacement applied. Finally, any judgement concerning possible limb ataxia can only be made after taking into account any weakness, sensory loss,

akinesia, or apraxia that may also be present.

Cerebellar dysarthria may often simply manifest as slurred speech, as if intoxicated. However, in addition some patients may have either scanning or explosive speech, due to an inability to modulate its rate, rhythm, and force appropriately. Dysarthria is usually present with lesions of the vermis, whole cerebellum, or its connections, but may be absent if one lateral hemisphere alone is involved.

Eye movements are frequently abnormal in disease of the cerebellum or its connections. The following may be seen: gaze-evoked, rebound, downbeat, or positional nystagmus, dysmetric voluntary saccades and jerky pursuit, square-wave jerks (macrosaccadic oscillations), impaired vestibulo-ocular reflex suppression, and skew deviation. The presence of diplopia usually implies additional pathology outside the cerebellum proper.

The thalamus

Structure and function

The two thalami sit at the head of the brainstem, their medial borders largely separated by the third ventricle, but often partially fused as the massa intermedia. Their blood supply derives from the posterior circulation via the posterior cerebral arteries and perforators from the terminal part of the basilar artery. They constitute the largest nuclear mass in the diencephalon (the others being the hypothalamus and subthalamus), and occupy a strategic position both anatomically and functionally.

The structure of the thalamus, already complex, is further confused by the existence of different nomenclatures (the one used here is that of Walker). Broadly speaking, there are three nuclear groups (anterior, medial, and lateral). The lateral group is divided into the lateral and ventral masses, each of which contain a number of nuclei. The ventral lateral cell mass is the main region where somatosensory afferents terminate.

The thalamus receives inputs from cerebral cortex, sensory tracts, basal ganglia, and cerebellum. Almost all of its output is to the cerebral cortex, either in the form of reciprocal circuits or of more complex loops (see later) from cortex through other subcortical structures to thalamus and back to cortex again, but there is a small output to striatum.

Thalamic afferents

Somatic and visceral afferents

Somatic and visceral afferents from the body pass via the medial lemniscus and spinothalamic tract into the ventral posterolateral nucleus caudalis, where caudal body parts are represented laterally and rostral parts medially. Inputs from the face (via trigeminothalamic tracts) pass even more medially into the ventral posteromedial nucleus. Somatotopic representation is maintained through the connections to the parietal lobe in the form of the sensory homunculus with legs medially, arms high, and face low over the convexity. Taste afferents feed into ventral posteromedial nucleus parvocellularis, and hearing and vision into the medial and lateral geniculate bodies, respectively.

Basal ganglia input

The medial globus pallidus projects to the centromedian nucleus, to ventral anterior nucleus parvocellularis, and to ventral lateral nucleus oralis and medialis, and its homologue the substantia nigra pars reticulata to the mediodorsal nucleus and ventral anterior nucleus magnocellularis.

Cerebellar input

Afferents from intrinsic cerebellar nuclei ascend to the ventral lateral nucleus caudalis, to the ventral posterolateral nucleus oralis, and to the adjacent zone x.

Thalamic efferents

All the thalamic nuclei project to the cerebral cortex with the exception of important outputs from the intralaminar centromedian-parafascicular nuclear complex to striatum.

Clinical aspects

From the above it is clear that, depending on the nuclei involved, thalamic lesions might influence either sensation or motor function or sometimes both. Most commonly an infarct or haemorrhage (10 to 15 per cent of all intracerebral haemorrhages) causes contralateral sensory loss or impairment. A small lacunar infarct in the ventral posterolateral nucleus may give rise to a pure sensory stroke, sometimes sparing the face. A larger lesion may cause the thalamic syndrome of Dejerine and Roussy, in which an initial mild and transient hemiplegia is accompanied by persisting superficial and deep sensory impairment, mild hemiataxia, and astereognosis. These are commonly accompanied by choreoathetoid movements and severe, persistent, paroxysmal, often intolerable pains on the affected side. When mild, the movements may be pseudoathetotic due to deafferentation; when severe, they suggest that the lesion may extend beyond the thalamus to involve basal ganglia connections. Other movement disorders described after thalamic strokes are myoclonus, asterixis, tremor, dystonia, and a delayed-onset syndrome of choreiform and dystonic movements associated with slow rhythmic jerks at 2 to 3 Hz involving the contralateral arm. A significant, persisting hemiplegia implies either a large thalamic lesion also involving internal capsule or the possibility that the stroke is primarily capsular and not thalamic. A particular form of subcortical aphasia has been described in thalamic lesions.

Finally, surgical lesions have been stereotactically placed in the ventral lateral nucleus caudalis (also known as the ventral intermediate nucleus—Vim in Hassler's nomenclature) to relieve tremor in Parkinson's disease and benign essential tremor, and also rigidity (but not akinesia) in the former. Chronic electrical stimulation of the same area is also effective. However, the thalamus as a target for surgery in Parkinson's disease has now largely been superseded by the subthalamic nucleus (see later) because inactivation of the latter target also improves the other features of parkinsonism.

The basal ganglia

Structure and function

There is no uniform agreement on how many of the subcortical nuclei one should include under the terms basal ganglia and extrapyramidal motor system, but all definitions at least include the neostriatum (caudate nucleus and putamen, often together called simply the striatum) and the palaeostriatum (the lateral and medial globus pallidus with the latter's homologue, the substantia nigra pars reticulata). The term corpus striatum refers to neostriatum plus palaeostriatum, and lentiform nucleus to putamen plus globus pallidus. The substantia nigra pars compacta and the subthalamic nucleus and the limbic amygdaloid complex of archistriatum should also be considered part of the basal ganglia. The claustrum, substantia innominata, red nucleus, pedunculopontine nucleus, and even the thalamus are considered in some classifications to be part of the basal ganglia, but will not be dealt with here under that heading.

The putamen lies lateral to the thalamus, separated from it (and from most of the caudate nucleus, except anteriorally) by the internal capsule. The caudate nucleus, whose head lies anterodorsomedial to the putamen, describes most of a circle as it follows, and progressively tapers with, the lateral ventricles through its body posteriorally, its tail swinging forward until its anteriorly pointing tip terminates in the amygdaloid nucleus. The pallidum lies medial to the putamen but still lateral to the internal capsule, and is divided into lateral and medial pallidal segments. The substantia nigra lies in the midbrain, transversely above the cerebral peduncles. Its pars reticulata, the termination of the striatonigral pathway, is homologous with medial globus pallidus, and its pars compacta contains the dopaminergic neurones which form the nigrostriatal pathway. Below the thalamus, medial to the internal capsule and rostral to the midbrain, is the subthalamic nucleus.

Most of the caudate, putamen, and globus pallidus derive their arterial supply from anterior circulation via the lateral lenticulostriate arteries and branches of the anterior choroidal and anterior cerebral arteries. Like the thalamus, the subthalamic region, and also the substantia nigra, are supplied by posterior circulation.

The basal ganglia and their (inter-) connections, rich in neurotransmitters, have been extensively studied. The 'striopallidal complex' receives a wide variety of inputs

from cerebral cortex. Its principal output is to the thalamus, which in turn projects back to the cortex to complete a basal ganglia–thalamocortical circuit. However, it is important to note the existence of additional output to the brainstem in the pallidotegmental tract which terminates in the pedunculopontine nucleus. This structure is believed to play an important role in the control of balance and locomotion, and in the maintenance of rigidity. The caudate and putamen are the afferent, and the globus pallidus and substantia nigra pars reticulata the efferent, parts of the striopallidal complex. There is additional dopaminergic input from substantia nigra pars compacta and the adjacent ventral tegmental area in the midbrain which modulates striatal activity. A highly simplified schema concentrating on the motor circuit is presented in Fig. 2.

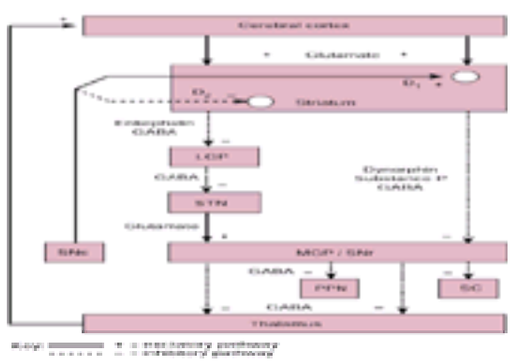

Fig. 2 A simplified schematic diagram showing the principal connections of the basal ganglia. Excitatory synapses are indicated by +, inhibitory ones by –. D [1] signifies dopamine D^1, and D^2 dopamine D^2, receptors. LGP and MGP, lateral and medial globus pallidus; STN, subthalamic nucleus; SNr and SNc, substantia nigra pars reticulata and pars compacta; PPN, pedunculopontine nucleus; SC, superior colliculus.

The massive cortical inputs into the striatum are largely excitatory, using glutamate as a neurotransmitter. Other inputs come from the intralaminar thalamic nuclei, amygdala, and dorsal nucleus of the raphe. In the nigrostriatal pathway from the substantia nigra pars compacta, dopamine preferentially stimulates dopamine D_1 receptors to activate neurones of the direct pathway to the medial globus pallidus which contain dynorphin, substance P, and GABA, and are therefore inhibitory. Dopamine D_2 receptor stimulation preferentially inhibits the first neurones of the indirect pathway to the lateral globus pallidus which contain enkephalin and GABA. These neurones inhibit subthalamic neurones which in turn, using glutamate, excite cells in the medial globus pallidus and substantia nigra pars reticulata. These in their turn use GABA to inhibit thalamic neurones, which finally complete the loop with an excitatory pathway back to the cortex.

This model can be used to predict the functional consequences of over- or underactivity of individual parts, either in human disease states or in experimental animals. In the latter, 2-deoxyglucose autoradiographic studies can be used to confirm such predictions elegantly and validate the model. Thus, the consequences of cell loss in the substantia nigra pars compacta that occur in Parkinson's disease would be as follows: along the direct pathway there is impaired stimulation of the striatal cells that normally inhibit the neurones of the medial globus pallidus/substantia nigra pars reticulata, so the latter are overactive. Along the indirect pathway, there is impaired inhibition (hence overactivity) of the neurones that inhibit the lateral globus pallidus, which is therefore underactive. However, this leads to less inhibition (hence overactivity) of the subthalamic nucleus, which increases excitatory input to the medial globus pallidus/substantia nigra pars reticulata (already overactive via the direct pathway). This overactivity in turn inhibits thalamic, and then cortical, activity. The model would predict that making a lesion in the overactive subthalamic nucleus or medial globus pallidus might relieve parkinsonism, and indeed this has been demonstrated in MPTP-treated primates and patients with Parkinson's disease, respectively.

The model can also be used to understand hyperkinetic movement disorders. Hemiballism (severe unilateral proximal chorea) is classically caused by a destructive lesion in, or close to, the subthalamic nucleus. In this instance an underactive subthalamic nucleus would release the thalamus and hence the cortex from inhibition by the medial globus pallidus/substantia nigra pars reticulata, and again this sequence has been confirmed by 2-deoxyglucose experiments in animals.

All that has been mentioned so far concerns motor function, traditionally equated with the function of the basal ganglia. However, as the complexity and diversity of basal ganglia anatomy, circuitry, and function has become apparent, the concept of multiple basal ganglia–thalamocortical circuits has developed. Although some overlapping of cortical input to the striatum does indeed occur, rather than cortical inputs being simply funnelled through the circuits, thereafter the loops are increasingly non-overlapping, allowing more separate and independent processing throughout the basal ganglia. Five such circuits have been proposed: (i) the motor and (ii) the oculomotor, involved in sensorimotor functions of the body and eyes; (iii) the dorsolateral prefrontal and (iv) orbitofrontal, involved in cognitive aspects of behaviour; and (v) the anterior cingulate circuit, related to limbic functions. A simplified representation of these loops is given in Fig. 3.

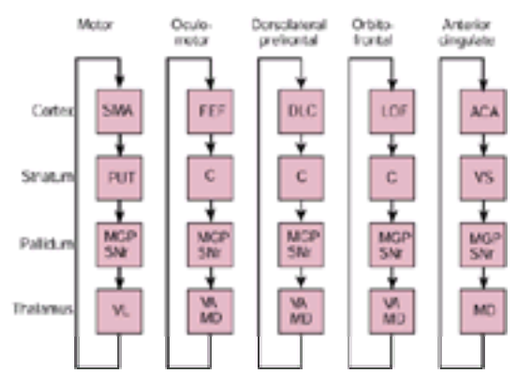

Fig. 3 A highly simplified diagram of proposed basal ganglia–thalamocortical loops (after Alexander *et al*., 1986, with permission). Same abbreviations as for Fig. 2; SMA, supplementary motor area; FEF, frontal eye fields; DLC, dorsolateral prefrontal cortex; LOF, lateral orbitofrontal area; ACA, anterior cingulate area; PUT, putamen; C, caudate; VS, ventral striatum; VL, ventrolateral thalamic nucleus; VA, ventral anterior nucleus; MD, mediodorsal nucleus. Segregated parts of the striatum, pallidum, and thalamus convey largely separate loops.

The last decade has also seen considerable advances in our knowledge of striatal anatomy and neurochemistry. Morphological techniques have long demonstrated a variety of striatal neuronal types. These are either projection neurones (spiny medium type I, the vast majority, and large type II), or intrinsic neurones (aspiny types I to III). However, the striatum as a whole seemed rather amorphous until neurochemical markers gave a new perspective. Thus, the medium type I spiny projection neurones are the major targets of nigral dopaminergic transmission, and make synaptic contact with large aspiny cholinergic interneurones. The former cells are selectively lost in Huntington's disease, resulting in a loss of their inhibitory transmitter GABA, together with colocalized metenkephalin or substance P. In contrast, type I aspiny interneurones containing neuropeptide Y and somatostatin, and type II aspiny interneurones containing acetylcholine, are largely spared in Huntington's disease.

It is now recognized that striatal neurones are also organized into a mosaic pattern comprising patches or striosomes with high levels of μ-opiate receptors and low levels of acetylcholinesterase, suspended in a matrix of cells containing high levels of aceytlcholinesterase, somatostatin, and calbindin. Patch and matrix receive different inputs from the midbrain, thalamus, and cortex. In particular, deeper levels of prefrontal or limbic cortex tend to project to striosomes and more superficial layers of sensorimotor cortex to matrix. Patches mainly project to substantia nigra pars compacta, whereas matrix neurones may take either the direct or indirect route to the medial globus pallidus/substantia nigra pars reticulata.

Clinical aspects

On the basis of the above evidence, we can no longer assume that basal ganglia pathology produces only motor symptoms and signs. Thus, in patients with

Parkinson's disease, Huntington's disease, and progressive supranuclear palsy—all of which principally (but not exclusively) involve basal ganglia— affective disorder, 'subcortical dementia', or 'frontal lobe deficits' may be seen.

Nevertheless, the most striking clinical features of basal ganglia disease remain those in the motor sphere, comprising tremor, rigidity, akinesia, and postural abnormality as evidenced by Parkinson's disease, and hyperkinetic movement disorders such as chorea and dystonia seen, for example, in Huntington's disease and in subjects with Parkinson's disease chronically treated with levodopa preparations.

The classic tremor of Parkinson's disease is slow (4 to 6 Hz), pill-rolling, and disappears and diminishes on movement, to reappear once a new posture has been adopted. In animal studies a nigral lesion seems necessary, but not sufficient, to cause this tremor.

Akinesia is a symptom complex comprising slowness of movement (bradykinesia), poverty of movement, progressive diminution and fatigue of rapid alternating movements, and difficulty in initiating and sequencing movements and in accomplishing simultaneous motor acts. Since changes in neuronal discharge relating to movement seem to occur later in the basal ganglia than in the motor cortex, it has been proposed that the basal ganglia are more concerned with using information from a previous movement to set up the premotor areas to select the correct parameters for running subsequent motor programmes. In Parkinson's disease levodopa strikingly improves akinesia. Lesions or high-frequency deep brain stimulation (which functionally causes inhibition) in the thalamus does not relieve akinesia in humans, but lesions or deep brain stimulation in the internal pallidum or subthalamic nucleus do so.

Rigidity almost always accompanies akinesia. Resistance to passive movement is broadly similar in flexion and extension. It is described as lead-pipe or, if there is superimposed tremor (visible or invisible), as cogwheeling. Abnormalities of the tonic stretch reflex are felt to contribute to its pathophysiology.

As well as akinesia, both tremor and rigidity respond to levodopa. Unlike akinesia, both also respond to thalamotomy, but the lesion needs to be larger for rigidity than for tremor.

Postural instability is another feature of parkinsonism. This is in part due to impairment of anticipatory responses and postural adjustments associated with movement, and problems in controlling body sway. Unlike the above features, this may often be levodopa resistant.

Of the hyperkinetic movement disorders, chorea (in the case of Huntington's disease) and dystonia (when secondary to discernible brain pathology) can be related to basal ganglia disease. Although chorea can be produced by making lesions in the subthalamic nucleus in intact monkeys, or by chronic dopaminergic treatment of primates with a lesioned nigrostriatal tract, it is not usually possible to produce spontaneous chorea in animals solely by making a caudate lesion analogous to that in Huntington's disease. Similarly, although dystonia may be seen in humans after lesions of the putamen (principally), caudate, or thalamus, there is again no good animal model, although it can be induced by dopaminergic drugs in MPTP-treated primates.

24.11 Visual pathways

Christopher Kennard

Introduction

Diagnosis of disturbances of the visual pathways requires both a thorough knowledge of their anatomy and physiology, as well as the ability to carry out a thorough neuro-ophthalmological examination. It is the examination which should enable the character and extent of the visual disturbance to be documented as well as the topographic localization of the lesion, so that the relevant investigative techniques, such as imaging, can be appropriately requested.

Clinical evaluation of visual function

Examination of visual function initially requires an accurate assessment of the visual acuity. Acuity should be tested separately in each eye using the Snellen or some other optotype chart, which contains rows of letters of diminishing size. If an impairment (> 6/6) is noted, the patient should be allowed to wear glasses or alternatively to view the chart through a pinhole which eliminates any significant refractive error or optic media distortion. If the acuity does not improve, it is necessary to try and distinguish media opacities and retinal abnormalities from optic nerve dysfunction using the swinging flashlight test. In a darkened room each eye is alternatively stimulated with a bright light, which is moved rhythmically from one eye to the other. A dilatation of the pupil of the defective eye when the light is swung from the good eye on to it is termed a 'relative afferent pupillary defect', and signifies optic nerve dysfunction. Another good indicator of an optic nerve disturbance is a defect of colour vision, which may be tested using one of several available booklets of colour plates such as the Ishihara pseudo-isochromatic plates.

The photostress test is a useful test to distinguish a maculopathy from optic nerve dysfunction. The retina of the 'normal' eye is bleached by shining a bright light at the pupil for 10 s, and measuring the time for normal acuity to be re-established. The test is repeated in the 'abnormal' eye and if the difference in recovery time between the two eyes is greater than 60 s, the test is considered abnormal, indicating that the impairment is retinal and not due to an optic nerve disturbance.

Careful fundoscopic examination of the eye is essential to identify abnormalities of the optic media, retina, and optic nerve head.

Finally, examination of the visual fields is essential for topographic localization, since due to the invariate ordering of nerve fibres along the visual pathway, lesions at specific sites produce field defects of specific shapes (Fig. 1). Simple confrontation tests provide a qualitative method of investigating the visual fields. The examiner sits opposite the patient, maintaining a constant distance, and each eye is tested separately. With the patient fixating the examiner's nose, he/she is asked to count stationary fingers presented on either side of the vertical meridian in each quadrant in turn. If the patient cannot identify the fingers in a particular area, the fingers are gently wiggled, and the hand moved towards fixation until they are visible to the patient so mapping out the field defect. To examine the central field a red, 5 to 10 mm hatpin is moved away from or towards the central point of fixation. The patient is asked to describe any changes in the perception of colour or brightness, and whether or not the object disappears at any point. Perimetry provides a quantitative technique for measuring the fields, but a full description is beyond the scope of this chapter.

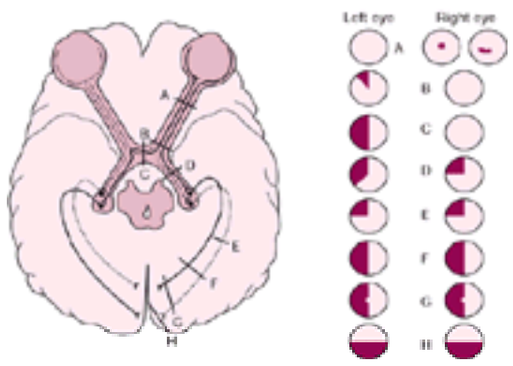

Fig. 1 Patterns of visual field loss due to lesions at different locations along the visual pathway. (a) Optic nerve lesions result in a central scotoma or arcuate defect. (b) Optic nerve lesions just prior to the chiasma produce junctional scotoma due to ipsilateral optic nerve involvement with the inferior contralateral crossing fibres (dashed lines). (c) Chiasma lesions produce bitemporal hemianopia. (d) Optic tract lesions result in incongruous hemianopic defects. (e) and (f) Lesions of the optic radiation result in either homonymous quadrantinopia or hemianopia depending on the extent and location of the lesion (upper quadrant, temporal lobe; lower quadrant, parietal lobe). (g) Lesions of the striate cortex produce a homonymous hemianopia, sometimes with macular sparing, particularly with vascular disturbances. (h) Lesions of the superior or inferior bank of the striate cortex result in inferior or superior altitudinal defects, respectively.

Abnormalities of the optic disc

Optic disc anomalies

Optic nerve hypoplasia

Hypoplasia of the optic nerve may be mild or severe, unilateral or bilateral, and may be associated with normal or impaired visual function. It may occur in isolation, or be associated with central nervous system anomalies, such as the absence of the septum pellucidum in the De Morsier's syndrome (septo-optic dysplasia).

Optic nerve dysplasia

Optic nerve dysplasia presents with a spectrum of abnormalities, including optic nerve colobomas, optic pits, and the morning glory syndrome, all considered to be associated with abnormal closure of the embryonic optic stalk and cup fissure. They are sometimes associated with basal encephaloceles and other forebrain anomalies.

Optic disc colobomas

These are deeply evacuated nerve head anomalies with blood vessels exiting from the margins which are associated with defects in the retinal nerve fibre layer, leading to an appropriate visual field loss.

Optic pits

Optic pits are crater-like depressions in the optic disc with a dark grey hue, usually situated in the temporal disc margin with an accompanying nerve fibre layer defect.

The morning glory syndrome

In this condition, an enlarged dysplastic disc is associated with an elevated centrally retained mass of glial and embryonic glial and vascular material, which radiates outwards in a sunburst pattern.

Tilted discs

An asymmetrically shaped, tilted disc is produced when the optic nerve leaves the globe at an extremely oblique angle. It is often associated with a crescentric zone of exposed sclera along one edge that results in elevation of the superior disc. The disc may appear hypoplastic and patients with this condition often have moderately high myopia and oblique astigmatism.

Optic nerve drusen

Drusen of the optic disc can give rise to an elevation of the optic nerve head. Drusen are intrapapillary, prelaminar refractile concretions that arise from degenerating nerve fibres. Anomalous discs due to drusen are usually smaller than normal, have an absent central optic disc cup, and exhibit an aberrant branching pattern of the central retinal vessels. Initially the drusen are buried with simple elevation of the disc, but become more apparent in later years when they appear to give rise to a typical lumpy disc, with a scalloped margin.

Myelinated nerve fibres

In slightly less than 1 per cent of the population some portions of retinal nerve fibres are myelinated, although normally optic nerve myelination stops at the lamina cribrosa. It appears on fundoscopy as a white area, usually adjacent to the disc, which has a centrifugal feathered edge.

Optic disc swelling

Although optic disc swelling and papilloedema have in the past been used synonymously, it is now usual only to refer to papilloedema as optic disc swelling when it is associated with raised intracranial pressure. Other cases of optic disc swelling are either due to local abnormalities in the optic nerve or orbit, or due to congenital anomalies as described above.

Local causes of optic disc swelling are usually associated with impaired visual acuity and colour vision, central arcuate or altitudinal field defects, and often an afferent pupillary defect. This contrasts with papilloedema when the acuity remains normal, except in the final stages, and is usually bilateral.

Papilloedema

The evolution of the disc changes in papilloedema due to raised intracranial pressure are usually classified into four stages: early, fully developed, chronic, and atrophic.

In early papilloedema there is disc hyperaemia, mild disc swelling with blurring of the fine peripapillary nerve fibre layer striations, dilatation of retinal veins with loss of spontaneous venous pulsations, and occasionally fine splinter haemorrhages at the disc margin.

In fully developed papilloedema, disc elevation is moderate to marked, and there is increased venous distension and tortuosity, an increasing number of peripapillary haemorrhages, cotton wool spots, and dilated capillaries on the disc surface. The retinal blood vessels and disc margin become increasingly indistinct.

In chronic papilloedema, there is resolution of the haemorrhages and exudates leaving a dome-shaped ('champagne cork') disc swelling, which often contains hard exudates. White refractile bodies may appear on the disc surface, known as corpora amylacea. As time goes on there is increasing nerve fibre attrition, leading to progressive visual field loss.

Finally, there is post-papilloedema (consecutive) atrophy, in which the disc acquires a milky opalescence and the retinal vessels are sheathed.

Clinical features

Usually papilloedema is bilateral and there is an absence of visual symptoms. However, unilateral or bilateral transient visual obscurations may occur, which last a few seconds and are often associated with postural changes. Although it has been suggested that such obscurations herald permanent visual loss, there is no evidence to support this view. The longer the papilloedema persists, the more likely there is to be progressive visual field loss, which usually starts as a peripheral field constriction. Occasionally, sudden visual loss occurs in a patient with papilloedema due to ischaemic optic neuropathy.

Pathogenesis

Papilloedema is due to impairment of axonal transport in the retinal nerve fibres, leading to axonal distension which is seen as disc swelling at the level of the prelaminar optic nerve.

Aetiology

There is a vast array of different causes leading to increased intracranial pressure, in particular space-occupying lesions such as tumours (Table 1).

Management

Treatment primarily depends on the underlying cause of the raised intracranial pressure. If due to a mass lesion which cannot be completely removed, or due to a non-surgically remediable cause, then a shunting procedure or medical measures, for example osmotic agents or diuretics such as acetazolamide, may be used. Increasingly, optic nerve sheath fenestration is being used for patients with intractable papilloedema who are developing early visual loss.

Ischaemic optic neuropathy

Ischaemic optic neuropathy is due to infarction of the optic nerve head, and can either be arteritic, as part of giant cell arteritis, or non-arteritic (idiopathic ischaemic neuropathy, anterior ischaemic optic neuropathy), which is the commoner form of the condition.

Non-arteritic ischaemic optic neuropathy

This tends to occur in patients aged between 45 and 80 years, and is characterized by abrupt, painless, and generally non-progressive visual loss, associated with an arcuate or altitudinal visual field loss. In nearly all cases, there is optic disc oedema, often associated with one or more splinter haemorrhages at the disc margin. Although previously considered irreversible, as many as 40 per cent of patients may show some improvement.

There is a 40 per cent chance of involvement of the fellow eye within five years. Optic atrophy rapidly ensues after the ischaemic event. The cause of non-arteritic ischaemic optic neuropathy remains obscure, and there is no treatment of proven benefit. The most important aspect of management is to exclude the possibility of the arteritic form, since in such cases the fellow eye is particularly vulnerable to similar involvement.

Arteritic ischaemic optic neuropathy

The arteritic form of ischaemic optic neuropathy usually occurs in giant cell (cranial, temporal) arteritis, but also rarely occurs in lupus and polyarteritis nodosa. Anyone with non-arteritic ischaemic optic neuropathy over the age of 50 should be suspected of having giant cell arteritis. This often occurs in the context of headache, malaise, weight loss, anorexia, anaemia, proximal muscle ache or stiffness, temporal artery tenderness, jaw claudication, and fever. These symptoms and signs usually precede the visual loss. The disc infarction is similar to that seen in non-arteritic ischaemic optic neuropathy.

A high index of suspicion is required for giant cell arteritis, and if suspected, an urgent erythrocyte sedimentation rate and temporal artery biopsy should be arranged. At the same time as the blood for the erythrocyte sedimentation rate is taken, the patient should be started immediately on systemic steroids (prednisolone at 80 mg daily, plus 200 mg of intravenous hydrocortisone immediately). In most patients the erythrocyte sedimentation rate is markedly elevated, as is the C-reactive protein. Occasionally the erythrocyte sedimentation rate may be normal. A biopsy of the superficial temporal artery should be obtained as soon as possible after the diagnosis has been considered. The biopsy will not be affected by the use of corticosteroids for at least 48 h. A positive temporal artery biopsy confirms the diagnosis of giant cell arteritis, but in 25 per cent of patients skip areas are found in biopsy specimens, and therefore a negative biopsy may sometimes be obtained.

Steroid treatment should not be tapered or withdrawn too early, since a relapse of symptoms is common. The dose of prednisolone can be gradually tapered after 2 to 3 weeks to maintain a normal erythrocyte sedimentation rate and the patient asymptomatic. Treatment should be continued for at least 6 to 12 months.

Optic atrophy

Optic atrophy is the final result of a variety of disturbances to the optic nerve or retina. The disc appears pale, and there is an absence of disc vasculature and retinal nerve fibres (Fig. 1).

Optic atrophy occurs after any disease process that results in death of the retinal ganglion cells with a dying back of their nerve fibres. This can, therefore, be due to diseases that directly involve the ganglion cells themselves or from damage to the axons in the pregeniculate visual pathway, resulting in retrograde atrophy. The development of optic atrophy is usually slow, dependent on its cause. In most instances the optic atrophy is bilateral, the disc appearing chalky-white in colour with clearly defined margins. The differential diagnosis of optic atrophy is considered in Table 2.

Optic neuritis

Optic neuritis is a term used to describe an idiopathic optic neuropathy or one resulting from inflammatory, infectious, or a demyelinating aetiology. In most cases the optic disc is normal on ophthalmoscopy and the term retrobulbar neuritis is used. In those cases in which the optic disc is swollen, the terms papillitis or anterior optic neuritis are used.

Clinical features

It is important to distinguish between those features of typical optic neuritis of idiopathic or demyelinating causation from atypical optic neuritis. In typical optic neuritis there is usually acute unilateral loss of visual acuity and of visual field, which may progress over hours or a few days, reaching its maximal effect within one week. Ninety per cent of patients complain of ocular pain which is noted especially with eye movement, and which may precede the visual impairment by a few days. The visual loss may range from contrast defects with maintained acuity, to no light perception. The patient is usually aged under 40 years, although optic neuritis may occur at any age, and improvement takes place in most patients (90 per cent) to normal or near normal visual acuity over several weeks. There may be persistent subtle residual defects of colour vision, depth perception, and contrast sensitivity, which may continue for several months. Subsequent disc pallor may occur but does not correlate closely with the level of visual recovery. An afferent pupillary defect is present in over 90 per cent of patients with acute optic neuritis. Although optic neuritis is generally associated with a central scotoma, a wide variety of field defects may be found ranging from a central scotoma, to altitudinal and nerve fibre layer defects.

Atypical optic neuritis may involve bilateral simultaneous onset of optic neuritis in an adult patient. There is often lack of pain and there may be other ocular findings suggestive of an inflammatory process, such as an anterior uveitis. Other features include a worsening of visual function beyond 14 days of onset, in a patient outside the 20- to 50- year age span. They may also have evidence of other systemic conditions, particularly inflammatory or infectious diseases (Table 3).

The evaluation of patients with optic neuritis rather depends on whether or not it is a typical or atypical case. Typical optic neuritis probably does not necessitate any additional laboratory investigations, although an abnormal MRI of the brain significantly increases the likelihood of developing multiple sclerosis.

Those patients with atypical optic neuritis should have a chest radiograph, laboratory tests including a blood count, biochemistry, and tests for collagen and vascular disease and syphilis serology. Examination of the cerebrospinal fluid is probably justified in this group of patients.

Management

Although intravenous methylprednisolone leads to a more rapid visual recovery, at the end of 6 months the visual acuity is no better than without the treatment. Therefore, steroid treatment of patients with typical optic neuritis is unnecessary, unless there is severe ocular pain that cannot be managed with analgesics, or if there is already poor vision in the fellow eye due to some other disease process.

Heredofamilial optic neuropathies

The hereditary optic neuropathies can either be those which are autosomal dominant or recessive, or those which are due to point mutations in mitochondrial DNA. The autosomal conditions usually present in childhood with impaired vision and pale optic discs.

Leber's hereditary optic neuropathy

This mitochondrial disorder develops primarily in males (approximately 14 per cent in women) in the second to third decade of life. It is characterized by an abrupt loss of central vision in one eye, usually followed by a loss of vision in the remaining eye which may occur weeks, months, or sometimes years later. Occasionally visual loss may occur simultaneously in the two eyes. There is no associated pain on eye movement in contrast to acute optic neuritis, and the visual loss is usually permanent with optic atrophy and large absolute central scotomas. However, the fundoscopic picture in the acute phase often shows swelling of the papillary nerve fibre layer, circumpapillary telangiectatic microangiopathy, and tortuosity of the retinal vessels.

There is a maternal pattern of inheritance and point mutations in mitochondrial DNA, particularly at the 11778 nucleotide and less frequently at 3460 and 14484, have been identified. The significance of the point mutation at 14484 is that a much higher percentage (37 per cent as opposed to 4 per cent) of patients show some visual recovery when compared with patients who have a defect at 11778. It is, therefore, appropriate to carry out genetic testing in those individuals presenting with atypical optic neuritis of the appropriate sex and age, even if a positive family history is not available. There is no effective treatment for this condition.

Nutritional and toxic optic neuropathies

Bilateral, slowly progressive central visual loss with centro-caecal scotomas, and usually normal or mild temporal atrophic optic discs characterizes optic nerve failure due to either nutritional deficiency or a toxic cause. Once a family history of one of the hereditary familial diseases has been excluded, this condition should be considered, and is usually due to a combination of alcohol abuse, deficiencies within the B vitamin complex, and frequently a high tobacco consumption. With treatment by abstinence of the likely toxic agents and vitamin supplementation, recovery of vision usually occurs, unless the condition is so long standing that optic atrophy has intervened. Recent epidemics of optic neuropathy in Cuba and in West Africa have probably been related to multiple dietary deficiencies.

Toxic optic neuropathy has been associated with ethambutol, chloramphenicol, halogenated hydroxyquinolones, lead, isoniazid, and vincristine.

Tumours of the optic nerve

Optic nerve sheath meningiomas

Although optic nerve sheath meningiomas may arise directly from the optic nerve sheath, usually in the orbital regions of the nerve, they frequently arise from the tuberculum sellae, sphenoid wing, and olfactory groove, leading to secondary invasion or compression of the nerve. Primary optic nerve sheath meningiomas, most frequently found in middle-aged women, are usually unilateral, but if bilateral raise the possibility of central neurofibromatosis (NF-2). Although most patients will have mild (2 to 4 mm) proptosis at the time of their initial consultation, they complain of dimming of vision and decreased colour vision. Visual loss progresses over years with optic disc swelling gradually being supplanted by optic atrophy, with or without the evolution of optociliary venous (retinochoroidal anastamoses) shunt vessels.

The CT picture in patients with these tumours is most often one of diffuse narrow enlargement of the optic nerve, with bulbous swellings of the nerve in the region of the globe and orbital apex. 'Railroad-track' calcification of the optic nerve sheath in the orbit is a characteristic feature. Use of MRI has enabled optic nerve sheath meningiomas to be distinguished from optic nerve gliomas, where the former but not latter shows that the nerve is readily distinguished from the optic nerve sheath.

Management of patients with optic nerve sheath meningiomas is controversial. While there is general agreement that nerve sheath tumours are most aggressive in children and become progressively more indolent with advancing age, there is no consensus as to the best way to treat these lesions. Clinical resection, particularly when there is intracranial spread, is usually incomplete. These patients rarely die from the meningioma and it is probably best to observe. In some instances radiotherapy has shown to result in some visual improvement.

Optic nerve gliomas

Optic nerve gliomas, which may also involve the chiasma, are of two distinct types. By far the commoner is the benign glioma of childhood, and the other the malignant glioblastoma in adults. Approximately a quarter of cases occur in the setting of NF-1.

Benign optic nerve gliomas usually present within the first two decades of life, with a peak incidence from 1 to 6 years of age. The usual presenting manifestations are proptosis and visual loss, which may be so mild as to be undetectable, although a profound reduction in acuity is more common. The fundus may show either papilloedema or optic atrophy.

The clinical course of childhood optic nerve gliomas is highly variable. In some, tumour enlargement proceeds slowly for a time but then reaches a plateau, while in others the enlargement proceeds unabated. Necropsy has suggested that they are in fact hamartomas rather than true neoplasms. Optic nerve gliomas are generally managed conservatively, although some practitioners favour radiation therapy for lesions with chiasmal involvement and surgery for at least those tumours restricted to the orbit.

Optic nerve gliomas of adulthood are malignant gliomas which usually arise in males aged 40 to 60 years. These patients often present with a rapid onset of visual failure, which on some occasions may mimic acute optic neuritis. The tumour rapidly progresses and the patient usually dies within a short period.

Other optic nerve tumours

Metastatic cancer may lead to optic nerve involvement, either as a result of infiltration of the meninges as occurs with cancer of the breast and lung, or by direct tumour infiltration as with lymphoproliferative disorders and certain types of leukaemia and non-Hodgkin's lymphoma. Paraneoplastic optic neuropathy has also been described in patients with small cell carcinoma of the lung.

Disorders of the optic chiasm

Approximately 25 per cent of all brain tumours occur in the chiasmal region and since half of these cases initially present with visual loss, an appreciation of the various field abnormalities is important. Although there are a number of other causes for the chiasmal syndrome, such as trauma and demyelination, these are rare. The neuro-ophthalmological signs of a compressive optic chiasm lesion are primarily a field defect and deterioration of visual acuity, which depend on the relationship of the chiasm to the pituitary. The classic field defect of a chiasmal lesion is a bitemporal hemianopia. This may be complete or incomplete and may or may not be symmetrical. It is unusual to have a bitemporal hemianopia without some reduction in central visual acuity in at least one eye, due to the optic nerve being compromised in addition to the chiasm.

In large series of patients with pituitary tumours the most common field defect is a bitemporal hemianopia (67 per cent); less common are junctional scotoma (29 per cent), homonymous hemianopia (7 per cent), and prechiasmal field loss (2 per cent). Other signs include optic disc pallor, but its absence usually denotes a virtual complete return of visual function with successful decompression.

Other causes of chiasmal compression in addition to pituitary adenomas (50 to 55 per cent) include craniopharyngiomas (20 to 25 per cent), meningiomas (10 per cent), and gliomas (7 per cent).

Optic tract lesions

The optic tract is the first point in the visual pathways where the ipsilateral temporal and contralateral nasal retinal nerve fibres come together, and so the field defect is usually a partial or complete homonymous hemianopia. When partial, there is often gross incongruity between the visual field defects found in each eye, which may also be found with lesions of the lateral geniculate nucleus and more rarely the optic radiations.

The most frequently encountered lesions causing the optic tract syndrome are aneurysms, craniopharyngiomas, and pituitary tumours.

The optic radiations

As the geniculostriate fibres leave the lateral geniculate nucleus, the ventral fibres (subserving the superior visual field) pass anteriorly around the temporal horn of the lateral ventricle to form Meyer's loop. Lesions in this region usually result in a wedge-shaped congruous homonymous field defect, mainly affecting the superior quadrant. The visual acuity and pupillary responses are both normal. Lesions involving the optic radiation are due to vascular occlusion, tumours (intrinsic or metastatic), or abscesses.

Although lesions of the dorsal optic radiation in the parietal lobe may result in a homonymous hemianopia primarily affecting the lower fields, large lesions usually result in a complete homonymous hemianopia with macular splitting. Damage to the parietal or occipitoparietal cortex may result in the phenomenon in the contralateral visual field called unilateral visual inattention or visual extinction. A test object presented in this field is perceived normally, but when an identical object is similarly presented equidistant from the fixation point in the ipsilateral visual field, the stimulus in the field contralateral to the parietal lobe lesion disappears.

Occipital lobe

On reaching the occipital lobe there is a high degree of order in the fibres of the optic radiation and lesions, which are usually due to infarction, trauma, or tumour, produce homonymous congruent field defects. The only features of the field defect which help localize the lesion to the occipital lobe, rather than the anterior optic radiation, are the presence of sparing of the macula or temporal crescent areas in a homonymous hemianopia.

In macula sparing there is preservation of the visual field within a region of 1 to 2° up to 10° around the fixation point in the hemianopic field. In the more usual situation the hemianopic field is split along the vertical meridian through the fixation point (macula splitting).

Altitudinal (dorsal/ventral) field defects involving either the upper or lower occipital poles may occur as a result of trauma or vascular lesions.

Cortical blindness

Cortical blindness usually indicates selective involvement of the occipital visual cortex. The essential features are: (i) complete loss of all visual sensation, (ii) loss of reflex lid closure to threat, (iii) normal pupillary light reactions, and (iv) normal retina and full extraocular eye movements. The commonest aetiology is hypoxia of the striate cortex.

Disorders of higher visual processing

In the extrastriate cortex there is parallel processing of different aspects of visual information before an organized synthesis of the visual scene can be generated. Specific lesions in one or other of these areas might be expected to give rise to an appropriate specific loss of a visual modality such a colour (achromatopsia), movement (akinetopsia), or faces (prosopagnosia).

Acquired disorders of colour vision due to lesions of the central nervous system are of two types. In one type there is an inability to see colours (dyschromatopsia or achromatopsia). These patients have lesions in the region of the lingual and fusiform gyri, which lies in the anterior inferior region of the occipital lobe. They complain that they cannot see colours and that everything looks grey or in varying shades of black and white. They are unable to identify the figures on pseudo-isochromatic test plates although they are able to name the colours of brightly coloured objects correctly. Other functions such as visual acuity, object recognition, and depth perception are all normal, but there is often an associated visual field defect, usually a bilateral superior homonymous quadrantanopia. In the other type of disorder the colour sense is normal but the naming and recognition of colour is impaired. This can occur as part of an aphasia, such as Wernicke's or anomic, in the syndrome of alexia without agraphia, or as one feature of visual agnosia (see below).

Rare cases of patients who exhibit a selective deficit of movement perception (akinetopsia) have been reported. The patients have bilateral lesions involving the lateral occipito-parieto-temporal junction.

Visual agnosia

The term visual agnosia refers to a rare condition in which there is an inability to recognize, name, or demonstrate the use of an object presented visually, in the absence of a language deficit, general intellectual dysfunction, or attentional disturbances. The patient is, however, able to name the object when using other sensory modalities such as touch or sound.

One classification depends on the specific category of visual material that cannot be recognized. A disturbance of recognition of objects (object agnosia), faces (prosopagnosia), or colour (colour agnosia) may occur in isolation or in various combinations. When patients are able to copy and match-to-sample objects that they fail to name or recognize visually, the agnosia is termed associative; but if there is an inability to perform all these tasks, the agnosia is termed apperceptive.

Prosopagnosia is a specific inability to recognize familiar faces despite a normal ability to recognize everyday objects, and is, therefore, different from visual agnosia. Most cases of prosopagnosia are due to infarction, head injury, or hypoxia resulting in bilateral lesions in the ventromedial aspects of the occipitotemporal region.

Visual illusions

Visual illusions occur when the visually perceived target appears altered in size, shape, colour, position in space, and in number of images. The illusory type of defects may occur in the entire field of vision, or may affect only the object or the background. The term 'dysmetropsia' indicates the apparent smallness (micropsia), largeness (macropsia), or irregularity of shape (metamorphopsia) of objects. Dysmetropsia usually occurs as a result of retinal disease due to distortion of the relative distance between rods and cones.

Visual hallucinations

Visual hallucinations occur under many circumstances, such as drug withdrawal, anoxia, migraine, infection, and schizophrenia, in addition to those related to focal neurological disease in the occipital or temporal lobes. Those in the latter category may be unformed, consisting of flashes of light (coloured or white), lines, or simple shapes, or they may be complex highly organized hallucinations of people or objects.

Palinopsia

Palinopsia is a rare disorder in which there is persistence (perseveration) or recurrence of visual images after the exciting stimulus has been removed.

24.12.1Eye movements and balance

Thomas Brandt and Michael Strupp

Introduction

The main objective of this chapter is to describe the clinically relevant principles of ocular motor and vestibular disorders. The anatomical and functional overlap of the vestibular and ocular motor systems warrants a joint discussion.

Eye movements

Different types of eye movement can be distinguished, each with particular functions, physiological properties, and specific anatomical substrates. Many abnormalities of eye movement are thus distinctive and often indicate the site and the side of a lesion. This is useful for topographic diagnosis, a method that still frequently proves superior to imaging techniques. It is therefore important that the physician examines in detail the eye movements of a patient suffering from, for example, double vision, oscillopsia, or vertigo, for he can by this means often differentiate between 'peripheral' and 'central' ocular motor or vestibular disorders. In their excellent book *Neurology of eye movements*, Leigh and Zee (1999) correctly state that 'an understanding of the properties of each functional class of eye movements will guide the physical examination; a knowledge of the neural substrate will aid topological diagnosis'.

Normal vision relies on eye movements in two essential ways. On the one hand, eye movements make it possible to shift the gaze and to view objects of interest. On the other, when the head moves during locomotion, the eyes move in a direction opposite to that of the head and compensate for these head movements, thereby preventing involuntary shifts of the visual images projected on the retina. The retinal images are kept steady. Optimal functioning of the eye movements is ensured by the co-operation between the optokinetic reflex and the vestibulo-ocular reflex.

In essence, there are three types of conjugate eye movements: smooth pursuit, saccades, and the vestibulo-ocular reflex. In the following paragraphs we summarize their properties, main function, clinical examination, and pathological findings as well as the typical features of vestibular nystagmus and gaze-evoked nystagmus.

Smooth pursuit keeps the image of a moving object on the fovea. The pursuit system generates smooth tracking eye movements that closely match the pace of a target; its examination is illustrated in Fig. 1. Various anatomical structures (motion-sensitive visual cortex, frontal eye fields, pontine nuclei, cerebellum, vestibular and ocular motor nuclei) are involved in smooth pursuit eye movements. Therefore, topographically impaired smooth pursuit (reduced gain) is an unspecific finding, which may be further influenced by alertness, a variety of drugs, and age. Moreover, vertical smooth pursuit is worse than horizontal, and downward tracking worse than upward. Marked asymmetries of smooth pursuit, however, indicate a central lesion; strongly impaired smooth pursuit is observed in intoxications and degenerative disorders involving the cerebellum or extrapyramidal system.

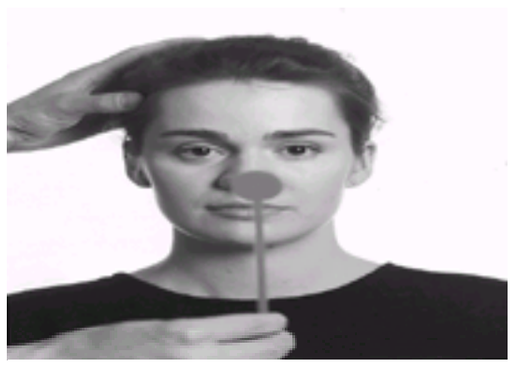

Fig. 1 Clinical examination of smooth pursuit. The patient is asked to track visually an object moving slowly in horizontal and vertical directions (10 to 20°/s) with the head stationary. Look for corrective (catch-up or back-up) saccades; they indicate an inappropriate smooth pursuit gain.

Saccades bring images of objects of interest on the fovea; their clinical examination is illustrated in Fig. 2. Slowing of saccades—often accompanied by hypometric saccades—is also often a side-effect of many types of medications/toxins and is found in neurodegenerative disorders. Slowing of horizontal saccades is observed in brainstem lesions, for example of the ipsilateral paramedian pontine reticular formation; slowing of vertical saccades may be due to a midbrain lesion and is observed in progressive supranuclear palsy. Lesions of the cerebellum or cerebellar pathways may cause hypermetric saccades, followed by corrective saccades that can be easily observed. For example, in Wallenberg's syndrome, a saccadic overshoot toward the side of the lesion is due to an interruption of the inferior cerebellar peduncle; interruption of the superior cerebellar peduncle leads to contralateral hypermetric saccades. In internuclear ophthalmoplegia the adducting saccade is slower than the abducting saccade. Delayed-onset saccades are most often caused by cerebral cortical lesions.

Fig. 2 Clinical examination of saccades. First observe spontaneous saccades to visual or auditory targets. Then ask the patient to glance back and forth between two horizontal and two vertical targets, keeping the head stationary. The velocity, accuracy, conjugacy, and the initiation time of the saccade should be observed. Normal individuals can immediately reach the target with a fast single movement or one small corrective saccade.

The vestibulo-ocular reflex holds images of the seen world steady on the retina during brief head rotations and locomotion. Halmagyi and Curthoys (1988) described an important clinical bedside test of the horizontal vestibulo-ocular reflex, which is illustrated in Fig. 3. This simple test allows the physician to find out whether there is a unilateral or a bilateral peripheral vestibular deficit.

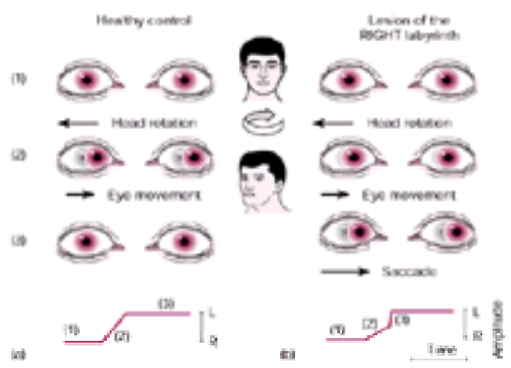

Fig. 3 Clinical bedside testing of the horizontal vestibulo-ocular reflex by the Halmagyi–Curthoys test. Fast 20 to 30° rotations of the head toward the side of the lesion show the dynamic deficit of the horizontal vestibulo-ocular reflex. In contrast to the healthy control (a), the patient is not able to generate a fast contraversive eye movement and has to perform a corrective (catch-up) saccade to fixate the target (b). It is important to instruct the patient to look carefully at the examiner's nose and to apply brief, high acceleration head thrusts to detect a unilateral peripheral vestibular deficit, for example due to vestibular neuritis or acoustic neuroma.

Finally, two clinically important pathological eye movements should be mentioned: gaze-evoked nystagmus and spontaneous nystagmus. As illustrated in Fig. 4 and Fig. 5, gaze-evoked nystagmus should be observed when the patient is fixating with both eyes. It is most often a side-effect of medication/toxins such as anticonvulsants, hypnotics, or alcohol. Horizontal gaze-evoked nystagmus may be due to structural lesions of the brainstem (medial vestibular nucleus and nucleus prepositus hypoglossi, that is, the neural integrator to maintain gaze position after execution of a gaze shift), or the flocculus. Vertical gaze-evoked nystagmus is observed in midbrain lesions involving the interstitial nucleus of Cajal. A dissociated horizontal gaze-evoked nystagmus (greater in the abducting than the adducting eye) and an adduction deficit are the signs of internuclear ophthalmoplegia due to a lesion of the medial longitudinal fasciculus.

Fig. 4 Clinical examination of the eyes in nine different positions to evaluate ocular alignment, fixation deficits, nystagmus, range of movement, and gaze-holding abilities. The examination can be performed using an object (left) or an examination lamp. In primary position look for (a) abnormal eye movements such as nystagmus (for example, peripheral vestibular: horizontal-rotatory, suppressed by fixation; central vestibular: vertical (upbeat, downbeat), horizontal or torsional, poorly suppressed or even increasing with fixation; congenital: usually horizontal, variable in frequency and amplitude, increasing with fixation); square-wave jerks (small saccades of 0.5 to 5° that cause the eyes to move from the primary position, for example in progressive supranuclear palsy or certain cerebellar syndromes); ocular flutter (intermittent bursts of horizontal oscillations); or opsoclonus (combined horizontal, vertical, and rotatory oscillations); the latter two may have different aetiologies, for example encephalitis, tumours, or drugs/toxins and (b) misalignment of the visual axes. Then establish the range of motion with ductions (one eye viewing) and versions (with both eyes viewing) in the eight end-positions; this can indicate, for example, ocular muscle or nerve palsy. Gaze-holding deficits can be evaluated in eccentric gaze position (Fig. 5).).

Fig. 5 Clinical examination of the eye positions/movements using an examination lamp. The advantage of the lamp as opposed to an object is that the reflected light on the eye can be observed and thus ocular misalignments can be easily detected. In addition, the patient can fixate with one or both eyes in the end-positions.

Spontaneous nystagmus indicates a tone imbalance of the vestibulo-ocular reflex which may be central or peripheral; when peripheral—as in vestibular neuritis—it is typically damped by visual fixation. Therefore, spontaneous nystagmus should be examined by Frenzel's glasses (Fig. 6).

Fig. 6 Clinical examination with Frenzel's glasses. The magnifying lenses (+16 dioptres) have light inside to prevent visual fixation, which could suppress spontaneous nystagmus. Frenzel's glasses enable the clinician to observe spontaneous eye movements better. Examination should include spontaneous and gaze-evoked nystagmus, head-shaking nystagmus (instruct the patient to rotate his head about 20 times and observe eye movements following head shaking), positioning and positional nystagmus, as well as hyperventilation-induced nystagmus.

As a general rule, it is often necessary to combine the pathological clinical findings of the different eye movement systems to differentiate between a central and peripheral vestibular disorder and to make an exact topographical diagnosis.

Dizziness and vertigo

Vertigo, dizziness, and disequilibrium are common complaints of patients of all ages, particularly the elderly. As presenting symptoms, they occur in 5 to 10 per cent of all patients seen by general practitioners and 10 to 20 per cent of all patients seen by neurologists and otolaryngologists. The clinical spectrum of vertigo is broad, extending from vestibular rotatory vertigo with nausea and vomiting to presyncope light-headedness, from drug intoxication to hypoglycaemic dizziness, from visual vertigo to phobias and panic attacks, and from motion sickness to height vertigo. Appropriate preventions and treatments differ for the various types of dizziness and vertigo; they include drug therapy, physical therapy, psychotherapy, and surgery.

Vertigo usually implies a mismatch between the vestibular, visual, and somatosensory systems. These three sensory systems subserve both static and dynamic spatial orientation, locomotion, and control of posture by constantly providing reafferent cues. The sensory information is partially redundant in that two or three senses may simultaneously provide similar information about the same action. Thanks to this overlapping of their functional ranges, it is possible for one sense to substitute, at least in part, for deficiencies in the others. When information from two sensory sources conflicts, the intensity of the vertigo is a function of the degree of mismatch; it is increased if information from an intact sensory system is lost, as for example in a patient with pathological vestibular vertigo who closes his eyes. The distressing sensorimotor consequences of the mismatch are frequently based on our earlier experiences with orientation, balance, and locomotion, that is, there is a mismatch between the expected and the actually perceived pattern of multisensory input.

Vertigo may thus be induced by physiological stimulation of the intact sensorimotor systems (height vertigo; motion sickness) or by pathological dysfunction of any of the stabilizing sensory systems, especially the vestibular system. The symptoms of vertigo include sensory qualities identified as arising from vestibular, visual, and somatosensory sources. As distinct from one's perception of self-motion during natural locomotion, the experience of vertigo is linked to impaired perception of a stationary environment; this perception is mediated by central nervous system processes known as 'space constancy mechanisms'. Loss of the external stationary reference system required for orientation and postural regulation contributes to the distressing mixture of self-motion and surround motion.

Physiological and clinical vertigo syndromes are commonly characterized by a combination of phenomena involving perceptual, ocular motor, postural, and autonomic manifestations: vertigo, nystagmus, ataxia, and nausea. These four manifestations correlate with different aspects of vestibular function and emanate from different sites within the central nervous system.

1. The vertigo itself results from a disturbance of cortical spatial orientation.
2. Nystagmus is caused by a direction-specific imbalance in the vestibulo-ocular reflex, which activates brainstem neuronal circuitry.
3. Vestibular ataxia and postural imbalance are caused by inappropriate or abnormal activation of monosynaptic and polysynaptic vestibulospinal pathways.
4. The unpleasant autonomic responses with nausea, vomiting, and anxiety travel along ascending and descending vestibulo-autonomic pathways to activate the medullary vomiting centre.

About 50 per cent of all patients presenting with dizziness, vertigo, or disequilibrium in a neurological dizziness unit will be suffering from one of the five following common syndromes (Table 1):

1. benign paroxysmal positioning vertigo;
2. somatoform vertigo (phobic postural vertigo);
3. basilar migraine (vestibular migraine);
4. Menière's disease; or
5. vestibular neuritis.

A clinician unfamiliar with dizzy patients can most effectively deepen his knowledge by acquainting himself with these five most frequently met and challenging conditions of vertigo. Diagnosis and management of vertigo syndromes always require interdisciplinary thinking, and history taking is still much more important than recordings of eye movements or brain imaging techniques. Although most clinicians welcome the attempts to develop computer interview systems for use with neuro-otological patients and expert systems as diagnostic aids in otoneurology, their application in a clinical setting is still quite limited.

Dizziness is a vexing symptom, difficult to assess because of its purely subjective character and its variety of sensations. The sensation of spinning or rotatory vertigo is much more specific; if it persists, it undoubtedly indicates acute pathology of the labyrinth, the vestibular nerve, or the caudal brainstem, which contains the vestibular nuclei.

History taking allows the early differentiation of vertigo and disequilibrium disorders into seven categories that serve as a practical guide for differential diagnosis:

1. dizziness and light-headedness (such as presyncopal dizziness or drug intoxication);
2. single or recurrent attacks of (rotatory) vertigo (such as Menière's disease, vestibular migraine);
3. sustained (rotatory) vertigo (such as vestibular neuritis, Wallenberg's syndrome);
4. positional/positioning vertigo (such as in benign paroxysmal positioning vertigo, central positional vertigo);
5. oscillopsia (apparent motion of the visual scene, such as in bilateral vestibulopathy, downbeat nystagmus);
6. vertigo associated with auditory dysfunction (such as Menière's disease, Cogan's syndrome); and
7. dizziness or to-and-fro vertigo with postural imbalance (such as phobic postural vertigo, episodic ataxia).

Management of the dizzy patient

The prevailing good prognosis of vertigo should be emphasized because of the following.

1. Many forms of vertigo have a benign cause and are characterized by spontaneous recovery of vestibular function or central compensation of a peripheral vestibular tone imbalance.
2. Most forms of vertigo can be effectively relieved by pharmacological treatment (Table 2), physical therapy (Table 3), surgery (Table 4), or psychotherapy.

There is, however, no common treatment, and vestibular suppressants provide only symptomatic relief of vertigo and nausea. A specific therapeutic approach thus requires recognition of the numerous particular pathomechanisms involved. Such therapy can include causative, symptomatic, or preventive approaches.

The essential characteristics are given for benign paroxysmal positioning vertigo (Table 5; see Fig. 7), Menière's disease (Table 6), vestibular neuritis (Table 7), bilateral vestibular failure (Table 8), and vestibular migraine (Table 9).

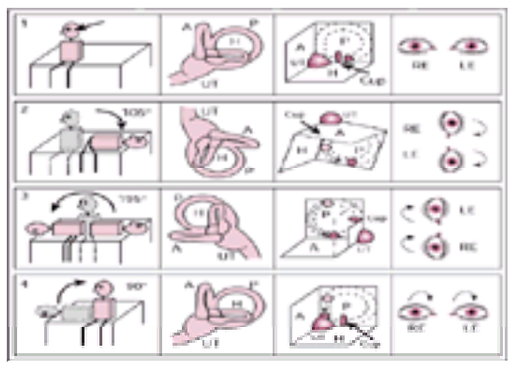

Fig. 7 Schematic drawing of the Semont liberatory manoeuvre in a patient with typical benign paroxysmal positioning vertigo (BPPV) of the left ear. Boxes from left to right: position of body and head, position of labyrinth in space, position and movement of the clot in the posterior canal and resulting cupula deflection, and direction of the rotatory nystagmus. The clot is depicted as an open circle within the canal; a black circle represents the final resting position of the clot. (1) In the sitting position, the head is turned horizontally 45° to the unaffected ear. The clot, which is heavier than endolymph, settles at the base of the left posterior semicircular canal. (2) The patient is tilted approximately 105° toward the left (affected) ear. The change in head position, relative to gravity, causes the clot to gravitate to the lowermost part of the canal and the cupula to deflect downward, inducing BPPV with rotatory nystagmus beating toward the undermost ear. The patient maintains this position for 2 min. (3) The patient is turned approximately 195° with the nose down, causing the clot to move toward the exit of the canal. The endolymphatic flow again deflects the cupula such that the nystagmus beats toward the left ear, now uppermost. The patient remains in this position for 2 min. (4) The patient is slowly moved to the sitting position; this causes the clot to enter the utricular cavity. Abbreviations: A, P, and H: anterior, posterior, and horizontal semicircular canals; Cup, cupula; UT, utricular cavity; RE, right eye; LE, left eye. (From Brandt *et al*. 1994.)

24.12.2Disorders of hearing

Linda M. Luxon

> Our hearing is a choice and dainty sense, and hard to mend, yet soon it may be marred. Blows, falls and noise...all these...breed tingling in the ears and hurt our hearing.
>
> (Physicians of the Medical School of Salerno)

Hearing loss is the most common sensory impairment and the World Health Organization has estimated that at least 120 million people are affected worldwide. In the United Kingdom, about 20 per cent of the adult population are affected and, of these, three-quarters are over the age of 60 years. Age, gender, occupational group, and occupational noise exposure are factors affecting the prevalence of hearing impairment in adults, while a neonatal intensive-care unit history, a family history of childhood hearing loss, and craniofacial abnormalities explain over half of the population of congenitally hearing-impaired children. The most frequent form of acquired hearing impairment in children is a conductive hearing loss due to chronic secretory otitis media, while meningitis, in particular meningococcal meningitis, is the commonest cause of acquired sensorineural hearing loss. In the developing world, many of the preventable causes of hearing impairment remain common: consanguineous marriages, birth trauma, childhood infections, noise exposure, and the unlicensed sale of ototoxic drugs.

Tinnitus, defined as a noise in the head or ears lasting for more than 5 min, increases with age and affects approximately 20 per cent of the population over the age of 60 years, but only 4 per cent of the population complain of this symptom.

Hearing impairments

Pathophysiology

For clinical purposes the ear is separated into three parts: the external, middle, and internal ear (Fig. 1). The external ear is important in funnelling sound to the tympanic membrane and in the localization of sound. The middle ear ossicles connect the tympanic membrane to the oval window of the cochlea, such that sound waves cause displacement within the fluid-filled compartment of the membranous labyrinth. Within the internal ear, the mechanical activity at the oval window is transduced into neural responses by the hair cells of the Organ of Corti (Fig. 2).

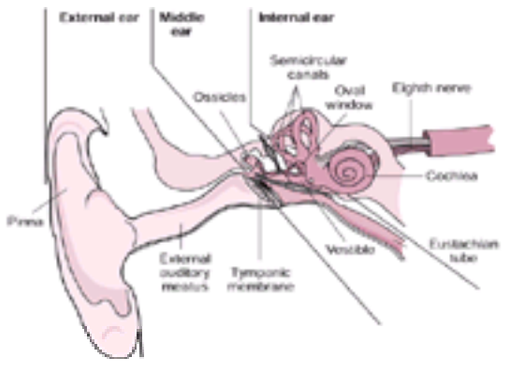

Fig. 1 Diagram to illustrate the anatomy of the peripheral auditory system.

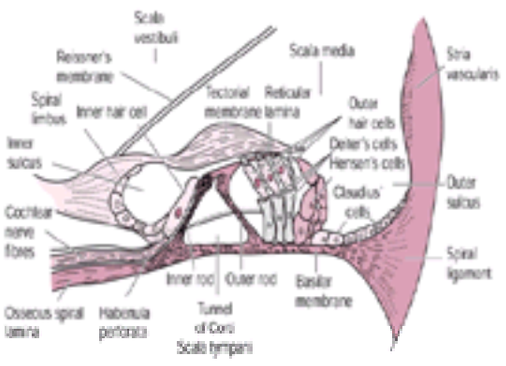

Fig. 2 Diagram of the Organ of Corti.

Disorders of the external and middle ear result in abnormalities of the mechanical transmission of sound from the environment to the internal ear, and give rise to a conductive hearing loss. Common examples include impacted wax, serous otitis media (glue ear), chronic otitis media, and disorders of the ossicular chain, for example otosclerosis, and traumatic discontinuity.

Disorders of the internal ear and the VIIIth cranial nerve characteristically give rise to a sensorineural hearing loss, in which the perception of both bone- and air-conducted sounds is reduced and the appreciation of the intensity of sound and the frequency resolution of complex sounds are impaired. Many conditions may affect the cochlea, ranging from inherited, congenital or iatrogenic non-syndromal or syndromal malformations to ototoxic damage (aminoglycoside, antimalarial, loop diuretics), ischaemia including vertebrobasilar ischaemia, diabetic vasculitis, infections (mumps, rubella, syphilis, cytomegalovirus), autoimmune disorders, degenerative disorders, trauma, and idiopathic conditions such as Menière's disease. Pathology of the VIIIth nerve leading to hearing impairment has been defined in spinocerebellar degenerations, trauma, cerebellopontine angle tumours, bony disorders such as Paget's disease, infective disorders (meningitis), and inflammatory conditions (sarcoidosis). Much doubt has been cast on so-called 'presbyacusis', which may merely reflect an accumulation of toxic/traumatic insults to the ear over many years, and recent advances in molecular biology and genetics have shown the role of genetic mutations/deletions in late-onset/progressive hearing impairments.

Clinical examination

Clinical examination requires examination of the anatomy of the external ear to define visible signs of congenital ear disease (pits, tags, nodules, or malformations)

and evidence of other craniofacial features suggestive of syndromal hearing impairment. In addition, a detailed examination of the tympanic membrane is required to define the presence of pathology within the middle ear. Wax or debris obstructing the external auditory meatus should be removed by or under the supervision of a clinician with experience in this field. Syringing should never be undertaken in the presence of an infection or if it is unknown whether the tympanic membrane may be perforated. Tuning-fork tests remain the most valuable clinical test of auditory function and frequently enable a clinician to distinguish a conductive from a sensorineural hearing loss (Fig. 3). The tests are based on two physiological facts: first, the inner ear is normally more sensitive to sound conducted by air than to that conducted by bone; and second, in the presence of a purely conductive hearing loss the affected ear is subject to less environmental noise, making it more sensitive to bone-conducted sound. A general medical and neurological examination is mandatory to define syndromes and the plethora of general medical conditions associated with hearing impairment.

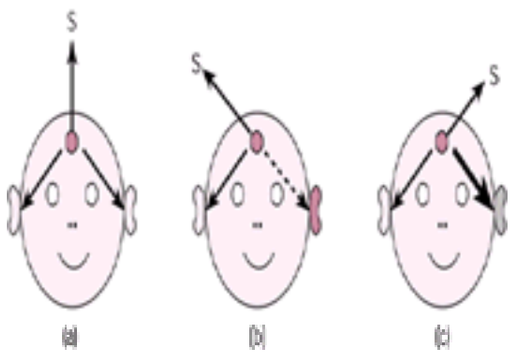

Fig. 3 Diagram to illustrate the Weber tuning fork test in (a) a normal subject, (b) a case of unilateral sensorineural hearing loss, and (c) a unilateral conductive hearing loss, in which the sound is heard more effectively in the affected ear because of the lack of masking by environmental sounds. (s, sound heard; •, tuning fork)

Investigations

A battery of audiological tests is required to:

- quantify audiometric thresholds at each frequency;
- differentiate a conductive from a sensorineural hearing loss;
- differentiate a cochlear from a retrocochlear abnormality;
- identify central auditory dysfunction in the brainstem, midbrain, or auditory cortex; and
- identify a non-organic component.

Each test can be defined as being subjective (dependent upon patient co-operation) or objective (independent of patient co-operation) in terms of providing auditory data. To differentiate a sensorineural hearing loss of cochlear origin from that of an VIIIth nerve dysfunction or neurological disorder, two pathophysiological phenomena are of importance:

1. *Loudness recruitment* is defined as an abnormally rapid increase in loudness, with an increase in intensity of the stimulus, and is characteristic of disorders affecting the hair cells of the Organ of Corti, but is absent in pathology of the VIIIth nerve.
2. *Abnormal auditory adaptation* is a decline in discharge frequency with time, observed following an initial burst of neural activity in response to an adequate continuing stimulus applied to the Organ of Corti. This phenomenon is characteristic of VIIIth nerve and brainstem auditory dysfunction.

Puretone audiometry is the most widely available, subjective, quantitative test of auditory thresholds. Electronically generated pure tones are delivered by earphones and the subject is required to respond to the quietest tone, at given frequencies between 125 and 8000 Hz in each ear. The sound may be delivered by air conduction (**AC**) or, if the tones are delivered by a bone vibrator on the mastoid process, by bone conduction (**BC**). In the latter test condition, because the intra-aural attenuation for a bone-conducted sound is negligible, masking of the ear not under test with narrow-band noise is mandatory. Bone-conduction thresholds significantly better than air-conduction thresholds indicate a conductive hearing loss, whereas similar bone-conduction and air-conduction thresholds are characteristic of sensorineural hearing loss (Fig. 4).

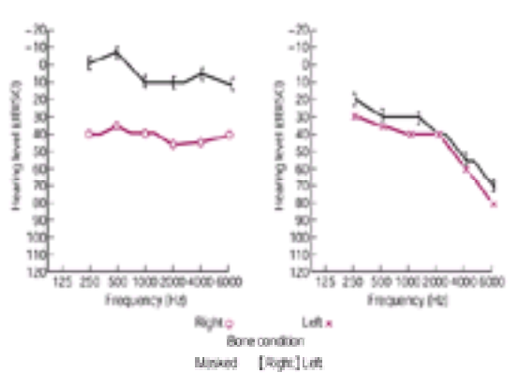

Fig. 4 Pure tone audiograms showing both air- and bone-conduction thresholds and illustrating a right conductive hearing loss (A) and a left sensorineural hearing loss (B).

The stapedius muscle in the middle ear contracts bilaterally in response to loud sound directed into either ear. Using an impedance bridge, the minimum intensity of sound at a given frequency required to produce contraction of the stapedius muscle and thus a movement of the tympanic membrane can be measured (the acoustic reflex threshold). This objective measure enables recruitment and abnormal auditory adaptation to be measured, and allows assessment of middle ear, cochlear, VIIIth nerve, and brainstem auditory function.

Otoacoustic emissions are weak signals that can be recorded in the ear canal and are the result of contractile properties of the outer hair cells of the cochlea. Measurement of otoacoustic emissions thus provides objective information about cochlear function.

Speech audiometry is a subjective test requiring the subject to repeat standard lists of words delivered at varying intensities through headphones. The responses are scored and provide an assessment of auditory discrimination. They are of particular value in assessing the efficacy of hearing-aid provision.

Electrophysiological tests provide the major objective means of assessing auditory function and siting pathology in the auditory system. Electrocochleography enables the measurement of the electrical output of the cochlea and VIIIth cranial nerve in response to an auditory stimulus, while brainstem auditory evoked responses are of particular value in discriminating between cochlear and VIIIth nerve dysfunction. Recordings are obtained by averaging a series of time-locked responses generated by the major processing centres of the auditory system in response to a repetitive sound stimulus (Fig. 5). Analysis of the waveform must be undertaken in conjunction with knowledge of the puretone thresholds if appropriate and valid conclusions about auditory function are to be obtained . Cortical or late-evoked auditory responses are the most effective method of defining auditory threshold at each frequency in an uncooperative patient, and are essential in legal cases in which a non-organic loss should always be excluded.

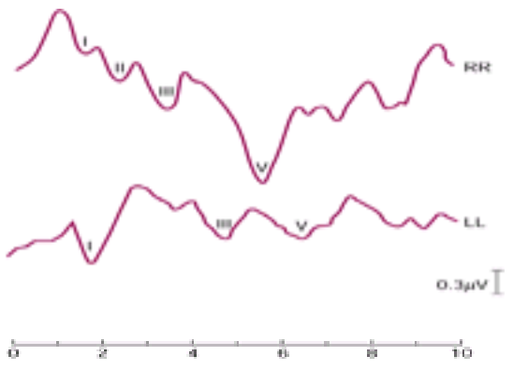

Fig. 5 Illustration of auditory evoked brainstem responses showing normal waves I, II, III, and V from the right ear (RR) and delayed waves III and V from the left ear (LL) in a case of a left acoustic neurinoma.

Management

Appropriate management requires a detailed history and examination to ensure both appropriate management of related general medical conditions and protection from leisure (discotheques) and occupational noise hazards and ototoxic drugs. Auditory rehabilitation is a problem-solving exercise centred on each individual patient, and depends on assessing both the auditory disability of the individual and the relevance of this to other important people in the patient's life. Not only auditory impairment, but also communication skills, including lip-reading ability, the use of visual cues, and the level of speech and language, together with psychological and sociological factors must be considered.

The remedial process may be straightforward in a highly motivated patient in whom there is an uncomplicated hearing loss. However, in the presence of a complicating factor, such as a hearing loss that is difficult to aid or arthritis making hearing aid manipulation difficult, the particular problem must be addressed to ensure optimal use of subsequent hearing-aid provision. In patients who have a negative view of hearing aids, environmental aids and instruction in communication skills prior to the introduction of a hearing aid may facilitate long-term rehabilitation. In general, the provision of a hearing aid is only effective when the patient himself, rather than well-meaning family members, wishes to pursue matters.

Although hearing aids play a pivotal role in audiological rehabilitation, a detailed description of their provision and selection is outside the scope of this short review. For many patients, wearable hearing aids, which bring sound more effectively to the ear, are invaluable, but environmental aids (assisted-listening devices such as amplification systems, alerting warning devices—for example, flashing lights connected to a doorbell or an alarm clock), may be adequate. In addition, sensory substitution systems, for example where visual signals are generated in response to auditory cues such as a telephone or doorbell ringing, or a baby crying, may be helpful to a hearing impaired person.

The general principles of hearing-aid provision include the fitting of a comfortable earmould which provides a secure mounting for the aid and a good acoustic connection between the aid and the ear canal. Hearing-aid selection involves matching the amplification required from the aid at specific frequencies with that required by the user. A particular disability experienced in most hearing-impaired subjects is that of hearing speech in a noisy environment and, although programmable digital processing hearing aids are of some help in this situation, conventional aids provide selective amplification of the frequencies relevant to speech, with minimal amplification at the peak frequency of background noise. Conventional aids may be divided into body-worn and head-worn aids, which can be in spectacles, behind the ear, in the ear, or in the canal in design. The major advantage of body-worn aids is the very high gain and maximum output that can be achieved, whereas the disadvantage is the unsightly nature of the device and the poor microphone placement.

Cochlear implants are electronic devices that convert sound into electrical current for the purpose of directly stimulating residual auditory nerve fibres to produce hearing sensations. The devices are implanted in the cochlea, usually with an electrode array, with an externally worn microphone and processor. Cochlear implants have been used in totally deafened adults and children with good results, and should be considered in all cases of profound acquired hearing loss and in children in whom there is good evidence of auditory nerve preservation in both congenital and acquired hearing impairment.

The value of counselling for the hearing-impaired person by a skilled hearing therapist must be emphasized. Such simple hearing tactics as encouraging the individual to ensure that the light is always on the speaker's face, that he or she places himself so that the better ear is towards the speaker, and sitting close to the sound source thereby minimizing background noise, can greatly improve communication ability. For the profoundly hearing-impaired, psychological problems associated with isolation are significant and it is therefore essential that psychological, medical, and social support are readily available.

Tinnitus

Tinnitus may be defined as a perception of sound, which originates from within the head rather than from within the external world. Rarely, the sound may have an externally detectable component and is then termed 'objective tinnitus' as opposed to the more common 'subjective tinnitus.' The experience of tinnitus is universal, but the complaint of tinnitus is rare.

Many conditions are associated with tinnitus, but it is frequently, although not always, associated with hearing impairment. The proposed pathophysiological mechanisms include:

- decoupling of the stereocilia of the hair cells;
- misinterpretation of auditory neural activity by higher auditory centres;
- self-sustaining oscillation of the basilar membrane;
- spontaneous otoacoustic emissions;
- an abnormality of the spontaneous resting activity of primary auditory nerve fibres, either secondary to the hypo- or hyperexcitability of damaged hair cells or as a direct consequence of the derangement of primary neurones themselves;
- damage to the myelin sheath between auditory nerve fibres allowing ephaptic transmission (cross-talk) between adjacent nerve fibres; and
- derangement of efferent fibres of the vestibulocochlear nerve, producing aberrant auditory behaviour.

A number of studies have demonstrated that tinnitus complaint does not correlate with psychoacoustic features of the tinnitus, but there is a significant correlation between tinnitus complaint and psychological symptoms. Importantly, the onset of tinnitus complaint may be associated with negative life events such as retirement, redundancy, bereavement, and divorce.

The assessment of tinnitus includes a detailed history, clinical examination, and audiometric investigation as outlined for hearing impairment. The commonest causes of objective tinnitus include palatal myoclonus, temporomandibular joint abnormalities, vascular abnormalities such as and arteriovenous fistula, and vascular bruits. Rarely, a patulous auditory tube may give rise to tinnitus in which the patient complains of a blowing sound associated with respiration.

Bilateral subjective tinnitus with evidence of a cochlear hearing loss is associated most commonly with presbyacusis, endolymphatic hydrops, vascular labyrinthine lesions, and noise-induced hearing loss. However, it is also common with head injury, whiplash injury, ototoxicity, barotrauma, surgical intervention, and after such simple clinical practices as syringing. Unilateral subjective tinnitus, with or without an associated sensorineural hearing loss. must be fully investigated to exclude an underlying cerebellopontine angle lesion, in particular an acoustic neurinoma.

Management

The primary management of tinnitus is medical, although surgical intervention is required for the correction of arterial stenoses giving rise to bruits and for glomus jugulari tumours and arteriovenous malformations. Destructive surgery, for example labyrinthectomy or auditory nerve section, has no place in the management of

tinnitus as there is no evidence that destruction of the peripheral cochlear elements brings about improvements in tinnitus complaint.

The medical management of tinnitus can be divided into psychological, pharmacological, and prosthetic intervention.

The psychological aspects of tinnitus management include an explanation of tinnitus, reassurance that the symptom will not progressively deteriorate or indeed remain unchanged, the exclusion of sinister pathology to allay fear, and, if necessary, the appropriate formal psychiatric management of depression/anxiety.

In the presence of a hearing impairment, the provision of hearing aids to 'mask' tinnitus with desirable environmental noise may be of value. In the absence of such a loss, tinnitus maskers and noise generators have been advocated to promote 'adaptation', but it must be emphasized that there is no hard evidence that tinnitus maskers are superior to placebo devices.

Pharmacologically, intravenous lidocaine (lignocaine) has been shown to result in the disappearance or amelioration of tinnitus, but no oral preparation has been found to be equally effective. Psychiatric drugs may be required for psychological management, although no single drug has been shown to be uniformly effective.

Tinnitus retraining therapy is a management strategy based on a neurophysiological model of tinnitus. The retraining is a combination of prosthetic and psychological intervention, which in essence provides a structured framework for the various well-established mechanisms of tinnitus management outlined above.

In conclusion, positive reassurance, appropriate psychiatric management, and prosthetic support remain the mainstays of the medical management of tinnitus.

24.13.1 The unconscious patient

David Bates

It is important to distinguish transient unconsciousness occurring with syncope, seizures, cardiac arrhythmias, or metabolic abnormalities from unconsciousness that persists and is coma. Prolonged loss of consciousness is seen commonly in three clinical situations: following head injury, after an overdose of sedating drugs, or in the situation of 'non-traumatic coma' where there are many possible diagnoses but the most common are anoxia, ischaemia, systemic infection, and metabolic derangement. It is important that the physician asked to see a patient in 'non-traumatic coma' should remember that the patient may be harbouring delayed effects of trauma such as subdural haematoma or meningitis arising from a basal skull fracture. The possibility of raised intracranial pressure following a parenchymal haematoma in a patient with hypertension, the decompensation of a cerebral tumour, or the collection of pus means that all causes of loss of consciousness must be considered; in the diagnosis of medical coma it is not easy to exclude the possibility of head injury.

Urgent assessment of the patient in coma is required to identify and, where possible, correct the pathological cause, protect the brain from the development of irreversible damage, and identify those patients in whom the prognosis is hopeless. In this last group the institution and continuation of resuscitative measures is inappropriate and will serve only to prolong the anguish of relatives and carers.

Definition

Normal consciousness

Consciousness is the state of awareness of the self and the environment when provided with adequate stimuli; normal consciousness is exhibited by those patients who are fully responsive to stimuli and show appropriate behaviour and speech. Patients who are asleep can be roused and are then able to perform normally. Normal consciousness depends upon the integration of activity in the ascending reticular activating substance of the brainstem and the neuronal connections between areas of the cerebral cortex. The ascending reticular activating substance determines arousal, which is shown by awakening with eye opening, motor responses, and verbal communication. The content of consciousness, which is the combination of psychological responses to feeling, emotions, and mental activity, is mediated by the cerebral cortex. (Fig. 1)

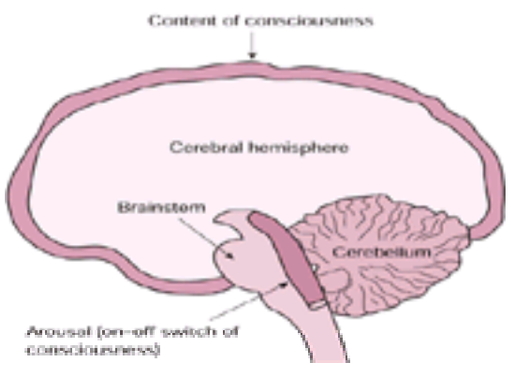

Fig. 1 Normal consciousness.

Coma

Coma is a state of unrousable unconsciousness without any psychologically understandable response to external stimuli or inner need. The patient may appear to be asleep but is incapable of responding normally to external stimuli other than by showing eye opening to pain, flexion or extension of the muscles in the limbs to pain, and occasionally grunting or groaning in response to painful stimuli. It occurs when there is damage to the ascending reticular activating substance or bilateral damage to areas of the cerebral hemispheres, or both (Fig. 2, Fig. 3, Fig. 4, and Fig. 5).

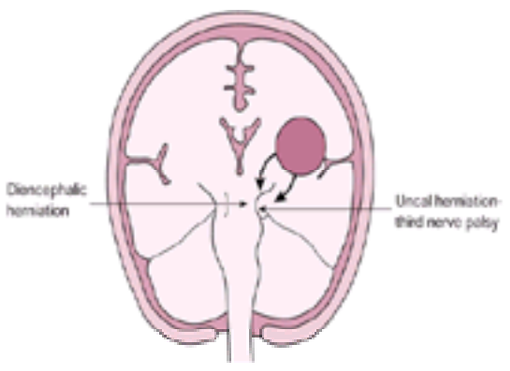

Fig. 2 Supratentorial mass.

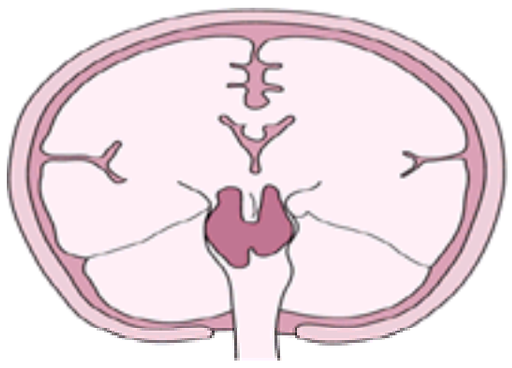

Fig. 3 Brainstem lesion—intrinsic.

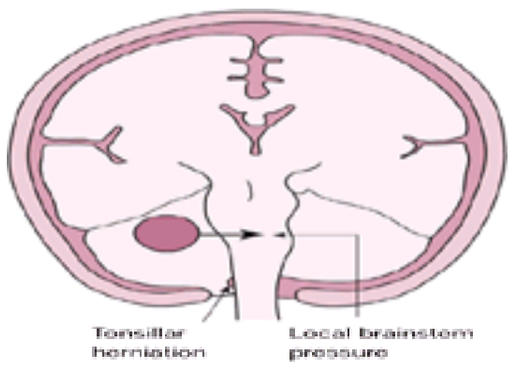

Fig. 4 Brainstem lesion—local pressure.

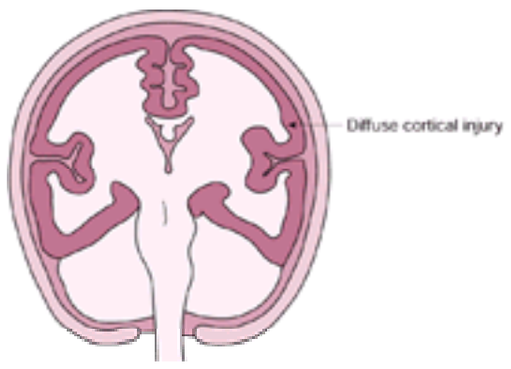

Fig. 5 Bihemispheric damage.

Confusion

Patients are usually disorientated with lowered attention, an inability to express thoughts, drowsiness, and defects in memory. There is a clouding of consciousness characterized by an impaired capacity to think, understand, respond to, and remember stimuli. It is important to differentiate acute confusion from dysphasia, amnesia, acute psychosis, severe depression, or dementia. Confusion is most commonly seen as the result of toxic or metabolic disturbances, particularly in the elderly.

Delirium

There is motor restlessness, hallucination, disorientation, and delusion. The patient is often frightened and irritable and the state can be regarded as a more profound example of confusion; both states should alert the doctor to impending coma. Delerium is most commonly seen in patients with toxic or metabolic disorders but can be mimicked by degenerative brain disease, acute psychosis, and hypomania.

Stupor

The patient appears to be asleep and will show little or no spontaneous activity, respond only to vigorous stimulation, then lapse back into somnolence. It may be difficult to differentiate stupor from catatonic schizophrenia or severe retarded depression, but in stupor due to organic disease the electroencephalogram will always be abnormal.

The vegetative state

The patient breathes spontaneously, has a stable circulation, and shows cycles of eye opening and eye closure which may simulate sleep and waking, but they are unaware of self and environment. It can be seen transiently in the recovery from coma or it may persist to death. This state is usually seen in patients with diffuse bilateral cerebral hemisphere disturbance with an intact brainstem, although it can occur with bilateral damage to the most rostral part of the brainstem. It is most commonly seen following head injury or as the result of hypoxic-ischaemic damage following cardiac arrest. The patient appears to be awake but is unaware, a condition that frequently causes distress to carers and relatives (Fig. 6).

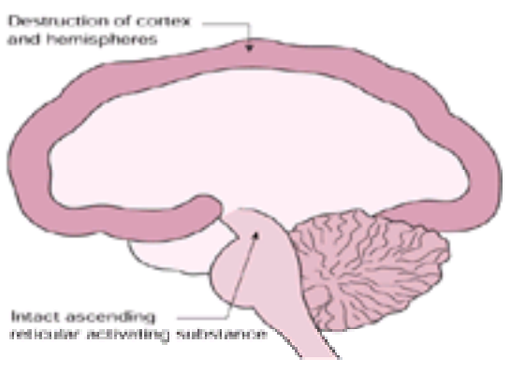

Fig. 6 Vegetative state.

The locked-in syndrome

Damage to the ventral portion of the pons below the level of the third nerve nuclei results in the rare condition of total paralysis of the limbs and lower cranial nerves but intact consciousness (Fig. 7). The patient can open, elevate, and depress the eyes but cannot move the eyes horizontally and there is no voluntary movement or speech. The diagnosis is made when the doctor recognizes that the patient is able to open the eyes voluntarily and allow them to close in response to command and can therefore respond to verbal and sensory stimuli by blinking. The commonest cause is infarction of the ventral pons, usually in a patient with hypertension, although it can also be seen with pontine tumours, multiple sclerosis, in central pontine myelin-olysis following profound hyponatraemia, and after head injury. The prognosis is poor although some patients recover, usually with residual spasticity. An electroencephalogram may help by showing an alert state, reactive to external stimuli and neurophysiology can be used to exclude similar incapacities occurring in myasthenia gravis or the Guillain–Barré syndrome.

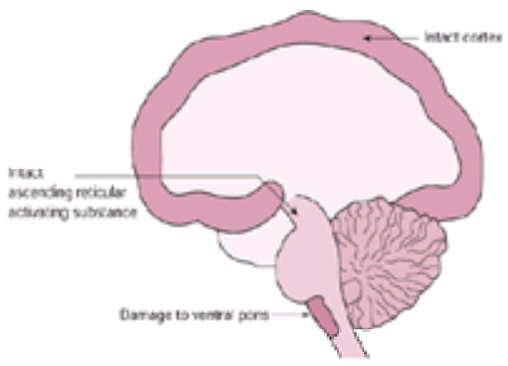

Fig. 7 Locked-in syndrome.

Psychogenic unresponsiveness

The term 'pseudocoma' or psychogenic unresponsiveness is used for patients who appear to be unconscious and in coma but who are not. The simplest way to identify this condition is to undertake oculovestibular testing (see below), which will reveal the presence of nystagmus and indicate that the patient has an intact brainstem and cortex.

The management of patients in coma

History

Once the patient is stable it is important to obtain as much information as possible from those who accompanied the patient to hospital or who observed the onset of coma. The circumstances in which consciousness is lost are of vital importance in helping to identify the diagnosis. Generally, coma is likely to present in one of three ways: as the predictable progression of an underlying illness; as an unpredictable event in a patient with a previously known disease; or as a totally unexpected event. In the first category are patients following focal brainstem infarction who deteriorate or those with known intracranial mass lesions who show similar deterioration. In the second category are patients with recognized cardiac arrhythmia or the known risk factor of sepsis from an intravenous cannula. In the final category it is important to distinguish whether there has been a previous history of seizures, trauma, febrile illness, or focal neurological disturbances. The history of a sudden collapse in the midst of a busy street or office indicates the need for different investigations from those required when the patient has been discovered at home in bed surrounded by empty bottles that previously contained sedative tablets. Where there is uncertainty, a telephone call to relatives and medical attendants may be useful.

Clinical assessment and examination

Estimation of the temperature, pulse, blood pressure, and respiratory rate, and examination of the skin, cardiovascular system, chest, and abdomen may often yield important clues in establishing the cause of a loss of consciousness. Fever, though not diagnostic, will usually indicate the presence of a systemic infection, meningitis, encephalitis, or abscess; seizures increases the likelihood of the latter two diagnoses. Hypothermia is most commonly seen following exposure to low environmental temperatures, intoxication with alcohol or barbiturates, the presence of peripheral circulatory failure, or profound myxoedema. Tachy- or bradyarrhythmias, evidence for valvular heart disease, or peripheral emboli raise the possibility of a cardiogenic cause; bruits over the carotid vessels suggest cerebrovascular disease; and splinter haemorrhages suggest endocarditis or collagen vascular disease. Hypotension raises the possibility of shock, myocardial infarction, or septicaemia and Addison's disease should be considered. Hypertension is less helpful as a clinical sign since it may be seen both as the result of cerebral insult or as an indicator of hypertensive encephalopathy.

The odour of the breath of an unconscious patient may indicate the presence of alcohol, a ketotic fetor raises the possibility of diabetes, and the fetor of hepatic or renal failure provide important clues. Clubbing of the finger nails suggests the possibility of a respiratory or gastrointestinal abnormality, and evidence of tracheal deviation, fluid in the chest, or collapse of the lung suggests the possibility of a respiratory cause. In the abdomen the finding of enlargement of an organ might indicate portal hypertension, polycystic kidneys, and an associated subarachnoid haemorrhage, or abnormality in the blood-forming organs. The general colour of the skin and mucous membranes might reveal anaemia, jaundice, cyanosis, or the pink discoloration of carbon monoxide poisoning. Purpura suggests a bleeding diathesis and bruising around the head indicates the possibility of trauma or a base of skull fracture. A rash may indicate an infective or inflammatory disease and hyperpigmentation raises the possibility of Addison's disease. The evidence of puncture wounds might identify an individual who is diabetic or a recreational drug user.

Neurological examination

This requires observation and an assessment of reflex responses. The position, posture, and spontaneous movements of the patient should be noted; the skull and spine should be examined with testing for neck stiffness and Kernig's sign to identify meningeal irritation. Ophthalmoscopy to identify papilloedema, fundal haemorrhages, emboli, and subhyaloid haemorrhages is important but it must be remembered that the absence of papill-oedema does not necessarily exclude raised intracranial pressure. The ears and fauces should be examined.

Level of consciousness

The level of consciousness must be documented by the initial observer and can then be monitored by medical and nursing staff to determine the progress of the patient and identify the need for further investigation, therapy, and decision. The most useful hierarchical grading scale to assess the level of consciousness is the Glasgow coma scale in which the patient's response to graded stimuli of eye opening, motor response, and verbal response are recorded (Table 1); all four limbs are observed for responses to pain and the best response is recorded, although asymmetry should be noted and may be important in identifying lateralization. The scale measures consciousness and it is possible to score gradations from the fully conscious patient (eye opening—4, motor response—6, verbal response—5) to the totally unresponsive patient (eye opening—1, motor response—1, verbal response—1). If the level of consciousness can be shown to be improving, then urgent decisions may be delayed, but if deterioration is occurring, it is imperative that a decision about management be made.

Brainstem function

The brainstem reflexes identify those lesions which affect the reticular activating substance and determine the viability of the patient. Most of the reflexes involve the eyes and the pattern of respiration, although the latter may be compromised by requirements of ventilation.

Pupillary reactions

Unilateral dilatation of a pupil with lack of a light response suggests an uncal herniation of the temporal lobe over the tentorium entrapping the third nerve, although it may also be seen with a posterior communicating artery aneurysm or other third nerve damage. Midbrain lesions typically cause loss of the light reflex with pupils in the mid-position, lesions in the pons cause small pupils with retained light responses, and fixed dilatation of the pupils suggests significant brainstem damage but must be differentiated from the fixed dilatation caused by atropine-like agents instilled by earlier observers. A Horner's syndrome may be seen with lesions in the hypothalamus or brainstem but can also be seen when diseases affect the wall of the carotid artery. Small pupils that react briskly to light raise the possibility of metabolic causes of coma such as hepatic or renal failure; drug intoxications tend not to affect the pupillary light responses.

Corneal responses

The corneal reflex is usually retained until very deep coma; if absent in a patient who appears to be otherwise in light coma, there is a distinct possibility that the cause may be drug intoxication. The loss of the corneal reflex in the absence of drug overdose is a poor prognostic indicator.

Spontaneous eye movements

Conjugate deviation of the eyes suggests a focal hemispheric or brainstem lesion, depression of the eyes is seen with damage to the midbrain at the level of the tectum, and skew deviation of the eyes suggests a lesion at the pontomedullary junction. Incoordinate eyes suggests damage to the ocular motor or abducent nerve in the brainstem or pathways, but a minor degree of divergence of the eyes is normal in the unconscious patient. Patients in light coma will often have normal roving eye movements, similar to those of sleep, which may be conjugate or dysconjugate. They cannot be mimicked and, when present, exclude the possibility of psychogenic unresponsiveness, when eye movements are likely to be more jerky.

Reflex eye movements are important in assessing brainstem activity. The oculocephalic response obtained by rotating the patient's head from side to side and observing the position of the eyes is likely to show Doll's eye movements when the brainstem is intact but the eyes will remain in the mid-position of the head when the brainstem is depressed. Oculovestibular testing is undertaken by the installation of 50 to 200 ml of ice-cold water into an external auditory meatus. The conscious patient, and those in psychogenic coma, will develop nystagmus with the quick phase away from the side of the stimulation indicating an active pons and intact corticopontine connections. A tonic response with conjugate movement of the eyes towards the stimulated side indicates an intact pons and suggests a supratentorial cause for the coma, whereas a dysconjugate response or no response at all implies a lesion within the brainstem.

Respiration

The techniques of ventilation limit the value of observation of respiration in patients with coma, but if testing is possible before respiration is controlled, then deep breathing suggests acidosis, regular shallow breathing is consistent with drug overdose, long-cycle Cheyne–Stokes respiration suggests damage at the level of the diencephalon, and short-cycle Cheyne–Stokes respiration damage at the level of the medulla. Central neurogenic hyperventilation occurs with lesions in the low midbrain and upper pons, and reflex responses such as yawning, vomiting, and hiccoughing may occur with brainstem disturbances.

Motor function

Motor function is assessed as part of the level of consciousness in the Glasgow coma scale, but lateralizing abnormalities are important and indicate the likelihood of a focal cause, although they may occasionally be seen in the context of hepatic encephalopathy or hypoglycaemia. The presence of generalized or focal seizures implies hemispheric damage and may help in lateralization; multifocal myoclonus suggests a metabolic or anoxic cause with diffuse cortical irritation.

Investigation

After performing the resuscitation, history, examination, and assessment the physician should identify one of the three following states (Table 2).

Coma with focal signs or evidence of head injury

In such patients, whether the focal signs indicate a brainstem or supratentorial problem, a CT scan or MRI should be undertaken. A normal scan may be seen in patients with hypoglycaemia or hepatic coma and the presence of structural pathology will be identified allowing a decision to be made about the indications for surgery or other therapy.

Coma with meningeal irritation but without focal signs

Such patients will most commonly have subarachnoid haemorrhage, acute meningitis, or meningoencephalitis as the cause of their coma. Brain imaging is the ideal investigation to identify the presence of subarachnoid blood and to exclude the possibility of focal collections. Depending upon the results of the scan a lumbar puncture can then be undertaken and may give diagnostic information. If the index of suspicion of meningitis is high then treatment should be commenced and, in the absence of focal signs or pupilloedema, lumbar puncture may precede imaging.

Coma without focal lateralizing neurological signs and without meningismus

Most patients will have suffered diffuse anoxic-ischaemic disease, metabolic derangement, or drug insult. It may be necessary to undertake imaging techniques but the probability of finding a focal abnormality is low and it is more likely that haematological or biochemical tests or a search for toxins in the blood will provide the diagnosis, or help identify an episode of ischaemia or hypoxia in the past. There may occasionally be an indication to undertake a lumbar puncture in such patients to exclude an inflammatory or infective cause. Patients who are in coma as the result of drug overdose will usually be identified from the history and the circumstances of discovery, but the possibility of drug-induced coma should always be considered in patients without focal signs and without meningism. A discrepancy between marked depression of brainstem responses in a patient who appears to be in relatively light coma suggests the diagnosis, the importance of which is that such patients have a good prognosis provided that they are given adequate respiratory and circulatory support during the coma.

Prognosis

The prognosis of individual patients depends upon the aetiology, the depth of the coma, the duration of the coma, and certain clinical signs.

Aetiology

Following head injury, prognosis is dependent upon the presence of intracranial haematoma, the age of the patient, and the severity of systemic injury and its effects. Patients in coma following drug overdose have, in general, a good prognosis provided that they are adequately resuscitated and protected. Patients who are in coma as a result of causes other than head injury or drug overdose for a period of more than 6 h have only a 10 per cent chance of making a good recovery. Those who have suffered subarachnoid haemorrhage or stroke have a less than 5 per cent chance of making such a recovery and those with hypoxic or ischaemic injury, typically following cardiac arrest, about 10 per cent. Those with metabolic or infective causes have almost a 30 per cent change of making a good recovery. A vegetative state is most likely to occur after head injury or hypoxic-ischaemic damage.

Depth of coma

Patients with no response to eye opening, no focal response to pain, and a poor response to pain have a poorer outcome than those who respond with eye opening, grunting, and flexion of the limbs.

Duration of the coma

When patients have been in coma for 6 h about 12 per cent may make a good recovery, those who remain in coma for 24 h have only a 10 per cent chance of recovery, and at the end of a week only 3 per cent of patients can be expected to make a good recovery. In general, patients who remain in coma for more than 7 to 14 days either die or enter a continuing vegetative state.

Clinical signs

Brainstem reflexes are the most important clinical signs in defining prognosis; the absence of corneal or pupillary reflexes or of oculovestibular responses for 24 h, in the absence of sedative drugs, is almost incompatible with recovery to independence whatever the cause of coma. Most brainstem reflexes are useful indicators of a poor prognosis but some, such as the development of nystagmus and oculovestibular testing or vocalization of any recognizable word within 48 h, identify patients with a good chance of recovery.

Continuation of care

The long-term care of patients in coma may be undertaken in an intensive care unit, on a specialist ward, in a rehabilitation unit, or long-stay hospital. It is important that those in whom prognosis is hopeless should not be permanently exposed to the rigors of intensive care medicine but should continue to receive basic care within routine hospital wards or a more long-stay environment. So long as patients are considered to have a potential for recovery they should be looked after in an intensive care unit or in a specialist ward. Their respiration, skin, circulation, and bladder and bowel function need attention, seizures must be controlled, and the level of consciousness should be regularly assessed and monitored. It is important that the mobility of joints and circulation to pressure areas are maintained during the long-term care of the patient and the possibility of aspiration pneumonia, peptic ulceration, and other complications of long-term intensive care need to be avoided. Techniques such as mechanical ventilation and steroid therapy should not be used routinely in the management of comatose patients; they do not improve prognosis and may compromise recovery. Investigations are of little help in identifying long-term prognosis because various types of electroencephalogram pattern have been recorded from patients in prolonged coma and CT scans simply show cortical atrophy with ventricular dilatation. Some somatosensory-evoked responses have been reported to show loss of the cortical component in long-term unconsciousness and positron emission tomography (PET) is reported to show metabolic underactivity, but at present, neither test can provide decisive information as to prognosis.

24.13.2 Headache

Peter J. Goadsby

Headache is perhaps the commonest of human maladies, and while no less interesting, varied, or biologically based than some of its neurological cousins it has been the subject of less attention than its clinical load demands. If only for cynical reasons of practicality, the general reader will need some basis with which to approach the patient with headache. Diagnosis and management of headache is clinically based, offering the doctor the opportunity to be a physician not a filter for test results, with the chance to treat and improve symptoms. Moreover, there is a sufficient biological basis now for headache to satisfy even the most scientific of inquisitors. Here the principles will be set out: the secrets and enjoyment remain, as with anything truly medical, in the clinic.

General principles

A formal classification system exists for headache, and it might surprise the casual observer that this runs to nearly 100 pages. The International Headache Society system is explicit in the sense that it uses features of the headache to make the diagnosis, summing features to make the diagnosis more certain. In clinical practice a broad categorization that serves well, and is consistent with the International Headache Society system, is the concept that there are primary and secondary forms of headache. Such a system is outlined in Table 1. Primary headaches are those in which headache and its associated features are the disease in themselves, and secondary headaches are those caused exogenously, such as headache associated with fever. Mild secondary headache, such as that seen in association with upper respiratory tract infections, is common but only rarely worrisome. The clinical dilemma remains that while life-threatening headache is relatively uncommon in Western society, it is present and requires suitable vigilance by doctors. Primary headache, in contrast, while not life-threatening is often disabling over time.

Secondary headache

Key clinical features of secondary headache

There are certain issues which are vital to establish in the patient presenting with any form of head pain so that important secondary headaches will not be missed. Perhaps the most crucial is the length of the history. Patients with a short history require prompt attention and may require quick investigation and management, whereas patients with a longer history generally require time and patience rather than speedy consultation. There are some important general features, including associated fever or sudden onset of pain (Table 2), and these demand attention. Unless a benign diagnosis can be positively established, patients with a history of headache of recent onset or neurological signs need referral for specialist neurological assessment. A similar rule can be applied to computed tomography (**CT**) or magnetic resonance imaging (**MRI**). Patients with a history of recurrent headache over a period of a year or more, fulfilling International Headache Society criteria for migraine (Table 3) and with a normal physical examination, have positive brain imaging in only about one in a 1000 images. It should be noted that brain tumour is a relatively rare cause of headache, and rarely a cause of isolated long-term histories of headache. The management of secondary headache is generally self-evident—treatment of the underlying condition such as an infection or mass lesion. An exception is the condition of chronic post-traumatic headache in which pain persists for long periods after head injury. This is an interesting generic problem which may be seen after central nervous system infection, trauma, both blunt and surgical, intracranial bleeds, and other precipitants. While the syndrome is generally self-limiting up to 3 to 5 years after the event, it may require treatment of the headache (see Chronic Daily Headache below).

Primary headache syndromes

The primary headaches are a group of fascinating syndromes in which headache and associated features are seen in the absence of any exogenous cause. The common syndromes (Table 1) are tension-type headache, migraine, and cluster headache and the collection of headaches known as primary chronic daily, or frequent, headache. Some other less well known syndromes will be mentioned because they are easily treated when diagnosed.

Pathophysiology of headache

Understanding of headache has advanced considerably over the last decade. The severe primary headaches—migraine and cluster headache—have been studied extensively. In experimental animals the detailed anatomy of the connections of the pain-producing intracranial extracerebral vessels and the dura mater has built on the classical human observations that it is these structures, and not the brain, that are responsible for generating pain from within the head. The key structures involved in the nociceptive process are:

- the large intracranial vessels and dura mater;
- the peripheral terminals of the trigeminal nerve that innervate these structures;
- the central terminals and second-order neurones of the trigeminal nucleus.

Together these structures are known as the trigeminovascular system. The cranial parasympathetic autonomic innervation provides the basis for symptoms such as lacrimation and nasal stuffiness that are prominent in cluster headache and paroxysmal hemicrania, and which may also be seen in migraine. It is clear from human functional imaging studies that vascular changes in migraine and cluster headache are driven by these neural vasodilator systems so that these headaches should be regarded as neurovascular. The concept of a primary vascular headache should be abandoned since it neither explains the pathogenesis of what are complex central nervous system disorders nor necessarily predicts treatment outcomes.

Migraine is an episodic syndrome of headache with sensory sensitivity, such as to light, sound, and head movement, probably due to malfunction of aminergic brainstem/diencephalic sensory control systems (Fig. 1). The first of the migraine genes has been identified for familial hemiplegic migraine, in which about 50 per cent of families have mutations in the gene for the a_1 subunit of the neuronal P/Q voltage-gated calcium channel. This finding, together with the clinical features of migraine, suggests that it might be part of the spectrum of diseases known as channelopathies—disorders involving malfunction of voltage-gated channels. Functional neuroimaging has suggested that brainstem regions in migraine, and the posterior hypothalamic grey matter, site of the human circadian pacemaker cells of the suprachiasmatic nucleus in cluster headache, are good candidates for specific involvement in primary headache.

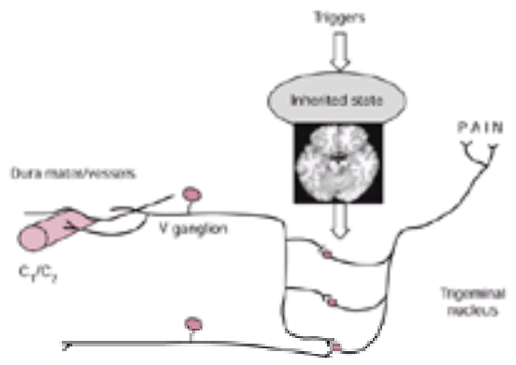

Fig. 1 Illustration of the some elements of migraine biology. Patients inherit a malfunction in brain control systems for pain and other afferent stimuli which can be triggered and are in turn capable of activating the trigeminovascular system as the initiating event in a positive feedback of neurally driven vasodilatation. The trigeminal innervation of pain-producing intracranial structures—dura mater and blood vessels—passes through the trigeminal ganglion (V ganglion) to terminate in the most caudal part of the trigeminal nucleus. Cervical inputs which terminate in the trigeminocervical complex accounts for the non-trigeminal distribution of pain in many patients. Migraine thus has a pain system for its expression and brain centres—modulatory systems—which define the associated symptoms and periodicity of the clinical syndrome. (Brainstem changes after Weiller and colleagues.)

Migraine

Migraine is generally an episodic headache with certain associated features, such as sensitivity to light, sound, or movement, and often with nausea or vomiting accompanying the headache (Table 3). None of the features is obligatory, and indeed given that the migraine aura, visual disturbances with flashing lights or zig-zag lines moving across the visual field or other neurological symptoms, is reported regularly in only about 15 per cent of patients, a high index of suspicion is required to diagnose migraine. A headache diary can often be helpful in making the diagnosis but perhaps more so in measuring the burden of the disease to the individual and then observing the effects of treatment. At a minimum the diary would mark on a calendar each day with headache, the length of the attack, what medication was taken and the doses, and what life events may have been taking place, such as a menstrual period. In differentiating the two main primary headache syndromes seen in clinical practice, migraine at its simplest level is headache with associated features, and tension-type headache is headache that is featureless (see below). Useful rule in practice is that most disabling headache is probably migrainous in biology. As for management, it is preferable to misdiagnose tension-type headache as migraine as opposed to the reverse, since there is so much good that can be done for migraine sufferers and so little for tension-type headache that patients may gain by such a diagnostic bias.

If headache with associated features describes migraine attacks, then 'headachy' describes the migraine sufferer over their lifetime. The migraine sufferer inherits a tendency to have headache that is amplified at various times by their interaction with their environment, the much discussed triggers. The brain of the 'migraineur' seems more sensitive to sensory stimuli and to change; and this tendency is even more notably amplified in females over the course of their menstrual cycle. The migraine sufferer does not habituate to sensory stimuli easily and so is often and adversely stimulated in the world in which they live and work. Migraine sufferers may have headache when they sleep in, when they are tired, when they skip meals, when they are stressed, or when they relax. They are less tolerant to change and part of successful management is to advise them to maintain regularity in their lives in the knowledge of this fluctuating brain sensitivity.

It has been said that migraine can never occur daily, but few biological phenomena respect absolute rules. This author takes the view that there is a very distinct syndrome of Chronic Migraine that is simply the most severe end of a complex phenomenon and often requires referral for specialist advice. Chronic Migraine is part of the group of headaches known as Chronic Daily Headache (see below) whose final nosology will only be settled when there are clearer biologically based development of disease markers. After making a diagnosis the next step in the clinical process is to be sure that the burden of the condition has been understood: how much headache does the patient have and, more important, what can't the patient do; what is their degree of disability? One can ask the patient directly to get a flavour, obtain a diary, or get a quick but accurate estimate using the Migraine Disability Assessment Scale (MIDAS), which is well validated and very easy to use.

Management of migraine

After diagnosis, the management of migraine begins by an explanation of certain things to the patient, notably:

- Migraine is an inherited tendency to headache, and cannot be cured.
- Migraine can be modified and controlled by the adjustment of lifestyle factors and the use of medicines.
- Migraine is not life-threatening nor associated with serious illness, the exception being in females who smoke and receive oestrogenic oral contraceptives, but migraine can make life a misery.
- Migraine management takes time and co-operation when information, such as that from a headache diary, has to be collected or inquiry made concerning the effect of the disease on the patient's life: the disability accrued to the disease.

Non-pharmacological management

Non-pharmacological management of migraine involves helping the patient identify things that aggravate the problem and encouraging them to modify these. Many patients will not find any joy in this approach; they should not be disparaged for this, but for those who do identify such factors, it will be a rewarding strategy. The crucial lifestyle advice is to explain to the patient that migraine is a state of sensitivity of the brain to change. This implies that the migraine sufferer needs to regulate their life with a healthy diet, regular exercise, regular sleep patterns, avoiding excess caffeine and alcohol and, as far as practical, modifying or minimizing changes in stress. A balanced life with fewer extremes will benefit most migraine sufferers. Patients also need to know that the brain sensitivity that is migraine varies, so that triggers will vary in their likelihood of resulting in headache.

Preventative treatments for migraine

The decision to start prophylactic treatment requires consideration from both doctor and patient. The basis for considering preventative treatment from a medical viewpoint is a combination of frequency of acute attacks and the tractability of these attacks. Attacks that are unresponsive to medications for acute management are targets for prevention, while attacks which are simply treated may be less obvious candidates for prevention. The other part of the equation relates to what is happening with time. If a patient diary shows a clear trend to increased frequency it is better to get in early with prevention than wait for the problem to become chronic. A simple rule for frequency might be that for one to two headaches a month there is usually no need to start preventative treatment; for three to four discussion may be needed; and for five or more a month prevention should be considered. Options available for treatment are covered in detail in Table 4 and vary somewhat by country. The problem with preventative treatments is not that there are none, but that they were all developed for other conditions. Often the doses required to reduce headache frequency produce marked and intolerable side-effects. It is not clear how preventatives work, although it seems likely that they modify the brain sensitivity that underlies migraine. Generally each drug should be started at a low dose and gradually increased to a reasonable maximum to determine if there is going to be a useful clinical effect.

Treatments for acute attacks of migraine

Treatments for acute attacks of migraine can be usefully divided into disease non-specific treatments—analgesics and non-steroidal anti-inflammatory drugs—and disease specific treatments—ergot-related compounds and triptans (Table 5). It must be said at the outset that most medications for acute attacks seem to have a propensity to aggravate headache frequency and induce a state of refractory daily or near-daily headache—analgesic-associated Chronic Daily Headache (see below). Codeine-containing compound analgesics are a particularly pernicious problem when available in over-the-counter preparations; the author recommends avoiding their frequent (more than twice a week) use. Many patients who stop taking regular analgesics will have no change to their headache, although some will have a distinct reduction in their headache frequency. Almost all who reduce acute attack medication overuse feel in some way better and will be easier to treat with standard preventatives.

Treatment strategies

Given the array of options for controlling an acute attack of migraine, how does one start? The simplest approach to treatment has been described as 'stepped care'. In this model all patients are treated, assuming no contraindications, with the simplest treatment, such as aspirin 900 mg with an antiemetic. Aspirin is an effective strategy (as proven by double-blind controlled clinical trials) and is best used in its most soluble formulation. The alternative would be a strategy known as 'stratified care', by which the physician determines, or stratifies, treatment at the start based on the likelihood of response to levels of care. An intermediate option may be described as stratified care by attack. The latter is what many headache authorities suggest and what patients often do when they have the options. Patients use simpler options for their less severe attacks relying on more potent options when their attacks or circumstances demand them (Table 6).

Non-specific treatments for acute attacks

Since simple analgesics such as aspirin and paracetamol (acetaminophen) are cheap and can be very effective, they can be employed in many patients. Dosages should be adequate, and the addition of domperidone (10 mg orally) or metoclopramide (10 mg orally) can be very helpful. Non-steroidal anti-inflammatory drugs can very useful when tolerated. Their success is often limited by inappropriate dosing, and adequate doses of naproxen (500 to 1000 mg orally or *per rectum*, with an antiemetic), ibuprofen (400 to 800 mg orally), or tolfenamic acid (200 mg orally) can be extremely effective. Tolfenamic acid has been shown in a double-blind placebo-controlled study to have comparable efficacy to sumatriptan 100 mg, a result that reinforces the general clinical view that non-steroidal anti-inflammatory drugs can be very useful compounds in treating migraine.

Specific treatments for acute attacks

When simple measures fail, or more aggressive treatment is required, the specific treatments are required. While ergotamine remains a useful antimigraine compound, its place as the treatment of choice has slipped in recent years. There are particular situations in which ergotamine is very useful, but its use must be strictly controlled as ergotamine overuse itself produces severe headache and a host of vascular problems. The triptans have revolutionized the life of many patients with migraine and are clearly the most powerful option available to stop a migraine attack. They can be rationally applied by considering their pharmacological, physicochemical, and pharmacokinetic features, as well as the formulations that are available.

Tension-Type Headache

As its name suggests Tension-Type Headache (TTH) is a term that describes the headache form most seeking understanding. One might challenge the reader to define the essence of TTH, which eludes this author, or consider for a moment how hard it is to study something that is commonly considered to be well understood. TTH has two forms, episodic TTH, where attacks occur on less than 15 days a month and chronic TTH where attacks, on average over time, are seen on 15 days or more a month. The latter is part of the broader clinical syndrome of Chronic Daily Headache (see below), but the terms are not equal.

Clinical features

TTH has been defined by the International Headache Society both for its episodic and chronic forms, but by the time this chapter is read that definition will have changed. In the initial classification admixtures of nausea, photophobia, or phonophobia in various limited combinations, without clear biological rationale, were permitted in either the episodic or chronic form of TTH. These are being removed as the classification is being revised. A useful clinical approach is to diagnose TTH when the headache is completely featureless: no nausea, no vomiting, no photophobia, no phonophobia, no osmophobia, no throbbing, and no aggravation with movement. Such an approach neatly divides migraine, which has one or more of these features and is the main differential diagnosis, from TTH. For research I would further divide up the patients with attacks of a TTH phenotype who have migraine at other times, a family history of migraine, migrainous illnesses of childhood, or typical migraine triggers to their attacks, to try and understand what the TTH biology alone imparts to the sufferer.

Pathophysiology

The pathophysiology of TTH is incompletely understood. This results from the fact that the name implies to most that it is a product of nervous tension, for which there is no clear evidence, and the definitions employed have undoubtedly admitted patients with migraine to the studies. It seems likely that TTH will be due to a primary disorder of central nervous system pain modulation, to contrast with migraine which is a much more generalized disturbance of sensory modulation. There are data suggesting a genetic contribution to TTH but one must question these since they applied the current, faulty, diagnostic criteria.

Management

Adopting the clinical approach to TTH outlined above results in diagnosing a headache form that is usually less disabling, and more in the category of irritating. Its episodic form is generally amenable to simple analgesics, paracetamol (acetaminophen), aspirin, or NSAIDs, which can be purchased over the counter. There are clear clinical studies to demonstrate that triptans in TTH alone are not helpful, although germane to the above discussion, triptans are effective in TTH where the patient also has migraine. For chronic TTH amitriptyline is the only treatment with a clear evidence base; the other tricylics, selective serotonin reuptake inhibitors, or the benzodiazepines have not been shown in controlled trials to be effective. Similarly, there is no controlled evidence for the use of EMG biofeedback, relaxation therapy, or acupuncture, and both positive and negative studies using botulinum toxin. At the time of writing botulinum toxin is regarded as experimental. Stress management has been shown to be an effective approach in a controlled trial.

Cluster headache

Cluster headache is a rare form of primary headache with a population frequency of 0.1 per cent. Most standard textbooks cover the topic and the reading list contains specialized books on cluster headache. Cluster headache is part of a spectrum of primary headaches with prominent cranial autonomic activation, lacrimation, conjunctival injection or rhinorrhoea, collectively known as the Trigeminal-Autonomic Cephalgias (TACs). Cluster headache is probably the most painful condition known to humans; of more than 500 patients on our data base we are yet to talk with one who has had a more painful experience, including childbirth, severe burns and multiple limb fracture. A neurologist should manage cluster headache, if possible. Its core feature is periodicity, be it circadian or in terms of active and inactive bouts over weeks and months (Table 7). The typical cluster headache patient is male (male:female ratio 3:1) who has one to two attacks of unilateral pain of relatively short duration (30 to 180 minutes) every day for bouts of 8 to 10 weeks a year. Sufferers are generally perfectly well between times. Patients with cluster headache tend to move about during attacks, pacing, rocking, or even rubbing their head for relief. The pain is usually retro-orbital, boring, and very severe. It is associated with a red or watering eye, the nose running or blocking, and eyelid droop, the cranial autonomic symptoms, on the same side as the pain. Cluster headache is likely to be a disorder involving central pacemaker regions of the posterior hypothalamus, which is likely to share much with the other TACs but may be usually differentiated on clinical grounds from them (Table 8).

Management of cluster headache

Cluster headache is managed using treatments for acute attack and preventative agents. Treatments for acute attacks are usually required by all cluster headache patients at some time, while preventatives can almost be life-saving for those patients with chronic cluster headache and are often needed to shorten the active periods.

Preventative treatments

The options for preventative treatment in cluster headache are a little different depending on whether the patient has the episodic or chronic variety of the condition (Table 9). Most experts would now favour verapamil as the first-line preventative treatment, although for some patients with the episodic variety and short bouts limited courses of oral corticosteroids or methysergide can be very useful.

Verapamil has been suggested as a useful option for the last decade and compares favourably with lithium. What has clearly emerged from clinical practice is the need to use higher doses than had initially been considered and certainly higher than those used in cardiological indications. Although most patients will start on doses as low as 40 mg twice daily, doses of up to 960 mg daily and beyond are now employed. Side-effects, such as constipation and swelling of the legs, can be a

problem, but the issue of cardiovascular safety is more difficult. Verapamil can cause heart block by slowing conduction in the atrioventricular node, as demonstrated by prolongation of the A–H interval. Given that the PR interval on the ECG is made up of atrial conduction, A–H, and His bundle conduction, it may be difficult to monitor subtle early effects as verapamil dose is increased. This question needs study in this group of patients but at present it seems appropriate to do a baseline ECG and then repeat the ECG 10 days after a dose change, usually 80 mg increments, when doses exceed 240 mg daily.

Treatment of acute attacks

Attacks of cluster headache often peak rapidly and thus require a treatment with a quick onset. Many patients with acute cluster headache respond very well to treatment with oxygen inhalation. This should be given as 100 per cent oxygen at 8 to 12 litre/min for 15 to 20 min. It is important to have a high flow and a high oxygen content. Injectable sumatriptan has been a boon for many patients with cluster headache. It is effective, rapid in onset, and with no evidence of tachyphylaxis. Sumatriptan is not effective when given pre-emptively as 100 mg orally three times daily, although the nasal spray has now been shown to be effective in a placebo-controlled study.

Chronic Daily Headache

Daily headache gives the subspecialty a bad name but can be very rewarding when tackled clinically in a methodical manner. Chronic Daily Headache is not one entity but a collection of very different problems requiring different approaches to their management. Certainly not all daily headache is simply Tension-Type Headache (Table 10), and this is the commonest clinical mistake in headache diagnosis confusing the clinical phenotype with the headache biotype . The current definition for 'Daily Headache' requires pain on 15 or more days a month. Both terms are used here because the subject is under intense discussion. Population based estimates of Daily Headache are remarkable, demonstrating that 4.5 to 4.8 per cent of Western populations, notably in Spain and the United States, have daily or near daily headache. Daily Headache may again be primary or secondary, and it seems useful to consider the possibilities in this way when making decisions about clinical management (Table 10). It should be said that population based studies bear out the impression that many patients with refractory daily headache overuse various over-the-counter analgesic preparations.

Chronic daily headache and migraine

While it is widely accepted that chronic variants exist in some of the primary headaches— notably tension-type headache, cluster headache, and paroxysmal hemicrania—chronic migraine is a somewhat controversial entity in some quarters. Most authorities would agree that migraine may sometimes be chronic in terms of frequency but whether this occurs often or not is frequently argued. The issue of whether patients with frequent headache, some of which fulfils standard criteria for migraine and some for tension-type headache, have a single migrainous problem with two phenotypic manifestations is a very vexed one. Given that tension-type headache describes a phenomenon that is indistinct at best it seems unlikely that all such headaches will have a single underlying mechanism.

Considering the population based surveys quoted above, about two-thirds of daily headache patients have chronic tension-type headache and about one-third satisfy the Silberstein–Lipton criteria for 'transformed migraine' (now called Chronic Migraine). The philosophy behind Chronic Migraine is that some patients who inherit a migrainous predisposition end up with Chronic Daily Headache on a migrainous basis. The typical patient will have a dull daily often-featureless pain, punctuated by more severe attacks which would often, in isolation, fulfil standard criteria for migraine. This group is dominant in headache specialty clinics, with about 90 per cent of patients referred to headache clinics having transformed migraine, usually accompanied by overuse of analgesics. It might be that these patients have a more intractable organic problem which explains their over-representation in referral centres. If it is accepted that all other forms of primary headache have chronic counterparts, particularly the typically episodic primary headache, cluster headache, then having frequent migraine is not such a fanciful concept— it can then be called Chronic Migraine, by analogy with the other primary headaches.

Treatment of frequent primary headache with or without migrainous features, whatever view of the biology or nomenclature one takes, requires control of analgesic, ergotamine, or triptan overuse when present and instigation of preventative medicines. It is exceptional for a patient misusing medication to be successfully treated with preventatives unless these other excessive medications are stopped. Preventatives used in episodic migraine are all employed, including tricylics, Valproate (divalproex), Gabapentin, Flunarizine, Methysergide and monoamine oxidase inhibitors. Comorbidity with depression is common in migraine, so that appropriate management of accompanying depression is important. Admission to hospital and treatment with a carefully monitored course of intravenous dihydroergotamine can be a very effective way to break the cycle of persistent headache.

Syndromes responsive to indomethacin

There are number of primary headache syndromes with distinct characteristics that respond to treatment with indomethacin. Many share features with cluster headache, and are collectively known as the trigeminal autonomic cephalgias (TACs) (Table 8), while others do not. They deserve some attention because they can often be very easily treated.

Paroxysmal hemicrania

Sjaastad and colleagues first reported eight cases of a frequent unilateral severe but short-lasting headache without remission, coining the term 'chronic paroxysmal hemicrania'. The mean daily frequency of attacks varied from seven to 22 with the pain persisting from 5 to 45 min on each occasion. The site and associated autonomic phenomena were similar to those of cluster headache, but the attacks of chronic paroxysmal hemicrania were suppressed completely by indomethacin. A subsequent review of 84 cases showed a history of remission in 35 cases whereas 49 were chronic. By analogy with cluster headache the patients with remission have been referred to as having episodic paroxysmal hemicrania, and those without can be labelled with chronic paroxysmal hemcrania. Pareja has recorded attacks which swap sides, just as is known for cluster headache, and attacks with autonomic features without pain. This has been observed in cluster headache after trigeminal nerve section, by this author and others, and is excellent evidence for a disorder which is primarily of the central nervous system.

The essential features of paroxysmal hemicrania are:

- Female preponderance.
- Unilateral, usually frontotemporal, with very severe pain.
- Short-lasting attacks (2 to 45 min).
- Very frequent attacks (usually more than five a day).
- Marked autonomic features ipsilateral to the pain.
- Robust, quick (less than 72 h), and complete response to indomethacin.

Other issues

The treatment of paroxysmal hemicrania is complicated by the gastrointestinal side-effects seen with indomethacin, but thus far there is no convincing replacement. The issue of triptan response is not clearly settled and may be both variable and dependent on the length of the attacks. Injection of the greater occipital nerve is not useful in paroxysmal hemicrania. Piroxicam has been suggested to be helpful, although again it is not as effective as indomethacin. By analogy with cluster headache, verapamil has been used in paroxysmal hemicrania, although the response is not spectacular and higher doses require exploration. Paroxysmal hemicrania can coexist with trigeminal neuralgia—paroxysmal hemicrania-tic syndome—just as in cluster-tic syndrome. Similarly, secondary chronic paroxysmal hemicrania has also been reported with a syndrome like Tolosa–Hunt and in patients with a pituitary microadenoma and a maxillary cyst. If there is any doubt regarding the differential diagnosis between paroxysmal hemicrania and cluster headache then either an oral indomethacin challenge, or a formal placebo-controlled indomethacin test by injection, should be completed.

Hemicrania continua

Sjaastad and Spierings reported two patients, a woman aged 63 and a man of 53, who developed unilateral headache without obvious cause. One of these patients noticed redness, lacrimation, and sensitivity to light in the eye on the affected side. Both patients were relieved completely by indomethacin while other non-steroidal anti-inflammatory drugs were of little or no benefit. Newman and colleagues reviewed the 24 previously reported cases and added 10 of their own, including some with pronounced autonomic features resembling cluster headache. They divided their case histories into remitting and unremitting forms. Of the 34 patients reviewed, 22 were women and 12 men with the age of onset ranging from 11 to 58 years. The symptoms were controlled by indomethacin 75 to 150 mg daily. The essential

features of hemicrania continua are:

- Unilateral pain.
- Pain is moderate and continuous but with fluctuations.
- Complete resolution of pain with indomethacin.
- Exacerbations may be associated with autonomic features.
- Migrainous features, such as nausea, photophobia or phonophobia, are frequently reported.

Apart from overuse of analgesics as a secondary aggravation, and a report in an HIV-infected patient, the status of secondary hemicrania continua is unclear. Injection of the greater occipital nerve is not useful in hemicrania continua.

Time to treatment response

Antonaci and colleagues proposed the 'indotest' by which the intramuscular injection of 50 mg of indomethacin could be used as a diagnostic tool. In hemicrania continua, pain was relieved in 73 ± 66 min and the pain-free period was 13 ± 8 h. The time elapsing between the thrice daily oral administration of 25 to 50 mg indomethacin and relief varied from 30 min to 48 h and thus a response to treatment can be rapidly assessed in the outpatient setting. Acute treatment with sumatriptan has been employed and reported to be of no benefit.

Idiopathic (Primary) Stabbing Headache

P>Short-lived jabs of pain, defined by the International Headache Society as Idiopathic (Primary) Jabbing Headache, are well documented in association with most types of primary headache. The essential clinical features are:

- Pain confined to the head, although rarely is it facial.
- Stabbing pain lasting from one to many seconds and occurring as a single stab or a series of stabs.
- Recurring at irregular intervals (hours to days).
- Cranial autonomic symptoms, such as lacrimation, conjunctival injection and rhinorrhoea, are not reported.

Raskin and Schwartz first described these sharp, jabbing pains about the head resembling a stab from an ice-pick, nail, or needle. They compared the prevalence of such pains in 100 migrainous patients and 100 headache-free controls and only three of the control subjects had experienced ice-pick pains compared with 42 of the migraine patients, of whom 60 per cent had more than one attack per month. The pains affected the temple or orbit more often than the parietal and occipital areas and often occurred before or during migraine headaches. The sites of the ice-pick pains generally coincide with the site of the patient's habitual headache.

Pains in the retroauricular and occipital region are also well described and these respond promptly to indomethacin. Ice-pick pains have been described in conjunction with cluster headaches, and are generally experienced in the same area as the cluster pain. Sjaastad described what he called 'jabs and jolts' lasting less than a minute in patients with chronic paroxysmal hemicrania. These longer attacks are almost certainly part of the spectrum of jabbing headache. It is of interest that jabbing pains generally are not accompanied by cranial autonomic symptoms. The response of idiopathic jabbing headache to indomethacin (25 to 50 mg twice to three times daily) is generally excellent. As a general rule the symptoms wax and wane, and after a period of control on indomethacin it is appropriate to withdraw treatment and observe the outcome.

Benign cough headache

Sharp pain in the head on coughing, sneezing, straining, laughing, or stooping has long been regarded as a symptom of organic intracranial disease, commonly associated with obstruction of the cerebrospinal fluid pathways. The presence of an Arnold–Chiari malformation or any lesion causing obstruction of cerebrospinal fluid pathways or displacing cerebral structures must be excluded before cough headache is assumed to be benign. Cerebral aneurysm, carotid stenosis, and vertebrobasilar disease may also present with cough or exertional headache as the initial symptom. The term 'benign Valsalva's manoeuvre-related headache' covers the headaches provoked by coughing, straining, or stooping but 'cough headache' is more succinct and so widely used it is unlikely to be displaced. The essential clinical features of benign cough headache are:

- Bilateral headache of sudden onset, lasting less than a minute, precipitated by coughing.
- May be prevented by avoiding coughing.
- Diagnosed only after structural lesions, such as a posterior fossa tumour, have been excluded by neuroimaging.

Comparing benign cough with benign exertional headache Pascual and colleagues reported that the average age of their patients with benign cough headache was 43 years more than their patients with exertional headache.

Management

Indomethacin is the medical treatment of choice in cough headache. Raskin has reported that some patients with cough headache are relieved by lumbar puncture which is a simple option when compared with prolonged use of indomethacin. The mechanism of this response remains unclear.

Benign exertional headache

The relationship of this form of headache to cough headache is unclear and certainly much is shared. Indeed the relationship to migraine also requires delineation. Credit must be given to Hippocrates for first recognizing this syndrome when he wrote 'one should be able to recognize those who have headache from gymnastic exercises, or walking, or running, or any other unseasonable labour, or from immoderate venery'.

The clinical features are:

- Pain specifically brought on by physical exercise.
- Bilateral and throbbing in nature at onset and may develop migrainous features in those patients susceptible to migraine.
- Lasts from 5 min to 24 h.
- Prevented by avoiding excessive exertion, particularly in hot weather or at high altitude.

The acute onset of headache with straining and breath holding as in weightlifter's headache may be explained by acute venous distension. The development of headache after sustained exertion, particularly on a hot day, is more difficult to understand. Anginal pain may be referred to the head, probably by central connections of vagal afferents, and may present as exertional headache, so-called cardiac cephalalgia. The link to exercise is the main clinical clue. Phaeochromocytoma may occasionally be responsible for exertional headache. Intracranial lesions or stenosis of the carotid arteries may have to be excluded as discussed for benign cough headache. Headache may be precipitated by any form of exercise and often has the pulsatile quality of migraine.

Management

The most obvious form of treatment is to take exercise gradually and progressively whenever possible. Indomethacin at daily doses varying from 25 to 150 mg is generally very effective in benign exertional headache. Indomethacin 50 mg, ergotamine tartrate 1 to 2 mg orally, ergotamine by inhalation, or methysergide 1 to 2 mg orally given 30 to 45 min before exercise are useful prophylactic measures.

H4>Other interesting primary headaches

Hypnic headache

This syndrome was first described by Raskin in patients aged between 67 and 84 who had headache of a moderately severe nature that typically came on a few hours after going to sleep. These headaches last from 15 to 30 min, are typically generalized, although they may be unilateral, and can be throbbing. Patients may report falling back to sleep only to be awoken by a further attack a few hours later with up to three repetitions of this pattern over the night. In the largest series (Dodick's) of 19 patients, 16 (84 per cent) were female and the mean age at onset was 61 ± 9 years. Headaches were bilateral in two-thirds of cases and unilateral in one-third, and in 80 per cent of cases pain was mild or moderate. Three patients reported similar headaches when falling asleep during the day. None of these patients had photophobia or phonophobia and nausea was unusual.

Management

Patients with this form of headache generally respond to a bedtime dose of lithium carbonate (200 to 600 mg) and in those that do not tolerate this verapamil or methysergide at bedtime may be alternative strategies. Two patients who responded to flunarizine 5 mg at night have now been reported. Dodick and colleagues reported that one to two cups of coffee or caffeine 60 mg orally at bedtime were helpful, and this is well worth trying as the first step in Hypnic Headache. This author has controlled a patient poorly tolerant of lithium by using verapamil at night (160 mg).

Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (the SUNCT syndrome)

It has been remarked (Lance) that as the duration of the pain in the cluster headache-like syndromes becomes shorter, their names become longer! Sjaastad and colleagues reported three male patients whose brief attacks of pain in and around one eye were associated with sudden conjunctival injection and other autonomic features of cluster headache. Attacks lasted only 15 to 60 s and recurred five to 30 times an hour. Attacks could be precipitated by chewing or eating certain foods, such as citrus fruits, and were not abolished by indomethacin. Most cases have some associated precipitating factors, particularly movements of the neck. Of the patients recognized with this problem males predominate and the paroxysms of pain usually last between 5 and 250 s, although longer duller interictal pains are recognized as well as attacks of up to 2 h in two patients. The conjunctival injection seen with SUNCT is often the most prominent autonomic feature and production of tears may be very obvious. SUNCT is more or less intractable to medical management although there is a modest benefit with carbamazepine that is nothing like its effect in trigeminal neuralgia. Recently, we have found that topiramate and lamotrigine are useful in SUNCT syndrome.

Secondary SUNCT and associations

There have been three reported patients with secondary SUNCT syndromes. The first two patients had homolateral cerebellopontine angle arteriovenous malformations diagnosed on MRI. The third patient had a cavernous haemangioma of the brainstem seen only on MRI. These cases highlight the need for cranial MRI in investigating for secondary SUNCT. Just as there is a reported case of chronic paroxysmal hemicrania associated with trigeminal neuralgia there is a single report of a patient with trigeminal neuralgia who developed a SUNCT syndrome.

Benign sex headache

Sex headache may be precipitated by masturbation or coitus and usually starts as a dull bilateral ache while sexual excitement increases, suddenly becoming intense at orgasm. The term orgasmic cephalalgia is not useful since not all sex headache requires orgasm. Three types of sex headache are discussed: a dull ache in the head and neck that intensifies as sexual excitement increases, a sudden severe ('explosive') headache occurring at orgasm, and a postural headache resembling that due to low cerebrospinal fluid pressure developing after coitus. The latter in the author's clinical experience is simply another form of headache due to low cerebrospinal fluid pressure arising from vigorous sexual activity usually with multiple orgasm and might be usefully considered with the secondary chronic daily headaches (Table 10). The essential clinical features of sex headache are:

- Precipitation by sexual excitement.
- Bilateral at onset.
- Prevented or eased by ceasing sexual activity before orgasm.

Headaches developing at the time of orgasm are not always benign. Subarachnoid haemorrhage was precipitated by sexual intercourse in 4.5 per cent of 66 cases reported by Fisher and 12 per cent of 50 cases studied by Lundberg and Osterman. One young man was reported to have developed a brainstem thrombosis and another a left hemisphere infarction.

Sex headache affects men more often than women and may occur at any time during the years of sexual activity. It may develop on several occasions in succession and then not trouble the patient again, although there is no obvious change in sexual technique. In patients who stop sexual activity when headache is first noticed it may subside within a period of 5 min to 2 h, and it is recognized that more frequent orgasm can aggravate established sex headache. About half of patients with sex headache have a history of exertional headaches but there is no excess of cough headache in patients with sex headache. In about 50 per cent of patients sex headache will settle in 6 months. Migraine is probably more common in patients with sex headache.

Management

Benign sex headaches are usually irregular and infrequent in recurrence, so management can often be limited to reassurance and advice about ceasing sexual activity if a milder, warning headache develops. When the condition recurs regularly or frequently, it can be prevented by the administration of propranolol, but the dosage required varies from 40 to 200 mg daily. An alternative is the calcium channel blocking agent diltiazem 60 mg three times daily. Ergotamine (1 to 2 mg) or indomethacin (25 to 50 mg) taken about 30 to 45 min prior to sexual activity can also be helpful.

Thunderclap headache

Severe headache of sudden onset may occur in the absence of sexual activity and it is appropriate to consider the issue here as it may be the sentinel bleed of an intracranial aneurysm and there are some issues that overlap clinically. Day and Raskin reported a woman with three episodes of very severe headache of sudden onset who was found to have an unruptured aneurysm of the internal carotid artery, with adjacent areas of segmental vasospasm. While headaches of explosive onset may certainly be caused by the ingestion of sympathomimetic drugs or tyramine-containing foods in a patient who is taking monoamine oxidase inhibitors, and can also be a symptom of phaeochromocytoma, the relationship between thunderclap headache and aneurysm in the absence of CT scan or cerebrospinal fluid evidence of subarachnoid haemorrhage is difficult. Wijdicks and colleagues followed up 71 patients whose CT scans and cerebrospinal fluid findings were negative for an average of 3.3 years. Twelve patients had further such headache, and 31 (44 per cent) later had regular episodes of migraine or tension-type headache. Factors identified as precipitating the headache were sexual intercourse in three cases, coughing in four, and exertion in 12, while the remainder had no obvious cause. A history of hypertension was found in 11 and of previous headache in 22. Markus compared the presentation of 37 patients with subarachnoid haemorrhage and 189 with a similar thunderclap headache but normal cerebrospinal fluid examination and could not discern any characteristic which distinguished the two conditions on clinical grounds.

Investigation of any severe headache of sudden onset, be it in the context of sexual excitement or isolated thunderclap headache, should be driven by the clinical context. The first presentation should be vigorously investigated with CT and cerebrospinal fluid examination and where possible MRI angiography. Formal cerebral angiography should be reserved to situations of high clinical suspicion. It is worth noting that of diffuse multifocal reversible spasm may be seen in thunderclap headache without there being an intracranial aneurysm.

24.13.3 Epilepsy in later childhood and adults

G. D. Perkin

Definitions

Using guidelines developed by the International League Against Epilepsy (**ILEA**), epilepsy is defined as recurrent (two or more) epileptic seizures, unprovoked by any immediate identifiable cause. Excluded are febrile seizures and neonatal seizures (the latter defined as those occurring in the first 4 weeks of life). Multiple seizures occurring within a 24-h period are considered to represent a single event. The epileptic seizure itself is defined as the clinical manifestation of an abnormal and excessive discharge of a set of brain neurones. The manifestation is a sudden transient phenomenon that may include alteration of consciousness, motor, sensory, autonomic, or psychic events which are perceived either by the individual or by an observer. Problems arise, when using the term epilepsy, with those individuals who may have had only two or three attacks in a lifetime. To take account of this, the terms active and inactive epilepsy are used, the former referring to patients with at least one seizure in the previous 5 years, the latter to patients who have been seizure free over the same period. The definitions are further qualified, for inactive cases, according to whether the individual is on drug therapy.

The idiopathic epilepsies are defined as those epileptic disorders (partial or generalized) which have characteristic clinical and electroencephalographic features coupled with a genetic predisposition. Cryptogenic epilepsy defines cases of partial or generalized epilepsy in which no aetiological factor has been identified. Symptomatic seizures are those occurring in association with a known risk factor. Epileptic syndromes have been defined by the ILEA on the basis of clinical characteristics, age of onset, and electroencephalographic findings.

Epidemiology

Incidence

Most reported incidence rates lie between 40 and 70 per 100 000. Figures for developing countries usually exceed 100 per 100 000. Age-specific rates show a bimodal distribution, with the highest peak in the first decade, falling thereafter until a second peak in later life.

Prevalence

Prevalence figures are more widely available. For adults, rates lie between 1.5 and 57 per 1000, with an average of 10.3 per 1000. Cumulative incidence (or lifetime prevalence) rates, excluding febrile seizures, are higher, producing a figure between 1.5 and 5 per cent (Fig. 1).

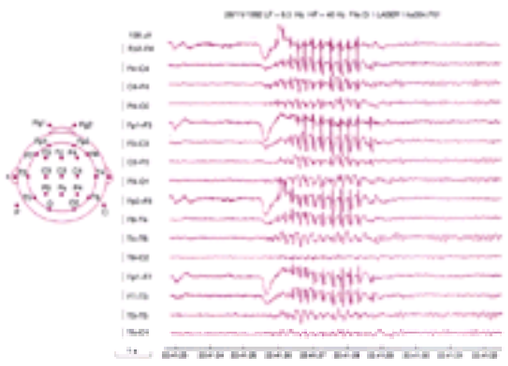

Fig. 1 Electroencephalogram of a typical absence seizure. The first 2.5 s of the record are entirely normal. The event begins with a large downward deflection which records eye closure, immediately followed in all channels by a spike-and-wave discharge at a frequency of 3 cycles/s. The seizure terminates as abruptly as it began. (Record kindly provided by Dr David Fish.)

Sex

Males have slightly higher prevalence rates than females.

Socio-economic status

Higher prevalence rates have been reported in the lower socio-economic groups, both in developed and developing countries.

Pathophysiology

Inherent in any discussion of epilepsy mechanisms is the need to define a homogeneous population. Generalized tonic–clonic seizures, for example, can occur with many different epileptic syndromes. Epileptic seizures are thought to arise at cortical sites. Partial seizures begin focally in the cortex, generalized seizures infer widespread, bilateral cortical involvement from the beginning. An interictal discharge occurs when a group of pyramidal neurones is synchronously activated. During the discharge, the cells develop a large and prolonged depolarization which is terminated by a hyperpolarizing potential. Seizures develop when any of the inhibitory processes suppressing interictal discharges fail.

The underlying mechanisms behind epileptic discharges have been best defined for absence seizures where a thalamocortical circuit is responsible for generating synchronous burst-firing of neurones. The circuit involves neocortical pyramidal neurones, thalamic relay neurones, and neurones of the nucleus reticularis thalami. The last are exclusively g-aminobutyric acid (**GABA**) in type. A voltage-dependent calcium channel (T-channel) appears critical in allowing burst-firing of neurones to appear. Following activation, the T-channels acquire repolarization via $GABA_B$ receptors present on thalamic relay neurones. $GABA_A$ receptors also play an important regulatory role in synchronized thalamocortical burst-firing.

Less information is available on the pathophysiological mechanisms of generalized convulsive seizures. Roles for $GABA_A$ receptors and for altered serotonergic neurotransmission have been suggested.

Classification

The ILEA classification scheme, as revised in 1989, is now widely used for epidemiological, management, and research purposes. The scheme divides seizures into focal, generalized, and unclassifiable forms (Table 1).

Though it is widely used, the classification has disadvantages. The ability to determine whether consciousness is preserved, in order to make the distinction between simple and complex partial seizures, is often limited. Some individuals, though appearing alert, can be shown to have impaired awareness when carefully tested.

An elaboration of the classification consists of a list of epileptic syndromes into which, theoretically, all generalized and partial epileptic seizures can be fitted. The idiopathic generalized seizures are classified according to age of onset and seizure type. The partial seizures, attributed to dysfunction of restricted cortical areas, are predominantly classified according to their clinical features, supplemented by electroencephalographic findings. Much criticism has been made of this syndromic classification. In routine clinical practice many cases (probably the majority) are left in non-specific categories. Moreover, the classification fails to incorporate data derived from CT or MRI.

Partial seizures

Simple partial motor seizures

Any part of the body can be affected by a focal motor seizure, according to the site of origin of the discharge. Sometimes the seizure remains localized to the same area (for example the hand), sometimes it 'marches' along the motor cortex, producing successional jerking of contiguous body parts (jacksonian seizures). During the focal stage, consciousness is preserved. With secondary generalization (that is, diffuse bilateral spread) consciousness is lost. The parts of the body most commonly affected by this type of seizure correlate with their area of representation in the motor cortex. Other focal motor disturbances reflecting epileptic discharges include rotation of head and eyes contralaterally (from the dorsolateral prefrontal cortex), tonic foot movements ipsilaterally (the paracentral lobule), and head turning with arm extension on the same side (supplementary motor cortex). Following such seizures there may be paralysis of the affected part lasting for minutes or hours (Todd's paresis).

Simple partial sensory seizures

Seizures emanating from the sensory cortex produce paraesthesias or numbness. The seizure can march in an analogous fashion to a motor seizure, and similarly, can then become generalized. Where the tongue or face are involved, the symptoms are sometimes felt bilaterally. More complex sensory phenomena may be experienced and with discharges in the second sensory area, the limb sensations can be ipsilateral, contralateral, or bilateral.

Occipital lobe seizures

Visual symptoms predominate, usually as simple rather than complex phenomena. The latter, producing alteration of size, shape, or depth of objects are associated with seizures arising at the occipito-parieto-temporal interface. In addition there may be ocular deviation, jerking, or forced closure of the eyelids. Visual hallucinations may occur.

Frontal lobe seizures

Frontal lobe seizures are commonly nocturnal and frequently associated with turning to a prone position. Vocalization is common and tends to consist of a continuous monotone with moaning or grunting. An aura before the attack is unusual. Other recognized features include pelvic thrusting, rocking of the body, and head movements. Rapid postictal recovery is common.

Simple partial (temporal lobe) seizures

The distinction between simple and complex partial seizures is difficult, based as it is on evidence of altered consciousness with the latter. Olfactory, gustatory, and vertiginous sensations occur. The taste and smell sensations are sometimes pleasurable but often disagreeable. A metallic taste is common. Abdominal sensations also occur, which are typically ill-defined and may ascend to the chest and throat. Psychic symptoms are more often associated with complex partial seizures. There may be intense pleasure or fear ushering in the attack. The patient can experience a sense of loss of personal or environmental reality (depersonalization and derealization, respectively). There may be a sense of intense familiarity (*déjà vu*) or unfamiliarity (*jamais vu*). Epileptic anger is unprovoked and rapidly subsides. Illusions are encountered, in the form of disordered visual perceptions, and visual or auditory hallucinations, sometimes of considerable complexity (Fig. 2).

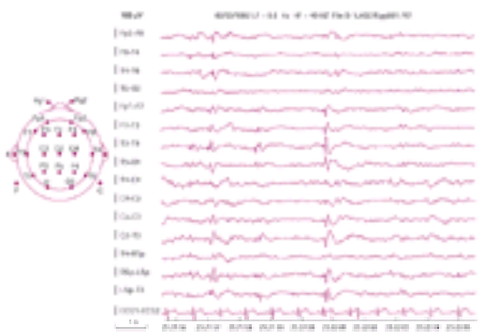

Fig. 2 Interictal spike and slow-wave complex in a patient with complex partial seizures. The discharges are particularly apparent over the left temporal lobe (T3 to T5), but there are some independent discharges over the right temporal lobe (T4 to T6). (Record kindly provided by Dr David Fish.)

Where consciousness is disturbed, various automatic activity or movement may occur of which the patient is unaware (automatisms). These may take the form of eating (chewing or swallowing), speaking, gesture, or more elaborate skilled activities. Some of these automatic movements are also seen with absence seizures. When elaborate, the patient may partly undress, or move about from one room to another. The symptomatology of mesial and lateral temporal lobe discharges has been distinguished, the latter having additional somatosensory, visual, or auditory manifestations to the other features mentioned above.

Other, rarer, focal seizure types are confined to childhood. In benign childhood epilepsy with centrotemporal spikes, consciousness is preserved. The sensory phenomena are usually confined to the mouth where motor activity may also occur. Speech arrest occurs if the dominant hemisphere is affected.

Any of the focal epilepsies can lead to secondary generalization. Consciousness is lost, and a tonic–clonic seizure is the usual outcome. Prolonged focal seizures (epilepsia partialis continua) lead to a repetitive or continuous focal motor activity which may last for weeks or months and is most often the consequence of a focal cortical insult.

Generalized seizures

Tonic–clonic seizures (grand mal epilepsy)

Some patients report a premonition for hours or even days before the attack. The symptoms are usually a vague sense of loss of well being and do not imply a focal origin for the attack. An aura, on the other hand, lasting a few seconds before the onset implies a focal origin for the attack, demanding classification as a focal seizure with secondary generalization. The tonic phase is associated with contraction of axial then limb muscles. If upright, the patient falls heavily. Injury is common. Contraction of the jaw can lead to tongue injury. Forcible contraction of the diaphragm results in a sudden gasp or epileptic cry. Cyanosis results from a loss of respiratory activity. Subsequently clonic movements appear and slowly increase in amplitude. Gradually, periods of relaxation intervene between the clonic contractions until finally all movements cease. The patient is then flaccid. Urinary or faecal incontinence or both may occur at this stage. Subsequently the patient is liable to sleep, often heavily. If the patient wakes, initial confusion and disorientation is the norm. Headache and muscle pains are common. Incomplete forms occur in which the clonic or tonic phase predominates.

In addition to injuries incurred in falling, and those resulting from biting of the cheeks or tongue (typically the lateral margin is affected), the seizures may be of such violence that vertebral compression fractures occur. Sudden death occurring soon after a tonic–clonic seizure is a recognized, though rare, complication. Its incidence lies between 1:500 and 1:1000 deaths per person-year.

Absence seizures (petit mal)

Patients are totally unaware of their absence seizures. Activity suddenly ceases but without loss of posture. Adventitious movements occur, for example slight contractions of the eyes or some lip movement. The head may drop slightly. More typically, the patient simply stares blankly and is unresponsive. Attacks last around 10 to 20 s. In some cases more overt limb movement occurs.

Atypical absences are defined as attacks which begin less abruptly, last longer, and frequently lead to loss of postural tone. They usually coincide with other seizure types. Absence seizures begin in childhood and usually cease in adult life, though some 50 per cent of patients will later develop tonic–clonic seizures.

Myoclonic seizures

Myoclonus consists of brief, shock-like contractions of muscle, occurring either in a generalized or focal distribution. Many forms of myoclonus are non-epileptic. Those associated with epilepsy are accompanied by an ictal electroencephalographic discharge. In primary generalized epileptic myoclonus, the myoclonus is accompanied by diffuse cortical epileptic discharges.

Atonic seizures

Atonic seizures result in sudden loss of muscle tone. If the hypotonus is generalized, falls occur, often with substantial injury. The attacks begin in infancy or childhood. The episodes are brief and recovery rapid unless injury has occurred.

Status epilepticus

Status epilepticus is defined as a single seizure lasting more than 30 min or successional seizures without recovery of consciousness between. The seizures are usually tonic–clonic. Both complex partial seizures and absence seizures can occur in the form of status epilepticus. In such cases, alteration of the conscious level is likely to be the major clinical feature with little motor activity, particularly with the latter.

Epilepsy syndromes

The need to define epileptic syndromes arises from the fact that individual seizure types may be a manifestation of a number of differing conditions, all with individual characteristics and prognosis. The epileptic syndrome is based on a combination of seizure type, presumed localization (according to clinical features and electroencephalographic characteristics) in the case of the partial seizures, and age of onset. In routine, as opposed to heavily specialized, practice only a third of newly diagnosed epilepsy can be fitted into such a classification system.

Causes of epilepsy

In most surveys, only about a quarter to a third of epilepsy cases have been attributable to a specific cause. With modern imaging methods, this proportion is likely to rise significantly.

Genetically determined

In some genetically determined disorders, epilepsy is only one feature of the condition. Many such disorders have features other than epilepsy and typically produce significant neurological disability. Examples include the forms of progressive myoclonic epilepsy associated with Lafora body disease and Unverricht–Lundborg disease. More relevant, in clinical terms, are those genetically determined conditions in which epilepsy is the sole or major manifestation. Among these are some with simple forms of inheritance, and some with complex forms. The epilepsies occurring with such syndromes may be generalized or partial in nature.

Epilepsy syndromes with simple inheritance

Examples in this category include benign familial neonatal convulsions and benign familial infantile convulsions. Linkage to chromosome 20q has been described for the former, coding for potassium channel proteins.

Epilepsy syndromes with complex inheritance

Examples include juvenile myoclonic epilepsy and benign rolandic epilepsy.

Juvenile myoclonic epilepsy

This epilepsy type usually begins between the ages of 12 and 18. Early morning, sudden myoclonic jerks of the arms and shoulders are characteristic. Subsequently, generalized tonic–clonic seizures occur in the majority of patients. Genes for this disorder, inherited in a dominant manner, have been localized to both chromosome 6 and 15.

Benign rolandic epilepsy

This condition presents between the ages of 5 and 10 years. Unilateral motor or sensory seizures occur in sleep. The condition is associated with centrotemporal spikes on electroencephalography. The epileptiform abnormality may be linked to chromosome 15.

Included within the umbrella of the genetically determined epilepsy syndromes (though often classified separately from the epilepsies) are febrile seizures. These occur in between 2 and 5 per cent of children, typically between the ages of 6 months and 3 years. Simple febrile seizures are generalized and last less than 15 min. Complex febrile seizures either have focal features, are longer lasting, or recur within a 24-h period. About two-thirds of children with a febrile seizure do not have a recurrence. Febrile seizures do not have an adverse effect on development but a proportion of children develop epilepsy at a later age. Inheritance of febrile seizures is considered to be as an autosomal dominant trait.

Migration disorders

Alterations of the migration processes that establish the cellular and laminar organization of the neocortex are now considered to underlie a number of cases of epilepsy, particularly those arising in childhood. The migration disorders may be generalized (such as agyria), hemispheric (hemimegalencephaly), or focal (such as cortical dysplasia). Several forms of the migration disorders are genetically determined, and linked to mutations on the X chromosome. Some of these migration disorders are detectable by high-resolution MRI. The epilepsies produced can be either focal or generalized, and typically are difficult to control.

Trauma

Approximately 70 per cent of those individuals who eventually develop post-traumatic epilepsy will have their first seizure within 2 years of the original injury. Risk factors that predict post-traumatic epilepsy include early seizures (those occurring in the first week), a depressed skull fracture, or evidence of intracranial haemorrhage. There is no justification for the use of prophylactic anticonvulsants in the hope of preventing the development of post-traumatic seizures.

Tumour

Though adult-onset epilepsy is often equated with the presence of tumour, the cause in later life of symptomatic epilepsy is more likely to be cerebrovascular or Alzheimer's disease. The likelihood of a tumour producing seizures increases as the tumour is sited more anteriorly in the hemisphere, so that over 50 per cent of patients with frontal lobe tumours have epilepsy. Adult-onset status, in someone without a history of epilepsy, is particularly suggestive of frontal lobe tumour. Epilepsy is more common with slow-growing tumours and may be generalized or focal in nature.

Cerebrovascular disease

The prevalence of epilepsy after stroke has been reported to lie between 6 and 15 per cent, and appears as likely with cerebral infarction as with cerebral haemorrhage.

Infection

In large-scale surveys, infection has been considered the cause of epilepsy in 3 to 5 per cent of cases. Differences in rate between countries are often attributed to the variable prevalence of certain agents, for example cysticercosis. Other tropical infections which have been considered potential contributors to epilepsy prevalence include malaria, schistosomiasis, and trypanosomiasis. Epilepsy is a recognized feature of bacterial, tuberculous, and fungal meningitis, and of viral encephalitis. Epilepsy is often the first symptom of a tuberculoma.

Cerebral degeneration

Epilepsy is more common in patients with Alzheimer's disease or multi-infarct dementia compared with age-matched controls.

Multiple sclerosis

The prevalence of epilepsy in multiple sclerosis is probably of the order of 2 per cent. Both generalized and focal seizures have been attributed to multiple sclerosis. Rarely, status epilepticus and epilepsia partialis continua have been recorded.

Alcohol

Alcohol lowers seizure threshold. Seizures may occur during binge drinking, or during a period of withdrawal after alcohol excess.

Metabolic disorders

Seizures may occur in association with hypocalcaemia, hypercalcaemia, hypomagnesaemia, hypoglycaemia, hyponatraemia, and hypernatraemia. Severe renal and hepatic failure can both precipitate seizures.

Certain drugs are considered to lower the seizure threshold and are relatively contraindicated in patients with epilepsy. The drugs in question include the tricyclic

antidepressants, the phenothiazines, and isoniazid. Rapid withdrawal of barbiturates or benzodiazepines can trigger seizures in those without a history of epilepsy.

Precipitants of epilepsy

Recognized precipitants of epilepsy include inadequate sleep, alcohol abuse, and ingestion of certain drugs. In catamenial epilepsy the attacks are confined to the menstrual period. Seizures confined to sleep are well recognized and indeed sleep electroencephalography recordings are characteristically more likely to register abnormal discharges than recordings made in the alert individual. In reflex epilepsy attacks are virtually inevitably triggered by a particular stimulus. Precipitants include photic stimulation, startle, noise, and movement. Rarer forms of reflex epilepsy have been linked to musical passages, eating, and performance of certain mental tasks.

Differential diagnosis

Syncope

Most individuals who faint experience a characteristic set of symptoms prior to loss of consciousness. These include mental slowing, fading of vision, altered hearing, malaise, and sweating. The process is the result, in varying combination, of bradycardia and profound arterial vasodilatation in skeletal muscle. Unless the individual lies down, loss of consciousness occurs and the patient falls to the ground. Characteristically the fall is gentle, and self-injury relatively uncommon. In falls associated with tonic–clonic or atonic seizures, the fall is precipitate and injury much more likely. Rarely, in complicated faints, there may be brief clonic jerks of the limbs. More commonly, multifocal myoclonus is observed, lasting a few seconds and following the loss of posture. The eyes tend to remain open. Lateral head turns, repetitive movements (such as lip licking), and hallucinations are all recognized features. After the episode there may be brief confusion and feelings of weakness, but these rapidly resolve. If, on the other hand, the upright posture is maintained (typically the individual is a soldier on parade) then stiffness of the limbs or repetitive generalized shaking occurs which is virtually indistinguishable from the movements occurring with epilepsy. Usually, however, a true tonic–clonic sequence does not occur in these circumstances.

Micturition syncope

Micturition syncope occurs predominantly in males, but of any age group. The attacks are almost always nocturnal, typically after an evening of alcohol consumption. Onset is usually during or shortly after micturition. The warning symptoms are often brief. The attacks seldom occur frequently; if they do, then the individual, if male, is advised to micturate in the sitting position.

Cough syncope

Patients with cough syncope effectively perform a Valsalva manoeuvre during a bout of prolonged coughing. Treatment is directed at the underlying chest condition.

Cardiac syncope

A variety of cardiac abnormalities, all having in common the end result of failing output and reduced cerebral perfusion, are associated with syncopal attacks. Mechanisms include complete heart block, paroxysmal ventricular tachycardia or fibrillation, and supraventricular tachycardia or bradyarrhythmia. In addition to disorders of rhythm, abnormalities of ventricular contractility or obstruction of outflow can have a similar outcome, usually when increased output is required during a period of exertion. Rarely, pedunculated masses within the heart, for example an atrial myxoma, cause outflow obstruction when the patient assumes certain postures. Features suggesting that a cardiac lesion may be responsible for a syncopal attack include a history of cardiac disease, palpitations or chest pain in association with the attack, and the finding of cardiac abnormalities on clinical examination.

Separate from these mechanisms are cases of syncope associated with postural hypotension. Autonomic failure resulting in postural hypotension is a feature of: multisystem atrophy; certain neuropathies with autonomic fibre involvement, such as diabetes; and drug therapy, for example with phenothiazines and tricyclic antidepressants. The correct diagnosis is usually readily established from the history.

Carotid sinus syncope

Patients with this condition usually present either with vertigo or with syncopal attacks. The syncopal attacks are sometimes followed by flushing and may be triggered by pressure over the neck, for example during neck rotation. In most patients, the syncope is related to atrioventricular block or asystole. Occasionally, a pure vasodilator reaction occurs, with peripheral pooling of blood.

Transient ischaemic attacks

These attacks should seldom be confused with epilepsy. In some patients with carotid occlusion (or severe stenosis), attacks of limb shaking occur in which involuntary limb movements described as shaking, trembling, or twitching occur, usually for seconds. The movements, which are coarse and irregular, predominate distally. Sometimes the attacks coincide with limb weakness or speech difficulty. The attacks are not influenced by anticonvulsants but can be relieved by endarterectomy where there is an underlying carotid stenosis.

Migraine

Loss of consciousness is a recognized feature of basilar migraine. The condition presents in children or adolescents. The headache is occipital. Visual disturbances are common, along with altered sensations (typically bilateral), ataxia, and dysarthria. Typically the patient, if unconscious, can be roused. Rarely, tonic–clonic seizures are seen with the attacks.

Hyperventilation

Most patients with the hyperventilation syndrome do not develop carpopedal spasm or tetany. Rather, they have a constellation of symptoms which are liable to be confused with other conditions such as epilepsy. Those symptoms include dizziness or vertigo, weakness, paraesthesiase, chest pain, and altered consciousness. Probably some 5 to 15 per cent of patients lose consciousness during hyperventilation, but never with a tonic–clonic progression that would cause real diagnostic difficulty.

Narcolepsy and cataplexy

Narcolepsy is defined as excessive daytime sleepiness, often occurring under unusual circumstances. The onset of sleep is usually preceded by a feeling of tension, tiredness, or a noise in the head. In some patients, onset occurs without warning. At times, patients have periods of semi-automatic behaviour for which they may subsequently be amnesic.

Cataplexy is typically triggered by sudden arousal. Attacks are brief, and may lead to such loss of muscle control that the patient falls. During the attack, the patient is flaccid, the eyes may roll or diverge, and the facial muscles flicker. Despite this, the patient usually remains fully alert.

Drop attacks

Drop attacks are almost confined to women in the last third of life. Typically, while walking, the patient drops to their knees without warning. The patient is aware of the fall, and is usually able to get up quickly, providing there is no injury. The attacks occur in otherwise fit individuals, are not due to vertebrobasilar ischaemia, and eventually remit completely. They are untreatable.

The parasomnias

Parasomnias are largley confined to children. They consist either of abnormal motor activity or excessive autonomic activity. Motor activity includes sleep starts, sleep myoclonus, bruxism, and head banging. Sleep myoclonus produces repetitive leg contraction, typically dorsiflexion of the feet. It increases with age and is usually idiopathic. Head banging, which may coincide with body rocking, is usually only seen in children or infants. The movements, typically occurring in clusters, are often accompanied by various forms of vocalization. In most cases, the child is normal. Sleep terrors usually happen within the first hour or two of sleep, occur in children, and result in a sudden cry followed by anxiety, tachycardia, sweating, and hyperkinesis. The child is not completely aware of the episodes, which sometimes necessitate short-term treatment with benzodiazepines.

Non-epileptic seizures

Non-epileptic seizures sometimes occur in isolation, but sometimes in those with true epilepsy. They account for 20 per cent of the patients referred to specialist epilepsy units, usually with a diagnosis of intractable epilepsy. The vast majority of sufferers are women. They are more likely to have a family history of psychiatric disorders, a past personal history of psychiatric disorder, a history of suicide attempt(s), evidence of sexual maladjustment, and current depressive symptoms. Indeed there is a substantial overlap, in terms of clinical characteristics, between non-epileptic seizures and multiple personality disorder. In addition to the features noted above, up to 90 per cent of patients give a history of sustained trauma, including childhood abuse, which may have been physical or sexual.

Certain features from the history should alert the physician. The attacks usually take place with witnesses present. They develop gradually rather than suddenly and the movements displayed are often unpredictable and bizarre. Attempt to constrain the patient are resisted. Vocalization is common. Incontinence is uncommon and tongue biting particularly so, but self-injury is a recognized feature. Typically the seizures are difficult to control. Serum prolactin levels taken 20 min after the event are normal, in contrast to tonic–clonic seizures where they are commonly, though not inevitably, elevated. Videotelemetry has proved of considerable value in differentiating epileptic from non-epileptic seizures. Management is extremely difficult. Drug withdrawal is resisted by the patient, who often resents suggestions of psychiatric referral and exploration of psychological morbidity.

Investigation

Investigation of a patient with suspected epilepsy (or a single seizure) is performed for three main reasons. The investigation may provide valuable support for the diagnosis, may give an indication as to which part of the brain has initiated the seizure, and finally, imaging may allow a statement as to the underlying structural process, where such exists.

Routine haematological and biochemical tests should be undertaken in all patients with suspected epilepsy although they seldom point to a metabolic disturbance that has not already been recognized.

Electroencephalography

Certain facts about the electroencephalogram must be understood before interpretation is attempted. Epileptiform discharges are encountered in between 0.5 and 4 per cent of individuals who have never had a seizure and who do not do so during a period of follow-up. Furthermore, a routine electroencephalogram in adults with established epilepsy shows epileptiform abnormalities in only some 40 to 50 per cent of cases. With repeat recording, with or without sleep records, the figure rises to 70 or 80 per cent. In other words, some patients with unequivocal epilepsy will have persistently normal or, at least, non-epileptic electroencephalograms. Serial electroencephalographic recording is sometimes helpful in an attempt to define the origin of the seizure and to delineate the seizure type better. If photosensitivity is suspected (10 per cent of individuals with seizures occurring between 1 and 7 years are photosensitive), serial recordings are appropriate, as they are in any individual with atypical status, or in whom cognitive impairment might be due to subclinical epileptic activity. Where surgical intervention is being planned for the epilepsy, routine and sleep recordings are followed by videotelemetry in order to record individual attacks. For some patients, depth electrodes will be needed to establish the seizure source. Magnetoencephalography localizes focal epileptic discharges by measuring the changes in extracranial magnetic fields which these discharges generate. The system costs some 25 times as much as a conventional electroencephalographic system. Depth electrodes are positioned stereotactically at sites determined by clinical and surface electroencephalographic criteria. Depth recordings are more accurate and sensitive in detecting focal discharges than either nasopharyngeal or sphenoidal electrodes.

The electroencephalogram has also been used to attempt prediction of seizure recurrence in individuals after a single seizure of unknown cause. Epileptic discharges, in one series, predicted a seizure recurrence over 2 years of 83 per cent, compared with a 12 per cent rate in individuals with a normal recording. The electroencephalogram has also been used to predict seizure recurrence during or after drug withdrawal in someone whose epilepsy has gone into remission on medication. The predictive value of electroencephalographic abnormalities in such cases has varied widely from series to series.

CT scanning

Neuroimaging is carried out in order to define whether a structural abnormality underlies the patient's epilepsy and, if so, whether some additional treatment, other than anticonvulsants, might be required. CT scanning was originally the most often used imaging process, prior to the more widespread availability of MRI. Some authors advocate MRI in all patients with epilepsy, other than for those epilepsies which are clearly idiopathic (such as absence seizures, juvenile myoclonic epilepsy, and benign rolandic epilepsy). In practice, this is probably unreasonable. For example, a patient with the onset of epilepsy in their 70s or 80s, who has a normal CT (at least, with no evidence of focal pathology) hardly merits MRI if the epilepsy is well controlled.

MRI

MRI is undoubtedly both more sensitive and more specific than CT in detecting small brain lesions and abnormalities of the cerebral cortex thought to be relevant in the genesis of epilepsy (Fig. 3). The most common abnormalities detected are hippocampal sclerosis, malformations of cortical development, vascular malformations, tumours, and acquired cortical damage. MRI is particularly indicated for partial seizures, onset of generalized or unclassified seizures in adult life, patients with fixed focal clinical or neuropsychological deficit, and for those patients with poor seizure control. Quantitative measures of the hippocampi improve the diagnostic sensitivity of MRI for hippocampal sclerosis. MRI is much more sensitive than CT for detecting malformations of cortical development. Magnetic resonance spectroscopy, examining nuclei ^{31}P and ^{1}H, has been used for assessment of patients with complex partial seizures for possible surgery.

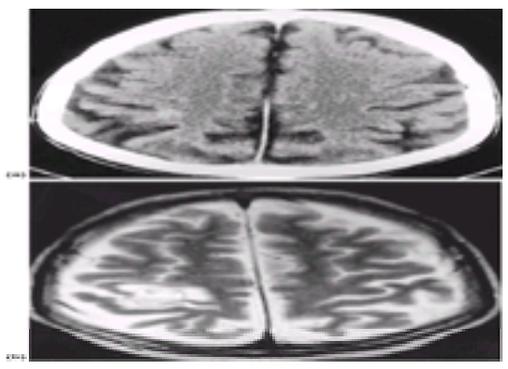

Fig. 3 CT scan (a) and MRI scan (b). The readily visible cavernome on MRI is only just visible on CT.

Single photon emission computed tomography (SPECT)

This technique allows measurement of cerebral blood flow and of specific brain receptors. Both ictal and interictal studies have been performed. Ictal SPECT can achieve a correct localization of over 90 per cent in unilateral temporal lobe epilepsy.

Positron emission tomography (PET)

PET scanning is used to measure cerebral blood flow, regional cerebral glucose metabolism, and the distribution of specific receptors, such as the benzodiazepine–$GABA_A$ receptor complex (Fig. 4 and Plate 1). The spatial resolution achieved is superior to SPECT. Epileptic foci, studied interictally, display reduced blood flow and reduced glucose metabolism. Typically, the abnormalities found are more extensive than the corresponding pathological lesion. Increasingly it appears likely that MRI and functional MRI will largely replace this technique in patient evaluation.

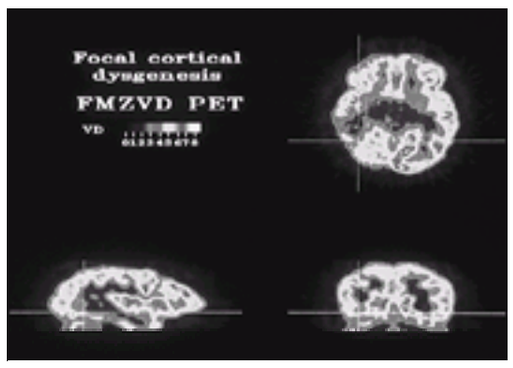

Fig. 4 FMZVD PET scan showing a region of probable cortical dysplasia in the right temporal lobe. The 11C-fluamzenil volume of distribution (FMZVD) is an index of $GABA_A$ receptor density. (See also Plate 1.)

Treatment—drug therapy

Choice of drug therapy

A number of principles can be stated in relation to drug therapy.

Does the patient require anticonvulsants?

The issue of whether isolated seizures should be treated remains unresolved. Seizure recurrence rate after a single seizure reaches 80 per cent in untreated individuals, the vast majority recurring within 2 years of onset. Many patients prefer to defer treatment after a single seizure, a decision substantially influenced by how soon they wish to start driving. For a patient who has very infrequent seizures, say 5 or more years apart, it may seem logical to withhold medication.

Choice of anticonvulsant

An algorithm can provide some guidelines regarding drug treatment (Fig. 5). For generalized seizures (tonic–clonic, absence, or myoclonic) sodium valproate is the drug of choice. Further choices are determined by seizure type. There is no controlled trial data indicating the most appropriate add-on drug or combination of drugs. Myoclonus can be exacerbated by carbamazepine, gabapentin, and lamotrigine and absences by carbamazepine and gabapentin. For partial seizures, with or without generalization, carbamazepine and valproate are probably the drugs of choice, though controlled studies have indicated that phenobarbitone and phenytoin are of comparable value.

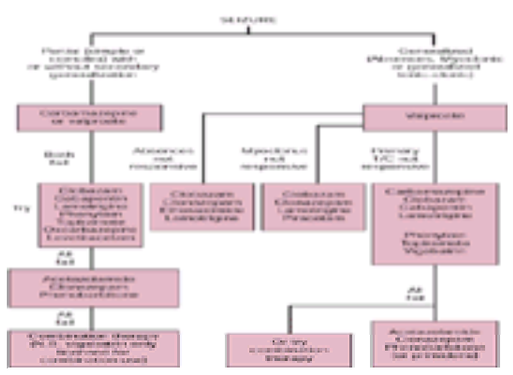

Fig. 5 Choice of anticonvulsant.

In addition, choice of drug will be influenced by the patient's age, sex (regarding the use of oral contraceptives and likelihood of pregnancy), and reliability of adherence to a particular drug regime. The patient should always be started on a single drug.

Dosage

Although standard dose regimes tend to be quoted, many anticonvulsants are sometimes effective in relatively low doses. Accordingly the drug is introduced in low dosage and is then gradually increased according to need and tolerance. Sometimes only dosages that lead to toxic serum levels appear effective. Some patients tolerate such toxic levels without difficulty.

Failure of first drug

When this occurs, a second drug should be gradually introduced without withdrawing the first. If the patient responds, the drug used originally can be slowly withdrawn.

Drug combinations

If drugs given individually have failed then drug combinations should be considered, remembering that they may interact with each other.

Generic prescribing

The bioavailability of the anticonvulsant drugs should be unaffected by whether they are prescribed generically, or as a specific branded product. Patients sometimes disbelieve this assumption and prefer branded products. If they are given generic prescriptions, they should be warned that the appearance of their medication may

change from prescription to prescription.

The problem of non-compliance

Non-compliance is a significant problem with the anticonvulsants and is a potent cause of poor control. A full explanation of each drug's side-effect profile and its potential interactions is essential and appears conducive to improved compliance. Drugs that are given once or twice a day are preferred to ones needing more frequent prescriptions. Slow-release preparations allow drug regimes to be simplified.

Mechanisms of action (Fig. 6)

The prime role of GABA-mediated inhibition in the epileptic process implies that drugs which enhance $GABA_A$-receptor-mediated inhibition will have anticonvulsant activity. The $GABA_A$-receptor complex comprises at least three subunits, a, b, and †, which appear to combine as a five-membered structure forming an anion-permeable channel. Both barbiturates and benzodiazepines act by potentiating $GABA_A$-mediated inhibition. The barbiturates bind to the b-subunit to potentiate action of endogenous agonist GABA and prolong the opening time of the chloride ion channel. Benzodiazepines bind to the a-subunit to potentiate the action of GABA and increase the frequency of opening of the chloride ion channel. GABA is metabolized by GABA transaminase. Vigabatrin irreversibly binds to GABA transaminase to inhibit degradation of GABA and thereby elevate brain GABA levels. GABA-mediated inhibition can also be enhanced by blocking GABA uptake into glia and neurones after its release into the synaptic cleft during synaptic transmission.

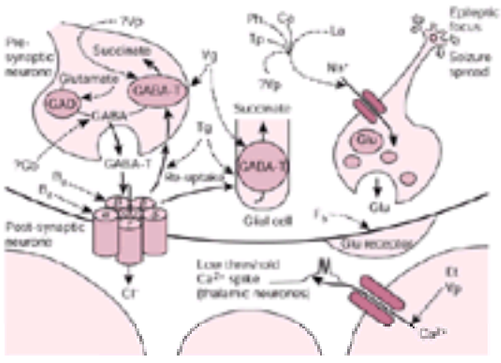

Fig. 6 Mechanism of action of some of the anticonvulsants. Ba, barbiturate; Bz, benzodiazepine; Ca, carbamazepine; Et, ethosuximide; Fb, felbamate; Gb, gabapentin; La, lamotrigine; Ph, phenytoin; Tg, tiagabine; Tp, topiramate; Vp, valproate; Vg, vigabatrin.

Tiagabine blocks uptake of synaptically released GABA into both presynaptic neurones and glial cells, allowing GABA to remain at its site of action for longer periods. Gabapentin acts presynaptically to promote GABA synthesis or release.

The second major neurotransmitter system involved in the genesis of epileptic activity is excitatory utilizing glutamate and, perhaps, aspartate as neurotransmitters. They act on several different receptors including a-amino-3-hydroxy-5-methylisoxazole-proprionic acid (AMPA) and N-methyl- D-aspartate (**NMDA**). The NMDA receptor is activated by glutamate or aspartate in conjunction with glycine. Blockade of the NMDA receptor results in antiepileptic effects.

Voltage-dependent calcium ion currents are thought to be of importance in the genesis of epileptic events. Ethosuximide acts by inhibition of one class of voltage-dependent calcium ion currents (T currents). Valproate may have a similar role.

Regulation of sodium channels also appears of relevance in the modification of the epileptic process. Phenytoin, carbamazepine, and possibly valproate reduce the rate of recovery from inactivation of depolarized voltage-dependent sodium channels, thereby blocking sustained repetitive firing of action potentials in depolarized neurones. Lamotrigine inhibits glutamate and aspartate release, suggesting it may act at voltage-dependent sodium channels to decrease the presynaptic release of glutamate. Lamotrigine may have additional effects on calcium channels. Oxcarbazepine may act by reducing glutamate release via a blocking action on presynaptic calcium channels. Topiramate influences sodium channel activity, suggesting that its anticonvulsant properties are similar to those of phenytoin. Felbamate probably acts primarily through its effects on the NMDA receptor.

Selected drugs

Carbamazepine

Carbamazepine is a first-line drug for both partial seizures and for generalized tonic–clonic seizures. In its standard form, it needs to be given three times per day, but a slow-release preparation allows twice daily prescribing. Dosage ranges from 300 to 1600 mg/day. Sedation is common and the drug should be introduced slowly. A drug rash occurs in perhaps 3 per cent of patients and demands immediate drug withdrawal. Signs of intoxication include drowsiness, blurred vision, and dizziness. Leucopenia occurs and can lead to a frank aplastic anaemia. Hyponatraemia and oedema are recognized features, associated with a mild degree of inappropriate antidiuretic hormone production. The drug influences atrioventricular conduction and should not be given to patients with atrioventricular conduction abnormalities unless they are already paced. The relationship between dosage and plasma concentrations is linear. Carbamazepine is a liver-enzyme inducer and is teratogenic (see below).

Sodium valproate

Sodium valproate is considered, at least by some physicians, to be the drug of choice for all epilepsy types. It is not enzyme-inducing, and therefore does not influence the metabolism of the oral contraceptive. Liver toxicity is a recognized, though rare, hazard. Elevated liver enzyme levels are more common, but usually return to normal without need for drug withdrawal. Thrombocytopenia occurs rarely. Gastrointestinal effects are fairly common. Nausea and weight loss are seen, but appetite stimulation with weight gain is more common. Tremor occurs, as a dose-related effect. Hair loss, of a mild degree, is not uncommon. After a few months, hair regrowth occurs, often more curly than before. Sedation is less troublesome than with other anticonvulsants. Disturbances of menstruation are recognized. It has been suggested that the drug can trigger polycystic ovarian disease. The dose ranges from 600 to 2500 mg/day and it is given twice or three times per day. A slow-release preparation can be given once daily. Plasma levels are not a useful guide to efficacy.

Other drugs

Phenytoin

Experience with phenytoin is vast and despite its side-effect profile and complex pharmacokinetics, large quantities of the drug continue to be prescribed. A 100 mg tablet, in the United Kingdom, costs approximately one-thirtieth of the price of a comparable dose of lamotrigine. The drug is effective in both generalized tonic–clonic seizures and in the partial seizures. It has a long half-life, and can be given once daily, conveniently at bed time. Sedation is common. Toxic effects, generally dose related, include drowsiness, ataxia, confusion, blurred vision, and dizziness. Most patients who are intoxicated with the drug have nystagmus. Permanent cerebellar ataxia and peripheral neuropathy are recorded. Other side-effects or toxic effects include rashes, gum hypertrophy, thickening of the facial features, chorea, and sleep disturbance. The drug is a potent enzyme-inducer and is teratogenic. The relationship between dosage and plasma concentrations is non-linear. Once the dose exceeds 300 mg/day, increments should be pegged to 50 mg or even 25 mg at a time.

Lamotrigine

Lamotrigine is licensed for both generalized and partial seizures. Occasionally it exacerbates myoclonus. Doses seldom exceed 400 mg/day. A drug rash occurs in

about 3 per cent of patients. It interacts with enzyme-inducing anticonvulsants, which lower its plasma level. Valproate enhances lamotrigine levels. The drug can be given once daily. It is said not to be teratogenic.

Phenobarbitone

Phenobarbitone is a very effective anticonvulsant but often badly tolerated. Children may become hyperactive on the drug, adults (and particularly the elderly) heavily sedated. Doses of up to 180 mg/day are used. It has a long half-life and can be given once daily. Rapid withdrawal of phenobarbitone in non-epileptic patients can trigger seizures. Over-rapid withdrawal in someone with epilepsy can trigger status epilepticus. Methyl phenobarbitone is largely converted to phenobarbitone by the liver and phenobarbitone is the main metabolite of primidone, although primidone's other metabolite phenylethylmalonamide probably possesses anticonvulsant activity.

Vigabatrin

Vigabatrin is probably a more potent anticonvulsant than many of the other recently introduced drugs. Increasingly, it has been recognized to cause retinal damage. Up to a third of patients develop concentric constriction of the visual fields, more marked nasally than temporally. The defect is often asymptomatic and probably irreversible. It is now recommended that vigabatrin should only be used as add-on therapy where other combinations have been unsuccessful. Dosage should not exceed 3 g/day. Regular visual field analysis is mandatory.

Gabapentin

Gabapentin is used as add-on therapy for partial seizures with or without secondary generalization. Up to 4.8 g is given in three divided doses. The drug is generally well-tolerated and does not interact with other anticonvulsants. Its anticonvulsant effect appears to be relatively weak.

Ethosuximide

Ethosuximide is seldom used in adults as its role is confined to the treatment of absence seizures. Gastrointestinal disturbances are common along with drowsiness, dizziness, and ataxia. Agranulocytosis or aplastic anaemia have been encountered rarely. The dose range is usually 1 to 1.5 g daily.

Clonazepam

Clonazepam is effective for tonic–clonic seizures but is particularly valuable in the treatment of myoclonic epilepsy. Sedation is a major problem, and the drug must be introduced cautiously. The maximum tolerated dose is about 8 mg/day.

Clobazam

Tolerance to clobazam tends to develop fairly readily. It is sedative. Adult dosage ranges from 30 to 60 mg daily. Used intermittently it can be very effective for the treatment of catamenial epilepsy.

Acetazolamide

Use of this drug is largely confined to childhood epilepsies.

Topiramate

This drug is licensed both for primary generalized tonic–clonic seizures, and as adjunct therapy for partial seizures. It is sedative and must be introduced slowly. The total daily dose (given as a twice daily regime) seldom exceeds 400 mg. Nausea, anorexia, and weight loss are encountered. Behavioural disturbances are reported, including emotional lability, mood change, and aggression. There is an increased incidence of renal stones in those taking the drug.

Tiagabine

Tiagabine is a GABA uptake inhibitor resulting in increased synaptic GABA levels. Initial doses in adults are 4 to 5 mg twice daily. Most studies have used 32 to 56 mg/day, in three divided doses. The drug is licensed as add-on therapy in refractory epilepsy. Side-effects include dizziness, tiredness, tremor, and altered mood.

Oxcarbazepine

This drug is closely related to carbamazepine. It is a less potent hepatic enzyme inducer however. It is licensed as monotherapy or adjunctive therapy, in partial seizures with or without secondary generalization. Its side-effect profile is similar to that of carbamazepine. Patients who are hypersensitive to carbamazepine should not receive oxcarbazepine. The dosage range lies between 600 and 2400 mg daily, in adults.

Levetiracetam

The mode of action of levetiracetam is not understood. It is not metabolized in the liver nor does it inhibit or induce hepatic enzymes. There are no known interactions with the other anticonvulsants. Two-thirds of an oral dose is excreted unchanged in the urine. A quarter is metabolized to an inactive metabolite, also excreted in the urine.

Levetiracetam is licensed as adjunctive therapy in the treatment of partial seizures with or without secondary generalization. The daily dose in adults ranges from 1000 to 3000 mg. The dose needs to be adjusted in the presence of renal impairment. It is not advised for use in pregnancy.

Side-effects include asthenia, somnolence, headache, gastrointestinal disturbances, mood changes, and skin rash.

Other drugs, with very restricted licences, or not yet licensed, include felbamate and zonizimade.

Particular issues

Enzyme-induction

Drugs that induce liver enzymes (phenytoin, phenobarbitone, carbamazepine, topiramate, and possibly lamotrigine) will alter the pharmacokinetics of other agents or drugs which undergo hepatic metabolism. Women on an oral contraceptive pill need to take a preparation containing at least 50 µg of ethinyloestradiol. If breakthrough bleeding still occurs, the dose of oestrogen can be increased to a maximum of 100 µg daily. Alternatively, an injectable long-term contraceptive can be used. The interactions between anticonvulsants are complex, another reason for avoiding drug combinations where possible.

All the enzyme-inducing anticonvulsants have the potential for accelerating vitamin D metabolism. Those individuals at risk for developing vitamin D deficiency (for example due to poor nutrition) are at risk of developing osteomalacia or rickets when taking certain anticonvulsants.

Drug monitoring

Anticonvulsant levels are measured far too frequently. There are specific circumstances where their measurement is of value:

1. to ascertain compliance;

2. to monitor dosage adjustment with phenytoin; and
3. to ascertain the unpredictable effect of combining anticonvulsant preparations.

Phenytoin undergoes saturable hepatic metabolism. Regular monitoring of the serum level is advisable, particularly after dose adjustment. Occasionally, measurement of the levels of carbamazepine, phenobarbitone, and ethosuximide aids management, particularly where epilepsy control has been poor. Carbamazepine epoxide, a metabolite of carbamazepine, can sometimes be the cause of carbamazepine toxicity even when carbamazepine levels are in the therapeutic range. There is no value in the routine monitoring of levels of valproate, vigabatrin, lamotrigine, gabapentin, topiramate, clonazepam, or clobazam.

When measuring levels, the same time after the last dose should be used, wherever possible. Examples of therapeutic serum levels are given in Table 2. The therapeutic ranges of the anticonvulsants should be interpreted with caution. Some patients respond to a drug with subtherapeutic levels. Others need toxic levels to achieve seizure control and can often tolerate such levels without overt difficulty.

Pregnancy

There is an increased risk of congenital malformations in women who have taken anticonvulsants during pregnancy (approximately 4 to 8 per cent overall risk). Most evidence has accumulated for phenytoin, phenobarbitone, valproate, and carbamazepine. There are very few data on the newer anticonvulsants, though lamotrigine is said not to be teratogenic. The critical period for development of the major malformations is from 3 to 8 weeks' gestation.

Phenytoin and phenobarbitone

Both these drugs are associated with cardiovascular malformations (2 per cent risk) and cleft lip/palate syndromes (1.8 per cent risk).

Valproate

Valproate leads to a 2 per cent risk of spina bifida compared with a 0.01 to 0.02 per cent risk for all births. Cardiovascular and urogenital malformations are also recognized to occur.

Carbamazepine

Carbamazepine is associated with spina bifida (1 per cent risk) and hypospadias.

A folic acid supplement of 5 mg daily should be given to women with epilepsy who are taking valproate or carbamazepine and who are contemplating pregnancy. Doses of valproate should be less than 1000 mg/day if possible and slow-release forms of the drug prescribed. For women on other anticonvulsants, a dose of 0.4 mg/day of folic acid suffices.

Seizure frequency increases in pregnancy in about a third of patients with epilepsy. Tonic–clonic seizures are associated with an increased risk of miscarriage. Vitamin K at 20 mg/day should be given in the last month of pregnancy in women on enzyme-inducing drugs to reduce the risk of haemorrhagic disease of the newborn baby.

The epilepsy risk in the offspring of an affected patient is around 2 to 4 per cent but higher where the epilepsy of the parent has a strong genetic basis.

Breast feeding

All the commonly used anticonvulsants are present in low concentrations in breast milk. If the mother is on a barbiturate or a benzodiazepine, significant sedation of the baby is possible. If breast feeding then ceases abruptly, a withdrawal reaction can occur in the infant with tremor and agitation.

Drug withdrawal

Generally medication is continued until at least a 2- to 3-year period free of seizures has been established. Approximately two-thirds of patients remain fit free after drug withdrawal. Factors known to predispose towards recurrence include neurological abnormalities on examination, an underlying structural basis for the epilepsy, the need for multiple drug therapy, and a history of difficulty in establishing initial control. The electroencephalogram is of limited value in predicting outcome although rather better in children than adults. Any drug withdrawal should be gradual, say over 3 to 6 months. Absence seizures usually remit spontaneously in late adolescence, but juvenile myoclonic epilepsy tends to recur after drug withdrawal.

Driving

In the United Kingdom, driving must cease for 1 year after any type of seizure. If a nocturnal pattern of seizures has been established for 3 years, driving can then continue even if nocturnal seizures are still occurring. The Driver and Vehicle Licensing Agency prefers patients not to drive during a period of drug withdrawal, and for 6 months after the withdrawal has been completed. For drivers of heavy goods vehicles a 10-year period of freedom must be established, during which there has been no anticonvulsant use. Furthermore, a continuing liability to epilepsy has to be excluded.

Status epilepticus

Status epilepticus has already been defined. The commonest type is tonic–clonic status. The commonest precipitants are sudden anticonvulsant withdrawal, poor compliance in a patient with known epilepsy, and alcohol abuse. The mortality figures for status epilepticus have varied substantially from series to series. In one recently published, prospective, population-based study, the overall incidence was estimated at 41 to 61 per 100 000 person-years with a mortality of 22 per cent. Incidence rises in the elderly, as does mortality. From other series, overall mortality figures lie between 8 and 37 per cent. At least half the cases occur in the absence of previous epilepsy. Although non-compliance and subtherapeutic drug levels are often quoted as causes of status, several studies have established that the majority of individuals with epilepsy who present in status have therapeutic drug levels at or around the time of presentation. Status in the absence of previous epilepsy is followed by unprovoked seizures in about half the cases.

The diagnosis is by no means straightforward. In one study, half the patients transferred to a specialist centre for management of their status were either in pseudostatus or in drug-induced coma. The diagnosis of pseudostatus should be considered if the attacks are atypical or if the status does not respond to initial therapy.

Analysis of immediate management of patients in status suggests that many are given inadequate loading and maintenance doses of anticonvulsants. The patient should be moved away from possible hazard, such as broken glass, an airway established, and oxygen administered. Lorazepam is probably the drug of choice. It is given in a dose of 0.l mg/kg intravenously at the rate of 2 mg/min. Alternatives included diazepam (Diazemuls) given intravenously in a dose of 10 to 20 mg at a rate of 5 mg/min or clonazepam given in a dose of l mg by slow intravenous injection.

Using the intravenous route, 50 per cent glucose should be administered to a total volume of 50 ml after blood has been taken to establish the glucose concentration. Thiamine in a dose of 250 mg (Pabrinex I/V High Potency) should be given by slow intravenous injection over 10 min if there is suspicion of alcohol withdrawal, but remembering that the infusion can produce an anaphylactic response. In addition to plasma glucose measurement, blood should be taken for urea, electrolytes (including calcium and magnesium), acid-base balance, liver function tests, and full blood count. A serum sample should be stored in case anticonvulsant or alcohol levels are required subsequently. Blood cultures should be performed if the patient is febrile.

If immediate therapy is successful and the patient is receiving phenytoin or valproate, those drugs can be given intravenously before reverting to oral therapy. If the patient is not on anticonvulsants, a phenytoin infusion at 20 mg/kg in 0.9 per cent sodium chloride should be given at a maximum rate of 50 mg/min. An alternative is Fos-Phenytoin, a water-soluble drug, which is metabolized to phenytoin with a half-life of 8 to 15 min. It is given intravenously in the same dose at 150 mg/min in order

to achieve a comparable effect. The drug is more expensive than phenytoin but causes less phlebitis, less hypotension, and is better tolerated.

Midazolam has been developed for intranasal use and may prove of value where immediate intravenous access is difficult, for example in young children.

If phenytoin infusion is unsuccessful, valproate infusions can be used, with 25 mg/kg as a loading dose delivered at 3 to 6 mg/kg/min. If seizures continue phenobarbital can be considered, given at 20 mg/kg intravenously at 50 to 75 mg/min. Intramuscular or rectal paraldehyde is now seldom used, most experts suggesting a move instead to thiopentone, propofol, or midazolam.

Propofol or midazolam are rapidly metabolized and have less hypotensive effects than the barbiturates. The suggested dose of propofol is l to 2 mg/kg followed by a continuous infusion of 2 to 10 mg/kg/h.

For all the therapies used in patients with refractory status, intensive care placement is essential with the patient intubated and haemodynamic monitoring in place.

Sudden death

Patients with epilepsy have an increased risk of death compared with age- and sex-matched controls. Sudden unexpected death in epilepsy predominates in younger age groups and in those with more severe epilepsy. It is likely that most of the deaths are the result of unwitnessed seizures producing either respiratory complications, cardiac arrhythmias, or both.

Surgery

Despite optimal treatment, some 30 per cent of patients with new-onset seizures continue to have attacks. Prerequisite in patient selection for surgery is accurate localization of the epileptic discharge and understanding of circumstances where a resection might prove detrimental in terms of functional deficit.

Assessment for epilepsy surgery demands localization techniques incorporating seizure characteristics, electrophysiological recording, and imaging. Equally important is the recognition by the physician that certain epilepsy syndromes are likely to be resistant to medical therapy and that early rather than delayed referral for surgical opinion is beneficial. Mesial temporal lobe epilepsy, secondary to hippocampal sclerosis, is the commonest cause of medically refractory partial seizures. In most such patients, a unilateral structural abnormality can be confidently established, resection of which leads to a 70 per cent chance of remission. Disabling neurological complications after surgery, such as hemianopia, hemiparesis, or dysphasia, occur in about 2 per cent of patients. Depression and psychosis are recognized complications of temporal lobectomy.

MRI characteristics of mesial temporal sclerosis include atrophy or increased signal on T_2-weighted images. The presence of atrophy is the best predictor for a good surgical outcome. Besides visual inspection, measurement of hippocampal volume and techniques for measuring the T_2 signal change are used to improve sensitivity.

SPECT and PET measure the changes in cerebral blood flow and cerebral glucose metabolism, respectively, which accompany the epileptic process. Both have relatively high sensitivity and moderate specificity for the diagnosis of temporal lobe seizures, but lower sensitivity for epilepsy arising at other sites. Interictal PET and ictal SPECT produce very similar results in predicting outcome after temporal lobectomy.

Proton magnetic resonance spectroscopy can contribute to recognition of the lateralization of the epileptic focus and to the identification of those patients with bilateral changes who are less likely to respond to surgery.

Continuous surface electroencephalographic monitoring is usually undertaken as part of the work-up for patients being considered for surgical intervention. The technique, however, has limitations. It often fails to detect seizure activity arising in areas distant from surface electrodes, such as the orbitofrontal cortex, and may falsely lateralize foci, particularly in the presence of large lesions. For improving electroencephalographic localization, some form of intracranial recording is necessary. Depth electrodes are used to sample deeper structures such as the hippocampus. Electrocorticography is performed at the time of surgery. Subdural electrodes, sometimes with depth electrodes, measure directly from the surface of the exposed brain.

Other less commonly performed surgical procedures include neocortical resections, lesionectomies, hemispherectomies, multilobar resections, and corpus callosotomy. Hemispherectomy is performed when a diffuse epileptogenic region has been localized within one hemisphere, the other hemisphere being normal. Division of the corpus callosum is performed in patients with severe secondary generalized epilepsy who have disabling drop attacks. Cortical dysplasia is increasingly recognized as a cause of intractable epilepsy. MRI criteria have been developed to allow recognition of areas of focal cortical dysplasia and assist in planning the extent of cortical resection.

Vagal nerve stimulation

Vagal nerve stimulation is achieved through the implantation of a small stimulator on the left vagus. The exact mechanism of action remains uncertain. The nucleus of the tractus solitarius, the main terminus for vagal afferents, has projections to the locus caeruleus, raphe nuclei, reticular formation, and other brainstem nuclei. These nuclei have been shown to influence cerebral seizure susceptibility. In patients with chronic partial seizures, there is reduction in the number of seizures, rather than their elimination. The long-term role of this procedure is not yet determined.

Psychiatric aspects of epilepsy

A substantial proportion of patients with poorly controlled epilepsy are likely to have psychiatric symptoms. Those symptoms may partly reflect the underlying structural process in the brain, the effects of repeated seizures, the effects of any social stigma attached to the diagnosis, and as a reaction to the patient's anticonvulsants. Psychiatric symptoms occurring around the time of the seizures tend to be affective or cognitive if before or with the seizure, but psychotic afterwards. Additional psychiatric morbidity is encountered as an interictal phenomenon. It correlates with multiple drug use, the serum concentrations of those drugs, and certain of the anticonvulsants including the newer agents, such as lamotrigine, vigabatrin, and topiramate.

Patients with poorly controlled epilepsy may require referral to a clinical psychologist, partly with a view to helping in the psychological adjustment to the condition, and partly to identify specific areas of cognitive impairment which might require attention.

The role of specialist nurses and the general practitioner

Patients almost inevitably indicate some dissatisfaction with the level of information and support that they receive for their epilepsy. Studies suggest that improvement in these areas can occur using a specialist nurse, working either in general practice or in association with a hospital clinic. Where joint care is to be achieved between general practice and hospital, it is vital that good quality communication and record keeping are achieved. Giving the patient files which document vital information, including their drug regime, is valuable. Patients prefer the continuity of care achievable through seeing the same doctor at each consultation and are more likely to adhere to medical advice under those circumstances.

Prognosis

Prognosis for patients with epilepsy followed in the community is considerably better than for a hospital-based population. Figure 7 records the percentage of patients in remission (defined as being seizure free for 5 years). The top curve indicates the percentage of patients achieving a 5-year period of remission at any time during the 20-year period of follow-up. The middle curve refers to those patients in remission for at least the last 5 years at the time of sampling. The difference between the top and middle curves represents those patients who have relapsed after achieving a 5-year remission. The bottom curve indicates the probability of being in remission whilst not taking anticonvulsants. The curves in Fig. 7 flatten off, indicating that remission becomes less likely the longer the seizures persist. Factors that influence outcome adversely include a combination of complex partial and tonic–clonic seizures, clustering of seizures, abnormal physical signs, and the presence of learning difficulties.

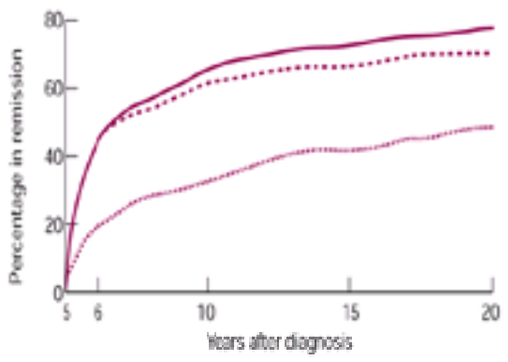

Fig. 7 Probability of seizure recurrence after a first epileptic seizure. (Data from the National General Practice Study of Epilepsy, reproduced by kind permission.)

Overall care

For many patients, shared care between hospital, a specialist nurse, and general practice is ideal. Such an arrangement necessitates a reasonable level of epilepsy experience from the general practitioner, allowing many issues to be resolved without recourse to hospital consultation. The complexities of epilepsy care in terms of new drug developments, issues relating to pregnancy, the question of non-epileptic seizures, and the potential for surgery for many patients with poorly controlled epilepsy makes the case for epilepsy clinics manned by physicians with a particular interest in epilepsy.

24.13.4 Narcolepsy

David Parkes

The narcoleptic syndrome

The prevalence of narcolepsy in Western Europe is about four per 10 000. Reported rates worldwide vary 100-fold. This variation may result in part from differences in true case ascertainment and broad definitions of 'narcolepsy'. Narcolepsy is as common in men as women. It usually starts in childhood or adolescence, with a second peak at 30 to 40 years. However, the age at presentation extends from under 1 to over 70 years. Narcolepsy is lifelong and spontaneous recovery does not occur.

Narcolepsy has two key features, cataplexy and daytime sleepiness. Cataplexy is unique to the syndrome but daytime sleepiness has many different causes. The presence of both symptoms is essential for a definite diagnosis. The initial symptom is usually sleepiness, followed by cataplexy within 2 years. Very occasionally this order is reversed and the gap may be prolonged to several decades. Cataplexy is provoked by emotional stimuli such as laughter, startle, excitement, or anger. There is a sudden loss of tone in antigravity muscles with a tendency to fall as well as mouth opening, dysarthria, mutism, and phasic muscle jerking around the mouth. Most attacks are mild and last a few seconds but self-injury can occur in more severe episodes. Several attacks may occur each day. Cataplexy is comparable to the atonia of rapid eye movement sleep but without loss of awareness. As cataplexy is seldom witnessed by the physician, an unequivocal history using clear language is essential to establish its presence.

Sleep, automatic behaviour, and failure of self-monitoring all reduce wakefulness. Sleep pressure increases with monotony and sleep attacks have a 3- to 4-h cyclicity throughout the day. Sleepiness is usually more disabling than cataplexy and causes chronic school and work failure, broken relationships, frustration, embarrassment, poor self-image, and depression. Despite daytime sleepiness, the total sleep period over 24 h is normal as multiple nocturnal arousals shorten night sleep. Insomnia, motor disorders bordering sleep, and vivid dream intrusion at the wake–sleep boundary are common. The old concept of four symptoms—sleepiness, cataplexy, sleep paralysis, and hypnagogic hallucinations—needs revision.

The diagnosis of narcolepsy is totally dependent on a clear sleep–wake history, supported by a sleep–wake diary and a disability rating scale such as the Epworth or Ullanlinna. Study in a sleep laboratory is never a substitute (Table 1).

Aetiology

Narcolepsy has a genetic not a psychological basis. Ninety five per cent of Caucasian subjects with narcolepsy have the HLA D-related (DR) serotype DR2 and oligotype DQ B1*0602. The DR association is slightly different in other ethnic groups. The HLA type is not specific to narcolepsy, being present in 25 to 30 per cent of white subjects, only 1 in 500 of whom have narcolepsy. Despite the HLA association there is no present evidence of an immune defect in narcolepsy, or of definite involvement of HLA systems in normal sleep mechanisms. Attempts to identify additional non-HLA genes in humans, with the possible exception of linkage to g-aminobutyric acid genetic systems on chromosome 4 and the monoamine oxidase X-linked locus, are unconvincing.

An unexpected pathway for sleep has been identified involving hypocretin. The hypocretins are neuropeptides made in the dorsal and lateral hypothalamic areas of the brain, and are implicated in the regulation of feeding and energy (Table 2). A mutation in a hypocretin receptor has been shown in dogs with narcolepsy, but not in DR2 positive humans with the disease. However, in most narcoleptics studied there is a near total absence of hypocretin in the cerebrospinal fluid and brain tissue. Further understanding here, and of the relationship between HLA and hypocretin systems, will be essential in the development of new treatments for narcolepsy.

Familial narcolepsy does occur but accounts for only 5 to 10 per cent of all cases, some of whom show dominant inheritance.

In the few reported studies of monozygotic twins, disease discordance has been found in up to 70 per cent of pairs. Narcolepsy thus appears to be caused by an environmental agent in a genetically susceptible subject. The nature of this external factor is not known.

Pathophysiology of narcolepsy and sleep laboratory investigation

The normal non-rapid eye movement–rapid eye movement sleep cycle of adults is reversed in narcolepsy, where periods of rapid eye movement occur at the onset of sleep. In addition two characteristics of rapid eye movement sleep, atonia and dreaming, are fragmented and intrude into wakefulness, resulting in cataplexy and vivid recall of dreams. Rapid eye movement sleep is generated in ventral pontine areas contiguous with neurones controlling voluntary eye movements. However, no anatomical defect in this area of the brain has been found in narcolepsy, and pursuit and saccadic eye movements are normal.

The mean sleep latency test measures the pressure for sleep using electroencephalographic parameters at 2-h intervals from 10.00 to 16.00 or 18.00 under standard conditions. A mean latency of under 5 min is usually considered abnormal and of over 10 min normal. Results between 5 and 10 min are in a grey area. Results of the mean sleep latency test do not always mirror behavioural tests of alertness. In addition to sleep latency, a mean sleep latency test will show rapid eye movement activity at sleep onset. However, this activity is not diagnostic of narcolepsy. Timing of rapid eye movement sleep varies with recording position, age, previous sleep deprivation, and drug treatment. Overall, polysomnogram findings are less specific and sensitive in the diagnosis of narcolepsy than a definite history of cataplexy. Diagnosis and treatment should therefore depend on the clinical picture rather than on sleep laboratory findings. In cases with an indefinite history, laboratory findings may add confusion rather than clarity and should never be used alone to establish diagnosis. Likewise, HLA tests will not confirm narcolepsy, although the diagnosis is unlikely if the DR2 antigen is absent.

Symptomatic narcolepsy

Narcolepsy has been associated with a wide range of other disorders. These are mostly uncommon and rarely if ever cause problems in differential diagnosis. In many cases there is obvious brainstem pathology and poor resemblance of symptoms with those of true narcolepsy. The occasional association of narcolepsy with multiple sclerosis may result not from a brainstem lesion but from a common genetic predisposition. There is an over-representation of the same HLA D-related antigen in both conditions.

Differential diagnosis

There are a number of narcoleptic syndrome variants with overlapping clinical features (Table 3).

In narcolepsy the commonest mistake is failure to diagnose, rather than incorrect diagnosis. Daytime sleepiness is never normal and is rarely psychological in origin. It is sometimes wrongly attributed to insomnia and most insomniacs have a low, not high, daytime sleep tendency. The symptom is serious and requires investigation rather than a pseudodiagnosis of laziness.

The second most common mistake is to label all forms of sleepiness as due to narcolepsy or sleep apnoea. Real difficulty lies in cases of apparent narcolepsy presenting before cataplexy and where at best the diagnosis can only be possible or probable, not definite narcolepsy. Follow-up is essential here whatever the sleep laboratory findings. Narcolepsy and sleep apnoea sometimes coexist, particularly in overweight males. Cataplexy is sometimes confused with epilepsy or drop attack,

but a careful history will usually separate these.

Hypersomnia without cataplexy or any feature of psychological or physical illness is common. Here exact diagnosis of the cause is often impossible. The idea of idiopathic hypersomnia is based on the concept of abnormal pressure for non-rapid eye movement sleep, with prolonged dream-free deep sleep by night and day, sometimes with a familial or genetic basis. In reality there is little or no distinction in sleep–wake behaviour in different forms of hypersomnia and prolonged follow-up sleep and laboratory studies are needed.

Other causes of sleepiness with medical or psychological illness are unlikely to be confused with narcolepsy. In addition to head injury, hypnotic drug and alcohol abuse, and sleep-related respiratory illness they include:

- depression (insomnia is more common than hypersomnia)
- postviral illness (often Epstein–Barr virus)
- cerebrovascular disease (sometimes with bilateral thalamic infarcts)
- multisystem atrophy
- shift work and circadian delay syndromes
- sleep apnoea treated with continuous positive airway pressure (this rarely completely reverses sleepiness).

Treatment

Treatment of narcolepsy is a problem for both physician and patient. The prescriber may refuse stimulant drugs owing to fear of abuse, or restrict dosage to prevent tolerance. Patients may demand large doses and complete freedom to overdose, not recognizing their own irritability and euphoria.

Most subjects with narcolepsy need a central stimulant drug to improve alertness, and two-thirds need an additional anticataplectic drug to prevent atonia. One drug from each group in Table 4 should be chosen. Dexamphetamine and methylphenidate but not modafinil have a partial anticataplectic as well as an alerting effect. Stimulant drug treatment should be supported by a 15 min nap once or twice a day. Adequate treatment is essential to restore school performance, work, driving ability, and quality of life. This is best achieved with an as-needed, variable dose rather than a fixed dose regime, dependent on factors such as day of the week, activity, and response level. A sleep–wake diary is an important aid to starting and monitoring treatment. Drug response is immediate, while sudden withdrawal may be followed by a severe rebound of sleepiness, cataplexy, or both lasting several days. Stimulant response is the same in hypersomnia as in narcolepsy.

Metabolic tolerance with the need for an increase in dose develops in one-tenth to one-third of subjects. Dose revision, changing to an alternative drug, or a 2-week drug holiday may be necessary. Psychological addiction does not occur and there is no evidence of stimulant abuse in narcoleptics of normal personality. Very occasionally a recreational drug user will feign a history of narcolepsy to obtain stimulants and a urinary drug screen may be appropriate.

Serious dose-related or idiosyncratic side-effects are uncommon. However, sweating and irritability with the stronger stimulants, mild headache with modafinil, and sexual side-effects, increased appetite, and weight gain with clomipramine sometimes limit treatment. Acute amphetamine psychosis is not a problem in narcoleptics and a lifetime of treatment does not cause vascular toxicity or hypertension. A poor drug response should lead to re-evaluation of diagnosis and treatment compliance. Management problems include pregnancy, with the need for the safety of mother and baby to be balanced against potential drug teratogenicity and secretion in breast milk, and cardiovascular disease where low- rather than high-dose treatment is indicated. Conventional treatment is unsatisfactory in about one-fifth of narcoleptics. If disability is severe, a therapeutic trial of morning venlafaxine, 37.5 mg with slow increase to 275 mg per 24 h should be considered but this regime must be carefully monitored.

24.13.5

Syncope

L. D. Blumhardt

Definition

Syncope (fainting) is a brief loss of consciousness that results from an acute reduction in cerebral blood flow (from the Greek 'synkoptein' to cut or break). It is the most common cause of recurrent episodes of disturbed consciousness.

Pathophysiology

Although there is a seemingly endless list of causes and predisposing factors (Table 1), the sequence of reflex events, once triggered, is relatively constant. Loss of consciousness (probably ultimately due to hindbrain ischaemia) results from a sudden reduction of cerebral perfusion as compensatory mechanisms fail, due either to a reflex reduction of venous return to the heart, or to an inadequate response of the heart when an increased cardiac output is required.

In the common faint (vasovagal syncope), the reduced venous return is caused mainly by a sudden reflex reduction in the resistance of the peripheral blood vessels with pooling, particularly in the lower limbs and abdomen. There is generally some associated, but less important, slowing of heart rate (hence the term vasovagal, originally coined by Sir Thomas Lewis), but in some individuals, an exaggerated reflex bradycardia or even sinus arrest due to vagal hyperactivity may be the dominant factor in reducing cardiac output (cardio-inhibitory syncope). This is a particular feature of loss of consciousness arising from painful pressure on the eyeball (oculocardiac reflex). In cough syncope, the high intrathoracic pressure generated by violent coughing (which may exceed 250 mmHg), triggers a reflex fall in cardiac output. Similar events underlie syncope associated with the Valsalva manouvre and possibly also contribute to the rare defaecation syncope. The proposed mechanisms responsible for carotid sinus syncope include hypersensitivity of the baroreceptors in a diseased carotid sinus and, possibly, contributions from an exaggerated vagal response or oversensitivity of the sinus node. In syncope associated with eating, a vagally induced bradycardia may be provoked by stretching of the oesophagus (swallow syncope) or by very cold stimuli (ice-cream syncope). In other subjects, critical cardiac slowing can be provoked by rectal stretch (for example during proctoscopy or prostatic massage). In micturition syncope, the mechanism is thought to be a combination of high nocturnal vagal tone, postural hypotension, and the sudden loss of the vasopressor effect of a full bladder.

Clinical features

In many subjects syncope is preceded by a characteristic sequence of premonitory symptoms (presyncope). A typical history may include light-headedness, sweating ('clamminess'), sensations of warmth or cold, nausea, and blurring of vision. Subjects may also report tinnitus, receding sounds, 'closing in of peripheral vision', weakness, increased salivation, urgency of micturition, vomiting, diarrhoea, and the need to get fresh air. These symptoms may be proffered in any combination and any, or all, may be missing. It is important to distinguish the usual complaints of dizziness, 'light-headedness', 'muzziness', or giddiness due to hypotension, from vertigo (dizziness with a rotational element) which does not occur in syncope. An eyewitness may report on the sweating, restlessness, excessive yawning, slow sighing respiration, and marked facial pallor. In some individuals the loss of consciousness may be abrupt with little or no warning, whereas in others the symptoms of presyncope may build up slowly. With sufficient warning and insight, some subjects may be able to prevent the syncope by lying down and increasing cardiac return by elevating their legs, but many seem either unaware of this possibility, or are unable to invoke it in time.

If no preventative action is taken, syncope, characterized by a sudden loss of consciousness and collapse with loss of muscular tone, may then follow. The subject is noted to be limp or floppy (no stiffness, rigidity, or tongue biting) and is usually motionless. In some subjects there may be flickering of the eyelids and perhaps an occasional irregular myoclonic twitch or jerk in a limb. Respiration is shallow, the blood pressure low or unrecordable and the pulse thready, rapid, or slow, and often difficult to feel. In uncomplicated syncope, the loss of consciousness usually lasts only seconds and recovery is rapid without confusion. Sweating and profound 'waxy' pallor due to intense vasconstriction of skin vessels may persist well after recovery. If the subject gets up too rapidly, a further episode of syncope may occur.

Most syncope is uncomplicated. Injuries are uncommon, but can occur depending on the circumstances of the faint. If the bladder is full there may be incontinence. If the anoxia is profound, the patient may vomit or be doubly incontinent. If a recumbent posture does not result from the fall, a secondary anoxic seizure may follow (convulsive syncope) in some predisposed individuals. This event is commonly mistaken for epilepsy if the sequence of events is not carefully established from a witness. To complicate matters further, syncope may rarely precipitate a true epileptic seizure.

Main variants of syncope

Vasovagal syncope

The common faint usually occurs for the first time in childhood or adolescence and recurs in well-recognized situations, for example venepuncture, dental procedures, at the sight of blood or injury, sudden emotions, acute pain, postural change, and prolonged standing in stuffy or warm surroundings (school assembly or church). There is almost invariably a postural element—faints occur when standing or sitting and only very rarely when lying (for example in pregnancy). Many secondary factors may increase the risk of faints in the susceptible subject including anaemia, blood loss, convalescence, hypoglycaemia, sleep deprivation, hypotension, cardiac or vascular disease, and drugs. Although there is often a recrudescence of faints later in life, caution should be exercised in diagnosing vasovagal syncope occurring *de novo* in the elderly (check for an earlier history of faints in appropriate circumstances), as the blackouts may be due to cardiac arrhythmias.

Susceptibility to fainting varies widely and some individuals may experience syncope only in association with particular triggers. The diagnosis is usually easy when intense pain such as abdominal colic, glossopharyngeal neuralgia, migraine, or diagnostic manipulation such as venepuncture, oesophagoscopy, or rectal examination provoke attacks. It may be more difficult when syncope complicates a severe vestibular vertigo.

Micturition syncope

The occurrence of loss of consciousness at night during or usually shortly after micturition is highly characteristic of this condition. Contrary to a surprisingly widespread misconception, it is not a complication of prostatism, but occurs almost exclusively in healthy men (some of whom also suffer from vasovagal syncope) with a peak incidence in the third and fourth decades. It does occur in women, but very rarely.

The condition usually responds to advice to mobilize slowly when arising at night and to micturate in the sitting down position.

Cough syncope

This condition is usually associated with chronic obstructive airways disease and smoking. A series of coughs, or sometimes even a single forceful cough, is followed by a collapse with brief loss of consciousness. Afflicted patients often appear unaware of the association between their coughing bouts and the syncope and an account from a witness is required. There may be muscular jerks or twitches during cough syncope and the differentiation from epilepsy is important. Careful clinical assessment is required as cerebellar ectopia with compression of the brainstem and atrioventricular conduction abnormalities may rarely present with similar symptoms. Treatment is usually directed towards the chest condition and education of the patient and relatives into the mechanisms and possible avoidance measures.

Carotid sinus syncope

This is a rare but important cause of syncope as it is potentially treatable. The diagnosis should be considered in elderly patients, usually men with atherosclerotic vascular disease, hypertension, or diabetes when blackouts are associated with a tight collar, head turning, or even the posture or pressure on the neck when shaving. It may also occur with infiltrating cervical tumours or radiation. If suspected, gentle sequential unilateral carotid sinus massage carried out with electrocardiographic control for 6 s per side may result in conduction block or cardiac arrest. Many would accept an asystole of more than 3 s as diagnostic, but the criteria remain controversial. Denervation of the carotid sinus or cardiac pacing is usually effective.

Cardiac syncope

This can be divided into syncope caused by outflow obstruction from the left ventricle and syncope due to disorders of cardiac rhythm. An inability to increase the cardiac output as required, for example during exercise or sexual activity, may cause syncope in hypertrophic cardiomyopathy, aortic stenosis, restrictive pericarditis, left ventricular insufficiency, or atrial myxoma. However, it is more common, even where structural heart disease exists, for loss of consciousness to be caused by an arrhythmia. Syncope may be sudden with no warning (as with with heart block or sinus arrest for example) or there may be dizziness, palpitations, dyspnoea, or chest pain (for example with tachyarrhythmias). The symptoms may closely mimic those of complex partial seizures (temporal lobe epilepsy) which can themselves generate cardiac arrhythmias. After transient cardiac arrest there may be facial flushing as the cardiac output is restored. The clinical presentation of a patient with a slow pulse and syncopal attacks has long been recognized (Stokes–Adams syndrome) and may be due to atrioventricular block, ventricular tachycardia, fibrillation, or standstill. Similar attacks occur with sinus node disease ('sick sinus' or tachycardia–bradycardia syndrome) and the long QT syndrome (see Section 15).

Syncope associated with exercise may also be associated with aortic arch disease, congenital heart disease, and pulmonary hypertension.

Reflex ('vagal') anoxic seizures

This particular form of reflex cardiac arrhythmia can be regarded as one end of the spectrum of fainting disorders. It is important because it is frequently misdiagnosed as epilepsy. In its most common form, a child (the condition may persist into early adult life) has faints that typically are triggered by minor trauma such as a painful knock in the playground. The brief loss of consciousness may be associated with rigidity, pallor, muscular twitching, and sometimes incontinence. There is usually a rapid recovery with little if any confusion. Simultaneous electrocardiographic and electroencephalographic recordings demonstrate that the primary cardiac asystole is followed by secondary anoxic changes (high-amplitude slow waves) on the electroencephalograph with no evidence of epilepsy. The attacks can be provoked in the laboratory by ocular pressure. Treatment if necessary is with long-acting atropine preparations.

Postural hypotension

Convalescent patients may be subject to large reductions of blood pressure on changing their posture. Many drugs, including diuretics, antihypertensives, levodopa, nitrates, major tranquillizers, antidepressants, alcohol, and calcium antagonists may play an important or primary role. Areflexic or 'paralytic' postural hypotension may complicate or be the presenting symptom of diseases affecting the autonomic nervous system, such as diabetes mellitus, idiopathic orthostatic hypotension, extrapyramidal diseases, tabes dorsalis, peripheral neuropathies, and high spinal cord disease. Some otherwise healthy individuals are peculiarly sensitive to mild postural hypotension. A lordotic posture may contribute to syncope in subjects standing to attention on a parade ground.

Diagnostic approach

The essential clues to the diagnosis of syncope are usually found in the history of the immediate circumstances of the collapse and the events leading up to it. A past or family history of similar events, perhaps in more obvious circumstances, will often provide the diagnosis. Factors favouring syncope may be the recent initiation of drugs or a prolonged period of erect posture or postural change. Was there a Valsalva factor present (for example, straining or lifting, or the forceful playing of a wind instrument) or an emotional or painful experience? Are there background factors favouring syncope, such as anaemia, recent convalescence, fatigue, cardiac disease, or blood loss? The history of the attacks themselves needs to be built up in an as much detail as possible including an eyewitness account of events immediately before, during, and after the attack. Was the subject's muscle tone appropriately limp? There should be no tongue biting, rigidity, or rhythmic tonic–clonic movements suggesting seizure activity. If a seizure appears to have occurred in a situation more appropriate to a syncopal episode, a careful history will often establish that the patient's position after the faint did not allow rapid restoration of cerebral blood flow (for example they were propped against a wall or held upright). A secondary anoxic seizure (convulsive syncope) is then the correct diagnosis, rather than epilepsy. Injuries (apart from a bitten tongue) do not particularly favour epilepsy, but confusion is unlikely after syncope, unless there was a complicating head injury or seizure.

Young men who collapse in the bathroom, or on the way back to bed during the night, are at risk of misdiagnosis, particularly if a secondary convulsive syncope has occurred. These circumstances should alert the clinician to the possibility of micturition syncope. The patient with chest disease and blackouts is often peculiarly 'amnesic' for his attacks which he does not associate with his respiratory condition. As for all forms of syncope the eyewitness account is critical to establish the associations, the correct sequence of events, and the diagnosis. The presence of other medical conditions such as chronic airways disease (cough syncope), cardiac disease (arrhythmias), or atherosclerosis (carotid sinus syncope) may provide the main diagnostic clue.

Management

Simple faints require usually require only reassurance, counselling, and education for patients and relatives. They should be instructed in the mechanisms and the avoidance of predisposing situations and trigger factors as well as measures to be taken during presyncopal episodes. Apart from a blood count if anaemia is suspected, or a blood sugar estimation if hypoglycaemia is a possibility, investigations are seldom indicated unless relevant abnormalities are present on history or examination. Investigating all patients with syncope is expensive and produces a low yield. Syncopal episodes occurring *de novo* in adults without obvious triggering factors, or precipitated by exercise, may require electrocardiography, Holter monitoring, treadmill tests, and perhaps sophisticated intracardiac conduction studies. Structural heart disease or failure should be excluded.

Where the diagnosis remains in doubt, or if epilepsy is a possibility, an electroencephalograph and perhaps simultaneous electrocardiographic/electroencephalographic recordings with video monitoring of attacks in a specialist unit may be indicated.

24.13.5.1 Head-up tilt-table testing in the diagnosis of vasovagal syncope and related disorders

Steve W. Parry and Rose Anne Kenny

In many patients, the diagnosis of vasovagal syncope or presyncope is evident from their history and physical examination. Where doubt exists, or a definitive diagnosis is needed to clarify atypical presentations or aid decision-making for driving or occupational purposes, head-up tilt-table testing should be considered.

The head-up tilt-table test employs prolonged, controlled orthostatic stress to provoke vasovagal syncope, with characteristic symptoms and concurrent haemodynamic changes confirming the diagnosis. In susceptible patients, head-up tilt causes relative central hypotension through displacement of venous blood to the lower limbs and capacitance vessels, with consequent vigorous left ventricular contraction and inappropriate cardiac mechanoreceptor activation. The resultant afferent neural traffic traverses unmyelinated C-fibres to the nucleus tractus solitarius, which then orchestrates the vagal activation and vasodilatation characteristic of the vasovagal response. In the absence of a 'gold-standard' diagnostic test, estimates of the sensitivity and specificity of head-up tilt-table testing from comparisons with healthy volunteers vary between 32 to 85 per cent and 60 to 90 per cent, respectively. The reproducibility of positive responses in patients with vasovagal syncope is up to 87 per cent in the short term (30 min) and 85 per cent over several days and months. The test's reliability, non-invasive nature, relative cheapness, and safety record make head-up tilt-table testing the current diagnostic test of choice in the investigation of unexplained syncope.

Haemodynamic responses during a positive test may also guide therapeutic strategies, and are divided into vasodepressor (predominant blood pressure fall in the absence of significant bradycardia/asystole), cardioinhibitory (predominant bradycardia/asystole), or mixed (a combination of the two) subtypes. Cardioinhibitory vasovagal syncope may benefit from permanent pacemaker therapy, whereas the predominant vasodepressor subtypes are unlikely to do so. Heart rate responses during tilt may also assist in the choice of medical therapy; for example beta-blockers are useful if pronounced tachycardia antedates symptomatic hypotension/bradycardia.

Head-up tilt-table testing is a relatively benign investigation, with few reported complications worldwide, most of which have anecdotally been related to inappropriate staff training and lack of resuscitation facilities. Relative contraindications include severe coronary or cerebrovascular arterial stenoses, clinically severe left ventricular outflow obstruction, and critical mitral stenosis.

Methodology

Tilt-table testing should be conducted in a quiet, dimly lit environment at a comfortable temperature to minimize confounding autonomic nervous activation. The table should have a foot-plate support, and be capable of smooth, rapid movement between supine and calibrated upright positions between 60° and 80° (lesser or greater angles increase the number of false-negative and false-positive studies, respectively). Subjects should be fasted for no more than 2 h before testing to avoid potential confounding from postprandial hypotension. Intravascular instrumentation is avoided in all but isoproterenol-provoked tilt testing as this markedly lowers the test's specificity. After 10 min rest in the supine position, subjects are strapped securely to the tilt table to prevent injury during syncope and collapse, and then tilted to 70° for 40 min.

A summary of the Newcastle protocols for head-up tilt-table testing is provided in Table 1. Continuous blood pressure monitoring is advised during the test, preferably with non-invasive beat-to-beat digital photoplethysmographic devices such as Finapres (Ohmeda, Wisconsin) or Portapres (TNO-TNM Biomedical, Amsterdam), though sphygmomanometric devices are widely used. Electrocardiography should be undertaken at baseline, continuously during symptoms or haemodynamic changes, and every 5 min otherwise. The test should be supervised by a nurse, physician, or technician trained in the management of the test and its potential complications, with advanced resuscitation equipment and a clinician trained in its use immediately available at all times.

The head-up tilt-table test is deemed diagnostic only if arterial hypotension and/or bradycardia are accompanied by symptoms reproducing the patient's syncopal or presyncopal symptoms. Haemodynamic changes without symptom reproduction should not be construed as vasovagal syncope.

Pharmacological and mechanical provocative agents in head-up tilt-table testing

Where the initial prolonged, passive tilt test is negative, several agents may be used to increase the sensitivity of the test.

Isoproterenol provokes the vasovagal response by simulating the catecholaminergic surge seen prior to syncope in susceptible subjects. Isoproterenol should be used with caution in subjects with known arrhythmias, coronary artery disease, significant aortic stenosis, left ventricular outflow obstruction, and uncontrolled hypertension. Tilt-testing should be terminated if sustained tachycardia (>150 beats/minute), hypertension (>180/100), arrhythmia, or intolerable symptoms supervene.

Nitrates, in particular sublingual glyceryl trinitrate, have more recently been used in this context, with nitrate-induced vasodilatation simulating the venous pooling which provokes spontaneous episodes. Nitrate-provoked tilt testing is as specific and sensitive, and better tolerated than, isoproterenol.

Developments incorporating intravenous adenosine and clomipramine are currently being evaluated, but are not yet in routine use.

Mechanical provocation, using a suction chamber to exert a lower-body negative pressure (again simulating venous pooling), has been successfully used in specialist centres.

Non-vasovagal indications for head-up tilt-table testing

Carotid sinus massage in the head-up tilt position (following an initial supine, bilateral, non-diagnostic massage) may increase the diagnostic rate for carotid sinus hypersensitivity by 30 per cent. Head-up tilt testing is used to diagnose orthostatic hypotension in patients unable to stand unaided for 3 min, while the postural orthostatic tachycardia syndrome may similarly be diagnosed during tilt-testing if the patient's heart rate rises by more than 30 beats/min (or to a maximum of 120 beats/min) during the presence of characteristic symptoms in the absence of hypotension. Tilt-table testing may also be useful in the differential diagnosis of apparently epileptiform events. Prolonged asystole during vasovagal syncope may result in myoclonic jerking, tonic–clonic movements, and (rarely) incontinence (urinary and faecal) which can be mistaken for generalized convulsions. The short duration of the event, rapid recovery, and the absence of postictal confusion and neurological signs should prompt tilt testing as part of the diagnostic work-up. Psychogenic and hyperventilation syncope result in symptom reproduction without haemodynamic changes during tilt, with hypocapnia being demonstrated in the latter. Head-up tilt testing may also be useful in demonstrating neurocardiovascular disorders as attributable causes of unexplained falls in older patients (in whom falls and syncope frequently overlap), with amnesia for loss of consciousness prompting a non-syncopal presentation.

24.13.6 Brain death and the vegetative state

B. Jennett

Cardiopulmonary resuscitation and intensive care are now commonplace in the developed world, so that life-threatening brain insults may now be followed by complete recovery. Sometimes, however, these interventions do no more than extend the process of dying for hours or days because the patient is brain dead. In others intervention comes too late after cardiorespiratory arrest to save the cerebral cortex and thalamus which are more vulnerable to hypoxia than is the brainstem. In that case, or when head injury has irretrievably damaged the cortical connections, the patient can survive for a long period in a vegetative state.

Brain death

Much of the controversy about brain death arose because it was not appreciated that death is a process rather than an event, with organs failing in various sequences. Most often the heart stops first, followed within minutes by respiratory arrest due to brainstem hypoxia. After primary respiratory arrest there is rapid hypoxic brain failure but the heart may continue to beat for 15 to 20 min. If the brainstem fails first due to an intracranial catastrophe and a ventilator takes over respiration the heart can beat for days (occasionally weeks)—this is the state of brain death.

The crucial lesion is irreversible loss of brainstem function with subsequent lack of downward drive to maintain respiration and of upward activation of the cerebral cortex by the ascending reticular pathways. When systemic hypoxia has not been the initial insult the cerebral cortex may be structurally intact, and islands of electrical activity may be detected on the electroencephalogram. Early definitions of brain death (for example the Harvard Criteria of 1968) implied that the whole nervous system was dead with a flat electroencephalogram and an absence of all motor activity. But the spinal cord is more resistant to hypoxia even than the brainstem, and is unaffected by intracranial catastrophes—so spinal reflexes often persist after brain death. To resolve this confusion the term brainstem death is now preferred in the United Kingdom. Although in the United States the most commonly used diagnostic criteria are those for brainstem death, most guidelines and statutes still refer to whole brain death. About half the cases of brain death result from head injury, after hours or days of intensive treatment following initial resuscitation. About a third have suffered severe non-traumatic intracranial haemorrhage, and the rest a variety of catastrophic intracranial events, including systemic hypoxia associated with cardiac arrest.

Criteria for diagnosis

Undue emphasis on the final confirmation that no residual brainstem function persists has sometimes distracted attention from the stepwise process of diagnosis, for which these tests are only the last stage. Indeed the most important step is the first one, satisfying the preconditions. These require that the patient be apnoeic and in deep coma due to irreversible structural damage to the brain. This implies that reversible causes of brainstem depression have been adequately excluded. It is usually obvious that structural brain damage has occurred—there has been a recent head injury or a classical history of spontaneous intracranial haemorrhage or of some less acute intracranial condition. Establishing the irreversibility of such brain damage depends on failure to improve after the correction of factors such as systemic hypotension and hypoxia and raised intracranial pressure. Other causes of temporary failure of brainstem function are depressant drugs (including alcohol), neuromuscular relaxant drugs, and physiological factors such as hypothermia and gross metabolic imbalance. The first two of these may complicate cases of structural brain damage but it is only in a minority of cases that serious doubts arise about confusing factors. For example, when a patient is found unconscious and no satisfactory history can be discovered it may be necessary to undertake formal screening for drugs. In all cases the diagnosis of brain death should be delayed until sufficient time has passed for the exclusion of all temporary causes of brainstem depression, usually at least 6 h.

The tests applied to indicate lack of brainstem function are simple to carry out and to interpret. There should be no response of the pupils to light, of the eyelids to corneal touching, of the facial muscles to pain, of the throat muscles to movements of the endoctracheal tube, or of the eyes to syringing each external auditory meatus with ice cold water (the caloric or vestibulo-ocular reflex). Only when there has been a negative response to all of these is the final crucial test applied—to verify that there is still apnoea. There must be no respiratory movement after disconnection from the ventilator for long enough to allow the $P\mathrm{a}\mathrm{CO}_2$ to rise to 6.65 kPa (6.8 kPa in the United States), oxygenation being maintained by delivering 6 litre/min of oxygen down the endotracheal tube. To exclude any possibility of observer error it is required that all these tests are carried out by two doctors and on two occasions.

Action after diagnosis of brain death

There is now wide acceptance of the concept that when the brain is dead the person is dead. In the United Kingdom the legal time of death is when the first tests confirm brainstem death, and not some later time when the heart stops. Some doctors are still reluctant to make this diagnosis explicitly and then to act logically and legally by disconnecting the ventilator. The useless ventilation of a brain dead patient deprives that patient of death with dignity, needlessly prolongs the distress of relatives, wastes resources for intensive care, and is bad for the morale of nursing staff. Moreover the opportunity to offer organs for transplantation is lost because gradual circulatory failure makes such organs useless for donation.

The persistent vegetative state

This term was introduced in 1972 by Jennett and Plum to describe the clinical condition resulting from loss of function in the cerebral cortex with a functioning brainstem. Because of the latter, vegetative patients breathe spontaneously and are not ventilator-dependent; another difference from brain death is that they can survive for many years if adequately fed and nursed. The commonest cause of vegetative survival after acute brain damage is severe head injury, the mechanism being severe diffuse axonal injury severing the subcortical connections over a wide area. Secondary hypoxic brain damage is a contributing factor in some traumatic cases. Most non-traumatic cases result from severe hypoxia/ischaemia of the brain following cardiac arrest, near drowning, or strangulation, whilst a few result from severe hypoglycaemia in diabetics. Other causes are acute intracranial haemorrhage or infection. In adults the vegetative state can evolve gradually during the late stages of chronic dementing conditions, and in children can result from severe congenital malformations of the brain or from progressive metabolic or chromosomal diseases affecting the brain.

At autopsy after acute hypoxic insults there is commonly a widespread loss of cortical neurones. After acute traumatic and non-traumatic damage leading to vegetative survival there is almost always severe bilateral thalamic damage, whilst the cortex may be relatively spared. There is also progressive degeneration over many months of neurones and nerve fibres and their myelin sheaths remote from the site of initial damage, which is reflected during life in progressive enlargement of the ventricles as visualized by computed tomography or magnetic resonance imaging. Findings on the electroencephalogram are variable, but there is often loss of evoked cortical responses to somatic stimuli. Positron emission tomography shows severe depression of glucose metabolism in cortical grey matter, to levels found only in experimental deep barbiturate narcosis.

Diagnosis

In practice the diagnosis depends on characteristic clinical features recorded by skilled observers over a period of time. The patient has long periods of spontaneous eye opening (hence the inappropriateness of calling this condition irreversible or prolonged coma). The eyes may briefly follow a moving object or the head turn reflexly to a sudden noise that may also produce a startle reaction. All four limbs are paralysed and usually spastic, with only reflex posturing and withdrawal from a painful stimulus, and often there is a grasp reflex. The face may grimace and groans may be heard but never words. There is no psychologically meaningful response to external stimuli or any learned behaviour—no evidence of a working mind. There may be emotional behaviours such as smiling, crying, or laughing but these are

not related to appropriate external stimuli. It is concluded that although awake these patients are not aware and do not suffer distress or pain. Misdiagnosis by non-experts is not uncommon, and care is needed to exclude the minimally conscious state in which there are very limited responses indicating some cognitive activity. It must also be ascertained that the patient does not have the locked-in syndrome, due to brainstem damage resulting in full awareness but widespread paralysis, leaving the patient able to communicate only by a yes/no code using the sole remaining motor power, blinking the eyelids or moving the eyes.

Prognosis

Patients in a vegetative state for some time can still make some recovery, and persistent does not mean permanent. Of patients in the vegetative state 1 month after an acute insult, about half of the head injured will regain some consciousness, but only a few of the non-traumatic cases do. Most who recover consciousness remain very severely disabled and dependent, particularly if they have been vegetative for several months. After head injury permanence cannot be declared until 12 months, but after non-traumatic insults after 6 months according to United Kingdom criteria and 3 months in the United States. There is a high mortality in the first year after becoming vegetative but once this period is survived patients can live for many years, if tube feeding and good nursing care is maintained and infective complications actively treated.

Action after permanence declared

There is now a consensus in many countries that survival for years in a permanent vegetative state is of no benefit to the patient, and that it is therefore appropriate to withdraw life-sustaining treatment once permanence is declared. Many courts in the United States and the United Kingdom have agreed that artificial nutrition and hydration is medical treatment that can be withdrawn if judged to be no longer of benefit to the patient. Once this is done a peaceful death occurs in 8 to 12 days, and the cause of death is regarded as the original brain damage. Only in the United Kingdom is it a legal requirement to seek court approval before withdrawing such treatment, although this situation is under review.

24.13.7 Stroke: cerebrovascular disease

J. van Gijn

Introduction

Cerebrovascular diseases include many pathological conditions: two main categories being infarction, (through occlusion of major arteries, small arteries, or venous sinuses) and haemorrhage (through rupture of small arteries, arterial aneurysms, or capillaries). Intracerebral haemorrhage was first recorded by the Swiss physician Wepfer, and in more detail by Morgagni in Padua. Non-haemorrhagic stroke, 'serious apoplexy', puzzled the medical community until cerebral softening ('ramollissement') was recognized as a pathological entity in 1820 by Rostan in Paris. Initially it was regarded as an inflammatory condition. The relationship of brain softening with arterial occlusion and atherosclerosis gradually dawned on pathologists in the nineteenth century when it was firmly established by Rokitansky and Virchow. Subarachnoid haemorrhages and their usual source, intracranial aneurysms, were first recognized at the beginning of the nineteenth century; the diagnosis could (sometimes) be made during life from the beginning of the twentieth century. In 1931 the Edinburgh neurosurgeon Norman Dott carried out the first intracranial operation for a ruptured aneurysm, by wrapping it in muscle.

Knowledge of cerebrovascular disease has received great impetus from the advent of computed tomography (**CT**) scanning. Previously, observations depended on postmortem studies and on indirect neuroradiological studies such as angiography and pneumoencephalography. CT scanning has allowed the rapid and reliable distinction between haemorrhagic and ischaemic stroke during life. Subsequently, CT and the newer technique of magnetic resonance imaging (**MRI**) have identified several subtypes of stroke, each requiring specific therapeutic measures. Examples are lacunar infarction, intracranial venous thrombosis, arterial dissection, and complications after aneurysm rupture (rebleeding, ischaemia, or hydrocephalus). The rapid increase in diagnostic accuracy coincided with dissemination of the randomized clinical trial and other methodological innovations in medicine. As a result, stroke research is no longer a backwater of medicine but a bustling area.

The consequences of stroke are often devastating. A sudden loss of a large amount of brain tissue affects much more than specific, localizable functions such as movement, sensation, vision, and language. The greater part of the brain has no defined task, but serves to connect and integrate the separate 'functions'. Mood, initiative, sense of humour, and speed of thought are examples of essential aspects of human life that can be severely affected by stroke, but which are often sadly ignored. There are no 'silent' areas in the brain that can be damaged with impunity.

Epidemiology of stroke

Worldwide, stroke is the third most common cause of death after coronary heart disease and all cancer deaths, and stroke is the most important single cause of disability in the Western world. Although the incidence of stroke is not technically difficult to measure, it does require the expenditure of much time and resources. The few reliable studies, mostly from developed countries, show that age- and sex-standardized annual incidence rates for subjects aged 45 to 84 years are between 300 and 500 per 100 000. The pathological type varies, even between studies with a high rate of CT scanning, but a general estimate is 82 per cent infarction, 15 per cent primary intracerebral haemorrhage, and 3 per cent subarachnoid haemorrhage. The incidence of transient ischaemic attacks (**TIAs**) has been rather consistently estimated at 35 per 100 000 of the entire population, or about 80 per 100 000 of subjects between 45 and 84 years of age.

In terms of an average general practice of 2400 people (1000 patients between 45 and 84 years of age), four patients will have a stroke per annum, whilst one will have a TIA. Intracerebral haemorrhage will occur about twice every 3 years, and subarachnoid haemorrhage once every 8 years.

Arterial occlusive disease

The cerebral circulation and its disorders

Brain tissue is critically dependent upon a constant supply of oxygen and glucose. The cerebral blood flow (800 ml/min) accounts for 15 to 20 per cent of the entire cardiac output, whereas the brain (1350 g) accounts for only 2 per cent of the adult body weight. Neurones in the brain require a constant supply of ATP to maintain concentration gradients of ions across their membranes, necessary for the generation of action potentials. The resting brain consumes energy at the same rate as a 20-Watt light bulb.

Whether occlusion of an artery in the brain or in the neck actually leads to ischaemia depends on collateral pathways. If an end artery is occluded and there is no collateral circulation at all, ischaemic symptoms will occur within seconds. Neurones will start dying within minutes, and within hours the entire supply area of the artery will be irreversibly damaged. In contrast, permanent occlusion of a major artery, such as the internal carotid artery, may be symptomless in the presence of an adequate collateral circulation. Broadly speaking, three levels of collateral circulation can be distinguished (Fig. 1; these can be thought of as three lines of defence):

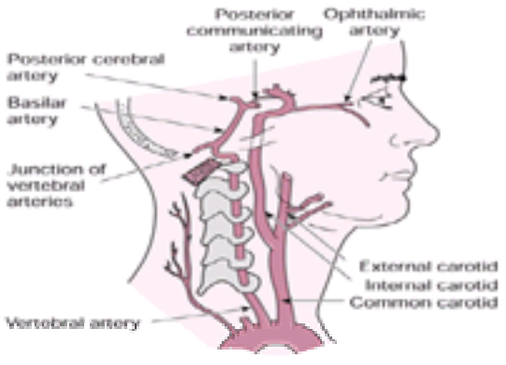

Fig. 1 Arterial supply of the brain. The drawing shows, on the right side, the internal carotid artery, external carotid artery, and vertebral artery. If a main artery is

occluded then collateral flow may occur via the circle of Willis (see also Fig. 2), or through connections between extracranial and intracranial branches.

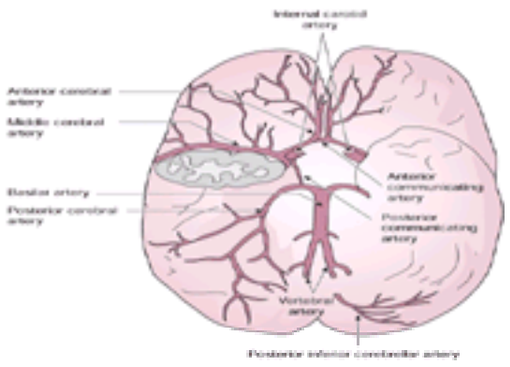

Fig. 2 The arterial circle of Willis, at the base of the brain.

1. *The circle of Willis* (Fig. 2). Even if there is no blood whatsoever flowing to the brain from one or even both internal carotid arteries, collateral flow from the other internal carotid artery or from the basilar artery, via an intact circle of Willis, may ensure an adequate blood supply in the territory of the occluded artery.
2. *Connections between extracranial and intracranial vessels*. If the internal carotid artery is occluded at its origin, collateral channels may develop via the external carotid artery. Branches supplying the outer orbit may connect with branches to the retina, resulting in a reversed flow in the ophthalmic artery. From there, blood reaches the distal part of the internal carotid artery. Similarly, branches of occipital arteries (normally supplying the neck muscles) may fill the basilar artery if this is occluded at its origin.
3. *Leptomeningeal anastomoses*. If, for example, the main stem of the middle cerebral artery is occluded, its terminal branches at the surface of the brain may anastomose with similar branches of the anterior and posterior cerebral arteries; in this way the cerebral cortex in the territory of the occluded artery is spared, partly or wholly, although the deep territory will still be ischaemic.

Atherothrombosis is the major cause of occlusion of the major arteries in the brain or in the neck. However, two important qualifications should be made. First, atherosclerosis of the intracranial arteries is relatively uncommon, at least in White people (other than in Black or Oriental people). This means that brain infarction in the West is usually caused by an embolism, in which a thrombus has been dislodged from an upstream lesion. The source can be the internal carotid artery, the aorta, or the heart. Second, atherosclerosis is not a sufficient cause in itself: not everyone with severe atherosclerotic disease suffers an ischaemic stroke. Other factors are irregularity of the plaque, turbulence of blood, platelet aggregation, and the balance of clotting factors.

Diagnosis of transient ischaemic attacks

Transient ischaemic attacks are important to diagnose because they are potential harbingers of stroke. They precede cerebral infarction probably in only 15 to 20 per cent of cases (it is difficult to be certain of the figure because almost all such information has been retrospectively collected in patients once they had suffered a stroke).

Unfortunately the term 'transient ischaemic attack' is rather imprecise, because it tacitly implies three restrictions. To begin with, it refers only to the brain and not to angina pectoris or intermittent claudication. Also excluded is transient ischaemia of the entire brain, for example in syncope or ventricular fibrillation. It is only ischaemia of a part of the brain that is conventionally covered by the term 'TIA'. Finally, how transient is transient? Traditionally the limit has been set at 24 h. Obviously this threshold has more to do with astronomy than with biology or disease. In fact, most TIAs last minutes, not hours. The longer an attack lasts, the greater the chance that CT scanning afterwards will show a relevant ischaemic lesion. In terms of patient management the essential question is not whether the attack has lasted 3 min, 3 days, or 3 weeks, but what its cause is and how recurrences can be prevented.

What actually happens in the brain during a given period of ischaemia can often only be guessed at. The usual assumption is that an embolus, consisting of platelets or loosely organized thrombus, temporarily blocks an intracerebral vessel and then dissolves into smaller fragments. There is scant evidence for this phenomenon, apart from chance observations during fundoscopy, angiography, or operation. Other explanations, applicable only to a minority of cases, include marginal flow, secondary to severe narrowing or occlusion of arteries.

The diagnosis of a TIA is problematic. That one has to rely on the history alone is a first difficulty (it requires time, skill, and patience), but not a unique one. A greater source of interobserver variation is that the term 'TIA' is an interpretation rather than a description.

Main varieties of transient ischaemic attacks

There are four kinds of symptoms that can safely be regarded as TIAs, given that the onset is sudden (within seconds), that all symptoms appear at the same time, without 'march', and that there is no better explanation.

Transient weakness of one half of the body

Apart from weakness there may also have been numbness. Isolated numbness or pins and needles on one side of the body are a rare manifestation of transient cerebral ischaemia; other causes such as overbreathing are more likely. Weakness and numbness are closely related perceptions, and one should not take these or other expressions ('an arm gone dead') for granted. It is important to make sure the problem had to do with moving the limbs or the face on one side (facial weakness on one side often manifests itself through slurred speech or drooling), and not with what it felt like when those body parts were touched or with spontaneous sensations. It is also critical to verify that the problem occurred in at least two of three body areas, and that, in the elderly, it was not just a leg or arm that had 'gone to sleep' after a mid-day nap. All four limbs may be affected at the same time in TIAs of the brainstem.

Transient loss of the ability to find words or to understand them

The medical term for this type of TIA is 'dysphasia' or 'aphasia'; the problem here is not that patients and relatives may not recognize the episode as representing a problem of language, but describe the attack as 'confusion'. It is helpful to ask specific questions about the patient's ability to put thoughts into words (motor dysphasia), and about having been able to understand what was said (sensory dysphasia). If a patient can write sentences but cannot speak, the cause is almost certainly psychological. A frequent problem is the distinction between dysphasia (disorder of language) and dysarthria (disorder of articulation). To ask whether pronunciation was difficult may not be very helpful. After all, in both cases the patient's thoughts are clear and the difference between finding the right words and forming the right sounds is not great. A useful question is whether the words made sense and whether they were in the right order. Dysphasia relates to the left hemisphere in right-handed people, and in 50 per cent of left-handers.

Transient loss of vision in one eye

The difficulty in this case is to distinguish transient monocular blindness from the loss of vision on one side in both eyes (hemianopia). Either type of attack can be experienced as a problem in one eye. The distinction is not academic, as monocular attacks of blindness should lead to investigation of the internal carotid artery in the neck with a view to angiography and operation, whereas hemianopia mostly (in 80 per cent) reflects a disorder in the posterior circulation, in which case treatment will often be medical. The vital question to ask is whether patients have alternately covered each eye during the attack. A surprisingly large proportion of patients have done so, but they will not always offer this information without prompting. On having covered the 'good eye' in case of hemianopia, the patient should still have been able to see with the 'bad eye', though only the nasal half of the visual field. With a monocular disorder the blindness should have been complete.

Transient loss of vision in one hemifield

Hemianopia reflects dysfunction of the occipital lobe. It is also a common aura in migraine attacks, which may occur without ensuing headache, especially in the elderly. It is therefore important for the physician to enquire about the mode of onset: flashing lights, bright colours, zig-zag lines, and a gradually expanding deficit all argue in favour of a migrainous attack rather than ischaemia in its restricted sense of a stroke warning.

Differential diagnosis of transient ischaemic attacks

Table 1 lists the types of attacks that should not be regarded as TIAs, either because of positive phenomena (such as rhythmic jerking) that are incompatible with the definition of focal ischaemia, or because other causes are much more likely. Especially the tendency to label any episode of 'dizziness' in the elderly as 'vertebrobasilar ischaemia' or, even worse, 'vertebrobasilar insufficiency' should be strongly resisted.

In addition, some specific disorders other than atherosclerosis may cause attacks that are more or less indistinguishable from true TIAs as defined above. They are listed in Table 2. These rare, but important, causes are reason enough for ordering a CT or MRI scan of the brain in patients with cerebral TIAs (not necessarily in those with transient monocular blindness). A chronic subdural haematoma should always be suspected in the elderly, especially if they are taking anticoagulants. Hypoglycaemia should come to mind in diabetic patients. Focal weakness may follow an epileptic seizure (Todd's paralysis) and may be misdiagnosed as TIA if the initial jerking is missed or misinterpreted. Tumours may also cause temporary deficits without focal epilepsy. Transient global amnesia is a disorder of memory probably caused by migrainous vasospasm; although technically ischaemic in nature, it is not associated with an increased risk of stroke or other vascular disease.

Prognostic implications of transient ischaemic attacks

In a population-based study of 184 patients in the United Kingdom after they had one or more TIAs, the actuarial risk of stroke was 12 per cent during the first year after a TIA (13-fold excess risk) and approximately 6 per cent per annum over the subsequent 5 years (sevenfold excess risk). The actuarial risk of death, stroke, or myocardial infarction over the first 5 years after a TIA was between 8 and 9 per cent per annum. Heart disease and stroke each accounted for about one-third of all deaths. Given that most of these patients were treated with aspirin, which reduces the rate of vascular events after cerebral ischaemia by about 15 per cent (see below), the risk of stroke without treatment can be estimated at 14 per cent in the first year and 7 per cent in subsequent years, and the average risk of death, stroke, or myocardial infarction in the first 5 years at 10 per cent per annum. In individual patients, these average risks will be modified by their age, specific risk factors, coexistent disease, and the interval since their first attack.

Investigations in patients with cerebral ischaemia

There is no great difference between searching for the cause of a TIA and searching for the cause of an ischaemic stroke. Very early CT or MRI scanning is mandatory: mainly to exclude intracerebral haemorrhage and the occasional structural lesion mimicking stroke, not so much to demonstrate infarcts. Table 3 lists the major and contributory causes of TIA and ischaemic stroke, with corresponding investigations. In general, first-line investigations are: a full blood count; erythrocyte sedimentation rate (**ESR**); plasma glucose, creatinine, and electrolytes; plasma lipids; treponemal antibodies; urinalysis; ECG; and unenhanced CT scan of the brain.

Diagnosis of cerebral infarction

Distinction from other types of stroke

From a practical point of view, the first step is to distinguish ischaemic stroke from intracerebral haemorrhage. In the past, when a certain distinction could be made only at operation or autopsy, a decreased level of consciousness and headache were considered typical of intracerebral haemorrhage. After CT scanning became available in the 1970s, it was soon clear that smaller haemorrhages were not associated with headache and drowsiness. Given that 3 out of 20 strokes are haemorrhagic, and on the assumption that two-thirds of all haemorrhages lack distinctive clinical features, a diagnosis of cerebral infarction based on clinical features alone is wrong in every tenth case on average. Even complex clinical scoring methods can hardly improve on this error rate.

CT scanning

Acute parenchymal haemorrhage is of a higher density than normal brain tissue on CT scanning (see Fig. 6). The hyperdensity occurs immediately and is caused by the iron molecules in haemoglobin. Signs of infarction are more difficult to detect at an early stage: in the first decade of CT scanning this was not possible until after 3 days, when frank tissue necrosis caused a hypodense lesion on the scan. With improved CT technology, subtle early signs of cerebral infarction have been recognized, at least with a large area of infarction. These features include loss of outline of the insular ribbon and the lentiform nucleus (Fig. 3), loss of normal differentiation between grey and white matter, and effacement of cortical sulci.

Fig. 6 Primary intracerebral haemorrhage in a 52-year-old man. This CT scan shows a hyperdense lesion in the right thalamus; the haemorrhage has ruptured into the ventricular system.

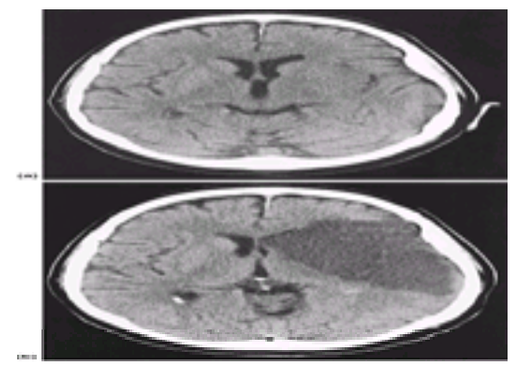

Fig. 3 Acute cerebral infarction in a 78-year-old man. (a) CT scan about 6 h after symptom onset. In the left brain hemisphere (on the reader's right) there are subtle changes in the region of the basal ganglia: other than on the normal side, it is difficult to distinguish the different brain nuclei and their separation by white matter. (b) CT scan 4 days after symptom onset shows marked hypodensity in the entire territory of the left middle cerebral artery.

Within the first few days, the area of infarction changes into a slightly hypodense, ill-defined, and somewhat swollen lesion on CT scanning, to become more clearly demarcated and hypodense towards the end of the first week (Fig. 3). Occasionally there may be massive swelling with brain herniation, or haemorrhagic transformation. During the second week the infarct may again gradually increase in density, because the degradation products of necrotic brain tissue more readily absorb X-rays. In the third and fourth week the infarcted area may even become isodense, thereby almost indistinguishable from normal brain, the so-called 'fogging effect'. Eventually a sharply demarcated, atrophic, hypodense (similar to cerebrospinal fluid) defect remains. It is not always possible to tell with certainty how old an infarct is, nor to distinguish it from the scar of a haemorrhage that occurred weeks or years before. Intravenous injection of X-ray contrast will, in the first week, cause some enhancement of gyri (if the lesion involves the cortex).

The proportion of patients in whom CT scanning shows an appropriate infarct depends not only on the time of scanning and the generation of the scanner, but also on the size of the infarct and on its location. With serial CT scanning, eventually more than 90 per cent of infarcts show up.

Magnetic resonance imaging

MRI is especially useful for demonstrating small infarcts and lesions in the posterior fossa; it is also more sensitive than CT scanning in the early phases of brain ischaemia. Signal changes on *T*2-weighted images occur after 6 to 8 h, and on *T*1-weighted images after 16 h. Infarcts of any size are more often and more quickly visible on fluid-attenuated inversion recovery (**FLAIR**) scans and on diffusion-weighted imaging, but these techniques are not widely available. The distinction from intracerebral haemorrhage is less obvious than on CT, but the paramagnetic effects of deoxyhaemoglobin can be identified after a few hours.

Classification of cerebral infarction

Time was often the guiding principle in the classification of stroke in the era before brain imaging and its positive effects on the accuracy of clinical diagnosis. From the point of view of management and prognosis, however, it is rather irrelevant to distinguish 'progressive stroke' from 'completed stroke', or 'permanent stroke' from 'reversible ischaemic neurological deficit' (**RIND**, a kind of 'extended TIA' with complete recovery within 3 or 6 weeks, depending on local convention). What counts is the eventual severity of the functional deficit and, conversely, what remaining function is at stake.

The anatomical classification distinguishes infarcts according to the territory of major cerebral arteries: in the cerebral hemispheres infarcts can be located in the supply areas of the anterior cerebral artery, middle cerebral artery, posterior cerebral artery, or in the border zones between these three main branches; the cerebellum and brainstem are supplied by the vertebral arteries, basilar artery, and their branches. Problems are that there is little if any relationship with function, that there is no distinction between partial and complete infarcts in a given territory, and that the boundaries between different territories vary substantially between individuals.

Classification according to the cause of ischaemic stroke is of interest for studies aiming to describe or influence the pathophysiological background of strokes. The so-called 'TOAST (Trial of Org 10172 in Acute Stroke Treatment) classification', for example, distinguishes five subtypes of ischaemic stroke:

1. large-artery atherosclerosis;
2. cardioembolism;
3. small-vessel occlusion;
4. stroke with other specific cause; and
5. stroke with undetermined cause.

At present, about 40 per cent of patients would presently end up in the category 'undetermined cause', even in specialized stroke services. Moreover, these distinctions can only be applied after a few days in hospital. Finally, and most important, the system is not suited for assessing the severity of stroke.

Rehabilitation specialists and geriatricians will be more interested in the functional abilities of patients than in the niceties of neurological nosology. They mostly grade patients' disability on a scale for activities of daily life (such as the Barthel scale, which ranks 10 in-house activities in hierarchical order, from bowel continence to taking a bath), or on a scale that includes some elements of social role fulfilment ('handicap'), such as the Rankin scale (Table 4).

A system that strikes a useful compromise between the functional and the anatomical point of view is the classification of the Oxfordshire Community Stroke Project, which distinguishes four categories:

1. total anterior circulation infarcts (**TACI**), with both cortical and subcortical involvement, representing about one-sixth of all ischaemic strokes in the community;
2. partial anterior circulation infarcts (**PACI**), with more restricted and predominantly cortical infarcts (one-third of all infarcts);
3. posterior circulation infarcts (**POCI**), clearly associated with the vertebrobasilar arterial territory (one-quarter); and
4. lacunar anterior circulation infarcts (**LACI**), confined to the territory of the deep perforating arteries (one-quarter).

Although the classes are anatomically defined, they contain important prognostic information: case fatality is highest by far in the TACI group.

Syndromes of cerebral infarction

Occlusion of the internal carotid artery may cause no symptoms at all or infarction in the entire territory of the ipsilateral anterior and middle cerebral artery (and sometimes of the posterior cerebral artery or contralateral anterior cerebral artery as well), depending on the presence of a complete circle of Willis and other collaterals. If arterial dissection is the cause of carotid occlusion, subadventitial bulging of the artery may cause Horner's syndrome and lower cranial nerve palsies, with or without infarction. Occlusion of the anterior, middle, and posterior cerebral arteries may lead to complete or partial infarction in their respective territories, depending on collaterals at the surface of the brain. Obviously, branch occlusions cause smaller infarcts. What follows is a description of syndromes associated with complete infarction in the average territory of the main cerebral arteries.

Infarcts in the area of the anterior cerebral artery

These cause contralateral hemiparesis more marked in the leg than in the arm, with no or only mild sensory deficit. Other frontal lobe features include mutism, incontinence, and apathy or, conversely, disinhibition.

Middle cerebral artery infarcts

If complete, these typically present with contralateral hemiplegia (most marked in the arm), sensory deficit, hemianopia, and cognitive defects such as aphasia (dominant hemisphere) or contralateral neglect (non-dominant hemisphere). Massive infarction of the entire territory of the middle cerebral artery may lead to such a degree of brain swelling that fatal herniation occurs, especially in young patients without cerebral atrophy.

Occlusion of a vertebral artery

Where this involves the origin of the posterior inferior cerebellar artery, such occlusion causes Wallenberg's syndrome, with ipsilateral cerebellar ataxia through infarction of the inferior part of the cerebellum. In addition, it causes a slightly bewildering combination of deficits through infarction of the dorsolateral medulla: decreased skin sensation in the ipsilateral half of the face and the contralateral half of the body, ipsilateral Horner's syndrome, ipsilateral weakness of the soft palate, larynx and pharynx, and rotatory vertigo.

Basilar artery syndrome

The full basilar artery syndrome, with infarction of most of the pons and midbrain, consists of coma, tetraparesis including facial movements, and loss of all eye movements and of pupillary and corneal reflexes. There are two characteristic partial syndromes of the basilar artery. One is the locked-in syndrome (infarction of the base of the pons), with tetraparesis including facial movements and loss of horizontal eye movements. Consciousness is preserved through sparing of the reticular

formation, but patients can communicate only through vertical eye movements; these may not always be correctly interpreted or even noticed. The other is the top-of-the-basilar syndrome, with variable combinations of hemianopia or complete cortical blindness (occipital lobes), amnesia (inferior temporal lobes), as well as vertical gaze palsies, pupillary disturbances, and hallucinations (perforating branches to the midbrain).

Posterior cerebral artery syndrome

This may include hemianopia (occipital lobe), amnesia (lower temporal lobe), and oculomotor disorders or disturbances of language or visuospatial function, through the involvement of perforating branches to the thalamus.

Occlusion of a single perforating artery

Such an occlusion, of one of the many arterioles that originate at right angles from a large parent artery to supply a small area in the deep regions of the brain or brainstem (Fig. 4), may be clinically silent, or cause a so-called 'lacunar syndrome'. A necessary condition for the clinical diagnosis of a lacunar syndrome is the absence of 'cortical' deficits, such as aphasia, neglect, hemianopia, and conjugate deviation of the eyes. The most common and archetypal form is pure motor stroke. In these cases the small, deep infarct strategically involves corticospinal fibres (pyramidal tract) to the motor neurones of the limbs, anywhere in its course. Analogous fibres to the facial nucleus in the pons may be affected as well. The infarct can be located in the corona radiata, adjoining the wall of the body of the lateral ventricle, or slightly more caudally, in the posterior limb of the internal capsule, or, less commonly, in the pons or the medulla. Other 'lacunar syndromes' are sensorimotor stroke (corona radiata or internal capsule), pure sensory stroke (thalamus), and ataxic hemiparesis (usually the base of the pons). Lacunar infarcts in the brainstem may lead to an almost infinite range of syndromes, often with the name of a French nineteenth century neurologist attached to it. Often such syndromes consist of an ipsilateral cranial nerve deficit and a contralateral hemiparesis.

Fig. 4 Small, deep infarct ('lacune') in a 63-year-old woman. CT scanning shows a small area of hypodensity (distinct from sulci) in the left brain hemisphere (on the reader's right), just lateral to the internal capsule.

Treatment of acute cerebral infarction

Several medical interventions aim at dissolving the occluding clot, or at least preventing it from growing: thrombolysis, antiplatelet agents, and anticoagulants. A different strategy, not yet well developed, is to protect ischaemic brain tissue. In addition, some underlying causes of stroke need urgent treatment, such as endocarditis. Before considering these specific measures, it is appropriate to consider the appropriate hospital setting in which stroke patients should be cared for.

Stroke units versus general wards

Specially organized stroke units can be a ward or team that exclusively manages stroke patients (a dedicated stroke unit) or a ward or team that provides a generic disability service (a mixed-assessment or rehabilitation unit). According to a meta-analysis of 20 randomized trials, care in a stroke unit reduces the risk of death or institutionalized care by 13 per cent. The observed benefits are independent of patient age, sex, stroke severity, and types of stroke-unit organization. No single element responsible for the benefits of organized stroke care has so far been identified, and probably there is none. The strength of stroke units lies in the integration of multidisciplinary efforts: stroke physician, nursing staff, physiotherapists, occupational therapists, speech therapists, rehabilitation physicians, and social workers.

Thrombolysis

Restoration of blood flow, to reperfuse the ischaemic brain as soon as possible after the cerebral artery has been occluded, and irrespective of its cause, should theoretically lead to a reduction in the volume of brain damaged by ischaemia and to an improvement in clinical outcome, analogous to myocardial infarction.

The main agents tested so far in the treatment of stroke (17 trials in over 5000 patients) are intravenous recombinant tissue plasminogen activator (**r-tPA**) and intravenous streptokinase, each in about half the patients. Almost all were treated within 6 h of stroke onset. Across all trials there was an excess of symptomatic intracranial haemorrhages (3 per cent in controls versus 10 per cent in treated patients). For every 1000 patients treated this corresponds to 70 extra intracranial haemorrhages, of which 44 are fatal. However, patients who survived the treatment were, on average, less disabled. For the outcome criterion 'death or dependence at the end of follow up' (3 months for most trials) the proportion was 59 per cent in the control group and 55 per cent among treated patients. This corresponds to a net gain of about 40 patients avoiding death or dependency for every 1000 patients treated with thrombolysis within 6 h, despite the excess haemorrhages.

There are still many unanswered questions about the role of thrombolysis in the treatment of ischaemic stroke. The first of these is the time window. The earlier treatment is given the better, which is confirmed by subgroup analysis of patients treated within 3 h, but inevitably this subgroup is biased towards more severe strokes (these get to hospital quickest). Second, is one agent better than another? For r-tPA alone, the balance of risks and benefits seems more favourable than for all agents together: per 1000 patients treated, an excess of 30 fatal intracranial haemorrhages, and a net result of 60 patients avoiding death or dependence, but the difference with streptokinase treatment is not statistically significant. Third, we can roughly identify patients in whom the risk of haemorrhage in the infarcted tissue is great (those with the most severe deficits and those with early signs of extensive infarction), but the potential benefits are also greatest in this group. More controlled studies are needed. Another question is whether the gains in patients with stroke are not offset by unbalancing the 'worried well' who will be also rushed to hospital, once stroke has been recognized as an emergency. There are many contraindications in view of the risk of cerebral haemorrhage, and only a minority of patients admitted with cerebral infarction can be treated with thrombolysis.

Antiplatelet agents

More than 99 per cent of the evidence from randomized trials in this area relates to the use of aspirin. The pooled results of two trials with aspirin (160–300 mg), started within 48 h of the onset of stroke, concluded that 13 fewer patients die or become dependent for every 1000 patients treated. There was no evidence of a net hazard in some 800 patients who had been inadvertently randomized after a haemorrhagic stroke. Only the combination with thrombolytic treatment should be avoided, because there are indications that aspirin enhances the danger of intracerebral haemorrhage.

Anticoagulants

Anticoagulants tested in clinical trials are standard unfractionated heparin, low molecular weight heparins, heparinoids, oral anticoagulants, and thrombin inhibitors. There is no evidence that anticoagulant therapy reduces the odds of being dead or dependent at the end of follow-up.

Neuroprotective agents

There are many steps in the destructive cascade between vessel occlusion and irreversible cell death where pharmacological intervention might be beneficial, at least

theoretically. The pharmaceutical industry has developed several compounds for clinical development and testing. There is no doubt that in animal models many neuroprotective agents, given either before or after the onset of ischaemia, reduce the area of cerebral infarction. So far, none of these agents has been proven to reduce disability in patients, despite dozens of clinical trials. Many other trials are under way, but reduction of disability by neuroprotective drugs is likely to be modest at best.

Surgical decompression of space-occupying infarcts

To prevent brain herniation, some centres in Germany have adopted the procedure of removing large parts of the skull vault in patients with massive supratentorial infarction, but all reports up to now have been uncontrolled. Clearly there is a need for randomized trials, which should take account of the quality of life of both patients and their carers.

With operations for space-occupying infarcts of the cerebellum there is a similar lack of controlled trials, but less controversy. Without operation, swelling of a cerebellar infarct can be fatal, whereas the deficits after surgical evacuation are surprisingly mild. In many patients, however, it is sufficient to relieve obstructive hydrocephalus, by external ventricular drainage.

Secondary prevention of ischaemic stroke

In the management of patients with TIAs or moderately disabling ischaemic strokes, it is often forgotten that the control of primary risk factors is by far the most effective way of diminishing the risk of stroke or other vascular events. First and foremost is blood pressure control, but also important are cessation of smoking, controlling diabetes and hyperlipidaemia, reducing overweight, and daily exercise.

Specific measures to reduce the risk of threatened stroke are discussed below. Drug treatment depends on whether the likely cause is embolism from the heart or arterial disease. With sources in the heart, mostly from atrial fibrillation, anticoagulant therapy (to give an **INR** (international normalized ratio) between 2.5 and 4) is the first choice in the absence of contraindications; no evidence exists for a fixed age limit. In all other patients, aspirin is the mainstay of treatment, but its preventive effect is only modest. Other antiplatelet drugs are only slightly more effective, if at all. Carotid endarterectomy is highly effective in patients with severe, symptomatic carotid stenosis (80–99 per cent reduction of the original lumen diameter), but this is found in less than 10 per cent of all eligible patients with ischaemic events.

Aspirin

The preventive effect of aspirin, in different doses, has been studied in 11 placebo-controlled randomized trials, in over 8000 patients after a TIA or moderately disabling stroke. There is virtually no difference in risk reduction for daily doses between 30 mg and 1300 mg. The overall risk reduction is 13 per cent (95 per cent confidence interval, 6 to 19 per cent). Side-effects, mainly indigestion, nausea, heartburn, or gastrointestinal bleeding are more common as the dose increases, but absolute rates are difficult to compare between studies, owing to differences in criteria.

Thienopyridine derivatives

These antiplatelet agents block the adenosine diphosphate pathway of platelet aggregation. The oldest derivative, ticlopidine, when given in a dose of 250 mg twice daily, is about as effective as aspirin (any dose above 30 mg). The major disadvantages are, however, that it is definitively more toxic (diarrhoea and skin rashes are reported in 15–20 per cent, and neutropenia in about 1 per cent of patients) and that it is much more expensive than aspirin.

Clopidogrel (75 mg daily) was tested in a single trial, which included patients with ischaemic stroke and those who had suffered myocardial infarction or who had peripheral vascular disease. It reduced the risk of the composite outcome event of vascular death, non-fatal stroke, or non-fatal myocardial infarction by 8.7 per cent (95 per cent confidence interval, 0.3 to 16.5). For the stratum of patients with an ischaemic stroke, the advantage was not statistically significant. Again, the cost makes it unattractive as the drug of first choice.

Dipyridamole

The pharmacological actions of this drug on platelets are unclear. Large trials of its efficacy in the secondary prevention of stroke have only tested it together with aspirin. In the analysis of all major vascular events the largest trial showed a benefit for the combination therapy in comparison with aspirin alone, but four earlier, smaller studies did not. The overall analysis shows a marginal difference in favour of the combination therapy, but without further evidence it should not be accepted as standard treatment.

Anticoagulants

So far there is little evidence to support the use of anticoagulants in the secondary prevention of stroke, except in patients with atrial fibrillation. A large trial of patients with cerebral ischaemia who were in sinus rhythm used a target intensity of an INR between 3.0 and 4.5, which is not unusual for preventing arterial thrombosis; patients in the control group were treated with aspirin. The study was prematurely stopped because of a significant excess of bleeding complications, mostly intracerebral. Anticoagulant therapy with an intensity of an INR between 2.0 and 3.0 deserves further study.

Carotid endarterectomy

Although this operation was increasingly performed from the 1960s onwards, it was not until the 1980s that two randomized surgical trials were performed: one in Europe and one in North America. In patients with severe, symptomatic carotid stenosis (80–99 per cent reduction in lumen diameter) the risk of disabling or fatal stroke substantially decreases after surgery. On average, about eight patients need to be operated upon to prevent one ipsilateral ischaemic stroke occurring within 4 years. This basic risk difference varies with age and sex, and it levels off after 3 or more years from randomization (that is, 3½ years after the qualifying event). It should be kept in mind that carotid endarterectomy is indicated in only a minority (less than 10 per cent) of patients with TIAs or moderately disabling ischaemic strokes: the attacks have to be in the carotid territory, the patients should be fit and willing to undergo the operation, and the angiogram should show an accessible stenosis of over 80 per cent at the carotid bifurcation.

Venous occlusive disease

The advent of non-invasive brain imaging methods in the 1970s and 1980s resulted in increased recognition of cerebral venous thrombosis. Before that time, physicians only rarely considered the diagnosis in patients with otherwise unexplained headache, focal deficits, seizures, impaired consciousness, or combinations of these features.

Causal factors

Unlike arterial occlusion, cerebral venous thrombosis is only rarely (some 10 per cent) associated with damage to the vessel wall, by infection, tumour growth, or trauma. Much more frequent causes are inherited disorders of coagulation. The most common form is the factor V Leiden mutation, found in some 20 per cent of patients without other causes. Stagnant flow (completing Virchow's triad of causes of thrombosis), contributes no more than a few per cent. In 20 per cent of patients no causal factors can be identified.

Often there is no single cause but a combination of contributing factors: for example, the postpartum period and protein S deficiency; pregnancy and Behçet's disease; or oral contraceptive drugs and the factor V Leiden mutation. The risk of cerebral venous thrombosis in the postpartum period increases with maternal age and with the performance of a caesarean section.

In neonates, cerebral venous thrombosis is usually associated with acute systemic illness, such as shock or dehydration; in older children, the most frequent underlying conditions are local infection (the leading cause before the antibiotic era), coagulopathy, and, in Mediterranean countries, Behçet's disease.

Diagnosis of cerebral venous thrombosis

The clinical features of cerebral venous thrombosis consist essentially of headache, focal deficits, seizures, and impairment of consciousness, in various combinations and degrees of severity. The symptoms and signs depend on which sinus is affected, and for a large part on whether the thrombotic process is limited to the dural sinus or extends to the cortical veins.

In the case of the superior sagittal sinus, which is affected in 70 to 80 per cent of all cases, cerebral venous thrombosis alone will lead to the syndrome of intracranial hypertension, that is headache and papilloedema. Up to 30 per cent of patients with so-called 'benign intracranial hypertension' may in fact have sinus thrombosis. Papilloedema can cause transient visual obscurations and sometimes irreversible constriction of visual fields, beginning in the inferonasal quadrants. The increased pressure of the cerebrospinal fluid may also give rise to VIth nerve palsies, and sometimes to other cranial nerve deficits. The onset of the headache is usually gradual, but in up to 15 per cent of patients it is sudden and may initially suggest the diagnosis of a ruptured aneurysm.

Involvement of cortical veins causes one or more areas of venous infarction, with or without haemorrhagic transformation. If the affected veins drain into the sagittal sinus the venous infarcts are typically located near the midline in the Rolandic and parieto-occipital regions, often on both sides. In the case of the lateral sinus the venous infarct is usually located in the posterior temporal area.

Clinically, the infarcts manifest themselves through epileptic seizures, or through focal deficits such as hemiparesis or dysphasia. If unilateral weakness develops (with thrombosis originating in the superior sagittal sinus), it tends to predominate in the leg, in keeping with the parasagittal location of most venous infarcts. Obstruction of cortical veins draining into the posterior part of the superior sagittal sinus or into the lateral sinus will commonly lead to hemianopia, dysphasia, or a confusional state. Impairment of consciousness may result from multiple lesions in the cerebral hemispheres, or from transtentorial herniation and compression of the brainstem. Either epilepsy or a focal deficit is a presenting feature in 10 to 15 per cent of patients; in the course of the illness seizures occur in 10 to 60 per cent of reported series, and focal deficits in 30 to 80 per cent.

Involvement of the cortical veins alone, without sinus thrombosis and its associated signs of increased cerebrospinal fluid pressure, is an extremely rare occurrence. Thrombosis of the deep venous system, including the great vein of Galen, may lead to bilateral haemorrhagic infarction of the corpus striatum, thalamus, hypothalamus, the ventral corpus callosum, the medial occipital lobe and the upper part of the cerebellum. In those cases the clinical picture is often dominated by deep coma and disturbance of eye movements and pupillary reflexes.

Investigations

CT

CT scanning will readily show 'venous' infarcts. These do not correspond to a known arterial territory, but often show haemorrhagic transformation (Fig. 5); they are sometimes bilateral, in the parasagittal area, or supra- as well as infratentorial, or they are in the deep regions of the brain. In addition, CT scanning will often provide evidence of the underlying sinus thrombosis: the hyperdense sinus sign or, less reliably, the so-called 'empty delta sign' after injection of intravenous contrast material.

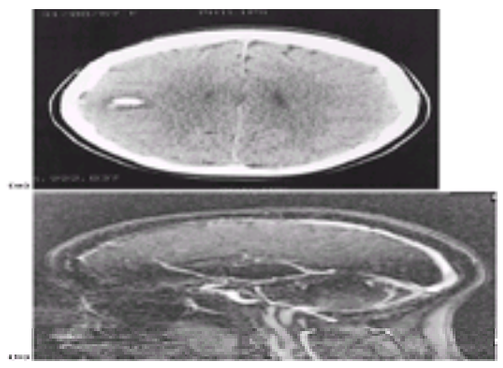

Fig. 5 Cerebral venous thrombosis in a 27-year-old woman. (a) This CT scan shows a small infarct with haemorrhagic transformation in the right brain hemisphere, adjacent to the top of the lateral ventricle. (b) Magnetic resonance imaging, focused on venous structures, shows non-filling of the frontal part (on the reader's left) of the superior sagittal sinus.

MRI

Magnetic resonance imaging has made catheter angiography redundant in the diagnosis of cerebral venous thrombosis. It is not sufficient to rely on non-visualization of a cerebral sinus on MR venography, since this may represent hypoplasia. Demonstration of the thrombus itself is essential, but this greatly depends on the interval from disease onset. Three stages can be distinguished. In the acute stage (days 1 to 5) the thrombus appears strongly hypointense in *T*2-weighted images and isointense in *T*1-weighted images. In the subacute stage (up to day 15) the thrombus signal is strongly hyperintense, initially on *T*1-weighted images and subsequently also on *T*2-weighted images. The third stage begins 3 or 4 weeks after symptom onset: the thrombus signal becomes isointense on *T*1-weighted images but remains hyperintense on *T*2-weighted images, though often inhomogeneously. Recanalization may occur over months in up to one-third of patients, but persistent abnormalities are common and do not signify recurrent thrombosis.

Treatment and prognosis

Anticoagulant treatment is plausible, but the evidence from controlled clinical trials is sparse. In the acute phase, heparin (low molecular weight heparin, either intravenously or subcutaneously) seems preferable to oral anticoagulants, because its intensity can be closely monitored. The totality of the evidence for heparin treatment consists of no more than 80 randomized patients; there is a non-significant trend towards a better outcome in treated patients. At least heparin treatment seems safe, even in patients with haemorrhagic infarcts. Local thrombolysis via endovascular catheters has only been performed in uncontrolled studies.

Death rates in different series range between 5 per cent and 30 per cent, and probably depend more on case mix than on treatment. Residual deficits consist mostly of hemispherical deficits or visual impairment from optic atrophy.

The risk of recurrence has seldom been addressed systematically, but is probably in the order of 10 per cent. It seems wise to advise other means of contraception than 'the pill'. In women with a peripartum episode of cerebral venous thrombosis the available evidence does not warrant the advice to avoid a further pregnancy, although in patients with the factor V Leiden mutation the risk of a recurrent episode is probably higher than average.

Primary intracerebral haemorrhage

Causes of primary intracerebral haemorrhage

In most cases there is no single cause for a primary intracerebral haemorrhage. Even in the classical example of a so-called hypertensive haemorrhage in the region of the basal ganglia, the question is what anatomical or other factors distinguished this patient from others, in whom there were similar degrees and duration of hypertension but no brain haemorrhage. Even a combination of recognized 'causes', such as that of hypertension and anticoagulants, does not invariably lead to intracerebral haemorrhage. In general, therefore, several causal factors combine. These can be broadly distinguished into three categories (Table 5): anatomical factors (lesions or malformations of the brain vasculature), haemodynamic factors (blood pressure), and haemostatic factors (to do with platelet function or with the

coagulation system). Abnormalities of the vascular system account for the vast majority of haemorrhages. The type of underlying abnormality varies with age: below the age of 40 years arteriovenous malformations or cavernomas are the most common single causes, whereas between 40 and 70 years the most frequent sources are ruptured perforating arteries (deep haemorrhages); in the elderly one also finds haemorrhages in the white matter ('lobar' haemorrhages), commonly attributed to amyloid angiopathy.

'Hypertensive' intracerebral haemorrhage

'Hypertensive' intracerebral haemorrhage results from degenerative changes in small perforating vessels, in the deep regions of the brain (basal ganglia and thalamus; Fig. 6), or in the cerebellum or brainstem. Microaneurysms occur on these vessels but are not necessarily the site of rupture. It is probable that rupture of a single small artery leads to a cascade of secondary haemorrhages from adjacent arterioles. This might explain the rapid expansion of intracerebral haematomas seen during a single scanning procedure or on serial scanning. A stable phase is usually reached in a matter of hours.

Deep brain haemorrhages are not always a one-time event. The recurrence rate in the first year is 7 per cent, against 2 per cent per annum over the subsequent 6 years.

Amyloid angiopathy

This condition accounts for about 10 per cent of intracerebral haemorrhages. Its frequency rises with age, but so does that of 'hypertensive' haemorrhage. The underlying abnormality consists of patchy deposits of amyloid in the muscle layer of small- and medium-sized cortical arteries of the occipital, parietal, and frontal lobes. Amyloid can also be found in asymptomatic individuals, the proportion increasing with age. It is not found outside the brain and does not represent generalized amyloidosis. Haemorrhages associated with amyloid angiopathy typically occur at the border of the grey and white matter of the cerebral hemispheres. Recurrent haemorrhage associated with amyloid angiopathy is much more common than with 'hypertensive' small-vessel disease. Autosomal dominant forms of amyloid angiopathy occur in The Netherlands and in Iceland.

Possible manifestations of amyloid angiopathy other than haemorrhage are transient episodes of focal neurological deficits, and also intellectual deterioration, associated with diffuse demyelination of the subcortical white matter (leukoaraiosis).

Cerebral arteriovenous malformations (AVMs)

AVMs are tangles of dilated arteries and veins, without a capillary network between them. On angiography, they are recognizable by large feeding arteries and a rapid shunting of blood to enlarged and tortuous veins via a central nidus of dilated vessels. Haemorrhage is the initial clinical manifestation in 50 to 60 per cent of symptomatic AVMs. Other clinical features include epileptic seizures, headaches, and progressive neurological deficits. Demonstrable AVMs are the most common single cause of intracerebral haemorrhage in patients under 45 years of age (about 30 per cent).

Between 10 and 20 per cent of AVMs are associated with thin-walled saccular aneurysms. These occur on peripheral feeding arteries, not at the classical sites at the circle of Willis, and are likely sources of bleeding. In AVMs in which one or more aneurysms have formed, the annual risk of rebleeding is as high as 7 per cent, against 2 to 3 per cent per annum for other AVMs. If there is no associated aneurysm, the site of rupture is mostly on the venous side of the malformation.

Cavernous angiomas (cavernomas)

Cavernous angiomas consist of sharply demarcated areas with widely dilated and thin-walled vascular channels, without intervening brain tissue. They are often asymptomatic and are encountered in 0.5 per cent of routine postmortems—in the white matter or cortex of a cerebral hemisphere in about one-half of all cases, in the posterior fossa in one-third, and in the basal ganglia or thalamus in one-sixth. If a cavernoma is at all symptomatic, epileptic seizures are at least as common a manifestation as haemorrhage. The annual risk of haemorrhage in patients in whom the lesion presents with seizures or focal deficits is rather low, between 0.25 per cent and 0.6 per cent. After a first rupture, rebleeding is more frequent, around 4.5 per cent per annum. Haemorrhages from a cavernous angioma are rarely fatal.

Familial forms of the disorder occur in several countries around the world, and should be suspected if multiple cavernomas are found.

Diagnosis of primary intracerebral haemorrhage

History

The history sometimes suggests the cause of the haemorrhage. Previous epileptic seizures should raise suspicions about the presence of an arteriovenous malformation, cavernoma, or a tumour. Amyloid angiopathy should come to mind with a history of transient ischaemic attacks, intellectual deterioration, or both. A record of long-standing hypertension indicates small-vessel diseases as the most probable underlying condition in a patient with a haematoma in the basal ganglia or in the posterior fossa; on the other hand, hypertension is so common that it may coexist with other conditions. If the patient is known to have had cancer, haemorrhage into a brain metastasis is a strong possibility. The use of oral anticoagulants is a vital piece of information in patients with intracerebral haemorrhage, because their action should be neutralized as soon as possible. It is equally important to know about the use of recreational drugs, particularly cocaine and amphetamines. Finally, the circumstances preceding an intracerebral haemorrhage may help to identify its cause, such as puerperium (intracranial venous thrombosis, choriocarcinoma), or neck trauma (dissection of the vertebral or carotid artery).

Physical examination

The physical examination will provide rather few clues to the cause of an intracerebral haemorrhage, except for petechiae or bruising, which indicate a generalized haemostatic disorder, signs of malignant disease such as cutaneous melanoma, a collapsed lung or enlargement of the liver or spleen, or telangiectasias in the skin and mucous membranes. Finding a high blood pressure on admission is the rule, but only in about 50 per cent is there is evidence of long-standing hypertension. Retinal haemorrhages indicate intracranial bleeding in general, most often a subarachnoid haemorrhage. Heart murmurs may be coincidental but should at least raise the possibility of infective endocarditis, as should the finding of needle marks in possible drug addicts. The neurological examination will show focal deficits corresponding to the site of the lesion, with or without a decreased level of consciousness.

Investigations

Investigations should start with the usual tests of blood and serum. These will sometimes uncover a cause of intracerebral haemorrhage, such as a low platelet count or massive liver damage. Brain imaging (CT or MRI) is the most important single investigation in patients with suspected intracerebral haematomas. The location of the haematoma may to some extent indicate the underlying cause. Intraventricular extension of the haemorrhage occurs relatively often with deep, 'hypertensive' haemorrhages. The presence of a fluid-blood level within the haematoma strongly suggests an underlying coagulopathy, either iatrogenic or from haematological disease. A grossly irregular margin of a lobar haematoma suggests amyloid angiopathy. Multiple or recurrent haemorrhages in the white matter suggest amyloid angiopathy, at least in the elderly. Intracranial venous thrombosis should be suspected with irregularly shaped haemorrhages in the parasagittal region. Repeat brain CT after injection of contrast may pick up underlying lesions. Sometimes these can only be identified weeks later, when the lesion is no longer obscured by mass effects.

Treatment of primary intracerebral haemorrhage

Factors predicting the prognosis for the survival of patients with primary intracerebral haemorrhage are: level of consciousness (Glasgow Coma Scale); age; volume of haematoma (poor prognosis if supratentorial haematoma >50 ml); and intraventricular extension of haemorrhage (poor prognosis if volume >20 ml). Of course, the possible interventions outlined below apply only to patients who have a chance of survival.

In patients taking oral anticoagulants the first step is the intravenous injection of 10 to 20 mg of vitamin K, at no more than 5 mg/min, followed by infusion of a concentrate of the coagulation factors II, VII, IX, and X, or of fresh-frozen plasma.

Intracranial pressure is often raised. Factors other than the local effects of the haematoma may contribute, such as fever, hypoxia, hypertension, seizures, and elevations of intrathoracic pressure. An unsolved question is the use, in comatose patients, of monitoring and, if judged appropriate, lowering intracranial pressure. There are many believers of this approach but few controlled studies. Insertion of a ventricular catheter may be a definitive measure in patients with cerebellar haemorrhage and no signs of direct compression of the brainstem.

There is insufficient evidence of benefit for the surgical treatment of supratentorial haematoma. Randomized trials have at best been inconclusive, including those employing endoscopic evacuation. In patients with cerebellar haematomas there is no doubt that surgical evacuation can be lifesaving, often with surprisingly few neurological sequelae. Sound indications for evacuation are the combination of a depressed level of consciousness with signs of progressive brainstem compression (unless all brainstem reflexes have been lost for more than a few hours, in which case a fatal outcome is unavoidable), or a haematoma greater than 3 to 4 cm. If the patient has a depressed level of consciousness and hydrocephalus, without signs of brainstem compression and with a haematoma less than 3 cm, ventriculostomy can be carried out as an initial (and sometimes only) procedure.

Subarachnoid haemorrhage

Causes of subarachnoid haemorrhage

Ruptured aneurysms are by far the most common source of non-traumatic subarachnoid haemorrhage (**SAH**), about 85 per cent of cases. Around 10 per cent are non-aneurysmal perimesencephalic haemorrhages, the remaining 5 per cent is made up by rarities (Table 6).

Cerebral aneurysms

Cerebral aneurysms are not congenital, they develop during the course of life. Therefore aneurysmal haemorrhage in a child is extremely rare. The aneurysms are saccular in shape and mostly arise at sites of arterial branching at the base of the brain, at or near the circle of Willis (see Fig. 7). It is largely unknown why some adults develop aneurysms. There are families with two or more affected first-degree relatives, but these account for less than 5 per cent of all SAHs. Many classical risk factors for stroke in general also apply to SAH: smoking, hypertension, heavy drinking, and oral contraceptives. Not all aneurysms rupture. Their prevalence can be estimated from angiographic studies (for other purposes) and autopsy studies at approximately 2 to 3 per cent in middle age, up to 5 per cent at the end of life. On the assumption that this proportion is 1 per cent for a standardized population across all age groups, and given that the incidence of SAH is approximately 6 per 100 000 (of the entire population), the annual risk of rupture of an aneurysm is 0.6 per cent.

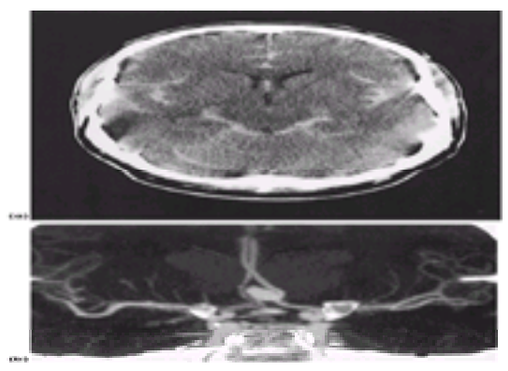

Fig. 7 Aneurysmal subarachnoid haemorrhage in a 31-year-old woman. (a) CT scanning shows evidence of extravasated blood throughout the basal cisterns. (b) CT angiogram, with intravenous contrast, shows an aneurysm at the anterior communicating artery.

Non-aneurysmal perimesencephalic haemorrhage

This is a distinct and benign variety of subarachnoid haemorrhage, in which the distribution of extravasated blood on the brain CT scan is different from that seen with aneurysms, in the cisterns around the midbrain or ventral to the pons. The angiogram is completely normal, and the long-term outcome is invariably excellent. This subtype constitutes 10 per cent of all subarachnoid haemorrhages and two-thirds of subarachnoid haemorrhages with a normal angiogram.

Diagnosis of subarachnoid haemorrhage

History

The key feature in the history is that of a sudden, severe, and unusual headache. However, 50 per cent of patients lose consciousness at the onset, and the headache may emerge only later. The diagnosis is most difficult in patients with headache as the only feature. In general practice, exceptionally sudden forms of common headaches outnumber ruptured aneurysms. The incidence of aneurysmal haemorrhage being about 6 per 100 000 of the population per year, the average general practitioner will, on average, see one such patient every 8 years. There are no single or combined features of the headache that distinguish reliably, and at an early stage, between SAH and innocuous types of sudden headache. The discomfort and cost of referring the majority of patients for only a brief consultation in hospital is a reasonable price to pay for avoiding misdiagnosis of a ruptured aneurysm.

Physical examination

The physical examination is unhelpful in patients with a headache alone, without loss of consciousness or focal deficits. Neck stiffness takes about 6 h to develop, so its absence soon after the onset does not make the diagnosis of SAH more unlikely.

Investigations

CT scanning is the most important investigation. This will show extravasation of blood in the basal cisterns of the brain in at least 95 per cent of patients with a ruptured aneurysm, if the scan is performed within 3 days (Fig. 7)—after this interval the sensitivity of CT scanning quickly decreases. In patients with a negative CT scan but a convincing history, lumbar puncture is indicated. If the cerebrospinal fluid (**CSF**) is blood-stained, it is essential to distinguish SAH reliably from a traumatic tap. For that purpose at least 6 h, and preferably 12 h, should have elapsed from symptom onset. In cases of SAH, sufficient lysis of red cells will have occurred in the meantime for bilirubin and oxyhaemoglobin to have formed. These pigments give the CSF a yellow tinge after centrifugation (xanthochromia); they are invariably detectable until at least 2 weeks later. The 'three tube test' (a decrease in red cells in consecutive tubes in the case of a traumatic puncture) is notoriously unreliable. If the supernatant seems crystal-clear, the specimen should be stored in darkness until the absence of blood pigments is confirmed by spectrophotometry. Cerebral angiography is necessary for demonstrating or excluding an aneurysm as the source of haemorrhage; catheter methods are rapidly being replaced by CT and MR angiography (Fig. 7).

Treatment of aneurysmal subarachnoid haemorrhage

Several complications may occur after a first episode of an aneurysmal SAH, of which rebleeding and cerebral ischaemia are the most dreaded. Despite advances in surgical and medical management, the population-based case fatality rate is still around 50 per cent, with half of the survivors remaining more or less disabled.

As general nursing measures, continuous observation and an intravenous access are essential. A bladder catheter is necessary for monitoring fluid balance. Headache should be relieved in a step-wise approach, with paracetamol and codeine as first steps. Distressing anxiety can be alleviated with short-acting

benzodiazepines. Stools should be kept soft with oral laxatives and also by an adequate intake of fluids.

Prevention of rebleeding is challenging, if only because any effective measure tends to be offset by an increased risk of ischaemia. Moreover, at least 10 per cent of all patients with SAH suffer a further bleed within hours of the initial haemorrhage. Over the next 4 weeks the rate of rebleeding without intervention is at least 30 per cent. The immediate case fatality rate of rebleeding is 50 per cent. Surgical clipping of the aneurysm is the most effective method of treatment, but the earlier the operation is performed, the greater the risk of ischaemic complications. Endovascular treatment ('coiling') is rapidly gaining ground; however, whether the balance between effectiveness and safety is more favourable than with surgery needs to be determined by clinical trials. Antifibrinolytic drugs decrease the rate of rebleeding but do not improve overall outcome.

Delayed cerebral ischaemia occurs in up to 25 per cent of patients with a ruptured aneurysm, mainly between days 5 and 14 after the initial bleed. Understanding its pathogenesis has been impeded by simplistic notions about 'vasospasm' or 'clots around vessels'. Narrowing of the arteries at the base of the brain is a factor, but not a sufficient one. The total amount of subarachnoid blood is a potent risk factor, but only after rupture of an artery, and the distribution of blood in the subarachnoid space does not predict the site of ischaemia. The calcium antagonist nimodipine, in a dose of 60 mg every 4 h by mouth or nasogastric tube, reduces the frequency of cerebral ischaemia and poor outcome by about one-third; its mode of action is incompletely understood. As a rule, hypertension should be left untreated; it is a compensatory reaction to maintain cerebral perfusion. The plasma volume should not be allowed to fall; hyponatraemia is caused by renal sodium depletion, and not, as still often believed, by dilution as a result of inappropriate secretion of antidiuretic hormone. Fluids should therefore be replaced and not restricted. The basic intake should be at least 3 litres per day, with intravenous fluids supplementing oral intake; compensation should be made for fever or a negative fluid balance.

24.13.8 Alzheimer's disease and other dementias

Clare J. Galton and John R. Hodges

Introduction

The definition of dementia has evolved from one of progressive global intellectual deterioration to a syndrome consisting of progressive impairment in memory and at least one other cognitive deficit (aphasia, apraxia, agnosia, or disturbance in executive function) in the absence of another explanatory central nervous system disorder, depression, or delirium (according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn (**DSM-IV**)). Even this recent syndrome concept is becoming inadequate, as researchers and clinicians become more aware of the specific early cognitive profiles associated with different dementia syndromes. For instance, in early Alzheimer's disease there may be isolated memory impairment many years before more widespread deficits develop.

Since dementia is predominantly a disorder of later life, it represents an increasing problem for individuals and society with the projected increase in the elderly population. It is estimated that the 18 million people with dementia worldwide will increase to 34 million by the year 2025. This increase is most marked in the developing countries, where the 11 million people with dementia in the year 2000 will reach 24 million by 2025. In the developed world, the equivalent figures are 7 million in 2000 and 11 million in 2025. In Europe alone, 4 million people will be affected by the year 2004.

Although the incidence of dementia is difficult to establish, community prevalence studies suggest that about 8 per cent of all people over 65 years of age suffer from dementia, this shows a marked increase with advancing age. The prevalence below 65 years is about 1:1000, this rises to 1:50 to the age of 70 and 1:20 from 70 to 80. Over 80 years of age the prevalence is 1:5.

Dementia has numerous causes that can be classified in many ways (Table 1 shows a classification by aetiology). Although a large number of medical and neurological conditions can occasionally cause a dementia syndrome, most of these are rare and have other neurological features that suggest the diagnosis, for example multiple sclerosis, the acquired immunodeficiency syndrome (**AIDS**) dementia complex, and the vasculitides. Routine investigation (see below) focuses on some of these rarer causes because, although rare, they often result in a reversible dementia. An alternative classification, based on the patterns of cognitive impairment, is that of subcortical and cortical dementias as illustrated in Table 2. This classification shows that disease of diverse cerebral structures can result in dementia but that the resultant patterns of cognitive deficits can be very different. Alzheimer's disease is the prototypical cortical dementia. Subcortical dementias are also discussed further below.

The most common causes of dementia before and after the age of 65 years are shown in Fig. 1. The relative frequencies of causes of dementia differ depending on age, but it is notable that Alzheimer's disease is the most common cause in both groups. The genetic forms of Alzheimer's disease and other rarer causes are more common in the younger age group. Before considering the common and treatable causes of dementia, we discuss the main differential diagnoses to be considered as alternatives to dementia.

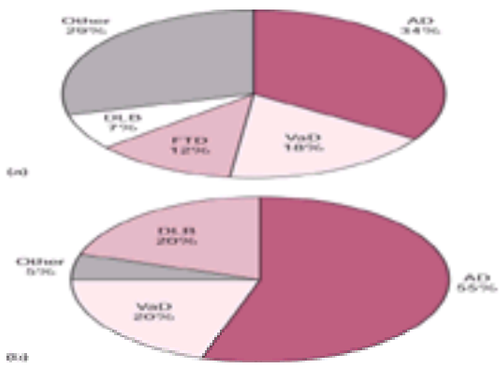

Fig. 1 (a) Relative frequencies of different dementia diagnoses in the under-65-year olds. (b) Relative frequencies of different dementia diagnoses in the over-65-year

olds. AD, Alzheimer's disease; VaD, vascular dementia; FTD, frontotemporal dementia; DLB, dementia with Lewy bodies.

Differential diagnosis

Pseudodementia

This term has been used to describe two disorders namely: depressive pseudodementia and hysterical pseudodementia. Cognitive symptoms are common in depression, particularly in the elderly population. The main complaints are of poor recent memory and concentration with distractibility. There is often a lack of subjective feelings of depression, thereby making the diagnosis difficult. The telltale signs are the so-called biological features of depression, such as sleep disturbance and a loss of appetite and libido. Other common symptoms are low energy and a lack of interest in hobbies and activities. There may be a past personal or familial history of depression. The cognitive picture is of impaired attention and subsequent patchy performance on memory and frontal tasks. There may be some inconsistency in test performance and patients easily give up on a task. Language output may be sparse but paraphrasic errors are not present. Even after detailed testing it may be difficult to distinguish depression from dementia, indeed there may also be some overlap between the syndromes in the elderly. For this reason, ideal practice would be for all newly presenting patients with dementia to undergo psychiatric assessment, and if any doubt remains a therapeutic trial of antidepressants may be warranted.

Hysterical pseudodementia commonly presents with a rapid onset of memory and/or intellectual impairment. There is loss of personal identity and salient personal and life events, which is unlike organic disorders of memory. There may be an obvious precipitant (such as marital problems, financial problems, or trouble with the law) and a past psychiatric history is common. 'Ganser syndrome' is a name for the condition where the patient gives bizarrely wrong answers to questions. For example, when asked 'How many legs does a horse have', they reply three or five. Even with such functional states, the examiner has to be aware of the potential concomitant organic disorder exaggerating the condition, as in other conversion disorders.

Delirium

This clinical syndrome is caused either by a diffuse brain pathology (for example, intracranial infections, head trauma, epilepsy (postictal states and non-convulsive status), raised intracranial pressure, subarachnoid haemorrhage) or is secondary to a large number of systemic illnesses or insults, including infections, metabolic derangements, hypoxia, and drugs.

The clinical features include the acute onset of attentional abnormalities and disturbance of consciousness (from clouding to coma), perceptual distortions, illusions and hallucinations, psychomotor disturbance (hypo- or hyperactivity and rapid shifts between the two), disturbance of the sleep–wake cycle, emotional lability, and marked fluctuations in performance and behaviour. The most consistent abnormality is in attention, with a reduced ability to maintain attention to external stimuli leading to distractibility and difficulty answering questions, and to appropriately shift attention to new stimuli leading to perseverations. The investigation and treatment needs to be focused in each case on the likely precipitants (although in about 5–20 per cent of the elderly no cause is found). Although the course and prognosis depend on the underlying diagnosis, if there is resolution of the precipitant there should be cognitive improvement to the baseline state.

Alzheimer's disease

Definition

Alzheimer's disease (**AD**) is the most common cause of dementia. Of the 5 to 10 per cent of the population aged over 65 years who have some kind of cognitive decline, over 50 per cent of cases will be due to AD and, although accounting for a smaller percentage of presenile cases, AD is still the single largest cause. The initial disease description by Alzheimer in 1907 was of a woman in her fifties with a progressive dementia and behavioural disturbance, who was found to have neurofibrillary tangles and amyloid plaques throughout her cerebral cortex. The term 'Alzheimer's disease' was then applied to similar cases with a presenile dementia, before it was realized that identical pathological changes were seen in the majority of elderly demented patients. Since plaques and tangles are found in a very high proportion of non-demented elderly subjects, debate continues about whether AD represents a continuum or a distinct disease process that increases in frequency with age. With recognition of a number of causative gene mutations (see below) AD is now generally believed to be a multifactorial disease with familial and sporadic forms.

Histological diagnosis remains the 'gold standard', but current research criteria, such as the widely used NINCDS-ADRDA (see Table 3), are accurate in up to 90 per cent of cases. Rather than merely being a diagnosis of exclusion, AD is now recognized as a clinicopathological entity amenable to positive diagnosis. Much recent research has focused on methods of early and accurate diagnosis, which is particularly important in view of the advent of potential disease-modifying treatments.

Epidemiology and risk factors

Age is the most important overall risk factor for AD. A positive family history is also a risk factor, although autosomal dominant presentations account for less than 5 per cent of cases. To date, three major causative gene mutations have been established: mutations in the presenilin genes I and II on chromosome 14 and 1, respectively, and involving the amyloid precursor protein (**APP**) gene on chromosome 21. In these families the onset is invariably at an early age (35–55 years), with remarkable consistency within families and, as with Huntington's disease, penetrance is complete. Dementia is rapidly progressive and seizures and myoclonus are common. Individuals with Down's syndrome (trisomy 21) develop Alzheimer's disease during their third and fourth decades. This is thought to be due to the extra copy of the amyloid precursor gene on chromosome 21.

Apolipoprotein E (**ApoE**) is a risk factor rather than a causative gene for AD in both early- and late-onset cases, which at present is thought to be the single most common genetic determinant of a susceptibility to late-onset Alzheimer's disease. ApoE is a component of several classes of plasma and cerebrospinal fluid lipoproteins. The brain is the most important site of ApoE production outside the liver, and ApoE is thought to be important in lipid homeostasis in the brain. There are three common alleles for the *ApoE* gene: *e2*, *e3*, and *e4*. One or two *e4* alleles confer an increased risk of Alzheimer's disease and lower the age of onset in a 'dose-dependent' fashion.

Many meticulous epidemiological studies have established that women are at an increased risk for AD, even after adjusting for confounding factors such as the increased longevity of women and their over-representation in the elderly population, and the increased vascular disease in men. Possible explanations include hormonal effects and the postmenopausal loss of potential protective effects of oestrogen. Significant head trauma in earlier life is also a risk factor that may summate with ApoE status, and there appears to be a unexplained protective effect of non-steroidal anti-inflammatory drugs.

Pathology

Pathologically, the macroscopic features of Alzheimer's disease are cortical atrophy, particularly involving the medial temporal lobe and parietotemporal association areas with relative sparing the primary sensory motor and visual cortices. The pathological process is thought to start in the entorhinal cortex, hippocampus, and other medial temporal lobe structures before spreading to the temporoparietal neocortex and basal frontal cortex, and then to the other association areas. The histological hallmarks are the senile plaques and neurofibrillary tangles (see Fig. 2 and Fig. 3, respectively). Neither lesion is specific for Alzheimer's disease, as both are found to a lesser extent in the ageing brain; neurofibrillary tangles are also seen in a range of diseases, including progressive supranuclear palsy, encephalitis lethargica, postencephalitic parkinsonism, cerebral trauma, and dementia pugilistica.

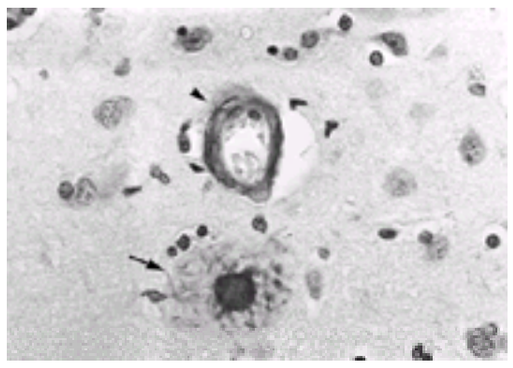

Fig. 2 Amyloid plaque.

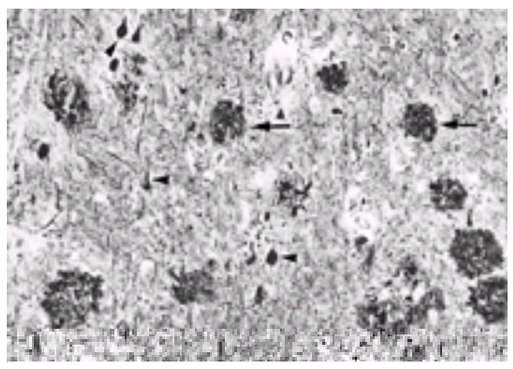

Fig. 3 Neurofibrillary tangle.

Neurofibrillary tangles are formed from bundles of paired helical filaments that replace the normal neuronal cytoskeleton. The central core of the paired helical filaments is the microtubule-associated protein tau. The abnormal phosphorylation of the tau protein causes the microtubular abnormalities and the subsequent collapse of the cytoskeleton. The neurofibrillary tangles are seen as intensely staining intraneuronal inclusions with silver stains or specific anti-tau immunochemistry.

A variety of amyloid plaques are observed in Alzheimer's disease. Diffuse amyloid plaques have a loose accumulation of b/A4 amyloid without surrounding abnormal neurites, and are considered to be precursors to neuritic plaques. The mature neuritic plaque consists of a dense core of b/A4 amyloid surrounded by a halo and ring of abnormal neurites, before this stage the plaque is a loose accumulation of b/A4 amyloid surrounded by abnormal neurites. A hypermature plaque has a dense core of b/A4 amyloid surrounded by reactive astrocytes but without abnormal neurones. The role of microvascular pathology in AD remains controversial. Cerebral congophilic angiopathy can be seen in a high proportion of cases and almost certainly contributes to the hyperintense lesions commonly seen on *T*2-weighted magnetic resonance imaging (**MRI**) scans.

Besides a reduction in synaptic loss from neurones, which may explain some cognitive sequelae of the pathology, there is a major loss of neurotransmitters—especially of acetylcholine. The 'cholinergic hypothesis' of neurotransmitter loss causing attentional and mnemonic dysfunction has been much investigated. There is certainly evidence of severe neuronal loss in the nucleus basalis of Meynert in the basal forebrain, the major site of cholinergic neurones, and the current therapies are armed at improving cognitive function through inhibition of anticholinesterases. There is also disruption to other neurotransmitters including the serotonin system.

Pathophysiology

The increased understanding of the genetics of Alzheimer's disease has led to some advances in theories of the molecular basis of this condition. The b/A4 amyloid is formed from the cleavage of a larger molecule, amyloid precursor protein (APP) of approximately 700 amino acids. Mutations in either the presenilin gene (presenilin I and II) or the amyloid precursor protein gene affect APP and its metabolism, supporting the amyloid cascade hypothesis of Alzheimer's disease pathogenesis (see Fig. 4). APP is cleaved by beta- and gamma-secretases to produce b/A4 amyloid at a length of between 39 and 43 amino acids: the shorter fragments remain in solution, while longer peptides, the result of abnormal cleavage sites, are more prone to aggregate and form insoluble amyloid deposits. Besides mutations in the *APP* gene altering the cleavage site, there is evidence that presenilin genes affect the gamma-secretase-mediated cleavage of the transmembrane section of APP. The amyloid hypothesis suggests that accumulation of beta-amyloid, by overproduction or failure to break down, leads to amyloid deposition, thereby causing amyloid plaques, and leading to neurofibrillary tangles and cell death. There is evidence that insoluble b/A4 amyloid is toxic and that this may disrupt calcium homeostasis and enhance the production of glutamate. This hypothesis is still controversial; it explains rare familial cases and the association with trisomy 21, but the role of tau pathology, the formation of neurofibrillary tangles, and ApoE are not yet fully incorporated into a unifying model.

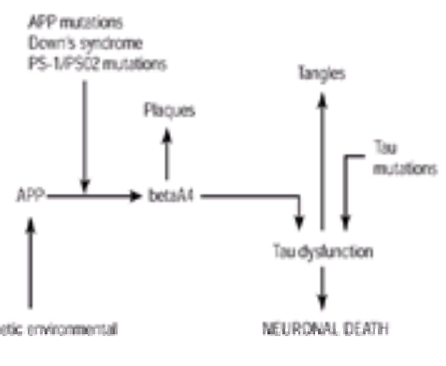

Fig. 4 Proposed pathogenesis of Alzheimer's disease.

Clinical features

The earliest cognitive deficit is impairment of so-called episodic memory (memories for events or episodes, including day-to-day memory and new learning), which is thought to reflect the earliest site of pathology in the medial temporal lobe structures. 'Minimal or mild cognitive impairment' (**MCI**) is a term increasingly used for people who are impaired on episodic memory tasks but who do not otherwise fit the criteria for a diagnosis of dementia. It is becoming clear that many, if not all, such people are in the predementia or early stage of AD, but progression to a full-blown dementia syndrome can take several years. The main clinical features at this stage are severe forgetfulness with often repetitive questioning and impairments in social function or job performance particularly concerning the retention of new information. As the disease progresses to mild Alzheimer's disease, memory function worsens, particularly affecting recall (for example, forgetting recent visits or family events), increasing disability in managing complex day-to-day activities such as finances and shopping, mental inflexibility and poor concentration, which reflects involvement of attentional and executive function. Insight is variably affected, often patients retain a partial awareness into their difficulties but underestimate the extent of the problem. Remote memory is relatively well preserved with a temporally graded pattern (that is, sparing of most distant memories). As the disease continues to progress patients often develop impairments in language, most typically word-finding difficulties, a shrinking vocabulary, and poor understanding of

complex words and concepts. Visuospatial impairments and apraxia, which may develop at this stage, are particularly disabling, causing difficulty in dressing, cooking, and performing other daily activities. In a small subgroup of patients, language or visuospatial difficulties can be the first or most prominent presenting feature. As the cognitive deficits progress there is worsening of language function and semantic memory, and behavioural problems can be prominent.

Neuropsychiatric symptoms are also common in the earliest stages of AD, particularly apathy, anxiety, and mood disturbance. Delusions and hallucinations occur in up to 50 and 30 per cent of patients, respectively, in the later stages. Agitation, restlessness, wandering, and disinhibition also cause considerable carer burden. The final stages of the disease are characterized by reduced speech output (or mutism), ambulatory difficulties, dependence, and incontinence. Seizures and myoclonus are common late features. There is considerable variation in the time to this stage, but the average time from diagnosis to death is around 10 years.

Neurological examination is unremarkable in the early stages, although increased tone (often frontal resistant, or gegenhalten, in type) and mild extrapyramidal features can occur as the disease progresses. Reflex changes such as extensor plantar responses (Babinski reflex) and—in contrast to frontotemporal dementia—pout, snout, and grasp reflexes occur late. In the final stages, there can be greatly increased rigidity and joint contractures.

Investigation

The aims of neuropsychological, imaging, and laboratory investigations in Alzheimer's disease are twofold: first to exclude other potentially reversible causes of dementia, and second to confirm the diagnosis of probable Alzheimer's disease. The extent and nature of investigation obviously needs to be tailored to the individual, but all patients should undergo brain imaging and have a neuropsychological assessment to confirm the diagnosis of dementia. The neuropsychological profile can also be informative in the differential diagnosis of dementia (see Table 2). Particularly characteristic is early impairment in delayed verbal recall of new material, followed by reduced category fluency (in which subjects are asked to generate exemplars from a given category, for example 'animals'), impaired naming of low-frequency words, and difficulty with complex visuospatial tasks such as copying complex figures or block design from the revised Wechsler Adult Intelligence Scale (**WAIS-R**).

The basic laboratory investigations required in all patients, particularly to exclude treatable causes of dementia, and some of the other investigations that may be indicated in certain cases depending on the patient's age, family history, or specific medical history are shown in Table 4. Research into biological markers of AD is yet to yield a consistent biological or surrogate marker. Screening for specific gene mutations in young-onset familial cases is only available in specialist centres.

Magnetic resonance imaging scans of patients with Alzheimer's disease in the earliest stages (including MCI) show evidence of atrophy of the hippocampus and entorhinal cortex (parahippocampal gyrus) reflecting the pathology (Fig. 5). Unfortunately, the variability in size of these structures in normal elderly subjects means that, at present, these imaging abnormalities are not specific enough to be of predictive value. The co-registration of serial MRIs appears capable of detecting abnormal rates of brain atrophy, even before the onset of clear-cut cognitive symptoms in at-risk familial cases, but it remains a research instrument. *T*2-weighted MRI often reveals periventricular high-signal changes even in 'pure' early-onset cases. Single-photon emission computed tomography (**SPECT**) scans similarly demonstrate typical abnormalities in the parietotemporal regions but the specificity is again low in individual cases. More recent technological developments, such as perfusion MRI, magnetic resonance spectroscopy (**MRS**), and photon emission tomography (**PET**) scans may enhance diagnostic accuracy but are expensive and not yet suitable for routine clinical use.

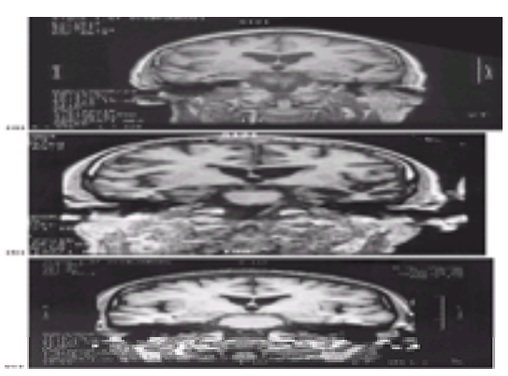

Fig. 5 (a) Coronal *T*1-weighted MRI scan of a patient with early Alzheimer's disease showing bilateral early hippocampal atrophy. (b) Coronal *T*1-weighted MRI image of a patient with FTD showing left temporal atrophy. (c) Coronal *T*1-weighted MRI scan of a normal subject.

Management and prognosis

The management of a patient with dementia involves many sensitive issues. It is crucial to provide medical and psychological support to patients as well as to their families and carers. During the progression of the disease there will be different treatment goals at different stages, ranging from aiding failing memory in the setting of independent living to managing behavioural problems and aggression, and eventually full supportive nursing care. There is great variation in the rate of progression, young-onset cases and those with prominent aphasia appear to deteriorate most rapidly. On average, patients spend several years in the mild or minimal stages (although it can be as long as 5 to 10 years), between 4 and 5 years in the moderate disease stages, and depending on the quality of care in the dependant stages, a year or more requiring full nursing care.

Non-pharmacological treatment

The mainstay of treatment is social support and increasing assistance with day-to-day activities. Issues such as driving and planning for future financial affairs are important and should be discussed early in the course of the disease. Throughout the course of the illness there will be differing requirements for the support services listed below:

- information and education;
- carer support groups;
- community dementia team, including home nursing and personal care;
- community services such as meals-on-wheels, community transport services, home maintenance assistance;
- sitter service;
- day centre;
- respite care; and
- residential/nursing home.

Pharmacological treatment

Pharmacological treatments can be divided into symptom- and disease-orientated approaches. Symptom modification relates to the treatment of depression, agitation, and psychotic phenomena and requires the input from a specialist psychiatrist. The cholinesterase inhibitors donepezil and rivastigmine are the only disease-specific drugs licensed for use in the United Kingdom. The importance of acetylcholine depletion in AD is established; these cholinesterase inhibitors generally achieve modest improvements in cognition in 25 to 50 per cent of the patients studied. However, the disease-modifying effects of these drugs remain controversial. Antioxidants (such as vitamin E), ginkgo biloba, and monoamine oxidase-B (**MAO-B**) inhibitors have shown benefits in some clinical trials, although again their long-term benefit is yet to be established. Pilot trials and experimental studies are being conducted at present in this area. Ideally, the goal is to prevent patients developing further cognitive deficits and to prevent those with MCI from progressing to dementia. The epidemiological findings of protection from cognitive decline in women using hormone-replacement therapy (**HRT**) is of interest in developing preventive strategies, and a trial is in progress to look at the effect of HRT in preventing or delaying the onset of dementia. Further research on the role of the amyloid and tau proteins in the pathogenesis of Alzheimer's disease will be the spur to both curative and preventive treatment for this common dementia.

Frontotemporal dementia

Definition

Frontotemporal dementia (**FTD**) is now preferred to the older term 'Pick's disease', to describe patients with focal frontal and/or temporal focal atrophy, since the underlying pathology of these syndromes can be variable. Arnold Pick (1851–1924) first described patients with both progressive aphasia, associated severe left temporal cortical atrophy at postmortem, and patients with behavioural disturbances associated with frontal lobe atrophy. In 1910, Alzheimer described the histological changes in patients with focal lobar degeneration as distinct from the syndrome that bears his name. Alzheimer described both argyrophilic intracytoplasmic inclusions (Pick bodies) and diffusely staining ballooned neurones (Pick cells). More recently it has become clear that these pathological changes are not the only features that accompany the clinical syndromes of frontal and temporal dementias; some patients have non-specific changes of neuronal loss, spongiosis, and gliosis only, while others have rather different ubiquitin-positive neuronal inclusions. The concept, therefore, has been broadened to accommodate differing underlying neuropathological features.

Epidemiology

FTD is increasingly recognized as a common cause of dementia, particularly in the younger age groups (see Fig. 1(a))—the peak incidence of onset being 45 to 65 years of age. In hospital series, the ratio of FTD to Alzheimer's disease has been found to vary from 1:5 to 1:20, with men and women being equally affected. Many cases are familial with up to 40 per cent having an affected family member.

Pathology and aetiology

The gross pathological appearance of FTD is that of profoundly atrophied frontotemporal regions that may be so severe as to produced the so-called knife-edged gyri and deep widened sulci. The histopathological hallmarks are widespread cortical and subcortical gliosis and loss of large cortical nerve cells. Severe astrocytosis with swollen neurones (Pick cells) and inclusions (Pick bodies), that are both tau- and ubiquitin-positive, are seen in about 20 per cent of cases. Pick bodies are intracytoplasmic argyrophilic neuronal inclusions composed of straight filaments, microtubules, and occasional paired helical filaments. In other patients there may be spongiform degeneration or microvacuolation of the superficial neuropil (cortical layer II) with no inclusions. Frontotemporal dementia can be seen with motor neurone disease, in which the histological changes above are combined with loss of anterior horn cells and motor neurone cells, particularly of the hypoglossal nuclei.

The aetiological basis of this disease is presently unknown. In some familial cases there is a mutation in the microtubule-associated protein tau gene on chromosome 17.

Clinical features

The presentation of frontotemporal dementia mirrors the neuropathological areas of disease; in the early stages frontal and temporal presentations can be distinguished.

Frontal presentations

Patients present with insidiously progressive changes in personality and behaviour that reflect the early locus of pathology in ventromedial frontal lobes. There is often impaired judgement, an indifference to domestic and professional responsibilities, and a lack of initiation and apathy. Social skills deteriorate and there can be socially inappropriate behaviour, fatuousness, jocularity, abnormal sexual behaviour, or theft. Many patients are restless with an obsessive–compulsive behaviour, such as hoarding food. Emotional lability and mood swings are seen, but other psychiatric phenomena such as delusions and hallucinations are rare. Patients become rigid and stereotyped in their daily routines and food choices. A change in food preference towards sweet foods is very characteristic. Of importance is the fact that simple bedside cognitive screening tests such as the Mini-Mental State Examination (**MMSE**) are insensitive at detecting frontal abnormalities. More detailed neuropsychological tests of frontal function (such as the Wisconsin Card Sorting Test or the Stroop Test) usually show abnormalities. Speech output can be reduced with a tendency to echolalia (repeating the examiner's last phrase). Memory is relatively spared in the early stages, although it does deteriorate as the disease advances. Visuospatial function remains remarkably unaffected. Primary motor and sensory functions remain normal. Primitive reflexes such as snout, pout, and grasp develop during the disease process. Muscle fasciculations, or wasting particularly affecting the bulbar musculature, can develop in the FTD subtype associated with motor neurone disease.

Temporal presentations

Temporal lobe degeneration presents with a form of progressive fluent aphasia, also known as semantic dementia, in which there is a profound loss in conceptual knowledge (or semantic memory) causing anomia and impaired comprehension of words, objects, or faces. The patient typically complains of 'loss of memory for words' and has fluent, empty speech with substitutions such as 'thing' 'one of those' etc., but the grammatical aspects are preserved. Naming is impaired with semantically based errors (such as 'animal' or 'horse' for zebra). Patients are unable to understand less frequent words and fail on a range of semantically based tasks such as matching words to pictures and matching pictures according to their meaning. Repetition of words and phrases is normal even though patients are unaware of their meaning. Unlike patients with Alzheimer's disease, day-to-day memory (episodic memory) with good visuospatial skills and non-verbal problem-solving ability is relatively preserved, at least in the early stages.

Another form of progressive focal atrophy, described by Mesulam, produces progressive non-fluent aphasia. Such patients present with a gradual loss of expressive abilities and gross impairments in the phonological (sound-based) and grammatical aspects of language production. This leads to non-fluent, agrammatical, and poorly articulated speech with multiple phonological errors (for example, sitter for sister or fencil for pencil). Repetition of multisyllabic words and phrases is impaired but, in contrast to semantic dementia, word comprehension and object recognition are well preserved.

Diagnosis

The diagnosis of frontotemporal dementia is based on the clinical, neuropsychological, and imaging assessments. The consensus broad clinical criteria are shown in Table 5. The differences between the various syndromes described above is obvious early in the disease, but there is increasing overlap between the temporal and frontal syndromes as the disease progresses. MRI demonstrates a characteristic pattern of frontal and/or temporal lobe atrophy: in contrast to Alzheimer's disease, the changes involve the polar and lateral temporal structures and are asymmetrical, commonly involving the left side to a greater extent (see Fig. 5). The functional imaging (single-photon emission tomography (**SPECT**) or positron emisson tomography (**PET**)) findings mirror the structural imaging results, with reduced frontotemporal perfusion and hypometabolism.

Management and prognosis

There is no curative treatment at present, thus the general management of the dementia sufferer and their family, as discussed above, is of prime importance. The prognosis can be variable with differing rates of progression between individuals. The disease is progressive and the average duration from diagnosis is around 5 to 10 years.

Dementia with Lewy bodies

Definition

Since the discovery in the 1960s that patients with Lewy bodies (ubiquitin-positive inclusions) in the cortex have a distinctive pattern of dementia with features of both Parkinson's and Alzheimer's disease, it has been increasingly recognized as an important cause of dementia. The terminology has been confusing with multiple designations including: Lewy body dementia, dementia of Lewy body type, diffuse Lewy body disease, and cortical Lewy body disease. The consensus clinical criteria for 'dementia with Lewy bodies' (**DLB**), the term now preferred, are shown in Table 6.

Epidemiology

Dementia with Lewy bodies is a common cause of dementia in the elderly population, although the true prevalence remains unclear. As many as 12 to 36 per cent of patients with a clinical diagnosis of Alzheimer's disease reach the pathological criteria for a diagnosis of dementia with Lewy bodies.

Pathology

Pathological criteria require the presence of cortical and subcortical Lewy bodies. Confusingly, there is considerable overlap with the histological features of both Parkinson's and Alzheimer's diseases, although the distribution of pathology is the key to distinguishing these conditions. Lewy bodies are intracytoplasmic eosinophilic neural inclusions formed from altered cytoskeleton components that can be seen on haematoxylin and eosin staining, but are more prominently shown using anti-ubiquitin immunohistochemistry. Cortical Lewy bodies are found in the temporal lobe, insular cortex, and cingulate gyrus, and are always accompanied by typical 'core and halo' Lewy bodies in the substantia nigra (the pathological hallmark of Parkinson's disease). Dystrophic ubiquitin-positive neurites are also seen in the hippocampus, amygdala, nucleus basalis of Meynert, and other brainstem nuclei.

Alzheimer changes—neurofibrillary tangles and amyloid plaques—are seen in up to 50 per cent of cases, raising nosological issues with Alzheimer's disease. The distribution of changes is of importance in distinguishing the conditions: for example, neurofibrillary tangles in DLB commonly spare the hippocampus, which is severely affected in Alzheimer's disease.

The neurotransmitter changes in DLB reflect the areas of pathology, with severe dopamine depletion in the basal ganglia and marked reduction in acetylcholine throughout the cortex.

Clinical features

Patients typically present with a progressive cognitive decline paralleling that seen in those with Alzheimer's disease. There are, however, a number of characteristic and distinguishing features. First, there is a tendency to marked spontaneous fluctuations in cognitive abilities, particularly alertness and attention, producing a delirious state lasting days or even weeks. Second, visual hallucinations, illusions, and fleeting misidentification phenomena occur in 50 to 80 per cent of sufferers even at an early stage and without drug provocation. The hallucinations are commonly well-formed images of people or animals. The marked cholinergic deficit is postulated to be the cause of their tendency to visual hallucinations. Third, is the occurrence of spontaneous parkinsonism, which is usually mild in the early stages. Rigidity, gait disturbance, and bradykinesia are all common, although in contrast to patients with Parkinson's disease the tremor is usually mild and atypical (with postural and action components) and symmetrical. Repeated falls also occur. In the later stages the akinetic rigid syndrome can cause severe disabilities in mobility and swallowing an increase in the number of falls. Fourth, there is often an exquisite sensitivity to neuroleptic medication, producing the malignant neuroleptic syndrome (delirium, hyperpyrexia, muscle rigidity, massive elevation of creatine phosphokinase, and renal failure).

Diagnosis

Neuropsychologically there is a mixture of subcortical and cortical features, with prominent cognitive slowing plus impairment of executive (planning and organizational abilities) and visuoperceptual abilities. Compared with patients with Alzheimer's disease, those with DLB tend to have greater deficits in attention and visuospatial processing. Memory loss may be less prominent than in Alzheimer's disease. There is no diagnostic test for this condition and the diagnosis *in vivo* relies on the clinical features described above and in Table 6. Brain imaging demonstrates similar changes to Alzheimer's disease, although there is a suggestion that medial temporal lobe atrophy is less pronounced.

Management

The symptomatic management of this disorder is complicated by the presence of both hallucinations and an akinetic rigid syndrome. Patients are notoriously sensitive to the side-effects of dopamine-enhancing medications used for the treatment of the akinetic rigid syndrome. However, although dramatic motor improvements are not to be expected, a cautious medication trial is worth attempting. Even though neuroleptic drugs should be avoided whenever possible, neuropsychiatric features, if severe, can be ameliorated with the newer atypical neuroleptics such as clozapine and olanzapine, without exacerbation of the parkinsonism. Thus the main aim is to maintain a balance between the patient being mobile and lucid.

Of considerable interest is the anecdotal improvement in the marked attentional cognitive deficits to treatment with cholinesterase inhibitors such as donepezil and rivastigmine. Although there have been no controlled trial reports as yet, patients with DLB may respond better than those with Alzheimer's disease to this drug therapy.

Vascular dementia

Definition and epidemiology

Vascular dementia can be defined as a dementia resulting from a cerebrovascular disorder. This is obviously a broad categorization and many different aetiologies may be included in this rubric, for example multiple infarcts from cardiac emboli, vasculitides including systemic lupus erythromatosus, primary cerebral amyloid angiopathy, and cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL). The term 'multi-infarct dementia' was introduced in the 1970s to emphasize the contribution of multiple cerebral infarcts to clinical dementia syndromes and to replace the older label of 'atherosclerotic dementia', although it is now apparent that diffuse small-vessel disease contributes significantly in the absence of clinically overt strokes. Traditionally regarded as the second commonest cause of dementia, it is increasingly difficult to estimate the true contribution of vascular disease. Postmortem studies of patients with multi-infarct dementia show that Alzheimer's changes commonly coexist. Conversely, the advent of sensitive instruments for detecting cerebral vascular lesions *in vivo* (magnetic resonance imaging), has revealed that presumed vascular changes are common in patients with the clinical diagnosis of Alzheimer's disease, even in young patients with known gene mutations, and that the presence of vascular lesions may be contributing to the severity of Alzheimer's disease. Finally, it is increasingly apparent that traditional risk factors for vascular dementia—including hypertension, diabetes, hypercholesterolaemia—are also factors which increase the likelihood of developing Alzheimer's disease.

Clinicopathological vascular syndromes

The variety of vascular diseases that affect the brain are legion, and the resultant clinical features and underlying pathology widely different (see Table 1). The most important vascular syndromes will be considered below.

Large infarcts

Recurrent cerebral infarcts involving multiple main arterial territories (for example, posterior or middle cerebral artery territories), resulting from thrombosis or embolism, can cause dementia with a step-wise cognitive decline. There is commonly a history of atherosclerotic risk factors (for example, hypertension, smoking, and hypercholesterolaemia), other evidence of atherosclerotic cardiac or peripheral vascular disease, and neurological signs on examination (for example, spasticity, hyperreflexia, extensor plantor responses, and a pseudobulbar palsy). There are often asymmetries on the neurological examination, and gait apraxia and/or bladder dysfunction can be early features. The cognitive picture is characterized by cortical features and is dependent on the sites of the lesions. There is often severe language impairment, visuospatial disturbance, amnesia, and dyspraxia, related to lesions in the middle and posterior cerebral artery distributions. Specific syndromes can result from discrete lesions: for example, lesions of the left angular gyrus result in a fluent aphasia, agraphia, acalculia, right–left disorientation, and finger agnosia or Gerstmann's syndrome.

Lacunar infarcts

The small multiple lacunar lesions are caused by occlusion in the deep penetrating arterial branches. The underlying pathogenic mechanism is a distinct small-vessel arteriopathy with replacement of the muscle and elastin in the arterial wall by collagen, leading to tortuous vessel and microaneurysm formation as a result of

long-standing hypertension. The basal ganglia, thalamus, and deep white matter are common sites for lesions, due to the nature of the arterial supply. These lacunes may coexist with the larger infarcts (described above) thereby contributing to a mixed picture. However, the typical presentation of the lacunar state is with a more subcortical syndrome causing impaired attention and frontal executive malfunction, forgetfulness, apathy, and emotional lability. Thalamic lacunes can result in a speech disorder and, if bilateral, in amnesia. Examination features are similar to those seen with larger infarcts, with rigidity, gait disturbance, and extrapyramidal and pyramidal signs.

Small-vessel disease (Binswanger's disease)

'Binswanger's disease' (or 'diffuse leucoaryosis') is the term applied to the radiologically defined syndrome of confluent subcortical and corpus callosal demyelination and loss of the cerebral white matter, which again typically complicates severe or accelerated hypertension. The clinical features are similar to those of the lacunar state described above. On CT there is symmetrical diffuse low-density periventricular hypodensity, which can be accompanied by ventricular dilatation. This is visualized with great sensitivity on *T*2-weighted MRI as a diffuse white-matter of high intensity. Pathologically, there is demyelination, axonal loss, and gliosis, thought to be due to diffuse ischaemia in the territory of the long perforating arteries.

Cerebral amyloid angiopathy

Amyloid is deposited in the cerebral vessels both with increasing age and in a proportion of cases with ordinary Alzheimer's disease. However, there is also a rare and sometimes familial form of cerebral amyloidosis that produces recurrent cerebral haemorrhages and an Alzheimer's type dementia. Amyloid deposition in the vessel walls causes structural weakness leading to intracerebral haemorrhages and narrowing of the vessel to produce ischaemia. The haemorrhages tend to be lobar and can be recurrent.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL)

This recently established disorder may be a commoner cause of vascular dementia than previously realized. Patients present in their early twenties with migraine-like headaches and subsequently develop stroke-like episodes, which are sometimes ascribed to migraine or may mimic the attacks of acute demyelination. A subcortical dementia syndrome develops during their fifth and sixth decades. MRI shows multiple subcortical infarcts and diffuse white-matter disease. Other clues to the diagnosis are the absence of risk factors for atherosclerotic disease and the strong family history. Pathologically there is a distinctive non-amyloid, non-atherosclerotic angiopathy of the leptomeningeal and perforating arteries of the brain, with eosinophilic granular substance replacing smooth muscle. The diagnosis can be also confirmed with the finding of the same pathological changes in the cutaneous blood vessels in a skin biopsy. Mutations in the *notch3* gene on chromosome 19 have been reported in patients with CADASIL.

Treatment of vascular dementia

The treatment should be directed to the amelioration of any underlying cause of the vascular disorder, such as reducing cardiac embolism and treating vasculitides and hypertension. The potential for altering the progression of the disease is alluring. Nevertheless, efforts directed at altering atherosclerotic risk factors tend to produce disappointing results. The course of vascular dementia can be as severe as or even more rapid than that of Alzheimer's disease.

Subcortical dementias

Despite shortcomings, the differentiation between cortical and subcortical dementias continues to be useful in clinical practice. This classification highlights the fact that, although disease of diverse cerebral structures can result in dementia, the resultant patterns of cognitive deficits are very different. Alzheimer's disease is the prototypical cortical dementia, vascular syndromes can present with a spectrum of features from cortical to subcortical, as can dementia with Lewy bodies. Purer forms of subcortical dementia result from pathology of the basal ganglia and white matter, the prototypical examples being Huntington's disease and progressive supranuclear palsy (Steele–Richardson–Olszewski syndrome). The typical cognitive pattern is that of attentional and executive dysfunction with marked cognitive slowing (bradyphrenia) causing problems with mentation and information retrieval. Memory is moderately impaired due to reduced attention and poor registration, but is not as severely impaired as in Alzheimer's disease. There is often an associated personality change and mood disturbance with prominent apathy. Spontaneous speech is impoverished and slow.

Huntington's disease

Huntington's disease is an autosomal dominant inherited disorder with an incidence of about 4 per 100 000. The mutation is an expansion of the trinucleotide repeat (CAG) in the IT-15 gene on chromosome 4, which encodes the polyglutamine protein, huntingtin, essential for nervous system development. There is a clear dose-response relationship between the length of the CAG repeat and the age of onset of the disorder. Psychiatric symptoms, such as depression, irritability, and personality changes often precede the motor disorder, which is typically choreiform. The other cognitive changes that develop over the next 10 to 20 years are of a subcortical pattern, with deficits in attention and concentration, executive function, and retrieval from memory.

Progressive supranuclear palsy

Progressive supranuclear palsy (**PSP**) is a rare, but increasingly recognized, disorder with an incidence of 1 to 2 per 100 000. The subcortical dementia is accompanied by an atypical parkinsonian syndrome. The motor deficits are symmetrical in onset, with severe rigidity in the axial muscle groups and bulbar symptoms. A supranuclear gaze palsy invariably develops, but in the early stages the only feature may be slowing of fast downward movement (saccadic slowing). Another early feature is a marked tendency to falls. The pathological features are neurofibrillary tangles, neuropil threads, and neuronal loss and gliosis in the subthalamic nucleus, red nucleus, substantia nigra, and dentate nucleus. The main neurotransmitter deficit is in dopamine. Unlike Parkinson's disease, progressive supranuclear palsy does not respond well to levodopa. The disease progresses rapidly with an average time course of around 5 years.

Parkinson's disease

Subcortical dementia occurs in about one-third to one-half of patients with Parkinson's disease, which develops at a late stage in the motor disorder in contrast to dementia with Lewy bodies.

Corticobasal degeneration

Corticobasal degeneration is a rare cause of a dementia and motor signs. Patients present with an asymmetrical akinetic rigid syndrome together with limb apraxia, and the almost pathognomic feature of alien limb phenomenon in which the hand(s) act as if 'with a will of their own'. Myoclonus and dystonia also occur. Dementia is common in the later stages and there is considerable overlap with frontotemporal dementia. The pathology is focused in the frontal and parietal cortices as well as the substantia nigra, basal ganglia, and thalamus.

Treatable causes of dementia

Normal-pressure hydrocephalus

Normal-pressure hydrocephalus has a classic triad of presenting features: cognitive impairment, gait disturbance, and incontinence. The cognitive features are typically those of a subcortical dementia with frontal features and psychomotor slowing. The gait disorder is a dyspraxia and may show the pathognomonic feature of 'being stuck to the floor', although there is an absence of signs when the patient is examined in the supine position. The condition may be secondary to a prior disturbance of cerebrospinal fluid flow (resulting from, for example, a head injury, meningitis, or a subarachnoid haemorrhage), but often no cause is found in the elderly. Neuroimaging shows ventricular enlargement disproportionate to the degree of cortical atrophy. The presence of periventricular lesions can make the distinction from vascular dementia difficult. The investigation and management of these patients should be undertaken by the neurosurgeons, the definitive treatment being ventricular shunting. If treated early the prognosis is good.

Chronic subdural haematomas

This treatable cause of dementia is caused by head trauma. It is common in individuals at risk of recurrent head injuries, such as the elderly, alcoholics, and people with epilepsy. Risk is also increased by coagulation disorders, either pathological or iatrogenic. The clinical features are of a subacute dementia with symptoms of raised intracranial pressure and fluctuating cognitive performance and focal neurological signs. Diagnosis is confirmed by neuroimaging, the peripheral mass lesions may be of varying signal density on CT, depending on the age of the lesion. If the lesions are isodense with the brain tissue, the diagnosis can be easily overlooked. Treatment is by neurosurgical evacuation, except in clinically insignificant collections. Although the outcome is good, about 10 to 40 per cent of patients have a recurrence that may require a further drainage.

Benign tumours

Subfrontal meningiomas are the classic tumours that present with features of a frontal dementia. The onset is usually insidious with personality changes and other frontal features. Besides the neuropsychological abnormalities there may be anosmia or unilateral visual failure and optic atrophy. Other relatively benign midline tumours occasionally present with hydrocephalus and cognitive impairment secondarily to this (for example, colloid cysts of the third ventricle and non-secretory pituitary tumours).

Metabolic and endocrine disorders

Metabolic derangements can give rise to acute-onset cognitive impairments, but the features are invariably those of a delirium rather than a dementia. Chronic hypocalcaemia and recurrent hypoglycaemia can result in a dementia often accompanied by ataxia and involuntary movements. Endocrine disorders can more frequently present with a dementia syndrome, with or without psychiatric features (for example, hypothyroidism, Addison's disease, and hypopituitism). The prominent complaints common to most disorders are mental slowing, apathy, and poor memory. Cushing's disease can present with psychiatric features, although a dementia syndrome is rarer. Although not strictly an endocrine disorder, Hashimoto's encephalopathy is a recently recognized cause of chronic delirium or dementia, often accompanied by seizures and fluctuating focal neurological signs. The diagnosis is made by finding extremely high levels of anti-thyroid antibodies despite a euthyroid state. Patients respond well to high-dose steroid therapy.

Deficiency states

Vitamin B12 deficiency can cause the classic picture of subacute combined degeneration of the spinal cord and a dementia. The dementia can be variable in severity and it is unusual to present without some features of peripheral neurological disease, at least, diminished vibration sense in the lower limbs and/or sensory ataxia. Reflexes can be increased, decreased, or mixed. Although most patients have a macrocytic anaemia, neurological manifestations can occasionally occur in the absence of haematological features. Severe thiamin (vitamin B1) deficiency results in the Wernicke–Korsakoff syndrome, with delirium, ataxia, and ophthaloplegia. The commonest causes are alcoholism and recurrent prolonged vomiting, such as hyperemesis gravidarum. If not promptly treated a chronic amnesic syndrome can occur.

Infections

Neurosyphilis, once a common cause of dementia, is now rare. The associated neurological features include pupillary abnormalities, optic atrophy, ataxia, and pyramidal signs. The diagnosis is confirmed with serology and examination of cerebrospinal fluid. Treatment with penicillin can result in some improvement. Those at increased risk are people inadequately treated for syphilis and those infected with the human immunodeficiency virus (**HIV**). HIV infection is an increasingly common cause of dementia in some parts of the world. The encephalopathy (AIDS–dementia complex) is characterized by psychomotor slowing, personality change, and other features of a subcortical dementia. Examination of the cerebrospinal fluid can show a pleocytosis and increased protein and oligoclonal bands. White-matter changes are visible on neuroimaging. Cognitive changes in patients with HIV may also be due to opportunistic infections such as cerebral toxoplasmosis and cryptococcal meningitis and progressive multifocal leucoencephalopathy, which all require specific treatment.

24.13.9Human prion diseases

R. G. Will

Introduction

Prion diseases, also known as transmissible spongiform encephalopathies, are fatal disorders of the central nervous system affecting both animals and humans (Table 1). The clinical features and patterns of occurrence of these diseases vary, but they are linked by a number of characteristics including experimental and natural transmissibility, shared neuropathological features, prolonged incubation periods measured in years, and the deposition of prion protein, which may be the causal agent, in the brain of the host. Prion diseases have become the subject of intense scientific and public interest because of the likelihood that they are caused by a new disease mechanism and because of the implications for public health following the identification of a new human prion disease, variant Creutzfeldt–Jakob disease, and the accumulating evidence that it is caused by the transmission of the cattle prion disease, bovine spongiform encephalopathy, to humans.

The causal agent

Scrapie was first transmitted experimentally from sheep to sheep in 1936 and to laboratory mice in 1961, but laboratory transmission of human prion diseases was not achieved until 1966 (kuru) and 1968 (Creutzfeldt–Jakob disease). The seminal discovery that apparently neurodegenerative diseases were transmissible stimulated extensive research into the nature of the infectious agent. No bacterium or virus has been isolated in these diseases and there is no immunological response to infection. This is of central importance as there is, as yet, no serological test to identify the presence of infection during the incubation period of any prion disease. The transmissible agent is remarkably resistant to inactivation procedures, including those that disrupt nucleic acids. Prusiner proposed in 1982 that the protein deposited in the central nervous system in these diseases was itself the causal agent. Purified infectious fractions of brain contain prion protein (for proteinacious infectious particle) which is a major, and perhaps the only, component of the infectious agent. This membrane-associated glycoprotein is present in all mammalian species. The normal function of prion protein is unknown. In prion diseases a post-translationally modified form of the protein, partially resistant to protease digestion, is deposited in the brain and is associated with neuronal dysfunction and death.

There is a range of experimental evidence supporting the hypothesis that the disease-associated form of prion protein is the causal agent in prion diseases, most notably a series of elegant studies in transgenic rodents. Cellular expression of prion protein is necessary for the development of the neuropathological changes and the disease. Hereditary forms of human prion disease are associated with, and perhaps caused by, mutations of the prion protein gene. However, the occurrence of multiple strains of the infectious agent and the stability of the transmission characteristics of the bovine spongiform encephalopathy agent in the laboratory following cross-species transmission are not readily explained by the prion theory. The importance of prion protein as a determinant of disease expression has become increasingly clear in human prion disease. The phenotype of different clinicopathological subtypes of Creutzfeldt–Jakob disease is related to the deposition in the brain of different molecular isotypes of prion protein, probably reflecting distinct tertiary protein structures, despite the identical amino acid sequences of the normal and disease-associated forms of prion protein.

In experimental transmission of prion diseases there are a number of key determinants of the efficiency of transmission, as judged by the incubation periods in recipient animals and the proportion of these animals that develop disease. The route of inoculation influences these variables. The intracerebral route is the most efficient. Intravenous, intraperitoneal, and oral routes are decreasingly efficient. The incubation period is inversely related to the infective dose, while the strain of the infectious agent influences both the incubation period and whether recipient animals develop disease. In some transmission studies, for example transmission of bovine spongiform encephalopathy to hamsters or transmission of scrapie to chimpanzees, recipient animals do not develop disease even after intracerebral inoculation of high levels of infectivity. Within-species transmission is more efficient than cross-species transmission and this 'species barrier' to transmission is influenced by characterisitics of both the host and the infective agent. The relative homology of amino acid sequences of prion proteins between species is not the only determinant of the species barrier. The relative efficiency of transmission between species cannot be predicted.

After ingestion, the agent replicates in the lymphoreticular system, including the spleen and lymph nodes, before entering the thoracic spinal cord or brainstem, probably via the autonomic nervous system, and then spreading caudally to the brain. Moderate levels of infectivity plateau in the lymphoreticular system and are not associated with organ dysfunction, while in the spinal cord and brain high levels of infectivity develop, for example 10^{12} infectious units per gram of brain in one model of hamster scrapie, leading to neuronal death and clinical disease. In some experimental and natural prion diseases infectivity in the lymphoreticular system can be detected at about one-third of the total incubation period by inoculation of tissues of the lymphoreticular system, such as spleen, into recipient animals. The implication is that, in the absence of an *in vivo* serological test for the presence of infectivity, animals or humans incubating a prion disease may harbour significant infectivity in some organs or tissues but cannot be identified as being infected. This has important implications for the control and public health implications of prion diseases.

Human prion diseases

Human prion diseases may be classified as sporadic, inherited, or acquired (Table 2).

Sporadic Creutzfeldt–Jakob disease

Sporadic Creutzfeldt–Jakob disease is a rare disease, with an annual incidence of about 1 case per million population. The disease occurs worldwide and the cause is unknown, with no convincing evidence of an environmental source of infection and in particular no proven link with the animal prion diseases. The regional clusters of cases identified in some countries are unusual and may reflect the chance aggregation of a rare phenomenon. Overall the geographical and temporal distribution of cases of sporadic Creutzfeldt–Jakob disease appear to be random and case control studies have demonstrated no consistent risk factors for the development of disease, with no good evidence of an increased risk through occupation, dietary factors, or animal contact. The current favoured hypothesis is that sporadic Creutzfeldt–Jakob disease is caused by a spontaneous mutation of prion protein to the abnormal form, which acts as a template for protein self-replication and eventual disease.

Clinically sporadic Creutzfeldt–Jakob disease presents with a rapidly progressive dementia associated with a range of neurological signs, most commonly myoclonus of the limbs, cerebellar ataxia, and rigidity. Less common features include dysphasia, pyramidal or extrapyramidal signs, primitive reflexes, cortical blindness, and lower motor neurone signs. Despite the predominantly cortical neuropathology epilepsy is rare. The rapidity of the progression of neurological deficits and cognitive decline is distinct from most other causes of dementia and the mean survival is only about 4 months from clinical onset, although in about 10 per cent of cases the illness is more prolonged and a small minority of patients survive for 2 years or more (Fig. 1). Terminally there is often a state of akinetic mutism.

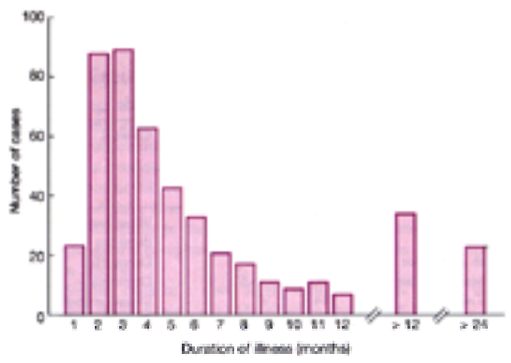

Fig. 1 Sporadic Creutzfeldt–Jakob disease—survival.

Although the clinical presentation in sporadic Creutzfeldt–Jakob disease is relatively stereotyped, a minority of cases present atypically, for example acutely mimicking stroke, with cortical blindness, or with an initially pure cerebellar syndrome.

The neuropathological characteristics of sporadic Creutzfeldt–Jakob disease include spongiform change, neuronal loss, and astrocytosis in the cerebral and cerebellar cortex, in accordance with the neurological signs seen in life (Plate 1). Neuropathological changes are widespread and deposition of prion protein can be detected with immunocytochemical techniques. In about 10 per cent of cases there are cortical deposits of prion protein in the form of amyloid plaques. There is heterogeneity in the distribution and morphology of the neuropathological changes, which correlate in part with the clinical phenotype and with two isotypes of prion protein which can be distinguished on Western blot of brain tissue (Fig. 2).

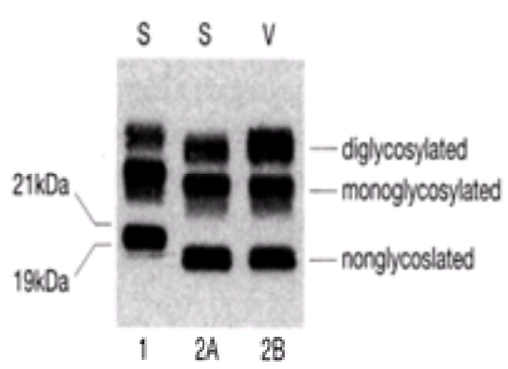

Fig. 2 Western blot of brain tissue showing type 1 and type 2 prion proteins. Lane 1 is sporadic Creutzfeldt–Jakob disease, lane 2A is sporadic Creutzfeldt–Jakob disease and lane 2B is variant Creutzfeldt–Jakob disease. Type 2A and type 2B have the same mobility but are differentiated by the relative proportions of different glycoforms—in variant Creutzfeldt–Jakob disease there is an excess of the diglycosylated form.

Sporadic Creutzfeldt–Jakob disease is mainly a disease of late middle age (Fig. 3) with a mean age at death of 66 years. In most systematic studies males and females are affected with equal frequency.

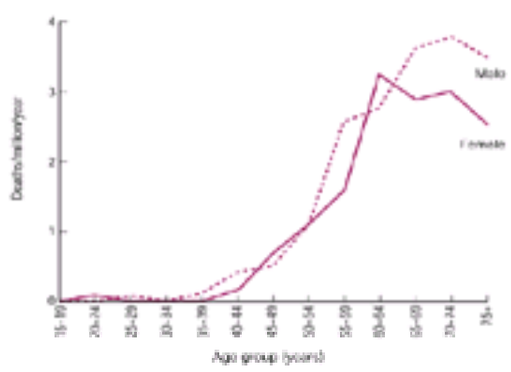

Fig. 3 Age- and sex-specific mortality rates from sporadic Creutzfeldt–Jakob disease in the United Kingdom, 1995 to 2000.

The human prion protein gene is situated on chromosome 20 and contains a polymorphic region at codon 129, which expresses either methionine or valine. Methionine homozygosity (MM) at codon 129 increases susceptibility to sporadic Creutzfeldt–Jakob disease (Table 3). The genotype distribution in sporadic cases is MM 80 per cent, valine homozygous (VV) 15 per cent, and heterozygous (MV) 5 per cent in contrast to the genotype distribution in the normal Caucasian population. There is accumulating evidence that the disease phenotype in sporadic Creutzfeldt–Jakob disease, as well as susceptibility, is influenced by an interplay between the codon 129 genotype and the prion protein isotype. The classical form of sporadic Creutzfeldt–Jakob disease, representing the great majority of cases, is associated with type 1 prion protein and an MM genotype, while alternative combinations of prion protein isotype and codon 129 genotype are often associated with atypical phenotypes.

Hereditary prion diseases

Familial clusters of Creutzfeldt–Jakob disease account for about 10 per cent of all cases and within pedigrees there is a dominant pattern of inheritance. The paradox of a transmissible disease that is also inherited was clarified by the identification of a mutation at codon 102 of the prion protein gene in two families affected by Gerstmann–Straussler–Scheinker syndrome (GSS), a condition known to be a human prion disease on the basis of the neuropathology and laboratory transmissibility. More than 20 prion protein gene mutations, including point and insertional mutations, have now been identified in familial Creutzfeldt–Jakob disease or Gerstmann–Straussler–Scheinker syndrome (Table 4), and all cases of hereditary human prion disease to date have been found to have a mutation of the prion protein gene. Fatal familial insomnia was first identified as a prion disease following the identification of a mutation at codon 178 of the prion protein gene in affected family members and it was only later that transmission in the laboratory confirmed the status of fatal familial insomnia as a prion disease. The current hypothesis is that mutations of the prion protein gene lead to an instabililty in the structure of prion protein and an increased chance of a spontaneous transformation of prion protein to the abnormal self-replicating disease-associated form. With the exception of the prion disease associated with a mutation at codon 200 of the prion protein gene, all hereditary human prion diseases are fully penetrant.

The incidence of Creutzfeldt–Jakob disease in localized areas of Slovakia and in Libyan-born Israelis was discovered many years ago to be 60 to 100 times greater than expected. Possible explanations for these clusters included excessive dietary exposure to sheep scrapie and a high coefficient of inbreeding. Following the identification of the mutations of prion protein in human disease, genetic studies have shown that in both clusters there is a high population frequency of mutations at codon 200 of the prion protein gene and that the excess of cases of Creutzfeldt–Jakob disease is due to an excess of familial cases, with an expected background incidence of sporadic cases.

Overall the age at death in hereditary prion diseases is about 5 to 10 years earlier than in sporadic Creutzfeldt–Jakob disease, but the duration of clinical illness is often more prolonged and the clinical features vary with the underlying mutation. With some mutations, notably the codon 200 mutation, the clinical course is similar to sporadic Creutzfeldt–Jakob disease, but cases of hereditary prion disease may present with ataxia, for example Gerstmann–Straussler–Scheinker syndrome, or with a highly atypical phenotype such as fatal familial insomnia in which the early clinical features include dysautonomia and insomnia. There may be variation in the clinical phenotype both within and between families even if these are associated with the same underlying mutation in the prion protein gene.

Neuropathologically there is great heterogeneity in hereditary prion diseases, and as with the clinical phenotype there is an overall relationship between the neuropathological features and the specific prion protein gene mutation, although there can be great variation within and between pedigrees (Plate 2). The neuropathology can be similar to sporadic Creutzfeldt–Jakob disease but in a significant proportion of hereditary prion diseases there is amyloid plaque formation and in fatal familial insomnia gliosis and neuronal loss may be restricted to the thalamus.

In some forms of hereditary prion disease the codon 129 genotype may influence clinical characteristics, including age at death, and the neuropathology. Variation at this locus has a profound effect on the disease phenotype in association with mutations at codon 178 of the prion protein gene. Cases with a codon 178 mutation and a methionine at codon 129 of the prion protein gene develop fatal familial insomnia, whereas with valine at codon 129 the phenotype is similar to sporadic Creutzfeldt–Jakob disease.

Iatrogenic Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease has been transmitted accidentally in the course of medical treatment by neurosurgical instruments, corneal grafts, cadaveric dura mater grafts, and human pituitary derived hormones (Table 5). The presumption is that infection from individuals with Creutzfeldt–Jakob disease was transmitted to uninfected individuals via these procedures and there is strong circumstantial evidence that this has occurred. In two of the transmissions by corneal grafts the donors died of sporadic Creutzfeldt–Jakob disease and in the neurosurgical transmissions there was a clear temporal link between surgical procedures on Creutzfeldt–Jakob disease cases and patients operated on using the same instruments who subsequently developed Creutzfeldt–Jakob disease. It is presumed that some human dura mater grafts and human pituitary hormones came from individuals suffering from Creutzfeldt–Jakob disease and there may have been cross-contamination in the production process leading to dissemination of infection. Infection via human pituitary growth hormone has been demonstrated in laboratory transmission studies. All cases of iatrogenic transmission of Creutzfeldt–Jakob disease have involved surgical instruments, grafts, or hormonal products potentially contaminated by central nervous system tissue and, by implication, high levels of infectivity.

There is a distinction between the clinical features in iatrogenic Creutzfeldt–Jakob disease which depends on the route of inoculation. In exposures in or adjacent to the nervous system (neurosurgical instruments, dura mater grafts, and corneal transplants) the majority of cases present with a progressive dementia similar to sporadic Creutzfeldt–Jakob disease. With a peripheral route of exposure to infection (pituitary hormones) there is a progressive cerebellar ataxia and cognitive impairment develops late in the clinical course, if at all.

The incubation period also varies according to the route of exposure to infection. With central exposure the mean incubation period ranges from about 18 months, similar to the incubation periods in primates after experimental intracerebral inoculation, to 6 years with dura mater grafts. With a peripheral route of exposure the mean incubation period is about 12 years, but may extend to over 30 years, which is similar to the extended incubation periods in kuru, a human prion disease also caused by a peripheral route of exposure to infection.

Homozygosity at codon 129 of the prion protein gene, either MM or VV, increases susceptibility to human growth hormone related Creutzfeldt–Jakob disease and heterozygosity may lead to a more prolonged incubation period. In dura mater related Creutzfeldt–Jakob disease 81 per cent of cases have an MM genotype, similar to the proportion of sporadic cases with this genotype, but the codon 129 genotype does not influence the incubation period.

Reducing the risks of iatrogenic transmission of Creutzfeldt–Jakob disease

Measures to reduce the risk of iatrogenic transmission of Creutzfeldt–Jakob disease have been introduced in many countries. There are strict selection criteria for obtaining corneal grafts, recombinant growth hormone replaced human growth hormone in 1985, and human dura mater grafts have not been licensed in the United Kingdom since the early 1990s. There is no evidence that Creutzfeldt–Jakob disease has been transmitted iatrogenically through non-central nervous system tissues such as blood, blood products, or organ transplantation, but continued vigilance is necessary as many of the mechanisms of iatrogenic transmission of Creutzfeldt–Jakob disease were not predicted. The possibility of secondary transmission of variant Creutzfeldt–Jakob disease through blood transfusion, the use of fractionated blood derivatives, organ transplantation, or contaminated surgical instruments is a matter of continuing concern.

Variant Creutzfeldt–Jakob disease

Bovine spongiform encephalopathy was identified in 1986 as a novel prion disease in cattle in the United Kingdom, and is thought to have been caused by feeding cattle material contaminated with sheep scrapie or, perhaps, to have been a previously unrecognized endemic prion disease of cattle. Bovine to bovine recycling of infection through cattle feed amplified the epidemic and there have now been over 180 000 cases of bovine spongiform encephalopathy in the United Kingdom. Small numbers of cases of bovine spongiform encephalopathy have been identified in other countries, mainly in Europe.

In 1996 ten cases of a novel form of human prion disease, variant Creutzfeldt–Jakob disease, were identified in the United Kingdom and a causal link with bovine spongiform encephalopathy was proposed as this was a new disease occurring only in the United Kingdom, the country with the greatest potential human exposure to bovine spongiform encephalopathy. Up to January 2002 there have been 114 cases of variant Creutzfeldt–Jakob disease in the United Kingdom, five in France, and one in the Republic of Ireland. The mean age at death in variant Creutzfeldt–Jakob disease is 29 years (range 15 to 74 years, Fig. 4) contrasting with a mean age at death in sporadic Creutzfeldt–Jakob disease of 66 years. The hypothesis that variant Creutzfeldt–Jakob disease is caused by the bovine spongiform encephalopathy agent has been supported by the consistent disease phenotype, and in particular the neuropathology which is distinct from other human prion diseases, the failure to identify similar cases in the past either in the United Kingdom or elsewhere, and laboratory transmission studies which have shown a remarkable similarity between the transmission characteristics of bovine spongiform encephalopathy and variant Creutzfeldt–Jakob disease in mice.

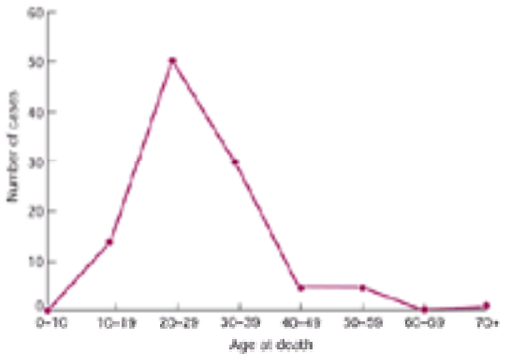

Fig. 4 Age distribution of cases of variant Creutzfeldt–Jakob disease in the United Kingdom (January 2002).

The clinical features of variant Creutzfeldt–Jakob disease are relatively distinct from other forms of human prion disease, including sporadic and iatrogenic Creutzfeldt–Jakob disease. Patients present with psychiatric symptoms, including depression, withdrawal, and anxiety, followed after a period of months by progressive ataxia, dementia, and choreiform or dystonic involuntary movements, which often evolve into myoclonus. The terminal stages are similar to sporadic Creutzfeldt–Jakob disease, but the overall duration of illness, mean 14 months, is significantly more prolonged. The distinctive neuropathological characteristic of variant Creutzfeldt–Jakob disease is the widespread deposition of deposits of prion protein with a halo of spongiform change, so-called florid plaques, throughout the

cerebral and cerebellar cortex, in addition to the spongiform change, neuronal loss, and gliosis seen in other human prion diseases.

Cases of variant Creutzfeldt–Jakob disease have been identified from throughout the United Kingdom and risk factors include residence in the United Kingdom and an MM genotype at codon 129 of the prion protein gene. All the United Kingdom cases and the case diagnosed in the Republic of Ireland had been resident in the United Kingdom during the 1980s to early 1990s when human exposure to bovine spongiform encephalopathy was likely to have been maximal. Three of the French cases had never visited the United Kingdom, implying that exposure to bovine spongiform encephalopathy must have occurred in France from indigenous bovine spongiform encephalopathy or export from the United Kingdom of cattle or food products. A case control study has not yet demonstrated any significant dietary risk factor in variant Creutzfeldt–Jakob disease, although the favoured hypothesis is that transmission of bovine spongiform encephalopathy to humans was through contamination of food, probably with tissues from the central nervous system such as brain or spinal cord which are known to contain high levels of infectivity in cattle affected with bovine spongiform encephalopathy. All tested cases of variant Creutzfeldt–Jakob disease to date have been MM homozygotes at codon 129 of the prion protein gene. This genotype is also present in about 80 per cent of cases of sporadic Creutzfeldt–Jakob disease and may represent a susceptibility factor for the development of variant Creutzfeldt–Jakob disease. Variation at this locus can, however, influence the incubation period and disease phenotype and it is possible that cases of human infection with bovine spongiform encephalopathy may yet be identified in individuals with a VV or MV genetic background.

The possible future number of cases of variant Creutzfeldt–Jakob disease is unknown, but there has been an increase in the annual number of deaths from variant Creutzfeldt–Jakob disease in the United Kingdom (Fig. 5) and statistical analyses, taking into account delays in referral and confirmation, have shown a significant increase in the temporal incidence of cases since 2000. Long-term predictions have estimated a total of 100 to over 136 000 cases of variant Creutzfeldt–Jakob disease in the United Kingdom. This wide range reflects the many uncertainties including the mean incubation period of bovine spongiform encephalopathy in humans, the level of the species barrier between bovines and humans, and the extent of human exposure to the bovine spongiform encephalopathy agent.

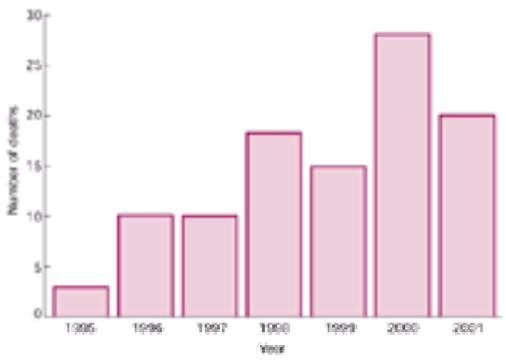

Fig. 5 Variant Creutzfeldt–Jakob disease—number of deaths per annum in the United Kingdom (January 2002).

Kuru

The transmissibility of human prion diseases was first demonstrated in 1966 with the transmission of a spongiform encephalopathy to chimpanzees 18 to 21 months after intracerebral inoculation of a brain extract from a patient who had died of kuru. This seminal experiment followed years of clinical, epidemiological, and anthropological research in the Fore region of Papua New Guinea where kuru was endemic. In the early 1960s kuru caused over half of all deaths in the affected population and there have been more than 3000 deaths from kuru in the at-risk population of 30 000 people.

The epidemiological characteristics of kuru are unusual with familial aggregation of cases and a high incidence of disease in women and children in the early years of the epidemic. Since 1960 there has been a decline in the incidence, particularly in women and children (Fig. 6), and there have been no cases in children born after 1959. After extensive investigation into a possible genetic or toxic origin, anthropological research established that kuru was transmitted in the course of ritual cannibalism. As a mark of respect, relatives consumed affected individuals and virtually all tissues were consumed, including the brain and viscera. Although men took part in these rituals, women and children are thought to have consumed the internal organs such as the brain which contained the highest levels of infectivity. It is also possible that there was transcutaneous transmission through rubbing of tissue on the skin. Detailed investigation of individual cannibalistic events has shown that a number of members of the same family, including those who came from different areas, developed kuru after attending a single cannibalistic rite. Ritual cannibalism ceased by 1960, explaining the subsequent decline in incidence of kuru, but there are still occasional cases with incubation periods exceeding 40 years. It is of interest that at the height of the epidemic many hundreds of women were affected by kuru during pregnancy and breastfed their children, but none of these children later developed kuru.

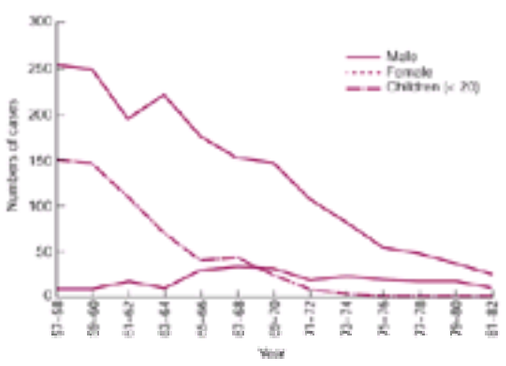

Fig. 6 Kuru—numbers of cases by age, sex, and time.

Clinically kuru presented with a cerebellar syndrome, initially truncal ataxia and titubation, followed by ataxia of gait and dysarthria. A prodromal phase of headache and limb pain was common and hypotonia was a prominent early feature. Involuntary movements such as myoclonus and rigidity of the limbs did not occur, in contrast to other forms of human prion disease. Terminally patients became immobile and communication was often impossible because of severe dysarthria. Dementia did not occur, and even in the terminal akinetic and mute state patients could obey simple commands. In children the clinical features were similar, but in the early stages there were often brainstem signs such as strabismus, nystagmus, and ptosis. The total duration of illness ranged from 12 to 18 months in adults and 3 to 12 months in children.

In kuru, neuropathological changes were most apparent in the cerebellum, consistent with the clinical features. Neuronal loss and intense cerebellar astrocytosis were uniform findings and about three-quarters of cases had amyloid plaque deposition, particularly in the granule cell layer of the cerebellum. The cerebral cortex showed mild spongiform change. The similarity of the neuropathology of kuru to scrapie was commented on by Hadlow in 1959, prompting the transmission studies which later demonstrated that kuru, like scrapie, was experimentally transmissible.

By using stored samples, analysis of the influence of the codon 129 polymorphism of the prion protein gene on susceptibility to kuru has shown that homozygosity, either MM or VV, increases susceptibility and that heterozygotes may have a more prolonged incubation period. The analysis of codon 129 genotype in kuru is complicated by the limited number of tested cases and the possible effect of the high mortality rate on the codon 129 distribution in a closed population.

The diagnosis of human prion diseases

Human prion diseases are rare, but the high public profile of Creutzfeldt–Jakob disease and variant Creutzfeldt–Jakob disease has resulted in an increase in the

number of cases in which the diagnosis of one of these diseases is suspected. Accurate diagnosis of any condition, including patients suffering from a human prion disease, is essential but the exclusion of a diagnosis is also important, particularly for a fatal and untreatable condition. Although symptomatic treatment, for example for involuntary movements, can be helpful in human prion diseases there is currently no available treatment that influences the clinical course nor any treatment to prevent the development of neurological disease after infection. An important objective is to improve diagnostic accuracy in human prion diseases and in particular to allow early diagnosis. In the absence of a test for the presence of the infectious agent, diagnosis depends on the recognition of the clinical characteristics of human prion diseases supported by a range of investigations, some of which have been developed in recent years. Diagnostic criteria for sporadic, iatrogenic, familial, and variant Creutzfeldt–Jakob disease have been formulated and validated (Table 6 and Table 7). In all human prion diseases a definite diagnosis can only be made by the examination of brain tissue, usually at post-mortem.

In the majority of cases of sporadic Creutzfeldt–Jakob disease the diagnosis is made in life because of the multifocal neurological deficits, the development of myoclonus, and in particular the rapidity in the progression of cognitive impairment. The clinical picture is distinct from more common forms of dementia. In forms of sporadic Creutzfeldt–Jakob disease with early focal neurological features such as a cerebellar syndrome the rapid evolution of other neurological deficits and dementia suggests the diagnosis of Creutzfeldt–Jakob disease. Diagnosis can be difficult in cases of sporadic Creutzfeldt–Jakob disease with atypical features such as long duration of illness, and in these cases investigations such as magnetic resonance imaging of the brain can be helpful. There is increasing evidence that cases of sporadic Creutzfeldt–Jakob disease may be atypical if there is an underlying MV or VV codon 129 prion protein genotype.

Hereditary prion diseases are often suspected because of a family history of a similar disorder, but in a significant proportion of cases of Creutzfeldt–Jakob disease associated with a prion protein gene mutation there is a family history of another neurodegenerative disorder or no relevant family history. The gradual clinical progression in many forms of hereditary human prion disease makes accurate diagnosis difficult and the diagnosis may only be recognized in life after prion protein gene analysis. Genetic testing should only be carried out with fully informed consent.

The diagnosis of iatrogenic Creutzfeldt–Jakob disease depends on the identification of a relevant risk factor, for example previous treatment with human growth hormone, and an assessment of the neurological presentation. Most patients with growth hormone related Creutzfeldt–Jakob disease present with a cerebellar syndrome, while after central iatrogenic exposure to infection the clinical picture is usually similar to that of sporadic Creutzfeldt–Jakob disease. The utility of specialist investigation in iatrogenic Creutzfeldt–Jakob disease is uncertain because of the rarity of these forms of Creutzfeldt–Jakob disease and limited information on investigations.

The clinical picture in the later stages of variant Creutzfeldt–Jakob disease is similar to that of sporadic Creutzfeldt–Jakob disease and, although the recognition of the diagnosis in the first cases of this new disease was difficult, the clinical phenotype is now well known and the diagnosis is usually apparent after neurological signs develop, often in young patients in an age group in which dementia is very unusual. Diagnosis in the early stages is, however, difficult as there is a period of many months in which the clinical picture is dominated by psychiatric symptoms, including depression, anxiety, and withdrawal. Clues to the possibility of variant Creutzfeldt–Jakob disease include cognitive impairment, subtle gait ataxia, and persistent painful sensory symptoms in combination with the psychiatric symptoms.

Investigations in human prion disease

Many of the investigations carried out in suspected cases of human prion disease do not show any specific disease related abnormality, but help to exclude other diagnoses, some potentially treatable. The interpretation of the results of investigations depends on the clinical picture because the sensitivity and specificity of surrogate markers for prion disease, such as 14-3-3 cerebrospinal fluid analysis (see below), depend on clearly defining the characteristics of the patients in which the test has been carried out.

Routine haematological and biochemical tests are usually normal. About a third of cases of sporadic or variant Creutzfeldt–Jakob disease may have minor abnormalities in liver function tests.

The electroencephalogram shows periodic triphasic complexes at about 1 per second in 60 to 70 per cent of cases of sporadic Creutzfeldt–Jakob disease (Fig. 7) and in some cases of iatrogenic Creutzfeldt–Jakob disease after central exposure to infection. These electroencephalogram changes are relatively specific, but similar appearances can be seen in hepatic encephalopathy, lithium or metrizamide toxicity, metabolic disturbance, and rarely in other forms of dementia such as Alzheimer's disease.

Fig. 7 Typical electroencephalogram in sporadic Creutzfeldt-Jakob disease.

There is no cerebrospinal fluid pleocytosis in any form of human prion disease, and cerebrospinal fluid protein is elevated in about a third of cases. Elevation of the 14-3-3 cerebrospinal fluid protein, a marker for neuronal damage, has a sensitivity and specificity of about 90 per cent in the diagnosis of sporadic Creutzfeldt–Jakob disease, but is less useful in the diagnosis of variant Creutzfeldt–Jakob disease.

A computed tomography scan of the brain is usually normal, but can show non-specific cerebral atrophy. Magnetic resonance imaging of the brain shows a high signal on T_2-weighted images in the caudate nucleus and putamen in about 70 per cent of cases of sporadic Creutzfeldt–Jakob disease (Fig. 8), but the sensitivity and specificity of these abnormalities has not been formally assessed. In variant Creutzfeldt–Jakob disease about 80 per cent of cases show a high signal on T_2-weighted images (and PD and FLAIR sequences) in the pulvinar region of the posterior thalamus (Fig. 9) and in the appropriate clinical context these abnormalities have a high sensitivity and specificity for the diagnosis of variant Creutzfeldt–Jakob disease. To date all cases of variant Creutzfeldt–Jakob disease classified as 'probable', a diagnosis requiring the abnormalities on magnetic resonance imaging, that have come to post-mortem examination have been confirmed as variant Creutzfeldt–Jakob disease.

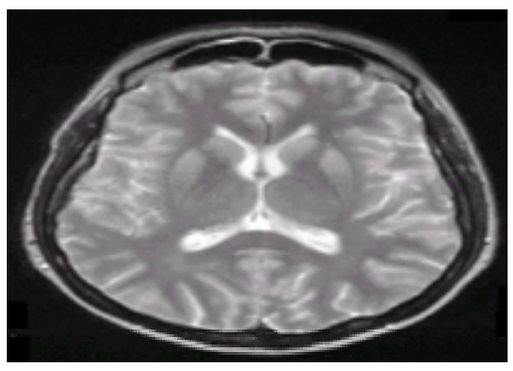

Fig. 8 MRI image of sporadic Creutzfeldt–Jakob disease showing high signal changes symmetrically in the caudate and putamen.

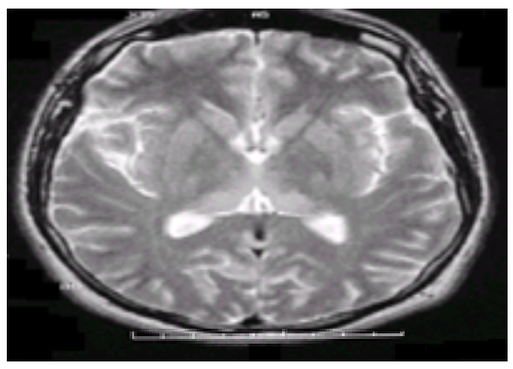

Fig. 9 MRI image of variant Creutzfeldt–Jakob disease showing high signal symmetrically in the posterior thalamus.

Brain biopsy can allow the confirmation of the diagnosis of a human prion disease in life, but this investigation has risks and is mainly carried out when there is a realistic possibility of an alternative diagnosis. Tonsil biopsy in variant Creutzfeldt–Jakob disease can also increase the likelihood of the diagnosis in life, but this procedure is also invasive and, although early diagnosis is important for the relatives of the patient and for clinicians, it does not benefit the patient.

Conclusion

There have been remarkable scientific advances in the understanding of prion diseases and it is hoped that this may lead to the identification of a diagnostic test in life for the presence of infection and to therapies to prevent the development of disease. Human prion diseases have attained a public notoriety disproportionate to the overall burden of disease caused by these rare conditions. However, the transmission of an animal prion disease, bovine spongiform encephalopathy, to humans has been a tragedy and the prolonged incubation periods characteristic of this group of diseases indicate that the eventual consequences of bovine spongiform encephalopathy for public health both in the United Kingdom and in other countries are unpredictable.

24.13.10 Parkinsonism and other extrapyramidal diseases

Donald B. Calne

The concept of extrapyramidal disease

The concept of extrapyramidal disease arose at the start of the twentieth century. Nineteenth-century anatomists, physiologists, and neurologists established the importance of the pyramidal pathway, but they later recognized that pathology outside this system also led to major disturbances of voluntary movement. It was concluded that alternative pathways within the central nervous system contribute to the control of movement and the term 'extrapyramidal system' was coined. Pathology in this extrapyramidal system was associated with involuntary movements, which became the hallmark of what were called 'extrapyramidal diseases'. Over the course of the twentieth century, however, the notion of a pyramidal pathway was criticized. In consequence, the idea of disease involving an extrapyramidal pathway was also discredited, so the term 'movement disorders' became fashionable, and is now widely used.

In spite of these changes in nomenclature, there is general agreement that certain structures, deep in the brain, play an important part in the planning and execution of voluntary movement. In particular, it has been shown through clinicopathological correlation, that the basal ganglia are linked to motor control. The basal ganglia comprise the caudate nucleus, the putamen, and the globus pallidus. In addition, certain nuclei feeding into this system, such as the substantia nigra, are usually included. Myoclonus and ataxia will not be discussed in this review, because their pathology does not involve the basal ganglia.

Parkinson's disease

Definition

The terms 'paralysis agitans', 'the shaking palsy', 'Parkinson's disease', 'idiopathic parkinsonism', and 'idiopathic Parkinson's disease' have all been used, at various times, to describe the same entity. The definition of this entity is, however, fraught with difficulties. Initially, it was thought that the presence of Lewy bodies in the substantia nigra was the pathological *sine qua non* for the distinction of Parkinson's disease from other disorders. However, it has recently been recognized that Lewy bodies are quite non-specific, occurring in such diverse entities as Hallervorden–Spatz disease, certain forms of dementia, and subacute sclerosing panencephalitis. Furthermore, it has also been recognized that some patients who looked in every way as if they had Parkinson's disease during life, proved to have degeneration of cells in the substantia nigra with tangles rather than Lewy bodies.

There have been different approaches to resolving the dilemma created by this difficulty with definition. Perhaps the most satisfactory solution, for the present, is the use of the term 'Parkinson's syndrome' until we understand the aetiology, or, more likely, the many aetiologies of 'Parkinson's disease'. But the old terminology persists in most of the current literature, so the term 'Parkinson's disease' will be used here for the idiopathic syndrome of parkinsonism.

Aetiology

We already know that several distinct aetiologies are responsible for Parkinson's disease. For example, genetic factors have been identified, including mutations of the a-synuclein gene, the parkin gene, and a gene located on chromosome 2. Genetic causes of parkinsonism tend to produce symptoms at a younger age than sporadic Parkinson's disease. Most cases are sporadic, and are likely to have environmental aetiologies.

We are left with the unproven probability that there exist several different causes for Parkinson's disease, just as there exist several different causes for meningitis, or peripheral neuropathy.

Epidemiology

The prevalence of Parkinson's disease is around 200 to 300 per 100 000. The incidence is about 20 per 100 000 per year. These figures apply to the United Kingdom, Canada, and the United States. Studies on the geographical distribution indicate a low rate in Africa, China, and Japan. Prevalence rises with age, and Parkinson's disease is slightly commoner in males. The prevalence also increases with distance from the equator. A recent Canadian study suggests that Parkinson's disease is commoner in healthcare workers, teachers, and those who share cramped living conditions for sleeping (for example, miners and loggers working in camps)—while those who live more secluded lives have a low prevalence. These finding suggest the possibility that a viral infection might contribute to causation in some cases.

Pathology

The classical hallmark of Parkinson's disease is the relatively selective degeneration of the dopaminergic nigrostriatal pathway. In particular, the ventral tier of the zona compacta of the substantia nigra undergoes degeneration, and there is a reduction of dopamine in the striatum with a characteristic spatial distribution. The loss is predominantly posterior in the putamen, extending, to a lesser extent, forward into the anterior putamen and the caudate. In most cases of Parkinson's disease, Lewy bodies can be found in the substantia nigra.

Clinical features

The principal clinical features of Parkinson's disease are resting tremor, rigidity, and bradykinesia. In addition, postural reflexes are impaired, though this is a rather

non-specific finding. These clinical features can be regarded as the inclusion criteria for a diagnosis. There are also exclusion criteria, for Parkinson's disease should not be considered if pyramidal signs, cerebellar signs, gaze palsies, or autonomic deficits are prominent. As Parkinson's disease progresses, many patients develop dementia.

It is usual to find asymmetry in the clinical presentation of patients with Parkinson's disease, and they almost always respond to dopaminomimetic treatment if there are no dose-limiting side-effects.

Natural history

Parkinson's disease starts several years before patients first notice symptoms. The full extent of this 'preclinical phase' has not been defined. However, we do know that the loss of dopaminergic nigral cells is slow, and that some 50 per cent of the nigrostriatal pathway is lost when symptoms first become apparent. Pathological observations, positron emission tomography, and clinical examination all indicate that the rate of progression of neuronal loss decreases over the course of Parkinson's disease.

The mean duration of Parkinson's disease depends on the time of onset. In general, progression is slower when Parkinson's disease presents in younger patients; it may run a course of over 35 years in these circumstances. In older patients, although the duration is shorter, life expectation is still only slightly reduced. Primarily, the patient is faced with a reduction in the quality, rather than the quantity, of life. Nevertheless, the late stage of the illness can entail cruelly protracted and profound disability.

Differential diagnosis

The most common disorder that can be confused with Parkinson's disease is essential tremor. While the classical description of a resting tremor has been employed to characterize Parkinson's disease, the early stage of the illness is often accompanied by a rather low-amplitude postural tremor, similar to that seen in essential tremor. This phase in the evolution of Parkinson's disease only lasts for a year or two. In contrast, postural tremor is present for many years in essential tremor, and it is only in advanced stages of essential tremor that a resting tremor appears.

Drug-induced parkinsonism is another important consideration in the differential diagnosis of Parkinson's disease. All drugs that block dopamine receptors or deplete dopamine in the brain are capable of producing a parkinsonian syndrome. While the major tranquillizing drugs used to treat psychosis are most frequently responsible, other drugs such as metoclopramide, used to control nausea and modify gastrointestinal motility, are now an important cause of parkinsonism.

The most common serious neurodegenerative disorder to be confused with Parkinson's disease is progressive supranuclear palsy (Steele–Richardson syndrome). It may take a year or two before the importance of gaze palsies, nuchal rigidity, dementia, and impaired balance all lead to the realization that one is not dealing with classical Parkinson's disease.

Multiple system atrophy is also easily mistaken for Parkinson's disease. Again, the clinician may have to wait until the autonomic deficits or cerebellar features of multiple system atrophy become prominent. Drugs used to treat Parkinson's disease tend to induce orthostatic hypotension, compounding the difficulty in differential diagnosis. The task of determining whether orthostatic hypotension is part of the underlying illness or a consequence of treatment often poses a challenge.

Treatment

Medical treatment

There is no convincing evidence that any current treatment slows down the course of Parkinson's disease, so all treatment is directed at reducing symptoms and improving quality of life. The cornerstone of treatment is dopaminomimetic therapy, to overcome the impact of reduced dopamine in the striatum. The standard therapy for many years has been levodopa, combined with a peripheral decarboxylase inhibitor. Evidence is now accumulating that for initial treatment in the younger parkinsonian patient, the new artificial dopamine agonists give the best initial results. A recent 5-year study has shown advantages with ropinirole—because of a substantially reduced prevalence of dyskinesia. Other artificial dopamine agonists seem have similar benefits.

Drugs that inhibit the enzyme catechol-*O*-methyltransferase (COMT) are also useful in the management of Parkinson's disease because of their ability to extend the duration of action of levodopa.

Most patients develop a fluctuating response to levodopa after 3 to 6 years. This may be a deterioration in symptoms at the end of the interval between doses (wearing-off reactions) or unpredictable loss of mobility (on–off reactions). COMT inhibitors smooth out wearing-off fluctuations. The first COMT inhibitor, tolcapone, helped many patients. Unfortunately, it produced very rare fatal hepatic toxicity, so its use is restricted. Another COMT inhibitor, entacapone, has recently been introduced and this drug does not damage the liver.

Ropinirole

Ropinirole, a non-ergot dopamine agonist, is usually started at a dose of 0.25 mg three times a day, after food. The regimen is then increased to a four-times a day schedule, with individual doses gradually built up 8 mg daily. All dopaminomimetics can cause nausea and hypotension. Taking drugs after meals reduces nausea, which can generally be abolished by the addition of 10 mg domperidone, 30 to 60 min before each dose of dopaminomimetic agent. Increasing the intake of salt and fluids usually alleviates hypotension. The response to ropinirole varies from individual to individual, and sometimes the dose has to be increased further, up to 24 mg daily. All dose adjustments should be undertaken slowly. Psychiatric reactions, in particular visual hallucinations, are commoner than with levodopa. The main advantage of ropinirole is that it produces less dyskinesia than levodopa.

A disadvantage of ropinirole is a propensity to cause somnolence during the day, which may exceed the sleepiness associated with levodopa and the ergot derivatives, bromocriptine and pergolide. This problem of daytime sleepiness is shared with the other new dopamine agonist, pramipexole (see below).

Pramipexole

Pramipexole is another non-ergot dopamine agonist. The usual starting dose is 0.375 daily, but this is slowly increased to a range between 1.5 and 6 mg daily in four divided doses. The benefits and side-effects of pramipexole are similar to those of ropinirole, but there has been no controlled comparison of the two drugs. Just as with ropinirole, daytime sleepiness can be a problem. In some countries, physicians have been instructed by government regulatory agencies to warn patients taking pramipexole of the dangers of driving when receiving the drug—several motor accidents have been reported. In rats, pramipexole can increase sleep, and it has been suggested that this effect is produced by excessive stimulation of dopamine D3 receptors.

Bromocriptine

Bromocriptine was the first artificial dopamine agonist to be used for Parkinson's disease. It is an ergot derivative, and, in common with other ergots, can rarely cause pleural or pulmonary fibrosis, pleural effusion, and erythromelalgia. It is useful to obtain a baseline chest radiograph before starting treatment—for comparison if dyspnoea later develops. The usual starting dose of bromocriptine is 0.25 mg once daily, gradually building up to a dose of 20 to 30 mg daily, distributed in four doses, after food, as for all antiparkinson drugs. Occasionally the dose of bromocriptine may need to be increased further, to 40 or 50 mg daily.

Pergolide

Pergolide, another ergot derivative, was the second artificial dopamine agonist to be introduced for the treatment of Parkinson's disease. The usual starting dose is 0.15 mg daily, which may be increased up to 6 mg daily. The benefits and side-effects of pergolide are similar to those of bromocriptine. Pergolide is an agonist at D1 and D2 dopamine receptors, in contrast to bromocriptine, which is an agonist at D2 receptors and an antagonist at D1 receptors. These differences in pharmacological profile do not seem to be reflected by corresponding differences in therapeutic results, so D1 agonism may not be achieved at the dose levels of

pergolide that are employed therapeutically.

Cabergoline

Cabergoline is the newest ergot-derived dopamine agonist. It has the unusual properties of a plasma half-life extending beyond 60 h, so that one dose a day suffices for treatment. The dose range is between 0.25 and 4 mg daily. While it is certainly useful to have a drug with a long duration of action, side-effects will, of course, persist longer than with other dopaminomimetic agents.

Levodopa

Levodopa is prescribed in combination with a decarboxylase inhibitor that does not cross the blood–brain barrier. Sinemet®, a combination of levodopa and carbidopa (co-careldopa), is marketed worldwide. Madopar® (or Prolopa®), a combination of levodopa and benserazide (co-beneldopa), is marketed in many countries. The usual starting regimens for levodopa/carbidopa and levodopa/benserazide is 50 mg of levodopa with 12.5 mg of the decarboxylase inhibitor, administered twice daily, increasing, at 3- to 5-day intervals, to 150 mg of levodopa four times daily. Levodopa, combined with a decarboxylase inhibitor, has the lowest prevalence of early side-effects—but with the artificial dopamine agonists, levodopa can cause nausea and hypotension. Over a longer period, levodopa frequently causes dyskinesia and fluctuations in mobility. While psychiatric side-effects can occur with levodopa, they are less common than with the artificial dopamine agonists.

Preparations of Sinemet and Madopar with prolonged action

Sinemet CR and Madopar HBS have both been marketed as formulations with longer plasma half-lives than standard Sinemet and Madopar. Because these longer acting preparations are often incompletely absorbed, a higher dose has to be given to achieve the same effect as the standard preparations. The increase is about 30 per cent, but there is considerable variation between patients—a usual dose would be 200 mg four times a day The longer acting preparations of Sinemet and Madopar are most useful in patients who have 'wearing-off' reactions.

Entacapone

Entacapone is a new COMT inhibitor given together with levodopa (plus a decarboxylase inhibitor), and the combination extends the plasma half-life of levodopa. Thus patients who have 'wearing-off' reactions get prolongation of the 'on period'. The usual dose is 200 mg with each dose of levodopa. Since entacapone can exacerbate dyskinesia, it is often necessary to reduce the dose of levodopa when introducing entacapone. A reduction of 20 to 30 per cent usually suffices.

Early medical treatment

Most neurologists tend to start elderly patients with Parkinson's disease on a combination of levodopa with a decarboxylase inhibitor, often using the long-acting preparations. This treatment achieves quite a rapid improvement in symptoms with minimal early side-effects. Unfortunately, with prolonged treatment, dyskinesia and fluctuations in mobility may develop and ultimately become significant problems. However, with older and frailer patients, the early period of excellent therapeutic response is given first priority.

With younger patients neurologists tend to place more emphasis on the long-term results. In these circumstances it is usual to start treatment with an artificial dopamine agonist, because of the lower risk for the development of fluctuations in mobility and dyskinesia.

Late medical treatment

After 2 or 3 years, patients who started treatment with an artificial dopamine agonist need the addition of levodopa. For most of the duration of their disease, therefore, parkinsonian patients take a combination of an artificial dopamine agonist and levodopa.

Surgical treatment

Some 30 to 40 years ago, there was widespread interest in achieving suppression of tremor by placing a lesion in the ventrolateral or the ventral intermediate nucleus of the thalamus. With the advent of levodopa this procedure was performed less often, but recently there has been a resurgence of interest in stereotactic surgery. Lesions placed in the globus pallidus consistently alleviate dyskinesia and also help tremor. To a lesser extent, pallidotomy can improve rigidity and bradykinesia.

The trend in surgery is now changing from producing lesions to electrical stimulation. 'Deep brain stimulation' produces good results, with less risk of unwanted consequences. Furthermore, deep brain stimulation of the subthalamic nucleus seems to result in greater benefit than stimulation of the pallidum. At present, the surgical treatment of Parkinson's disease is going through a period of active research extending to the transplantation of cells that produce dopamine or levodopa.

Other parkinsonian syndromes

Progressive supranuclear palsy

The classical diagnostic feature of progressive supranuclear palsy is paresis of conjugate gaze. Initially there is a problem with looking up and down on command, and as the condition advances there is difficulty in following objects up and down. Vertical movement of the eyes can only be achieved by central visual fixation while the neck is flexed and extended. Although the disturbance with gaze is first apparent in the vertical plane, ultimately horizontal gaze also becomes affected. There is over-reaction of the frontalis muscles and extension of the neck to compensate for the weakness of upward conjugate eye movement. Patients with supranuclear palsy usually have an akinetic syndrome involving all limbs, with prominent rigidity of the neck and impairment of righting reflexes. As the condition advances there is intellectual impairment. Progressive supranuclear palsy usually presents in middle or late life, and it advances more rapidly than Parkinson's disease. There is sometimes a family history suggesting autosomal dominant inheritance.

Neuronal loss occurs with neurofibrillary tangles and gliosis. Atrophy of the tectum may be seen on brain imaging. The pathology extends to the substantia nigra, globus pallidus, subthalamus, dentate nucleus, and periaqueductal grey matter.

In the early stages of clinical evolution, there may be some response to dopaminomimetic therapy. Ultimately, however, this is lost. Once it has been appreciated that a patient has an atypical form of parkinsonism with prominent gaze palsies, the differential diagnosis is vascular disease of the brainstem. During life, it is often difficult to distinguish between progressive supranuclear palsy and vascular disease.

Multiple system atrophy

The term 'multiple system atrophy' was coined by Oppenheimer. Included within this entity are three syndromes that usually overlap: (1) strionigral degeneration leading to parkinsonism; (2) autonomic failure; and (3) olivopontocerebellar degeneration.

Multiple system atrophy is a sporadic disorder that generally presents in later life. The pathology may be widespread, involving the basal ganglia, the dorsal nucleus of the vagus, Onuf's nucleus, the cerebellum, and the intermediolateral column of the thoracic spinal cord.

Multiple system atrophy runs a briefer course than Parkinson's disease. While there may be some initial response to dopaminomimetic drugs, these often exacerbate orthostatic hypotension, and hence are seldom useful in advanced illness. It is usually necessary to use agents such as fludrocortisone and midrodrine in an effort to raise the blood pressure, but sometimes the supine blood pressure is so high that treatment becomes extremely difficult.

Stridor, loud snoring, and sleep apnoea are frequently encountered in multiple system atrophy. Sometimes tracheostomy is necessary.

Drug-induced parkinsonism

Drugs that block dopamine receptors, or deplete the storage of dopamine, can produce a syndrome clinically indistinguishable from Parkinson's disease. Almost always, withdrawal of the offending drug leads to a restoration of normal motor function. In patients who are disabled by psychotic symptoms, it may be impossible to stop treatment in order to alleviate the parkinsonian syndrome. In these circumstances, the treatment of choice is clozapine, which has fewer tendencies to produce parkinsonism than any other antipsychotic agent. Clozapine carries a risk of bone marrow depression, so regular blood counts are mandatory when this drug is employed.

Essential tremor

Essential tremor is probably more common than all the other movement disorders put together. Sometimes the adjective 'benign' is attached to the disorder, but this can be quite misleading. Essential tremor may be severe and disabling, though it seldom evolves to produce other neurological deficits—an exception is the quite frequent occurrence of ataxia in long-standing essential tremor among the elderly.

Although essential tremor most often involves the hands, the neck is also vulnerable, so that the head shakes from side to side, or up and down. Sometimes the voice is affected and there may also be a tremor of the chin. Uncommonly, essential tremor can occur in the legs.

The characteristic feature of essential tremor is a postural shake that is sustained during movement. Essential tremor can start at any age, and it may interfere with work, for example in cases where dexterity is important. It is also troublesome when tremor, in front of the public, leads to difficulty in job performance. The impact of essential tremor is amplified through stress, for when a patient particularly wants to control the shaking, circumstantial anxiety leads to exacerbation of the tremor.

Essential tremor can progress to have a serious effect on the quality of life. For example, eating and drinking can become so difficult that patients will no longer eat in the company of others. Essential tremor tends to get worse in the later stages of life, when it can become prominent at rest, mimicking the resting tremor of Parkinson's disease. There may also be some 'cog-wheeling', when testing passive resistance to movement of the wrist. Thus essential tremor can easily be confused with early Parkinson's disease.

In about half the patients with essential tremor it is possible to obtain a family history, indicating autosomal dominant inheritance: genes have been identified on chromosomes 2 and 3. We do not know the site of the pathology of essential tremor, but interest has been focused on the internal olive, the red nucleus, and the dentate nucleus.

The treatment of essential tremor is usually difficult. Some 30 per cent of patients respond to b-blocking drugs, and benzodiazepines such as clonazepam can be helpful. Sometimes primidone is useful. Although essential tremor is characteristically alleviated by alcohol, it is obviously inadvisable for patients to use alcohol on a regular basis to stop the shaking.

When essential tremor is severe, and it is impossible to achieve an adequate response with drugs, improvement can usually be obtained by performing a thalamotomy. Recently, encouraging results have been achieved with deep brain stimulation using an electrode implanted into the ventrolateral nucleus of the thalamus. Deep brain stimulation carries less risk than thalamotomy.

Dystonia

The term 'dystonia' is used to describe a pattern of abnormal movements in which there is sustained contraction of muscles, which may last for several seconds and can induce distorted postures. If a joint can twist, dystonia usually produces torsion—hence the term 'torsion dystonia'. Superimposed on these slow muscle contractions are often quick involuntary movements, which may be regularly repetitive in space and time, or quite irregular.Dystonia is often exacerbated by voluntary movement.

In addition to the term 'dystonia' being applied to these physical signs, it is also used for the 'disease' where no cause can be found. If dystonia is limited to one group of muscles, it is termed 'focal dystonia', and when the entire body is involved it is termed 'generalized dystonia'.

Generalized idiopathic dystonia

This condition usually starts in childhood or early adult life. It is dominantly inherited and the gene responsible, *DYT1*, has been identified on chromosome 9. This form of dystonia is particularly common in Ashkenazim Jews. Dystonia generally progresses over several years and then reaches a plateau. Treatment is difficult; high doses of anticholinergic drugs such as trihexyphenidyl are most effective.

Dopa-responsive dystonia

In any patient with generalized dystonia it is most important to consider the possibility of dopa-responsive dystonia (hereditary progressive dystonia, Segawa's disease), because treatment for this disorder is so effective. Low doses of dopaminomimetic drugs are therapeutic throughout the life of the patient.

The pathogenesis of dopa-responsive dystonia has been worked out with considerable precision. Several mutations—about 60—can be responsible, all on chromosome 14, and all associated with the production of the cofactor for tyrosine hydroxylase, tetrahydrobiopterin. When this cofactor is lacking, tyrosine cannot be converted to dopa, so there is inadequate dopamine available in the striatum. This condition of dopamine depletion leads to dystonia, and in addition these patients usually have some parkinsonian features. Indeed, when dopa-responsive dystonia presents in late life, the parkinsonian features may overshadow the dystonia.

Hemidystonia

Dystonia involving one side of the body is often caused by a structural lesion in the contralateral basal ganglia. Infarcts are most often responsible, but brain imaging should be undertaken to exclude tumours.

Focal dystonia

The commonest form of dystonia is localized to the neck muscles; known as cervical dystonia or spasmodic torticollis. Sometimes there is a genetic basis for this condition, but usually it presents sporadically. Cervical dystonia generally responds to local injections of low concentrations of botulinum toxin. Blepharospasm is another focal dystonia that responds well to botulinum toxin, and dystonia of the vocal cords also responds, in many cases, to small injections of this toxin.

Tardive dyskinesia

Tardive dyskinesia is a syndrome of involuntary movements induced by long-term exposure to dopamine-blocking drugs. Major tranquillizers are usually responsible, but drugs employed to treat nausea, such as metoclopramide, are more recent culprits. While dystonic features usually predominate in tardive dyskinesia, there may also be obvious chorea.

Tardive dyskinesia is a chronic condition, and while it sometimes resolves spontaneously in younger patients, it is generally permanent in the elderly. Paradoxically, there is frequently an exacerbation—or initial appearance—of tardive dyskinesia when the drug responsible is reduced or stopped.

Treatment for tardive dyskinesia is withdrawal of the drug responsible when possible, and the administration of tetrabenazine. Unfortunately, tetrabenazine can cause depression, and is therefore contraindicated when tardive dyskinesia develops in a psychotic patient with depressive features. In this setting, serious psychotic disease with tardive dyskinesia is often managed by increasing the dose of the causal drug.

Chorea

The term 'chorea' derives from the Greek word for dancing. The physical sign of chorea is quick involuntary movement, irregular in space and time, generally most prominent in the extremities. Chorea is closely related to ballism, which is a high-amplitude displacement of the proximal muscles. In patients who develop ballism due to a stroke, the natural history of spontaneous improvement progresses through a phase of chorea, followed by a final resolution of the chorea.

Huntington's chorea

Huntington's chorea is an inexorably progressive disorder featuring a combination of chorea and dementia. The pathology primarily involves the caudate nucleus, but it extends beyond this initial focus.

Huntington's chorea is dominantly inherited; it is caused by a mutation on chromosome 4—the huntingtin gene—characterized by an expansion of CAG repeats.

Huntington's chorea generally starts in mid-adult life, around the age of 35 years. However, it can start in childhood, when it tends to have a more rigid presentation resembling parkinsonism. This is known as the Westphal variant. Sometimes Huntington's chorea can present in late-adult life, over the age of 70.

There is no effective treatment for Huntington's chorea. Tetrabenazine will reduce the involuntary movements, but the progressive dementia is resistant to all therapy.

Other forms of chorea

Neuroacanthocytosis is a rare autosomal recessive disorder associated with hypogammaglobulinaemia. It produces involuntary movements, of which the commonest is chorea—but neuroacanthocytosis can also cause parkinsonism or dystonia.

Sydenham's chorea is associated with rheumatic fever; both are now rare conditions, although they still occasionally occur in children. The chorea runs a benign course, with spontaneous remission usually taking place within 3 to 6 months.

Rarely, chorea can occur during pregnancy, or with exposure to oestrogens. Occasionally other drugs such as phenytoin and digoxin can cause chorea. Severe thyrotoxicosis may produce choreatic movements, as may systemic lupus erythematosus.

Tic

Although tics are usually quick involuntary movements, they may be more prolonged; the term 'dystonic tic' has been coined for the slow variety. Patients feel a compulsion to move, and the characteristic feature of all tics is the patient's ability to suppress them for brief periods of 30 to 60 s.

Tics confined to a single muscle group often persist through life. When tics move around from one part of the body to another, they are termed 'chronic multiple tic', or Gilles de la Tourette disease.

Gilles de la Tourette disease

Gilles de la Tourette disease is dominantly inherited, though the penetrance is variable, so that often a positive family history cannot be obtained. Gilles de la Tourette disease affects boys more often than girls, and it generally starts before the age of 15 years. Tics persist, waxing and waning in severity, over several years, though they often disappear in mid-adult life. In addition to the common movements of the face, shoulders, and hands, there are often truncal movements, and sometimes there are involuntary noises, such as excessive sniffing, throat clearing, or barking. Words may be uttered inappropriately and often these are expletives. Similarly, affected individuals may make obscene gestures.

The pathological basis of tics is not known, but they generally respond to drugs that decrease dopaminergic transmission. In the past, major tranquillizing drugs have been used, but these carry a risk of causing tardive dyskinesia, which, may itself, be expressed as a tic. Tetrabenazine is the most satisfactory treatment for most patients. Unfortunately, sedation can be a troublesome side-effect, particularly for children who are attending school. Depression can also develop and the drug should be withdrawn if this happens. It is therefore best to try to manage patients without using drugs, explaining that educating family, friends, employers, and teachers may help patients to cope. Sometimes, however, Gilles de la Tourette can cause severe tics and noises that are socially disruptive, and in such cases a minimal but therapeutic dose of tetrabenazine must be sought, usually between 12.5 and 100 mg daily.

Gilles de la Tourette disease is often associated with obsessive–compulsive behaviour and attention disorder with hyperactivity; in such cases psychiatric advice is necessary. Clomipramine or fluoxetine may be helpful in these circumstances.

Other conditions

The spectrum of movement disorders is extensive, and space does not permit consideration of all. For a more comprehensive survey, the reader is referred to Jankovic and Tolosa (1998), which provides descriptions of Creutzfeldt–Jakob disease, Hallervorden–Spatz disease, cortical basal ganglionic degeneration, dentatorubropallidoluysian atrophy, olivopontocerebellar atrophy, paroxysmal dystonia, restless leg syndrome, myoclonus, and ataxia. This source also describes the neurology of Wilson's disease, but for a discussion of the metabolic disturbance and treatment of Wilson's disease the reader is referred to Chapter 11.7.2.

24.13.11 Disorders of movement (excluding Parkinson's disease)

*Roger Barker**

Movement disorders typically result from diseases of the basal ganglia and can be classified into one of five main categories: dystonia, chorea, tremor, tics, and myoclonus (see Table 1 for definitions). Each type of abnormal movement may occur in several diseases and many treatments are empirical. However, the study of molecular genetics and the use of functional imaging has revealed subtle neurochemical abnormalities which should facilitate development of more rational therapies.

In this section, attention is drawn to abnormal movements that are a principal manifestation of the disease. Movement disorders have been divided into hyperkinetic and hypokinetic conditions; however, this classification may be misleading because a given disease often evolves with time. It is probably more useful to classify movement disorders by type.

The dystonias

Definition

Dystonias are characterized by prolonged muscle contractions, causing abnormal movements and postures.

Classification

When no symptomatic cause for dystonia can be discovered, the syndrome is described as idiopathic or primary dystonia, and if generalized then the disorder is synonymous with idiopathic torsion dystonia. Secondary dystonia is due to a defined exogenous, structural, or metabolic disorder. 'Dystonia plus' syndrome constitutes dystonia in combination with other abnormalities (for example myoclonic dystonia) and heredodegenerative dystonia occurs when there is an underlying brain degeneration. Dystonia may affect the whole body (generalized dystonia), adjacent parts such as an arm and neck (segmental dystonia), or may be restricted to one part (focal dystonia) as in spasmodic torticollis, dystonic writer's cramp, blepharospasm, oromandibular dystonia, and laryngeal dystonia.

Idiopathic dystonia is frequently inherited (see below), but the focal dystonias usually occur sporadically in middle life. However, focal dystonias may be isolated fragments of the syndrome of idiopathic torsion dystonia.

Aetiology

The many metabolic and other inherited or sporadic diseases that can cause dystonia (Table 2) usually produce other neurological symptoms and signs. A symptomatic cause for dystonia is found in about 50 per cent of children with the condition, but is rare in those with adult onset. In adults, dystonia is most likely to remain confined to its site of origin as a focal dystonia, and the legs are rarely affected. Children often develop symptoms in the legs and frequently develop segmental or generalized dystonia.

The recent identification of mutations in genes responsible for forms of dystonia gives hope for understanding its basis (see Table 2). Abnormalities within the basal ganglia and associated cortical motor areas have been found in some patients with secondary dystonia.

Idiopathic (torsion) dystonia

Symptoms

Idiopathic (torsion) dystonia may present in childhood, when it is frequently inherited as an autosomal dominant trait, or in adult life, when a family history is unusual. In many families with early onset disease, genetic linkage studies have localized the abnormal gene mutation to the *DYT1* locus on chromosome 9q34 which codes for torsin A, a protein of unknown function expressed in the brain (including the substantia nigra). Ashkenazi Jews are particularly prone to this condition. It usually presents in children with dystonic spasms of the legs on walking, or sometimes of the arms, trunk, or neck. The condition is usually progressive when it commences in childhood; the spasms spread to all body parts, leading to severe disability within about 10 years. The intellect is preserved and there are no signs of pyramidal or sensory deficit. Speech is often spared, permitting the pursuit of intellectual employment despite severe physical disability. A spontaneous remission of symptoms occurs in about 10 to 20 per cent of patients, usually within 5 years of onset. There is no way of predicting who will remit or when such a remission will occur. Most remissions are transitory, lasting a matter of weeks or months, but occasionally they may persist.

In adults, the condition usually presents as a focal dystonia (blepharospasm, oromandibular dystonia, spasmodic dysphonia, torticollis, axial dystonia, or dystonic writer's cramp). The legs tend to be spared, and progression is slow, with the dystonia remaining confined to its site of origin. Segmental dystonia develops in some cases.

Treatment

Dystonia is distressing and difficult to treat. Every child and young adult with dystonia should receive a trial of levodopa (for example, Sinemet-Plus up to two tablets

three times a day for 3 months), for they may have the condition of dopa-responsive dystonia-parkinsonism (see below).

The drugs which most patients find helpful, and continue to take to suppress muscle spasm, are benzodiazepines such as diazepam, often in a large dose of 20 to 50 mg daily, and an anticholinergic such as benzhexol, again in large doses (up to as much as 120 mg/day). Fifty per cent of children and 10 per cent of adults will be helped, but adults are more sensitive to anticholinergic side-effects. Phenothiazines and other neuroleptics, such as haloperidol, may also help some patients, as may tetrabenazine, but often at the expense of drug induced parkinsonism. Unfortunately, dystonia is far less responsive to neuroleptics than is chorea. Many other drugs have been tried in dystonia, but none has gained wide acceptance.

The recent interest in neurosurgery for movement disorders has extended to the treatment of dystonia, especially when the disease is advanced and disabling. Originally the thalamus was targeted for surgery but pallidotomy has recently been favoured in the management of patients with generalized dystonia (whereas selective denervation procedures have been used in focal dystonia—see below). In general, patients with generalized torsion dystonia respond erratically to this procedure and at present there is little evidence to support its use.

Dopa-responsive dystonia-parkinsonism (Segawa's syndrome)

This condition is inherited as an autosomal dominant condition with incomplete penetrance and has as its defect mutations in the guanosine triphosphate cyclohydrolase 1 gene. This generates a cofactor for maintaining the normal activity of tyrosine hydroxylase, the rate limiting step in the catecholamine biosynthetic pathway. Homozygous deficiency of this enzyme severely inhibits tyrosine hydroxylase activity and produces mental retardation, seizures, and truncal hypertonia. However, the more common partial deficiency in tyrosine hydroxylase results in dystonia affecting the legs which becomes worse as the day goes on. Rest without sleep does not help, but sleep relieves the dystonia. Many patients also have features of parkinsonism, although focal dystonia may be the presenting feature. The disease can easily be mistaken for cerebral palsy (given its lower limb predominance) or an unexplained 'spastic paraparesis'.

There is a reduction in turnover of dopamine due to the abnormality in tyrosine hydroxylase activity; patients respond well to low doses of levodopa without showing any of the long-term complications encountered in Parkinson's disease.

Spasmodic torticollis

Symptoms

Spasmodic torticollis may be the presenting feature of dystonia in childhood, but isolated spasmodic torticollis usually occurs in the middle aged or elderly. The onset is usually insidious, often with initial pain, and sometimes appears to be precipitated by trauma. The dystonic spasms affect sternomastoid, splenius, and other neck muscles to cause the head to turn to one side (torticollis) (Fig. 1), or occasionally to extend (retrocollis) or to flex (antecollis) the neck. The spasms may be repetitive to cause tremulous torticollis, or sustained to hold the posture. The trunk commonly shows a compensatory lordosis.

Fig. 1 Spasmodic torticollis in a 57-year-old man. The hypertrophy of the sternomastoid muscle is evident.

The condition is usually lifelong, but remissions of a year or more occur in about one-fifth of cases. Most patients are otherwise normal apart from their torticollis, although some may exhibit a postural tremor similar to that of benign essential tremor, and a minority may develop dystonia elsewhere. As with all types of dystonia, the frequency and intensity of the muscle spasms vary considerably, being particularly worse in conditions of mental or emotional stress. A feature characteristic of spasmodic torticollis is the 'geste antagonistique', in which the patient discovers some particular manual act which controls the deviation of the head. A touch of the forefinger to the jaw may suffice, but other more complex and bizarre actions are common.

Treatment

Spasmodic torticollis, like other types of adult onset focal dystonia, does not usually benefit from conventional drug therapy. The best treatment is injection of botulinum toxin A into the most affected muscles. Botulinum toxin prevents the release of acetylcholine and causes functional denervation with localized muscle weakness. Identification of the overactive muscles is a prerequisite to the administration of localized injections of botulinum toxin which, in the case of torticollis, typically involves injections into the sternomastoid and splenius muscles. These injections usually have an effect within a week although the maximum benefit is not apparent until several weeks later. Repeat injections are required approximately every 3 months as relapse, by terminal sprouting, occurs. In about 10 to 20 per cent of patients, antibodies eventually develop to the botulinum toxin A making it less effective with time. In these cases a switch to a botulinum toxin type F or B may be desirable; the long-term efficacy of this manoeuvre is under investigation.

Surgery is sometimes practised and local denervation procedures are still considered in patients with otherwise intractable cervical dystonias.

Dystonic writer's cramp

Symptoms

Inability to write (or to type, play a musical instrument, or wield any manual instrument) has many causes but in most patients no objective neurological deficit is found other than abnormal posturing of the hand and arm on writing. Typically, the pen is gripped with great force and driven into the paper (Fig. 2). However, in some patients the arm adopts a typical dystonic posture and in such cases of dystonic writer's cramp, other manual acts such as wielding a knife or screwdriver are similarly affected. Such dystonic writer's cramp may be the initial symptom of generalized torsion dystonia, but in adults it often remains as an isolated disability. The same considerations apply to other occupational cramps, such as pianist's cramp.

Fig. 2 (a) Dystonic writer's cramp in a 52-year-old man, whose right elbow rises and whose fingers grip the pen so tightly that they slide off. (b) Example of writing and drawing in this patient showing difficulty in executing the task and thus legibility of script and ability to copy simple figures.

Treatment

Writer's cramp, and related conditions, are usually permanent disabilities. Advice to write with the opposite hand allows most to cope with everyday events, but approximately 1 patient in 20 then develops the same problem in the non-dominant hand. Drugs (such as bezhexol and diazepam) are rarely of benefit but botulinum toxin injections into the muscles of the affected forearm may help some patients.

Blepharospasm and oromandibular dystonia (cranial dystonia)

Symptoms

Blepharospasm refers to recurrent spasms of eye closure. The orbicularis oculi forcibly contracts for seconds or minutes, often repetitively and sometimes so frequently as to render the patient functionally blind (Fig. 3). Spasms of eye closure commonly occur while reading or watching television, or in bright light; they often decrease or disappear when the subject is alerted or under scrutiny. Oromandibular dystonia refers to recurrent spasms of muscle contraction affecting the mouth, tongue, jaw, larynx, and pharynx, causing spasms of lip protrusion or retraction, jaw closure or opening (Fig. 4), and difficulty in speech and swallowing. Such patients may lacerate their lips and tongue or even dislocate their jaw, and are usually unable to cope with dentures. Speech may take on a characteristic, forced strained quality, and chewing and swallowing may be impaired.

Fig. 3 Blepharospasm in a 57-year-old woman. Her jaw also is forcibly clamped shut, biting her gums, and some spasm of orbicularis oris is evident, in addition to the obvious spasm of orbicularis oculi.

Fig. 4 Oromandibular dystonia in a 42-year-old woman. The spasm of forced jaw opening with tongue protrusion is evident.

These two conditions are closely related, for the patient with blepharospasm may develop oromandibular dystonia and vice versa. The term Brueghel syndrome is often used when the dominant (or only) feature is a dystonically opened jaw, whilst Meige syndrome has blepharospasm as its central feature. Both conditions may occur in generalized torsion dystonia, or result from drugs; they also appear in isolation in late life without evident cause.

Treatment

Unfortunately, both blepharospasm and oromandibular dystonia are notoriously difficult to control with drugs (for example benzhexol, diazepam, and/or a neuroleptic). Surgery cannot improve oromandibular dystonia but can relieve blepharospasm. The best treatment for blepharospasm is to inject botulinum toxin into the orbicularis oculi which gives relief in about 70 to 80 per cent of cases, thereby restoring normal vision for about 3 months. The injections can be repeated as necessary. Botulinum toxin injections can be used to control some jaw spasms.

Spasmodic dysphonia

Dystonic spasms of the muscles controlling the vocal cords cause spasmodic dysphonia, which impairs speech and singing, and may be severe enough to prevent communication. The most common type involves the adductor muscles, leading to a strangled speech with pitch breaks and stops. Less common is abductor dysphonia which produces a breathy, low-volume voice. The diagnosis can be established by direct non-invasive visualization of the vocal cords during talking. Spasmodic dysphonia may occur in association with cranial or generalized dystonia, or may appear as an isolated focal dystonia in adult life. Speech can be restored by injection of botulinum toxin into the overactive vocal muscles, identified by electromyography.

Paroxysmal dystonia

Focal dystonias often commence with the appearance of a dystonic posture or spasm only on one motor act (action dystonia), but there are rare, usually familial, disorders in which dramatic dystonia occurs intermittently in attacks, the patient being normal in between. These conditions are thought to be caused by mutations in genes encoding ion channels. Several families with paroxysmal dystonic choreoathetosis have now shown linkage to chromosome 2q35–37, where a number of candidate genes have been identified for study.

Chorea

Chorea is seen in many disorders (see Table 3, Fig. 5), but the most common cause other than the treatment of Parkinson's disease is Huntington's disease. There are also several non-inherited conditions in which chorea can occur and in which treatment is beneficial.

Fig. 5 Chorea due to polycythaemia rubra vera in a 57-year-old woman. The characteristic fleeting choreic movements are captured in these three sequential frames.

Huntington's disease

Definition

A dominantly inherited, relentlessly progressive disease, usually of middle life, characterized by chorea and dementia. It was first described in 1872 by George Huntington, a year after he had qualified in medicine, in a handful of families of English descent in a region of Long Island, New Jersey.

Aetiology

The prevalence of the disease is about 1 in 10 000 and it occurs in all ethnic groups worldwide. The condition is inherited as an autosomal dominant trait with full penetrance. The genetic defect is now known, can be tested for, and consists of an abnormal cytosine–adenine–guanine triplet repeat in the gene encoding huntingtin on chromosome 4 and represents one of a number of triplet repeat disorders causing neurological disease. Triplet repeat sequences normally exist in several genes but when an excess number of repeats occurs a disease state is produced. This pathological triplet (or trinucleotide) repeat occurs in the coding region of the huntingtin gene and the consequence of a large unstable DNA sequence is that the triplets can expand during mitosis and meiosis, resulting in longer triplet repeat sequences (dynamic mutation). The most likely time for triplet expansion is during spermatogenesis and subsequent fertilization/embryogenesis; this has two major implications. First, longer repeats tend to occur in the offspring of affected men, and secondly longer repeats tend to occur in the subsequent generations. This results in an earlier onset and more severe form of the disorder in subsequent generations—a phenomenon known as genetic anticipation; i.e. longer repeat sequences are associated with younger onset, more severe forms of the disease.

The abnormal expansion of the cytosine–adenine–guanine repeat in Huntington's disease (more than 36 repeats) causes a new gain of function in the mutant huntingtin. This new protein acquires a unique function that is central to the evolution of the neurodegenerative process. Furthermore this protein is known to interact with a number of other proteins (for example huntingtin associated protein 1), which may be critical for the development of selective pathology. Inclusion bodies resulting from the polymerization of polyglutamine sheets in the mutant huntingtin protein develop in neurones but the exact mechanism by which selective neuronal death at specific sites occurs is unknown.

The chorea of Huntington's disease appears to result from relative overactivity of dopamine mechanisms in the brain, perhaps because the intact dopaminergic nigrostriatal pathway is releasing approximately normal quantities of dopamine on to only a few remaining striatal neurones. Positron emission tomographic studies using ^{18}F-labelled deoxyglucose have revealed a profound reduction of glucose metabolism in the striatum, even in patients without discernible cerebral atrophy.

Pathology

The brain is generally atrophic, with conspicuous damage to the cerebral cortex and corpus striatum, where there is loss of nerve cells and reactive gliosis without inflammatory changes associated with extensive neurotransmitter changes.

Coronal section of the brain characteristically shows dilated lateral ventricles, in which the floor becomes concave rather than convex, due to marked caudate atrophy; commonly, cortical atrophy is also evident. The main histological abnormality is found in the caudate and putamen, where there is extensive loss of small neurones, leading to shrinkage, and a false impression of gliosis, although such changes are found elsewhere. More recently attention has focused on the early stages of the condition, as the identification of the genetic defect involved has allowed for the disease to be diagnosed with certainty. In early cases and in mice transgenic for the mutant human huntingtin protein the earliest histological findings are the neuronal inclusions, which precede the cell loss.

Symptoms

The onset is typically insidious, usually between the ages of 30 and 50 years, and can be with motor, cognitive, and/or psychiatric symptoms and signs. The initial symptoms are frequently those of a change in personality and behaviour, but chorea may be the first sign. At this stage the patient often retains distressing insight, fully aware of what is in store. Serious depression is common and suicide is a risk. Erratic behaviour at work or in society may lead to psychiatric referral, or rarely a frank schizophrenic-like psychosis may develop. As the disease progresses, cognitive deficits become more pronounced and chorea more severe with walking, speech, and the use of the hands are impaired. As the disease progresses, many patients develop increasing rigidity and akinesia, with reduction of the chorea. Finally the patient becomes bedridden with marked weight loss; death occurs on average about 14 years from the onset. Huntington's disease does not always present in this fashion, and a number of variants are recognized including an akinetic-rigid parkinsonian syndrome (the Westphal variant), which is most frequent in children.

Diagnosis

Despite the diverse clinical manifestations of Huntington's disease, with genetic testing the diagnosis is now straightforward. However, in some cases the characteristics of the disease are not obvious and a history is not available, which can mean that the diagnosis is overlooked (see Table 3).

Treatment

There is currently no cure for Huntington's disease. Drugs that modify the dopaminergic input to the striatum can be used (for example tetrabenazine and sulpiride) to treat the chorea but rarely provide a sustained benefit—in fact most patients with Huntington's disease rarely complain of their chorea. Other drugs may be required for psychiatric symptoms including selective serotonin reuptake inhibitors for depression, neuroleptics for psychotic symptoms, and carbamazepine and sodium valproate as mood stabilizers.

A further recent intervention in Huntington's disease has involved the use of neurotrophic factors, such as ciliary neurotrophic factor as well as neuroprotective therapies (for example coenzyme Q); the benefits of these measures are uncertain. Surgical treatment for chorea is poorly documented but there has been increasing interest in the possibility of neural transplantation in Huntington's disease.

Sooner or later chronic hospital care is required for patients with Huntington's disease. Increasing nursing problems may require admission to hospital where dietary advice (including gastrostomy for feeding) and physiotherapy may be of benefit. Particular attention should be directed towards supporting the family, for the nature of the disease poses great ethical and emotional problems.

Genetic testing

Predictive testing programmes are now available for individuals at risk, provided by multidisciplinary teams specializing in this condition and often directed by an

experienced neurogeneticist.

Sydenham's chorea

Definition

Chorea (St Vitus's dance) associated with psychological disturbance due to rheumatic fever (rheumatic chorea) in childhood and adolescence was first described by Thomas Sydenham in 1686.

Aetiology and pathology

Sydenham's chorea was associated with many streptococcal infections, but it is now most frequently associated with acute rheumatic fever, and as a result is rare in most parts of the world. The mechanism is thought to be antibody mediated, against epitopes within structures of the basal ganglia, which would help explain the characteristic radiological lesions seen within the basal ganglia of affected patients. Antineural antibodies have been isolated in cases of Sydenham's chorea and may result from cross-reactivity with elements of group A streptococcal membranes, although the pathogenic nature of these antibodies has not been demonstrated unequivocally.

Symptoms

About three-quarters of cases occur between the ages of 7 and 12 years. The onset is usually gradual, but may be abrupt. The initial symptoms are often psychological, with irritability, agitation, disobedience, and inattentiveness. A frank organic confusional state occurs in about 10 per cent of patients. Generalized chorea then appears and may worsen for a few weeks; speech is impaired in about a third of patients. The chorea is predominantly unilateral in about 20 per cent of patients, and in severe cases is accompanied by flaccidity and subjective weakness (chorea mollis). Although cardiac disease may be found, the child usually has no fever or other manifestations of rheumatic fever.

The chorea and psychological disturbance recover over 1 to 3 months, rarely up to 6 months, but recurrences occur in about a quarter of patients over the next 2 years. About a third of patients will show evidence of rheumatic cardiac involvement at the time of the illness, and about the same proportion later develop chronic rheumatic heart disease. Those who have suffered one or more attacks of Sydenham's chorea are at particular risk of developing chorea in adult life during pregnancy (chorea gravidarum), or when exposed to drugs including oral contraceptives, digoxin, or phenytoin. Although usually self-limiting, more persistent neurological deficits occasionally occur in Sydenham's chorea.

Treatment

Treatment as for rheumatic fever is necessary. The chorea may be controlled with diazepam, haloperidol, or tetrabenazine. A course of penicillin should be given, and prophylactic oral penicillin should be continued until about the age of 20 years to prevent further streptococcal infection.

Hemiballism (hemichorea)

Hemiballism refers to wild flinging or throwing movements of one arm and leg. These movements, like those of chorea, are irregular in timing and force, but involve the large proximal muscles of the shoulder and pelvic girdle. The occasional child or adolescent with Sydenham's chorea may present with hemiballism, but the syndrome usually occurs in elderly hypertensive and/or diabetic patients as a result of a stroke. The vascular lesion usually affects the subthalamic nucleus, although lesions at other anatomical sites may be responsible. It may appear as the hemiplegic weakness improves, when it is often accompanied by thalamic pain, although in other patients the hemiballism appears abruptly without weakness or sensory deficit. The intensity of the movements varies from mild to a severity that causes injury and requires urgent treatment.

Hemiballism due to stroke usually remits over 3 to 6 months. Treatment with a phenothiazine, haloperidol, or tetrabenazine will often control hemiballism until recovery occurs, but interventional neurosurgery is occasionally required and may be beneficial.

Tremor

Three types are generally recognized—static, postural, and action tremors (Table 4). Static tremor occurs when a relaxed limb is fully supported at rest. Postural tremor appears when a part of the body is maintained in a fixed position and may also persist during movement. Kinetic or action tremor occurs specifically during active voluntary movement of a body part. If the amplitude of such an action tremor increases as goal-directed movement approaches its target, this is an intention tremor. Psychogenic tremors are generally rare. They are often of sudden onset with a variable but rarely remitting clinical course and typically affect the trunk or limb with standing and/or using the limb respectively.

Physiological tremor has a frequency in the 7 to 11 Hz band and is typically symptomatic in states of increased sympathetic nervous activity and is increased by stimulation of peripheral b_2-adrenergic receptors in muscle. The fine postural tremors associated with stress and anxiety states along with thyrotoxicosis fall into this category and usually respond to b-adrenergic blocking drugs. Symptomatic postural tremors occur in association with many neurological disorders and can be shown to differ from physiological tremor by frequency analysis.

Benign essential (familial) tremor

Definition

A condition characterized by postural tremor of the arms and head which can present at any age, although usually in early adult life. It is only slowly progressive, generally causes mild disability, and is not associated with dystonia or parkinsonism.

Aetiology

The cause of benign essential tremor is unknown. A positive family history is obtained in over half of such patients with a pattern of inheritance that indicates an autosomal dominant trait.

Pathophysiology

No pathological or biochemical abnormality has been identified in benign essential tremor, but few cases have come to autopsy. Essential tremor is usually of a frequency of 5 to 8 Hz (Fig. 6). Recent functional imaging studies indicate abnormal activation of the cerebellum, red nucleus, and thalamus.

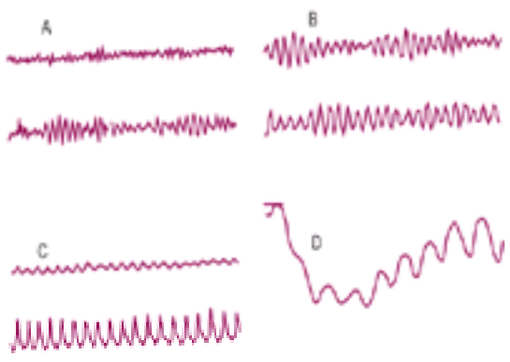

Fig. 6 Recordings of tremor with accelerometers placed on the right arm (above) and the left arm (below) in (a) a patient with enhanced physiological tremor of the outstretched arms (frequency 9 to 10 Hz), (b) a patient with benign essential tremor with the arms outstretched (frequency 7 Hz), (c) a patient with left-sided Parkinson's disease at rest (frequency 5 Hz), and (d) a patient with severe cerebellar disease and marked intention tremor attempting to touch his nose with the right hand (frequency 2 to 3 Hz). All recordings are of 4 s duration. (By courtesy of Dr M. Gresty.)

Symptoms

Tremor is present in one or both hands on maintaining a posture, as when holding a cup or glass. Handwriting becomes untidy and tremulous (see Fig. 7). There is no tremor at rest, but a rhythmic oscillation develops when the patient holds the arms outstretched. On movement, as in finger–nose testing, the tremor continues but does not get strikingly worse, as is the case with cerebellar intention tremor. Tremor of the head (titubation) and jaw is present at about 50 per cent of cases, and tremor of the legs occurs in about a third. Despite the tremor, tests of co-ordination are usually normal, walking is unaffected, and there are no other neurological abnormalities.

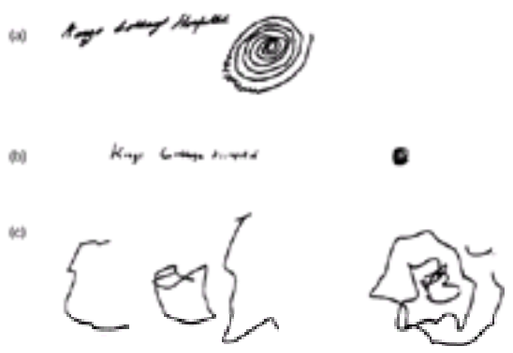

Fig. 7 Samples of handwriting and spiral drawings from (a) a 50-year-old woman with benign essential tremor, (b) a 38-year-old man with Parkinson's disease, and (c) a 20-year-old man with torsion dystonia (who attempts to write COLLEGE).

Two other factors are characteristic of this disorder. First, a family history and, secondly, the observation that small or moderate doses of alcohol may suppress the tremor. The illness is static or only slowly progressive in most patients, causing predominantly a social disability, but individuals dependent upon manual skill may be disabled.

Other variants of the syndrome are occasionally encountered. Thus isolated, inherited head tremor may occur, with either 'yes–yes' or 'no–no' movements, and tremulous 'writer's cramp' (primary writing tremor) is recognized. Tremor of the legs on standing, at around 5 to 8 Hz (orthostatic tremor), may occur as an isolated syndrome or in the context of essential tremor.

Treatment

Although alcohol may suppress the tremor effectively, and can be of value if used wisely, there is a risk of patients becoming alcoholics. Benzodiazepines, such as diazepam, may give some relief at times of stress, but have no major effect on the tremor. Thirty to 40 per cent of patients respond satisfactorily to a b-adrenergic receptor antagonist such as propranolol (up to a dose of 240 mg/day). Primidone, in standard anticonvulsant dosages, also helps some. Stereotaxic thalamotomy or deep brain stimulation of the thalamus may be required in the very small number of patients whose tremor is severe.

Tics

Tics occur in several disorders (see Table 5) and are defined as simple or complex. A simple tic is a sudden, rapid twitch-like movement always of the same nature and at the same site and occurs in about a quarter of all children, disappearing within a year or so (transient tic of childhood). Sometimes these persist into adult life, but are rarely considered as abnormal (chronic simple tic) such that only a minority seek assistance. Tics that are more widespread and severe, and take the form of complicated stereotyped patterns of motor action, are termed complex tics.

Characteristically, complex and simple tics can be suppressed voluntarily although this causes mounting inner tension which can only be relieved by expression of the tics. Complex multiple tics accompanied by vocal utterances, particularly swear words (coprolalia), and compulsive thoughts constitute the Gilles de la Tourette syndrome, which is an organic cerebral disease of unknown aetiology.

Gilles de la Tourette syndrome

Aetiology

George Gilles de la Tourette described the syndrome of chronic multiple tics with vocalizations in 1885, although Itard had described an earlier case. The condition appears to be inherited as an autosomal dominant trait, with variable penetrance. In affected families the genetic abnormality may be expressed as the full syndrome, as chronic multiple tics alone, or as an obsessive–compulsive neurosis (see below). Whilst the cause of this bizarre condition is unknown, the basal ganglia are believed to be involved because abnormalities within the striatum (and paralimbic areas) have been detected using positron emission tomography. Subtle abnormalities within the caudate and pallidum have been reported at post-mortem. Furthermore, drugs acting on the basal ganglia, such as haloperidol, may control the symptoms.

Symptoms

The illness usually begins between the ages of 5 and 15 years, with multiple involuntary repetitive muscular tics which vary in site, number, frequency, and severity with time. These particularly affect the upper part of the body, especially the face, neck, and shoulders, more than the limbs and trunk. Typical initial symptoms are eye blinking, head nodding, sniffing, or stuttering. With time other more complex tics affecting other parts of the body appear. The motor tics are often preceded by a sensory urge (sometimes called a sensory tic), and they can be controlled, albeit temporarily, by an effort of will. Eventually, however, the patient has to 'let the tics go'.

Sooner or later, most patients with multiple tics make involuntary noises, such as grunting, squealing, yelping, sniffing, or barking. Indeed, the coexistence of such noises with multiple tics is an essential feature of Gilles de la Tourette syndrome. In about 60 per cent of cases the noises become transformed into swear words (coprolalia). About a third of patients also exhibit echolalia—an involuntary tendency to repeat words or sentences just spoken to them. A smaller proportion of patients also exhibit copropraxia (involuntary obscene gesturing) and echopraxia (involuntary imitation of the movements of others), as well as palilalia (involuntary repetition of their own words or sounds).

Many patients with Gilles de la Tourette syndrome also exhibit features of an obsessive–compulsive disorder. These psychiatric manifestations of the condition may be even more disabling than the tics. A hyperactive attentional disorder is common in children.

Once established, Gilles de la Tourette syndrome is usually lifelong, although its severity waxes and wanes. A small proportion of cases, probably less than 1 in 20,

experience spontaneous remission of symptoms after adolescence, but in most the multiple tics and the vocalizations persist, although they usually become less prominent in adults. No other neurological abnormality develops; intellect and motor co-ordination are retained.

Diagnosis

Patients with tics and vocal utterances, which are essential components of Gilles de la Tourette syndrome, are often initially considered to have a psychiatric disorder or, if organic disease is considered, chorea or dystonia are diagnosed. Once coprolalia is evident there is no difficulty in establishing the correct diagnosis, although other diseases such as Wilson's disease with onset in childhood require consideration.

Treatment

The multiple tics and the vocalizations of coprolalia cause considerable distress, social isolation, and psychological harm. Neuroleptic drugs such as haloperidol or pimozide may satisfactorily control tics, noises, and coprolalia. The effective dose requires careful and gradual titration as there is risk of side-effects, especially the emergence of a tardive dyskinesia after months or years of therapy (see below). Since treatment must usually be for life, the harm must be carefully balanced against the need for any form of therapy. The obsessive-–compulsive symptoms of the illness may improve with drugs such as clomipramine or fluoxetine. In extreme cases psychosurgery has been undertaken with limbic leucotomies.

Myoclonus

Myoclonus is a feature of many neurological diseases and can be classified according to its aetiology (see Table 6).

Generalized or multifocal myoclonus can occur in four clinical settings:

i. as the solitary feature of the illness (essential myoclonus);
ii. as a dominant feature of a progressive brain disease (progressive myoclonic encephalopathy);
iii. as a residual feature of some transient brain insult (static myoclonic encephalopathy); or
iv. as a feature of obvious epilepsy (myoclonic epilepsy).

Benign essential myoclonus

This condition consists of widespread myoclonus affecting all four limbs, trunk, neck, and face, occurring at about 10 to 50 per minute, enhanced by action and sensory stimuli, often in the context of a positive family history. Onset is usually in childhood or adolescence, but disability is strikingly mild, there is no progression, intellect is normal, fits do not occur, and no other deficit appears. Some patients report that alcohol helps their jerks, and many respond to a b-adrenergic antagonist such as propranolol.

Progressive myoclonic encephalopathies

Most of the diseases causing a progressive myoclonic encephalopathy are described in detail elsewhere, particularly the lysosomal storage disorders and other metabolic disorders as well as the spinocerebellar degenerations. A discussion of other associated conditions lies outside the scope of this chapter.

Static myoclonic encephalopathies : postanoxic action myoclonus (Lance–Adams syndrome)

This is a distinct entity that may appear after a period of cerebral anoxia, typically respiratory arrests in the context of an acute asthmatic attack. After recovery of consciousness, such patients exhibit muscle jerks affecting the face, trunk, and limbs, often provoked by sensory stimuli, and strikingly elicited by willed voluntary action. The condition has been associated with abnormalities of brain 5-hydroxytryptamine, as 5-hydroxytryptophan produces a marked improvement in some patients. However, the side-effects of this therapy, in particular the development of the eosinophilia myalgia syndrome, have meant that other treatments such as clonazepam, piracetam, and sodium valproate are more commonly used

Myoclonic epilepsies

In the myoclonic epilepsies, epileptic seizures are the obvious and dominant feature of the condition. There is some confusion in separating the many conditions that may cause this syndrome, which occurs particularly in children. A convenient, if arbitrary, distinction is based on the age of onset and is discussed in more detail in the section on epilepsy.

Focal myoclonus

There are a number of conditions in which myoclonic muscle jerking may be restricted to one part of the body. Some pathological processes may cause focal myoclonus limited to those segments innervated by the part of brainstem or spinal cord affected (segmental myoclonus). Palatal myoclonus, with rhythmic contractions 60 to 180 per minute is an unusual variant. Sometimes this spreads to the pharynx and larynx and speech is disturbed; the ocular muscles maybe involved. Similar pathologies causing cerebral damage, particularly to the cerebral cortex, may cause rhythmic repetitive focal muscle jerking associated with electrical evidence of epileptic cortical discharge in the electroencephalogram (epilepsia partialis continua).

Spinal myoclonus

Repetitive, often rhythmical, myoclonic jerking restricted to a limb, or even to a few muscles of an arm or leg, may occur with myelitis, spinal cord tumour, or angioma, or after spinal cord trauma. The rhythmic muscle jerking occurs spontaneously, at 20 to 180 per minute, is not affected by peripheral stimuli, often persists in sleep, and is not associated with any change in the electroencephalogram. Anticonvulsants may help, but such segmental myoclonus is often very difficult to control.

Epilepsia partialis continua

Encephalitis, tumour, abscess, infarct, haemorrhage, or trauma to the cerebral cortex may rarely cause repetitive, rhythmic muscle jerking once or twice a second, confined to one collection of muscles, persisting even in sleep for days, weeks, or months. Usually the damage involves not only the cerebral cortex, but also deeper structures including the thalamus. Because of its large cortical representations, the most common site of epilepsia partialis continua is the hand. Typical Jacksonian focal motor fits, and grand mal seizures may also occur in such patients. The surface electroencephalogram usually shows a spike discharge over the opposite motor cortex preceding each jerk by a short interval. Treatment is with anticonvulsants, but may be difficult.

Hemifacial spasm

Hemifacial spasm occurs at a frequency of about 1 in 100 000 people and most commonly affects middle-aged or elderly women, and usually appears without obvious cause. Rarely, it may be symptomatic of demonstrable facial nerve compression. The condition consists of irregular, but repetitive clonic twitching of the muscles of one side of the face. Usually those around the eyes are first involved, producing a feeling identical to the benign myokymia of the lower eyelid which occurs in normal people when fatigued. However, the repetitive twitching spreads slowly to involve the whole face, each spasm closing the eye and drawing up the corner of the mouth. At this stage, a mild facial weakness and contraction becomes evident, but a frank facial palsy never develops. Facial sensation is normal and there are no other physical signs in idiopathic hemifacial spasm. The disorder is so distinctive and unilateral that it is rarely confused with other conditions. True facial myokymia, due to brainstem tumour or demyelination, consists of a continuous rippling contraction of the facial muscles, giving the appearance of a 'bag of worms'.

Treatment with drugs is usually unrewarding. Posterior fossa exploration, with separation of blood vessels from the seventh nerve gives long-lasting relief and failure, when it occurs, is normally evident within the first few months after surgery. However, injection of botulinum toxin into the facial muscles, repeated every 3 to 4 months, is a simpler and effective treatment.

Other movement disorders

Restless leg syndrome (Ekböm's syndrome)

This is a common and poorly understood condition in which patients have a desire to move their extremities often in association with paresthesiae and dysaesthesiae. This is made worse by rest and so is often mainly present at the end of the day and at night and is relieved by activity such as walking around. It is commonly associated with periodic limb movements during sleep. The aetiology of the condition is unknown, but may be due to abnormal cerebellar and thalamic activation. It can be seen with peripheral neuropathies, uraemia, pregnancy, iron deficiency, rheumatoid arthritis, and spinal cord lesions. In some cases there is a family history suggestive of an autosomal dominant inheritance. It responds to a number of drugs including L-dopa, dopamine agonists, baclofen, carbamazepine, clonazepam, clonidine, and opioid drugs.

Stiff man syndrome

This term includes a range of rare conditions which are characterized by muscle rigidity with or without spasms. This includes the stiff man syndrome which is characterized by axial rigidity involving the paraspinal muscles which leads to a hyperlordotic posture of the back and an abnormal gait often described as walking through treacle. These patients often have muscle spasms in response to sensory stimuli with an exaggerated startle response. The patients characteristically have antiglutamic acid decarboxylase antibodies which may account for the high incidence of diabetes mellitus and other autoimmune disorders in this condition. Treatment is usually with baclofen and diazepam, although clonazepam, sodium valproate, and vigabatrin have all been used successfully. Immunosuppressive therapy is often disappointing, although it may benefit some patients.

Hyper-rekplexia

Startle is a sterotypic response that involves a complex series of movements including eye closure, facial grimacing, and a typical body posture. In certain conditions it is exaggerated, and termed hyper-rekplexia. It can be seen in a number of conditions and with a range of central nervous system lesions as well as occurring in isolation. In some cases the condition is inherited in an autosomal dominant fashion and in these cases mutations in the glycine receptor are found. In general the condition responds to clonazepam.

Drug induced movement disorders

The extensive use of antipsychotic neuroleptic drugs has led to much iatrogenic extrapyramidal disease. These drugs, all of which block dopamine receptors in the basal ganglia and elsewhere, are used widely to control acute psychotic behaviour, whatever its cause, and to prevent relapse of schizophrenia. They also are employed as antiemetics, as are other similar drugs such as metoclopramide, and to treat vertigo. The major neurological complications of these drug therapies are summarized in Table 7.

Akathisia refers to an irresistible and unpleasant sensation of motor restlessness, and the inability to sit or stand still, all of which may be mistaken for a recurrence of psychotic behaviour. Akathisia remits if the offending neuroleptic is withdrawn, or if the dose can be reduced sufficiently: It does not usually respond to anticholinergic drugs, but may be helped by a benzodiazepine or propranolol.

Anticholinergic drugs may also be used to treat drug induced parkinsonism if the causative neuroleptic has to be continued for psychiatric reasons, although anticholinergics are not routinely administered to those on neuroleptics.

Acute dystonic reactions commonly consist of oculogyric crises, trismus, neck retraction, or torticollis, and may be mistaken for tetanus or meningitis. Although uncommon, acute dystonic reactions pose a repeated diagnostic problem in casualty departments. Such reactions rapidly disappear after intravenous injection of an anticholinergic drug such as Kemadrine or a benzodiazepine.

Chronic tardive dyskinesias are the most serious of the drug induced movement disorders for they usually persist despite drug withdrawal. About 20 per cent of those receiving chronic neuroleptic therapy will exhibit a tardive dyskinesia. The characteristic syndrome is one of orofacial mouthing, with lip smacking and tongue protrusion (orobuccolingual dyskinesia), accompanied by trunk rocking and distal chorea of the hands and feet. In younger patients the picture may be dominated by axial and cranial dystonia (tardive dystonia), a condition which persists and is largely refractory to treatment although is less likely to occur if the offending drug is discontinued within 5 years of being instituted.

Tardive dyskinesias usually appear after at least 6 months' neuroleptic drug therapy, and their incidence increases with exposure to the drugs and also with the age of the patients, although some of the more recent atypical antipsychotic drugs have less of a propensity to cause this condition. Tardive dyskinesias often get worse in the weeks immediately after stopping the offending drug, or may appear then for the first time. After drug withdrawal, tardive dyskinesias disappear in about 60 per cent or more of patients over the next 3 years, but continue unaltered in the remainder. They are difficult to treat and whilst the offending agent ideally should be stopped this is often not possible. Anticholinergic drugs tend to worsen orobuccolingual dyskinesia, but may relieve tardive dystonia. Baclofen may help some patients.

Other drugs that cause dyskinesias include levodopa in patients with Parkinson's disease. It seems likely that most such drug induced dyskinesias are due to pharmacological effects on dopamine mechanisms in the basal ganglia, resulting in dopaminergic overactivity, in contrast to the akinetic-rigid syndrome produced by dopamine depletion or blockade.

24.13.12 Ataxic disorders

Nicholas Wood

Introduction

The term 'ataxia', derived from the Greek, means 'irregularity' or 'disorderliness'. Unsteadiness can result from a number of causes, including poor vision, impaired postural reflexes, or a deficiency of sensory input, that is sensory ataxia. This chapter is devoted to the symptoms, signs, and the pathological and clinical features of the disorders of the cerebellum (and its connections). There are two basic clinical rules which can be applied: (1) lesions of the vermis generally cause ataxia of midline structure (that is, truncal and gait ataxia); (2) output from the cerebellar hemisphere is to the contralateral cerebral hemisphere, which provides output to the contralateral limbs, therefore cerebellar hemisphere lesions are ipsilateral. It should, however, be noted that clinical assessment is complicated by the fact that few patients with ataxia have pure cerebellar disease as there is often additional pathology in the brainstem, spinal cord, or elsewhere.

Symptoms of ataxic disorders

The history is extremely important. A clarification of what patients mean should also be sought. Many refer to 'giddiness' or 'dizziness' when they really mean unsteadiness of gait without associated vertigo or light-headedness. The age and speed of onset and development of other features provides important aetiological clues. Rate of progress and any precipitating or relieving factors should be noted. There has been a tremendous improvement in our understanding of the genetic basis of many ataxia disorders and a detailed family history is paramount.

Disturbances of gait

This is the most frequent presenting feature in ataxic disorders. Patients may report an inability to walk in a straight line and a tendency to bump into things. This may be significantly worse in the dark, thus indicating a sensory ataxia. Sudden changes of direction are particularly difficult and problems turning may be reported. The duration of the gait disturbance should be established, and it is worth asking about early motor milestones and athletic ability at school that may bring out a much longer history than previously appreciated. Collateral history should be sought especially if an insidious onset is suspected, as this may be difficult for a patient to report. A question as to diurnal variation particularly a history of morning unsteadiness that wears off later in the day, often associated with morning headache, suggests raised intracranial pressure even if examination is normal.

Limb incoordination and tremor

Clumsiness of the arms is often noted later in the course of their illness. Generally a tremor that is worse on action is reported and as this worsens patients notice clumsiness carrying objects and deterioration of their handwriting. This is more common in multiple sclerosis than in degenerative disease. Disturbance to the midline structures may result in titubation, and this, in combination with action tremor in the upper limbs and little in the way of gait disturbance, should raise the suspicion of Wilson's disease.

Dysarthria

This may be noted by friends and relatives before the patient. Classically described as having a staccato quality, it is a useful symptom or sign as it points against a purely sensory ataxia.

Visual and ocular motor symptoms

Visual symptoms are relatively rare in pure cerebellar disease and if present is more often associated with brainstem disturbance, especially episodic or persistent diplopia associated with ataxia. Vertical oscillopsia suggests downbeat nystagmus, and a structural foramen magnum lesion should be suspected. Acute or subacute oscillopsia, with chaotic involuntary eye movements observed by relatives, may be mentioned in the history of patients with viral cerebellitis, paraneoplastic cerebellar degeneration, and the dancing-eyes syndrome (opsoclonus). There are some very rare degenerative ataxias with gradual visual loss, due to either optic neuropathy or retinopathy.

Other symptoms

Details of any headache or vomiting should be sought, the presence of which may suggest a posterior fossa mass lesion. An acute history suggests cerebellar haemorrhage. If longer standing then a tumour becomes more likely. It should also be remembered that infections, especially an abscess, can cause similar symptoms. Intermittent symptoms and perhaps associated fever and malaise raise the possibility of posterior fossa cysticercosis, and a detailed travel history over the last 20 years should be sought.

Vertigo is more suggestive of neoplastic, inflammatory, and vascular disease rather than the more slowly progressive degenerative processes.

Direct questioning should cover the urinary system, skeletal deformities, cardiac disease, and assessment of cognitive abilities since many ataxias can be associated

with disease in other systems (see Table 1).

A detailed enquiry of drug ingestion (for both medical and recreational purposes, including alcohol) and occupational exposure is also required.

Signs of cerebellar disease

This section covers the examination in the sequence that it appears to the physician.

Gait and posture

A patient walking into the consulting room may have a broad-based gait with a poor turn, and there is often a lurching quality to the overall sequence. More detailed assessment of mild gait ataxia may be obtained by asking the patient to tandem walk (heel–toe). Asking the patient to stand still may reveal the broad base and unless there is additional proprioceptive loss or vestibular disease, this instability is not aggravated by eye closure.

Speech

It is often stated that cerebellar speech is very distinctive with an explosive quality, so-called scanning dysarthria. Although when this is heard it is characteristic, more often a combination of spastic and cerebellar features can be heard. Additional signs such as a slow moving tongue and brisk jaw jerk support the latter.

Muscle tone

Many textbooks state firmly that cerebellar disease gives rise to hypotonia, and some even include it within the symptoms. Not only do patients never complain of hypotonia but this is rarely detectable clinically in symmetrical slowly progressive or chronic disorders. Pendular knee jerks are also difficult to detect without the eye of faith and many patients with 'cerebellar' ataxic disorders have disease of the spinal cord, peripheral nerves, or both, which complicates the clinical picture.

Limb ataxia

Limb ataxia usually results from a combination of dysmetria and dysdiadochokinesis. Dysmetria refers to errors in the range and force of movement resulting in an erratic, jerky movement which may under- or overshoot the target. Dysdiadochokinesis is demonstrated by asking the patient to tap one hand on the other, alternately pronating and supinating the tapping hand, or rapidly opening and closing the fist. The tapping out of simple rhythms (with the hand or foot) is also useful in assessing both the rhythmicity and force of the tap.

Classically, testing of coordination is undertaken after the motor and sensory tests as the presence of weakness or sensory loss can confuse the picture. There is also a natural asymmetry in cerebellar function, with better performance, particularly for rapid alternating movements, in the dominant limb. About 40 per cent of patients with vermis lesions do not have limb ataxia but have striking gait ataxia.

Tremor

Intention tremor is present if a rhythmical side-to-side oscillation is seen on finger-to-nose testing. A combination of gross intention tremor and a postural component is often called rubral or red nucleus tremor, although peduncular tremor is probably a more accurate label. It is most commonly seen in ultiple sclerosis and occasionally in late-onset degenerative ataxias. A nodding head tremor (titubation) with a frequency of 3 to 4 Hz may be seen with midline cerebellar disease.

Eye movements

Square wave jerks may be seen in the primary position; these are inappropriate saccades that disrupt fixation and are followed by a corrective saccade within 200 ms. Assessment of pursuit may see a jerkiness with saccadic intrusions. Additional isolated or multiple lesions of the third, fourth, or sixth cranial nerves suggests brainstem pathology. Examination of the saccadic system can reveal hypo- or hypermetric saccades. An internuclear ophthalmoplegia may be found whilst examining this system, suggesting a diagnosis of multiple sclerosis, but it can rarely be associated with some degenerative ataxias. The vestibulo-ocular reflex (doll's head manoeuvre) should then be examined to look for any supranuclear component. An inability to suppress this reflex is evidence of pathology involving the vestibulocerebellum.

Acute or subacute presentation of almost any of the above eye movements, especially if associated with alcohol abuse or vomiting, raises the possibility of Wernicke's encephalopathy and requires urgent treatment with thiamin.

Gaze-evoked nystagmus is the most common type of nystagmus associated with cerebellar disease; eccentric gaze cannot be maintained, and the slow phase of the nystagmus is toward the primary position, with rapid corrective movements. It does not have much localizing value. Although downbeat nystagmus should raise the suspicion of a foramen magnum lesion, this is also seen in degenerative cerebellar disease.

Positional nystagmus in a patient with vertigo and unsteadiness should be attributed to benign labyrinthine disease only if it is transient, torsional, and fatiguable; if it does not have these features, a posterior fossa lesion should be suspected.

Other neurological signs and general examination

As the causes of ataxia are numerous, a large variety of other neurological and general physical signs may be found on examination. Table 1 lists the various signs and their possible diagnostic significance.

Disorders of the cerebellum

Numerous pathological processes can affect cerebellar function, some of which such as multiple sclerosis and neoplasia are discussed elsewhere. This section will approach the diseases with approximate reference to the time-course (acute, subacute, chronic) and the nature of the course of the disease.

Developmental disorders

The cerebellum has a long developmental period and is not fully mature until about 18 months of age. It is therefore susceptible to a large number of insults, including intrauterine infections, ischaemic damage, toxins, and genetically determined syndromes (see Table 2). Some of these developmental anomalies, such as dysgenesis or agenesis of the vermis, the cerebellar hemispheres, or parts of the brainstem, give rise to congenital ataxia. These are non-progressive disorders, and in most cases coordination improves with age.

Cerebellar dysfunction in an infant or young child may be overlooked, as it often gives rise to a relatively non-specific abnormal motor development. Later there is nystagmus, obvious incoordination on reaching for objects, and truncal ataxia when first attempting to sit. Associated mental retardation is common but unhelpful diagnostically.

Ataxia of acute or subacute onset

Cerebellar ataxia of extremely acute onset has two main causes: cerebellar haemorrhage (usually associated with headache, vertigo, vomiting, altered consciousness, and neck stiffness); and cerebellar infarction (in which cerebellar signs are usually combined with signs of brainstem ischaemia, and the presentation may mimic that of haemorrhage). Diagnosis should be made as a matter of urgency and imaging is required to clarify these two possibilities.

Subacute, reversible ataxia may occur as a result of viral infection in children between 2 and 10 years of age. There is usually pyrexia, limb and gait ataxia, and

dysarthria developing over hours or days. Although recovery occurs over a period of weeks and is usually complete, it can take up to 6 months.

In older patients the possibility of a postinfectious encephalomyelitis, particularly that related to varicella infection, should be considered. The postinfectious Miller Fisher variant of the Guillain-Barré syndrome may present with a triad that includes subacute ataxia, areflexia, and ophthalmoplegia. Nerve conduction studies and examination of cerebrospinal fluid (**CSF**) may be helpful, but the former are often normal. Other infective agents are shown in Table 3. Viral titres and CSF examination may be helpful, although serological evidence of viral infection may be difficult to establish.

Other causes of subacute ataxia include hydrocephalus, foramen magnum compression, posterior fossa tumour (primary or secondary), abscess, or parasitic infection in any age group. A number of important toxins and drugs also need to be considered, including thallium, lead, barbiturates, phenytoin, piperazine, alcohol, solvents, and antineoplastic drugs.

Vascular disorders of the cerebellum

Cerebrovascular disease is dealt with in detail in Chapter 24.13.7. Transient ischaemic attacks involving the vascular supply to the cerebellum rarely produce ataxia and dysarthria alone, usually there are associated symptoms of brainstem dysfunction. Cerebellar infarction (from embolus or, more commonly, vertebrobasilar occlusive disease) and haemorrhage (usually on a background of hypertension or, less commonly, secondary to a vascular malformation or tumour) are relatively rare. Imaging is often necessary for early diagnosis as the later the diagnosis the worse the prognosis. Both infarction and haemorrhage may be amenable to surgical therapy.

Ataxia with an episodic course

These attacks can be considered bizarre and some patients are misdiagnosed as hysterical. However, a good history can usually distinguish between the main causes (listed in order of approximate frequency): drug ingestion, multiple sclerosis, transient vertebrobasilar ischaemic attacks, foramen magnum compression, intermittent obstruction of the ventricular system due to a colloid cyst or cysticercosis, and dominantly inherited periodic ataxia. Autosomal dominant periodic ataxia is characterized by childhood or adolescent onset of attacks of ataxia, dysarthria, vertigo, and nystagmus; not all patients have affected relatives.

There are at least two forms of this disorder: episodic ataxia-1 and -2. Episodic ataxia-1 (**EA1**) is typified by brief attacks (minutes and occasionally hours) and clinically and electrophysiologically myokymia may be seen. Mutations in a potassium-channel gene (*Kv1.1*) have been found. These patients may benefit from treatment with acetazolamide or phenytoin. Patients tend to be neurologically normal between the attacks. In episodic ataxia-2 (EA2) the attacks tend to be longer lasting, hours or even days, usually associated with vertigo and consequent nausea and vomiting. The attacks tend to be more severe in childhood with associated drowsiness, headache, and fever. Although when the disease first begins the patients are well between attacks, an interictal nystagmus can be seen. A slow deterioration in the ataxia is seen as the disease progresses. MRI may reveal cerebellar atrophy. These patients tend to respond better to acetazolamide therapy than patients with EA1. Point mutations in a calcium-channel gene (*CACNA1A*) have been demonstrated in some families with this disorder.

In children and young adults a metabolic disorder should be suspected, particularly defects of the urea cycle, aminoacidurias, Leigh's syndrome, and mitochondrial encephalomyopathies. Screening investigations include blood ammonia, pyruvate, lactate and amino acids, and urinary amino acids.

Ataxia with a chronic progressive course

Chronic alcohol abuse is the commonest causes of progressive cerebellar degeneration in adults. Thiamin deficiency is probably the main (but not sole) explanation for the chronic progressive cerebellar syndrome found in alcoholics. Patients with this syndrome are almost invariably malnourished. Ataxia may develop during periods of abstinence, and identical cerebellar degeneration has been observed in non-alcoholic patients with severe malnutrition. Cerebellar ataxia is common in the Wernicke–Korsakoff syndrome, and the pathological features of both this syndrome and a cerebellar degeneration frequently coexist. With administration of thiamin some improvement may occur in early cases of alcoholic cerebellar degeneration, but if the patient is already chair-bound the response to treatment is limited.

Other deficiency disorders can give rise to a progressive ataxia. There is a rare syndrome associated with zinc deficiency which responds to oral replacement therapy. Deficiency of vitamin E, either genetic (for example, isolated vitamin E deficiency due to mutations in the a-tocopherol transfer protein, or abetalipoproteinaemia) or acquired, due to malabsorption, may also produce a progressive ataxia. Establishing the diagnosis of vitamin E deficiency is important as treatment with vitamin E may prevent progression of the neurological syndrome and can, in rare circumstances, lead to some improvement.

A number of toxic agents can produce progressive cerebellar dysfunction, including pharmaceutical products, solvents, and heavy metals. The most common cause of a cerebellar syndrome due to drug toxicity seen in neurological practice is that associated with anticonvulsant medication, particularly phenytoin. Transient ataxia, dysarthria, and nystagmus usually develop when serum concentrations of phenytoin, carbamazepine, or barbiturates are above the therapeutic range, and remit when they return to within the therapeutic range. Chronic phenytoin toxicity is reported to cause persistent cerebellar dysfunction, and this is associated pathologically with a loss of Purkinje cells. A persistent cerebellar deficit, with dysarthria and limb and gait ataxia and cerebellar atrophy on CT scan, has also been described as a sequel to the acute encephalopathy of lithium toxicity that is usually precipitated by fever or starvation. Serum lithium levels are not always raised in such cases.

Recreational or accidental exposure to a number of solvents, including carbon tetrachloride and toluene, causes cerebellar ataxia along with other neurological problems, including psychosis, cognitive impairment, and pyramidal signs in the case of toluene. The neurological deficit is potentially reversible but may persist after prolonged exposure in solvent abusers. Exposure to heavy metals including inorganic mercury, lead, and thallium can also produce cerebellar damage.

Structural lesions such as posterior fossa tumours, foramen magnum compression, or hydrocephalus must be excluded by imaging studies. Tumours which may involve the posterior fossa include: astrocytoma, ependymoma, haemangioblastoma, and cranial nerve neuromas.

Paraneoplastic cerebellar degeneration related to carcinomas of the lung or ovary or to the reticuloses usually follows a subacute course, with patients losing the ability to walk within months of onset. A variety of antineuronal antibodies may be found in these patients and help to confirm the diagnosis. Approximately half of patients with paraneoplastic cerebellar degeneration (**PCD**) have demonstrable antibodies directed against neurones in their serum and CSF. The most common antibody seen in PCD is called anti-Yo, and it specifically stains Purkinje cell cytoplasm. If antineuronal antibodies are detected then a search for the underlying malignancy should then be undertaken involving imaging and analysis of tumour markers. Presentation with ataxia precedes diagnosis of the malignancy in 70 per cent of cases and is usually subacute, progressing to severe disability over several months or even weeks, and then arresting. Onset may be acute and is sometimes accompanied by vertigo, mimicking a vascular event. There is severe truncal, gait, and limb ataxia and dysarthria. Opsoclonus may be combined with myoclonus, producing a disorder in adults similar to the dancing eyes syndrome of childhood, and which is sometimes associated with neuroblastoma. There is currently no evidence of a useful response either to immunosuppressant therapy or to plasma exchange. However, there are anecdotal reports of some improvement or stabilization following removal of the primary tumour. The best method of screening for the underlying malignancy is debated, but standard magnetic resonance imaging (**MRI**) may be complemented by whole-body positron emission tomography (**PET**) scanning. Searching for primary tumour markers may also be useful.

Rarely, infectious agents can cause slowly progressive ataxia (see Table 3), these include the chronic panencephalitis of congenital rubella infection in children and, in adults, Creutzfeldt–Jakob disease (**CJD**), the iatrogenic form of which should be particularly considered. A specific enquiry regarding potential risk-factor exposure should be sought, especially growth-hormone replacement. It is now known that the so-called variant form of CJD may also cause ataxia, often in association with psychiatric disturbance. Multiple sclerosis only exceptionally presents as an isolated chronic progressive cerebellar syndrome.

Some conditions that are not generally considered primarily as ataxic disorders may present with clumsiness, tremor, or definite cerebellar signs, particularly in childhood or adolescence. These include Wilson's disease and several inherited neuropathies, such as hereditary motor and sensory neuropathy (**HMSN**; Charcot–Marie–Tooth disease, including the so-called Roussy–Levy syndrome). Although intention and postural tremor are quite frequent in the demyelinating type of HMSN (type I), dysarthria and pyramidal signs do not occur. Other chronic demyelinating neuropathies, such as chronic inflammatory and paraproteinaemic neuropathies and Refsum's disease, may give rise to prominent tremor and ataxia; the same applies to giant axonal neuropathy.

Superficial siderosis is a rare disorder that causes slowly progressive cerebellar ataxia, mainly of gait, and sensorineural deafness, often combined with spasticity, brisk reflexes, and extensor plantar responses. The diagnosis may not be suspected clinically, but the neuroradiological abnormalities are striking, MRI showing a black rim of haemosiderin around the posterior fossa structures and spinal cord, and less often the cerebral hemispheres, on *T*2-weighted images. Superficial siderosis is most commonly secondary to chronic leaking of blood into the subarachnoid space. Treatment relies on identifying the source of bleeding; chelation

therapy does not appear to be effective.

After excluding acquired causes of ataxic disorders, there remains a considerable number of patients with degenerative ataxias, not all of which are overtly genetically determined. The inherited ataxias can largely be classified according to their clinical and genetic features (see below), and in a small proportion of cases a recognizable metabolic defect can be detected. It is important to make as accurate a diagnosis as possible in these disorders for the purposes of prognosis, genetic counselling, and, occasionally, specific therapy.

Progressive metabolic ataxias

Ataxia may be a minor feature of storage and other metabolic neurodegenerative disorders developing in early childhood. Some enzyme deficiencies that usually give rise to diffuse neurodegenerative disorders in which ataxia is a feature, either developing in infancy or early childhood, include the sphingomyelin lipidoses, metachromatic leucodystrophy, galactosylceramide lipidosis (Krabbe's disease), and the hexosaminidase deficiencies. Also included within this group is adrenoleucomyeloneuropathy, a phenotypic variant of adrenoleucodystrophy. This is diagnosed by estimation of very long-chain fatty acids. Although X-linked, approximately 10 per cent of carrier females may manifest neurological abnormalities. The role of diet and dietary supplements (for example, oleic acid and Lorenzo's oil) remains to be established. Ataxia may be prominent in Niemann–Pick disease type C (juvenile dystonic lipidosis), combined with a supranuclear gaze palsy. Sphingomyelinase activity is normal, but foamy storage cells are found in the bone marrow.

Cholestanolosis (also called cerebrotendinous xanthomatosis, **CTX**) is a rare autosomal recessive disorder caused by defective bile salt metabolism, due to a deficiency of mitochondrial sterol 27-hydroxylase. It gives rise to ataxia, dementia, spasticity, peripheral neuropathy, cataract, and tendon xanthomas in the second decade of life. Treatment with chenodeoxycholic acid appears to improve neurological function.

Various phenotypes classifiable as hereditary ataxias have been described in the mitochondrial encephalomyopathies, many of which are associated with a defect of mitochondrial DNA. These include late-onset ataxic disorders associated (for example, the Kearns–Sayre syndrome) with such features as dementia, deafness, and peripheral neuropathy. These features overlap with the syndrome of progressive myoclonic ataxia, which may also be caused by ceroid lipofuscinosis, sialidosis, and Unverricht–Lundborg's disease or so-called Baltic myoclonus. Most of these disorders can now be distinguished with appropriate gene tests or enzyme estimations.

Acquired metabolic and endocrine disorders causing cerebellar dysfunction

These include hepatic encephalopathy, pontine and extrapontine myelinolysis related to hyponatraemia, and hypothyroidism. The last of these is only very rarely a cause of a cerebellar syndrome in both children and adults.

Ataxic disorders associated with defective DNA repair

There are a number of rare conditions associated with a reduced capacity to perform excision repair of DNA damaged by ultraviolet light and some chemical carcinogens. The commonest is ataxia telangiectasia (**AT**). Clinically related conditions include xeroderma pigmentosum and Cockayne's syndrome. Characteristically, motor development is often delayed and ataxia noted at the time of first walking. Growth retardation and delayed sexual development are frequent, and there is mild mental retardation in some cases. A mixed movement disorder may be seen, often with a combination of ataxia, dystonia, and chorea. The cutaneous telangiectasia of AT tend to develop on the conjunctivas between the ages of 3 and 6 years, but occasionally are inconspicuous or absent in adult life. Ataxia telangiectasia is associated with abnormalities of both humoral and cell-mediated immunity. The gene for AT has now been cloned and is called *ATM*.

Degenerative disorders

The degenerative cerebellar and spinocerebellar disorders are a complex group of diseases, most of which are genetically determined. In some there is an underlying metabolic disorder, and it is important to diagnose these as there may be important implications for treatment and genetic counselling. There has been a rapid growth in our knowledge of the genetic basis of many of the spinocerebellar degenerations. The next phase will be to understand how these genes and the abnormal proteins they produce cause cell-specific neuropathology. Inherited ataxic disorders can be divided according to their mode of inheritance (Table 4 and Table 5). Most autosomal recessive disorders are of early onset (before 20 years of age), while autosomal dominant disorders are usually of later onset (over 20 years of age).

Autosomal recessive ataxias

Friedreich's ataxia is the most common of the autosomal recessive ataxias (see Table 4), accounting for at least 50 per cent of cases of hereditary ataxia in most large series reported from Europe and the United States. The prevalence of the disease in these regions is similar, between 1 and 2 per 100 000.

The onset of symptoms, generally with gait ataxia, is usually between the ages of 8 and 15 years. However, an onset between 20 and 30 years of age, but fulfilling all other diagnostic criteria, have been described. In addition to the progressive ataxia, a number of variable features are seen, including dysarthria and pyramidal tract involvement. Initially, this latter feature may be mild, with just extensor plantar responses, but invariably a pyramidal pattern of weakness in the legs is seen after 5 or more years' duration of the disease. Eventually this can lead to paralysis. Distal wasting, particularly in the upper limbs, is seen in about 50 per cent of patients with Friedreich's ataxia. Skeletal abnormalities are also commonly found, including scoliosis (85 per cent) and foot deformities typically pes cavus, in approximately 50 per cent of patients. Additional clinical support for a suspicion of Friedreich's ataxia include optic atrophy, which can be seen in 25 per cent of patients; however, it is rare (<5 per cent) for Friedreich's ataxia to produce major visual impairment. Deafness is found in less than 10 per cent of cases, but rather more have impairment of speech discrimination. Nystagmus is seen in only about 20 per cent, but the extraocular movements are nearly always abnormal, with broken-up pursuit, dysmetric saccades, square-wave jerks, and failure of fixation suppression of the vestibulo-ocular reflex.

Investigation of patients reveals an axonal sensory neuropathy; an abnormal ECG in 65 per cent of patients with widespread T-wave inversion. Diabetes mellitus occurs in 10 per cent of patients with Friedreich's ataxia, and a further 10 to 20 per cent have impaired glucose tolerance.

The gene encoding frataxin (*X25*) was cloned in 1996. The predominant mutation is a trinucleotide repeat (GAA) in intron 1 of this gene. Expansion of both alleles is found in over 96 per cent of patients. The remaining patients have point mutations in the frataxin gene. This was the first autosomal recessive condition found to be due to a dynamic repeat and, as it is a relatively simple matter to measure the repeat size, it has permitted the introduction of a specific and sensitive diagnostic test. On normal chromosomes the number of GAA repeats varies from 7 to 22 units, whereas on disease chromosomes the range is anything from around 100 to 2000 repeats. The length of the repeat is a determinant of the age of onset and therefore to some degree influences the severity, in that early-onset cases tend to progress more rapidly.

There is accumulating evidence that frataxin is mitochondrially located and may be involved in iron transport. Clinically, this fits; a syndrome of ataxia and neuropathy, in association with diabetes, cardiomyopathy, deafness, and optic atrophy, has the hallmarks of a mitochondrial disease.

Other autosomal recessive ataxias are individually rare and are listed in Table 4.

Autosomal dominant ataxias

The autosomal dominant cerebellar ataxias (**ADCAs**) are a clinically and genetically complex group of neurodegenerative disorders (see Table 5). ADCA type I is characterized by a progressive cerebellar ataxia and is variably associated with other extracerebellar neurological features such as ophthalmoplegia, optic atrophy, peripheral neuropathy, and pyramidal and extrapyramidal signs. The presence and severity of these signs is, in part, dependent on the duration of the disease. Although mild or moderate dementia may occur, it is usually not a prominent early feature. ADCA type II is clinically distinguished from the ADCA type I by the presence of pigmentary macular dystrophy, whereas ADCA type III is a relatively 'pure' cerebellar syndrome and generally starts at a later age. This clinical classification is still useful, despite the tremendous improvements in our understanding of the genetic basis (see below), because it provides a framework which can be used in the clinic and helps direct the genetic evaluation.

The genetic loci causing the dominant ataxias are given the acronym *SCA* (spinocerebellar ataxia). At the time of writing 17 *SCA* loci have been identified. Of these, the genes are established for *SCA1*, *-2*, *-3*, *-6*, *-7*, *-10*, *-12*, and *-17*. The last three are all extremely rare. *SCA12*, *-36*, and *-7* are all caused by a similar mutational

mechanism, an expansion of an exonic CAG repeat. The resultant proteins all possess an expanded polyglutamine tract, and at least eight conditions caused by these expansions are now known. Other types of ADCA are exceedingly rare.

Idiopathic degenerative late-onset ataxias

About two-thirds of cases of degenerative ataxia developing over the age of 20 years are singleton cases, and they represent a significant clinical problem; it is difficult even to know how to label them. The literature is confusing, mixing pathological terms such as 'olivopontocerebellar atrophy' (**OPCA**) with clinical terms, I prefer to use the term 'idiopathic late-onset cerebellar ataxia' (**ILOCA**). A proportion of patients in this group, progress to develop the features of multiple system atrophy (**MSA**). These patients may have, or develop, facial impassivity and extrapyramidal rigidity, whilst others present with features of autonomic failure such as postural hypotension, impotence, bladder dysfunction, and a fixed cardiac rate. A cerebellar presentation occurs in about 15 per cent of patients with MSA. The distinction of idiopathic late-onset cerebellar ataxia from MSA may therefore be difficult clinically at presentation.

Most patients with idiopathic late-onset cerebellar ataxia lose the ability to walk independently between 5 and 20 years after onset, and their lifespan is slightly shortened by immobility. Those who go on to develop MSA have a particularly poor prognosis. Investigations, apart from those excluding acquired causes of cerebellar degeneration such as malignancy and hypothyroidism, tend to be unhelpful. Electrophysiological evidence of a sensory peripheral neuropathy is found in about 50 per cent of cases, which can be a useful pointer to the presence of a degenerative multisystem disorder. CT or MRI scan may show cerebellar and brainstem atrophy, or pure cerebellar atrophy. The prognosis is worse in patients with clinical and radiological evidence of brainstem involvement, compared to those with a pure cerebellar syndrome and cerebellar atrophy alone on MRI.

24.13.13 The motor neurone diseases

Michael Donaghy

Introduction

The motor neurone diseases result from selective loss of function of the lower and/or upper motor neurones controlling the voluntary muscles of the limbs or bulbar region. The term 'motor neurone disease' is best used to describe a family of diseases within which there is extensive differential diagnosis; in the past the term has been used synonymously with amyotrophic lateral sclerosis, one of the most serious of these diseases. Precise diagnosis is essential for advising patients about prognosis, for identifying those diseases with genetic implications, and to offer immunosuppressant therapy to patients with some acquired lower motor neurone syndromes.

In practice, differential diagnosis requires clinical and electrophysiological classification as to whether the disease involves the upper or the lower motor neurones, or both. This anatomical differentiation is augmented by the age of onset, the rate of deterioration, and familial occurrence (Table 1). Sensation and cognition are normal on simple clinical assessment in the motor neurone diseases.

The clinical signs of lower motor neurone involvement consist of muscle wasting, fasciculations, and flaccid weakness. The tendon reflexes are often retained until profound denervation or fibrous replacement have affected the muscle. Fasciculations are visible flickerings within the muscle belly which are insufficient to produce movement around the joint; electromyography shows that they correspond to simultaneous discharge of all the muscle fibres within a diseased motor unit. Nerve conduction studies will exclude peripheral neuropathy. Electromyography helps to distinguish denervation from myopathy. Muscle biopsy is often required to exclude myopathy, particularly in syndromes causing slowly progressive proximal limb weakness, and bulbar weakness, such as inclusion body myositis.

Upper motor neurone involvement produces spasticity, clonus, extensor plantar responses, and weakness. Extensor plantar responses or clonus may be obscured by coexisting leg muscle atrophy. The abdominal reflexes are often preserved in motor neurone diseases involving the upper motor neurones. This contrasts with their loss in spinal cord disease due to tumours, compression, or demyelinating disease. Sphincter control and sexual function are usually preserved in motor neurone disease, although trunk and abdominal wall weakness may make excretion slow and awkward.

Motor neurone diseases are incurable for the most part and therefore treatment must aim to overcome, or minimize, the various sources of disability. Malnutrition due to dysphagia can be circumvented by nasogastric tube feeding or percutaneous endoscopic gastrostomy. Various forms of assisted respiration offset respiratory muscle weakness, including continuous positive airways pressure via a facial mask. Limb spasticity can be reduced by baclofen, dantroline, or diazepam. Wheelchairs and arm appliances may overcome inadequate limb function. Electronic communication devices should be supplied to those whose speech is incomprehensible. Amitriptyline may help contain the embarrassing emotional lability of pseudobulbar palsy. Housing and workplace modifications can allow patients to maintain independence despite their disability.

Combined upper and lower motor neurone syndromes

Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis occurs worldwide, usually with an incidence of 1 to 1.5 per 100 000 population and a prevalence of 4 to 6 per 100 000. It is commoner in men and the incidence increases with advancing age; it is unusual before the fifth decade of life. The cause of the common sporadic form of amyotrophic lateral sclerosis is quite unknown. Its incidence is particularly high in areas of the Western Pacific, particularly in Guam and the Japanese Kii Peninsula where it tends to occur in younger adults and can be associated with dementia or parkinsonism. Autosomal dominant inheritance is evident in approximately 5 per cent of patients with adult onset amyotrophic lateral sclerosis. Roughly 20 per cent of familial amyotrophic lateral sclerosis is associated with the 40 different missense mutations of the Cu/Zn superoxide dismutase (*SOD1*) gene on chromosome 21 which catalyses conversion of toxic superoxide anion radicals to hydrogen peroxide. The disease associated with various *SOD1* mutations shows varying degrees of penetrance and a variable phenotype. It tends to begin earlier in adulthood and may involve minor sensory symptoms. A rare juvenile onset autosomal recessive form of amyotrophic lateral sclerosis with prominent bulbar involvement has been described from North Africa and a rare juvenile onset autosomal dominant form without bulbar involvement occurs in the United States.

Pathology

Lower motor neurones are lost from clinically affected areas of the spinal cord and brainstem. Surviving neurones may show intracytoplasmic inclusions (Bumina bodies) and proximal axonal accumulations of neurofilaments (spheroids). The motor cortex is depleted of Betz cells and the pyramidal tracts degenerate. It is becoming increasingly recognized that other populations of neurones can also degenerate in motor neurone disease even though this is not usually evident clinically. These include peripheral sensory neurones and Clarke's column neurones. Up to 10 per cent of patients may eventually develop a mild dementia, often of frontal lobe type. These recent findings show that amyotrophic lateral sclerosis is either a generalized neurodegenerative disorder, in which the motor neurones take the vast brunt of the disease, or that it sometimes overlaps with other neurodegenerations. However, for the practical purpose of clinical diagnosis early in the disease, amyotrophic lateral sclerosis should be regarded as having purely motor manifestations.

Clinical features

At presentation, patients either have bulbar or spinal symptoms, although both usually become evident as the disease progresses.

The bulbar form causes dysphagia, dysphonia, and inhalation of foodstuffs due to weakness of the tongue, pharynx, and larynx. The tongue is wasted, weak, and fasciculating, palatal movements are reduced, and the ability to cough explosively is lost due to vocal cord paralysis. This bulbar palsy is usually accompanied by, or even preceded by, varying degrees of pseudobulbar involvement. The tongue is spastic and immobile with 'hot potato' speech and difficulty in inhibiting emotional responses such as laughing or crying. Ventilatory respiratory failure may develop due to weakness of the diaphragm and intercostal muscles. Occasionally, amyotrophic lateral sclerosis can present with dyspnoea. Diaphragm weakness can be detected clinically by noting that the upper abdomen is drawn inwards, rather than outwards, during the second half of inspiration. Furthermore, the forced vital capacity is substantially lower when the patient is lying down compared with

standing, because the weight of the liver no longer assists diaphragmatic descent.

The spinal form of amyotrophic lateral sclerosis usually presents with wasting and weakness of one limb, usually as intrinsic hand muscle wasting or foot drop. Occasionally the initial weakness predominantly affects the musculature of the shoulder girdle. Asymptomatic involvement of other limbs is often evident on examination. It is diagnostically important to demonstrate combined upper and lower motor neurone signs in at least two limbs. Wasted fasciculating muscles also exhibiting clonus or hyper-reflexia are a helpful finding. With time the limbs become useless due to progressive denervation. Patients become wheelchair- or bedbound, or unable to use their arms for grooming or feeding. Despite enforced recumbency, decubitus ulcers are relatively unusual because autonomic regulation of skin blood flow and secretion is unaffected. Sphincter control is not affected, although practical difficulties in excretion may result from immobility and because abdominal wall weakness prevents the exertion of intra-abdominal pressure.

Prognosis

Amyotrophic lateral sclerosis progresses relentlessly, both in the severity and the extent of muscular involvement. Death commonly results from ventilatory respiratory failure, from choking, or from inhalational pneumonia; malnutrition often contributes. The median survival from first symptoms in those with bulbar onset is approximately 20 months, with only 5 per cent surviving 5 years. The alternative diagnosis of X-linked bulbospinal neuronopathy should be considered in these long survivors. The median survival for those with spinal onset is approximately 29 months with nearly 15 per cent surviving 5 years. Although a subacute and reversible syndrome resembling spinal amyotrophic lateral sclerosis has been described, this is so extraordinarily rare that it should not influence the physician's prognostications.

Differential diagnosis and investigation

A diagnosis of amyotrophic lateral sclerosis is usually depressingly obvious on simple clinical grounds. Often only electrophysiological investigation is necessary to confirm denervation and to exclude a potentially treatable myopathy or demyelinating neuropathy. Sometimes upper motor neurone involvement is not clinically demonstrable, particularly in patients with absent Babinski responses due to severely denervated toe extensor muscles. Unfortunately measurement of central motor conduction following electromagnetic stimulation of the brain is less reliable for revealing upper motor neurone involvement in such cases than had been hoped. If patients present with the combination of arm denervation and upper motor neurone signs in the legs, the cervical spinal canal should be imaged with magnetic resonance scanning to exclude a compressive lesion, most often spondylitic radiculomyelopathy.

The usual diagnostic problem lies in differentiating amyotrophic lateral sclerosis from other motor neurone diseases. A lack of upper motor neurone involvement should raise the possibility of alternative diagnoses. The post-polio syndrome causes slow deterioration in limb or bulbar function some decades after acute poliomyelitis. X-linked bulbospinal neuronopathy is much more slowly progressive than bulbar amyotrophic lateral sclerosis; grimacing usually evokes characteristic lower facial contractions; gynaecomastia, diabetes mellitus, or abnormal sensory nerve conduction are often evident; and other male family members may be affected. Multifocal motor neuropathy or neuronopathy usually develops insidiously, characteristically produces marked weakness with little wasting, predominantly affects the arms, may be associated with paraproteinaemia or antiganglioside antibodies, and may involve motor nerve slowing or conduction block. Adult onset proximal hereditary motor neuronopathy is very slowly progressive, with early and symmetric involvement of proximal muscles, and rarely involves bulbar muscles.

Giving the diagnosis

Doctors or relatives are sometimes tempted on compassionate grounds not to tell patients about their diagnosis of amyotrophic lateral sclerosis. But when patients eventually detect this conspiracy of secrecy it can lead to serious loss of trust at a time when death looms and trustworthy relationships are of inestimable value. When given the opportunity, patients usually indicate that they wish to know the name of the disease and the likely outcome, and they may even wish a detailed discussion of likely modes of death. Of course questions should be answered honestly, although sometimes it may be preferable to discuss them in stages with the spouse present so as to soften the blow early on in the course of the disease. Once a patient has been told the diagnosis, the doctor must address the particular issues presented by that patient's own brand of amyotrophic lateral sclerosis before they become upset by the summary information which they may glean from lay reference books, journalism, or the Internet.

Treatment

No treatment is known to cure amyotrophic lateral sclerosis. Trials of drug therapy have concentrated upon slowing the downhill progression of disability or improving survival. The antiglutamate agent riluzole, administered orally, has been licensed for treatment of amyotrophic lateral sclerosis. The 100 mg dosage improved the chance of tracheostomy-free survival at 18 months by an extra 35 per cent although there was no significant benefit on muscle function. Criticisms of this study have included the nature of the Cox model statistical adjustment, and it should be noted that more of the placebo group had bulbar features at entry to the study. Riluzole is generally well tolerated by patients; nausea, gastrointestinal upset, and raised transaminase enzyme levels may occur and usually resolve with reduction in dose. Ineffective therapeutic trials have included mixtures of branched chain amino acids, dextromorphan, total lymphoid irradiation, and the free radical scavenger acetylcysteine.

Much can be done to overcome disability and alleviate distress by the care team of speech therapist, physiotherapist, occupational therapist, social worker, and physician. The Motor Neurone Disease Association is often able to provide equipment promptly. Severe dysphagia is most effectively bypassed by percutaneous endoscopic gastrostomy. Preferably the patient or their carer should have good hand function and vision so that they can change nutrient bags at home. If video-swallow shows that cricopharyngeal spasm is responsible for dysphagia, cricopharyngeal myotomy may help. Speech failure can be circumvented by computer-assisted communication devices operated through a practical modality, such as pressure, blowing, head nodding, or blinking depending upon which muscles remain strong.

Decisions regarding the advisability of instituting assisted respiration pose complex practical and ethical dilemmas. Patients with diaphragm weakness and nocturnal dyspnoea may be helped by continuous positive airways pressure delivered by a facial mask. Endotracheal intubation and ventilation are rarely recommendable in a disease causing such ubiquitous irreversible weakness.

Lower motor neurone syndromes

These forms of motor neurone disease generally follow a much more benign course than amyotrophic lateral sclerosis. They include syndromes previously described as spinal muscular atrophy and progressive muscular atrophy. Differential diagnosis within the lower motor neurone syndromes depends principally upon attention to the age of onset, the pattern of the weakness, and a possible family history.

Proximal hereditary motor neuronopathy

Acute infantile form (Werdnig–Hoffmann disease)

This is one of the commonest fatal autosomal recessive disorders of children. The disease frequency of approximately 1 in 25 000 in England results from a gene frequency of 1 in 160. Acute infantile spinal muscular atrophy has been linked to chromosome 5q11.2–13.3. Within this region two candidate genes have been isolated, *SMN* (survival motor neurone) and *NAIP* (neuronal apoptosis inhibitory protein). Mutations in these genes occur in up to 98 per cent (*SMN*) and 20 to 50 per cent (*NAIP*) of patients. Although a valuable aid to diagnosis, and potentially for prenatal diagnosis, it should be noted the *SMN* gene mutations occasionally occur in healthy relatives of an affected proband, and that these same mutations, particularly *SMN*, are also found in milder or later onset forms of spinal muscular atrophy including Kugelberg–Welander disease.

Before the age of 6 months, babies become inactive, weak, hypotonic, feed poorly, and are slow to attain motor milestones. They may be born with limb deformities, and in retrospect, fetal movements have been often absent or sparse. The tongue is weak and may fasciculate. Head control is poor and the infant's areflexic and proximally wasted limbs tend to assume a frog-like position. Respiratory movements are decreased with prominent involvement of intercostal muscles. Half the infants die by 6 months, and almost all have succumbed by 18 months, usually to respiratory complications.

Chronic childhood form (Kugelberg–Welander disease)

This form develops at any time from infancy to the early teens. It is also autosomal recessive, may be genetically heterogeneous, and may commence discordantly within families. It may resemble Werdnig–Hoffmann disease if the onset is early, but follows a comparatively benign course. More than 90 per cent of patients are able to walk or to sit unsupported at some time, although these abilities are often lost eventually. Tongue involvement occurs in only half, and significant dysphagia is unusual. Some patients develop respiratory insufficiency as a result of intercostal muscle involvement. The proximal limb weakness and wasting is only slowly progressive and may stabilize spontaneously. Those with severe early weakness often develop secondary spinal and joint deformities. The prognosis varies, although survival into middle age is usual. It is important, although initially difficult, to differentiate those with infantile onset and no family history from Werdnig–Hoffmann disease.

Adult onset forms

The autosomal recessive adult form starts from 15 to 60 years of age, usually in the fourth decade. Slowly progressive proximal limb weakness ensues, but significant disability for walking does not usually occur until the sixth or seventh decade. Life expectancy is only slightly reduced. Distal muscles can be involved too, the tendon reflexes are usually lost, but bulbar involvement is uncommon. The lack of upper motor neurone signs or of bulbar involvement, and the rather indolent progression, distinguish this from amyotrophic lateral sclerosis.

Autosomal dominant forms are rare, and fall into two groups with onset in childhood and in early middle age respectively. The limb weakness is predominantly proximal. Bulbar involvement does occur, although it is unusual. The childhood form may stabilize at adolescence and some patients retain walking ability into middle or old age. The adult onset form causes more severe disability. The lack of upper motor neurone signs distinguishes these conditions from hereditary amyotrophic lateral sclerosis.

X-linked recessive bulbospinal neuronopathy (Kennedy syndrome)

This disorder occurs only in men, with onset in the third to fifth decades of life. It is due to a mutation causing CAG (cytosine–adenine–guanine) repeat sequences of increased length within the androgen receptor gene. Molecular genetic analysis now forms the basis of a diagnostic test. Weakness usually first affects hand or pelvic girdle muscles and the bulbar symptoms may not be evident until 20 years later, if at all. Fasciculations are usually visible in the limb, tongue, and facial muscles. Characteristically, muscle contractions around the chin are induced by pursing the lips or grimacing. The disorder is only slowly progressive. Most patients survive into their seventh or eight decades except when bulbar involvement is unusually severe. The disorder is often misdiagnosed as amyotrophic lateral sclerosis until the unusually slow deterioration is questioned. Unlike amyotrophic lateral sclerosis, there are no upper motor neurone signs and patients commonly show gynaecomastia, diabetes mellitus, and absent sensory nerve action potentials.

Hexosaminidase deficiency

Autosomal recessive GM2 gangliosidosis presents a variable neurological picture, occasionally as a pure motor neurone syndrome due to lower and, rarely, upper motor neurone involvement. More usually there are also other neurological abnormalities such as cerebellar ataxia or dementia. Hexosaminidase assays should be reserved for those patients with early onset of unusual motor neurone disorders, particularly in Ashkenazi Jews.

Hereditary bulbar palsy of infancy and childhood

The Brown–Violetto–van Laere syndrome presents in the teens with bilateral sensorineural deafness, followed some years later by bulbar, facial, limb, and sometimes respiratory muscle weakness. Fazio–Londe disease is an autosomal recessive bulbar palsy of childhood, without deafness, and respiratory muscle involvement may lead to death within a few years.

Monomelic, focal, or segmental motor neuronopathies

This condition is also known as chronic asymmetric or focal spinal muscular atrophy, or monomelic motor neurone disease. Although most commonly described from Asia, especially Japan, it is seen regularly elsewhere in the world. It usually occurs sporadically and most patients are young adult males. It presents with distal wasting and weakness of one hand or forearm. This progresses steadily for the first 2 years before either stabilizing, or settling to a slow rate of subsequent progression. Initially there may be concern that this is the first presentation of amyotrophic lateral sclerosis, but the expected upper motor neurone and bulbar involvement fail to materialize, and spread to other limbs is unusual. Nerve conduction studies are necessary to exclude focal entrapment neuropathies, or multifocal motor neuropathy with conduction block. Magnetic resonance imaging of the cervical spine will detect syringomyelia or other spinal cord disease.

Post-irradiation lumbosacral radiculopathy

This may follow months or years after inclusion of the lower thoracic and upper lumbar spine in irradiation fields treating testicular tumours or lymphoma. It usually affects both legs, or occasionally one, and later causes mild symptoms affecting the sphincters and sensation. It is painless, and electrophysiology does not reveal the myokymic discharges or abnormal sensory nerve action potentials of irradiation plexopathy. The normal imaging of the lumbosacral plexus and cauda equina, and the absence of pain, exclude tumour recurrence.

Post-polio syndrome

After two or more decades, very slowly progressive weakness may affect muscles previously involved by acute paralytic poliomyelitis. Although this predominantly affects the limbs, approximately half of cases also have mild choking or dysphagia and weakness of the respiratory muscles which may lead to hypercapnic respiratory failure. The sluggish deterioration, lack of upper motor neurone involvement, and previous history serve to distinguish post-polio syndrome from amyotrophic lateral sclerosis. Electromyography reveals the giant motor units typical of extensive reinnervation during recovery from previous acute poliomyelitis. At least equally commonly, late deterioration after polio is due to a secondary degenerative arthritis or fibromyalgia.

Multifocal motor neuropathy and neuronopathy

Patients with these conditions may present at any stage of adult life with multifocal and slowly progressive muscle weakness for as long as 20 years. The clinical picture is immensely variable. Distal limb muscles are mainly involved, often notably asymmetrically. The first symptoms and most severe weakness usually affect the arms. Characteristically, severely weakened muscles show little or no wasting. Reflex loss is generally restricted to affected muscles. The condition is neurophysiologically heterogeneous, ranging from muscle denervation to multifocal conduction block in motor nerves, and occasionally a diffusely demyelinating pure motor peripheral neuropathy. Serum antibodies to GM1 gangliosides are detectable in a third of cases, but are of no proven pathogenetic significance. This antibody assay currently lacks specificity since positives are sometimes found in other neurological diseases. Paraproteinaemia is common, particularly immunoglobulin G. These motor neuropathies usually progress insidiously, sometimes in a stepwise manner, and occasionally spontaneous remissions occur. It is important to detect the subgroup of patients with multifocal motor conduction block, or with diffuse demyelinating neuropathy, because improvement may follow immunosuppressant therapy. Although cyclophosamide is reportedly effective, its potential toxicity should limit its use to those patients with severely disabling and progressive weakness. High-dose intravenous human immunoglobulin therapy can produce dramatic improvement lasting 6 to 8 weeks and repeated administration is the mainstay of treatment in severely symptomatic patients. Unfortunately, steroid therapy does not improve multifocal motor neuropathy, and may precipitate further deterioration.

Upper motor neurone syndromes

The pure upper motor neurone syndromes are the rarest forms of motor neurone disease. They should be considered only after magnetic resonance imaging has excluded structural or demyelinating disease of the spinal cord, foramen magnum, or brain. Spasticity is often severe in the purely upper motor neurone diseases, but unfortunately antispasticity medications are often relatively ineffective. Rarely, similar upper motor neurone syndromes may be seen with syphilis, Lyme disease, and HTLV-I infection.

Primary lateral sclerosis

This rare sporadic form of motor neurone disease has an average age of onset of 50 years, and slow progression thereafter for an average of 15 years. The clinical features are all attributable to symmetric degeneration of the upper motor neurones destined for the spinal cord and the bulbar motor neurones. Spasticity and weakness usually commence insidiously in the legs and ascend ultimately to involve the bulbar muscles. Less commonly patients present with an isolated spastic dysarthria, a symptom of pseudobulbar palsy. Pseudobulbar emotional lability may be distressing for these patients, given their normal cognition, and it often responds well to amytriptiline. Bladder function is generally preserved, at least until the later stages. Electromyography does not reveal the muscle denervation to be expected in predominantly upper motor neurone forms of amyotrophic lateral sclerosis. Magnetic resonance imaging may reveal atrophy of the precentral gyrus motor cortex reflecting loss of the Betz cells from which the pyramidal tract originates. Central motor conduction is notably delayed following electromagnetic stimulation of the motor cortex.

Autosomal dominant 'pure' familial spastic paraplegia

Various forms of slowly progressive symmetric spastic paraparesis may be inherited with linkage to chromosomes 2, 14, or 15, most usually on an autosomal dominant basis with onset in the fourth to sixth decades. The degree of leg spasticity often outweighs the severity of the weakness. Bulbar involvement is very rare, and arm function may be well preserved despite severe leg involvement. The condition is slowly progressive. It may remain asymptomatic in some family members, coming to light only when a familial basis for the disease is sought. Sphincter control is not impaired, but sexual impotence can develop. Sometimes varying combinations of other clinical features have been associated with hereditary spastic paraplegia, particularly with recessively inherited forms: distal amyotrophy, mental retardation, dementia, pigmentary retinopathy, optic atrophy, extrapyramidal features, sensory neuropathy, or ataxia.

Lathyrism

Neurolathyrism is a spastic paraparesis caused by regular consumption of the chickling pea (*Lathyrus sativus*) for some months. It is endemic in parts of India and may be epidemic in times of famine. Patients present either subacutely or chronically with a spastic paraparesis and a characteristic scissoring gait in which the balls of the feet take most of the weight. Once it has developed, neurolathyrism is usually not progressive, but little or no recovery occurs even after chickling pea consumption ceases.

Konzo

Konzo is a form of tropical myelopathy which can occur in epidemics at times of famine in several parts of Africa, including Zaire. It seems to be due to dietary cyanide exposure resulting from insufficient soaking of the cassava roots used to produce flour. There is an abrupt onset of symmetric spastic paraparesis which is non-progressive but permanent. Blood cyanide levels are raised at the onset of disease.

24.13.14 Diseases of the autonomic nervous system

Christopher J. Mathias

Introduction

The autonomic nervous system has two principal efferent pathways, sympathetic and parasympathetic, that innervate and influence every organ in the body (Fig. 1). Autonomic actions are predominantly involuntary and automatic, as indicated by the term 'autonomic' first proposed by Langley in 1898. The structure of the autonomic system, with numerous synapses centrally and peripherally as well as its multiple neurotransmitters, provides flexible control of organ function locally and in an integrated manner—as in the maintenance of systemic blood pressure and body temperature. Disease of the autonomic nervous system may cause local or systemic effects.

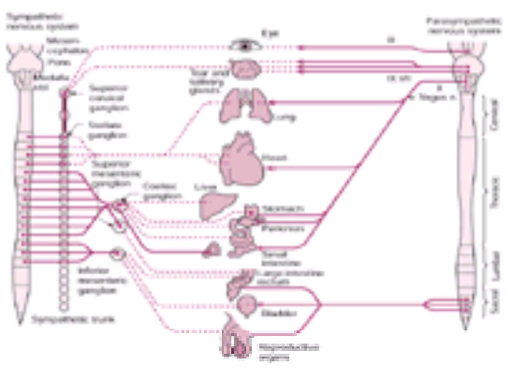

Fig. 1 Sympathetic (thoracolumbar) and parasympathetic (cranial and sacral) pathways that innervate a variety of organs. Janig W (1995). In: Schmidt RF and Thews G, eds. *Physiologie des Menschen*, 25th edn, pp 340–69. Springer Verlag, Heidelberg.

Basic principles

The autonomic nervous system is primarily a visceromotor system, in which each efferent pathway is influenced in a variety of ways. Feedback and central integration is important and virtually every sensory pathway can influence its activity. For example, in spinal cord lesions, activation of visceral, skin, and muscle receptors below the level of the lesion influences autonomic activity and blood pressure through spinal pathways while heart rate responses to classic afferent baroreceptor pathways are retained. Key cerebral autonomic centres are in the hypothalamus, midbrain (Edinger–Westphal nucleus and locus ceruleus), and brainstem (nucleus tractus solitarius and vagal nuclei), and through intracerebral connections. Many other areas affect autonomic activity. Examples are the insular cortex, anterior cingulate gyrus, and amygdala, that are important in processing of emotion and autonomic effects. Parasympathetic efferent pathways are craniosacral and sympathetic efferents are thoracolumbar; each has pre- and postganglionic fibres. The sympathetic ganglia are placed further from target organs than are the parasympathetic ganglia.

Autonomic nerve terminals at target organs vary in complexity; they have the capacity to synthesize neurotransmitters and a host of mechanisms affect uptake and interaction with local or bloodborne chemicals (Fig. 2(a) and Fig. 2(b)). There are differences between organs, especially the gastrointestinal system, in which the enteric nervous system is considered as a third autonomic division. The multiplicity of neural pathways, transmitters, and modulators results in selective control of responses in specific vascular territories and organs, making it a highly complex but precisely regulated and integrated system.

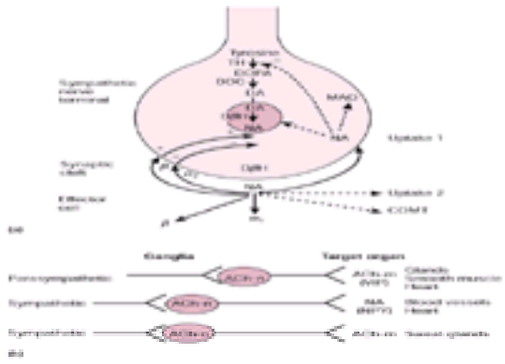

Fig. 2 Schema of some pathways in the formation, release, and metabolism of noradrenaline from sympathetic nerve terminals. Tyrosine is converted into dihydroxyphenylalanine (**DOPA**) by tyrosine hydroxylase (TH). DOPA is converted into dopamine (DA) by dopa decarboxylase (DDC). In the vesicles, dopamine is converted into noradrenaline (NA) by dopamine b-hydroxylase (Dbe). Nerve impulses release both dopamine b-hydroxylase and noradrenaline into the synaptic cleft by exocytosis. Noradrenaline acts predominantly on a_1-adrenoceptors but has actions on b-adrenoceptors on the effector cell of target organs. It also has presynaptic adrenoceptor effects. Those acting on a_2-adrenoceptors inhibit noradrenaline release; those on b-adrenoceptors stimulate noradrenaline release. Noradrenaline may be taken up by a neuronal process (uptake 1) into the cytosol, where it may inhibit further formation of DOPA through the rate-limiting enzyme tyrosine hydroxylase. Noradrenaline may be taken into vesicles or metabolized by monoamine oxidase (MAO) in the mitochondria. Noradrenaline may be taken up by a higher-capacity but lower-affinity extraneuronal process (uptake 2) into peripheral tissues, such as vasular and cardiac muscle and certain glands. Noradrenaline is also metabolized by catechol-*O*-methyl transferase (COMT). Thus, noradrenaline measured in plasma is the overspill not affected by these numerous processes. (From: Mathias CJ (2000). Disorders of the autonomic nervous system. In: Bradley WG *et al*., eds. *Neurology in clinical practice*, 3rd edn, pp 2131–65. Butterworth-Heinemann, Boston.) (b) Outline of the major transmitters at autonomic ganglia and postganglionic sites on target organs supplied by the parasympathetic and sympathetic efferent pathways. The acetylcholine (ACh) receptor at all ganglia is of the nicotinic subtype (ACh-n). Ganglionic blockers such as hexamethonium thus prevent both parasympathetic and sympathetic activation. Atropine, however, acts only on the muscarinic (ACh-m) receptor at postganglionic parasympathetic and sympathetic cholinergic sites. The cotransmitters, along with the primary transmitters, are also indicated—NA, noradrenaline; VIP, vasoactive intestinal peptide; NPY, neuropeptide Y. (From: Mathias CJ (1998). Autonomic disorders. In: Bogousslavsky J, Fisher M, eds. *Textbook of neurology*, pp 519–45. Butterworth-Heinemann, Massachusetts.)

Classification

Diseases of the autonomic nervous system may be primary without a known cause, or secondary with specific abnormalities (dopamine b-hydroxylase deficiency) or strong associations with other diseases (Holmes–Adie syndrome or diabetes mellitus) (Table 1). Drugs are a common cause of autonomic dysfunction (Table 2). Neurally mediated syncope is an intermittent autonomic abnormality. Orthostatic intolerance is listed separately.

Classification may be considered in various ways. Dysfunction may be localized (Table 3) or widespread. Diseases may result from lesions that are central (multiple system atrophy), spinal (spinal cord transection), peripheral (pure autonomic failure), or from a highly specific biochemical deficit (dopamine b-hydroxylase deficiency). Some are age-related, with presentation at birth (Riley–Day syndrome), second decade (vasovagal syncope), or adulthood (familial amyloid polyneuropathy). Autonomic failure commonly causes underactivity, but the reverse, overactivity, causes paroxysmal hypertension during autonomic dysreflexia in high spinal cord injuries. In neurally mediated syncope there is a combination of vagal overactivity and sympathetic withdrawal.

Clinical features

Sympathetic adrenergic failure causes orthostatic hypotension and ejaculatory failure in men, while sympathetic cholinergic failure causes anhidrosis. Parasympathetic failure results in a fixed heart rate, a sluggish urinary bladder and large bowel, and in the male erectile failure. With overactivity there may be hypertension, tachycardia, and hyperhidrosis; while parasympathetic overactivity causes bradycardia. In autonomic disorders there are many clinical manifestations and this may cause diagnostic difficulties, especially when the disorder is generalized.

The presenting complaints often provide clues. Palmar hyperhidrosis or gustatory sweating may indicate a localized disorder, or be a harbinger of widespread autonomic impairment, as the latter may complicate diabetes mellitus. A cardinal feature is orthostatic (postural) hypotension (defined as a decrease in systolic blood pressure of more than 20 mmHg and in diastolic pressure of less than 10 mmHg on standing or head-up tilt, Fig. 3); this impairs perfusion of vital organs, such as the brain. The symptoms vary from fainting (syncope, loss of consciousness) sometimes with ensuing injury, to fatigue and lethargy. Numerous factors in daily life enhance or reduce hypotension (Table 4). Some patients recognize these, with the self-introduction of corrective measures. Large meals, refined carbohydrate, and alcohol, which enhance postprandial hypotension, are avoided. Many sit down, lie flat, or assume curious postures, such as squatting or stooping, that now are recognized to raise blood pressure (Fig. 4). With time, symptoms of orthostatic hypotension wane, for reasons that include improved cerebrovascular autoregulation. In neurally mediated syncope, venepuncture or pain (in vasovagal syncope) or cervical movements and pressure (in carotid sinus hypersensitivity) cause hypotension and bradycardia. A history of impaired sweating and temperature intolerance, urinary disturbances, sexual dysfunction (in men) and gastrointestinal derangement (constipation), especially in combination with orthostatic hypotension, should suggest a generalized autonomic disorder (Table 5).

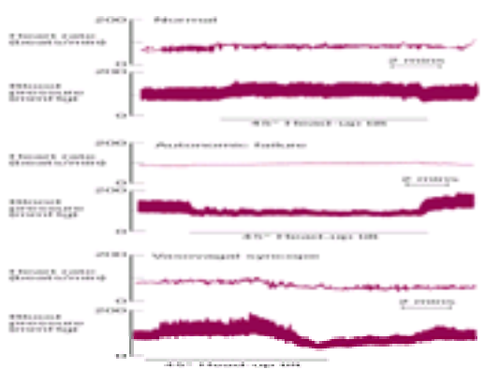

Fig. 3 Blood pressure and heart rate before, during, and after head-up tilt in a normal subject (uppermost panel), a patient with chronic autonomic failure (middle panel), and a patient with vasovagal syncope (lowermost panel). In the normal subject there is no fall in blood pressure during head-up tilt, unlike the patient with autonomic failure in whom blood pressure falls promptly and remains low with a blood pressure overshoot on return to the horizontal. In the patient with autonomic failure there is only a minimal change in heart rate despite the marked blood pressure fall. In the patient with vasovagal syncope there was initially no fall in blood pressure during head-up tilt; in the latter part of tilt, as indicated in the record, blood pressure initially rose and then markedly fell to extremely low levels, necessitating the return of the patient to the horizontal. (From Mathias CJ, Bannister R (1999). Investigation of autonomic disorders. In: Mathias CJ, Bannister R, eds. *Autonomic failure: a textbook of clinical disorders of the autonomic nervous system*, 4th edn, pp 169–95. Oxford University Press, Oxford.)

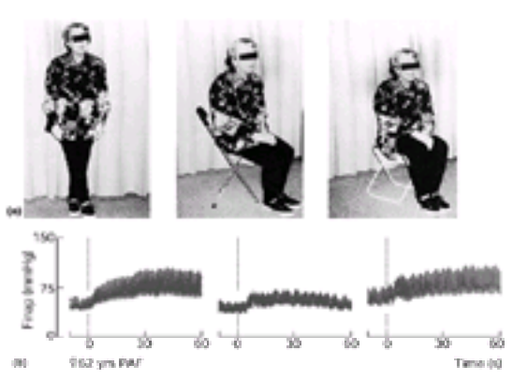

Fig. 4 The effect on finger arterial blood pressure (Finapres) of standing in the crossed-leg position with leg muscle contraction (left), and sitting on a Derby chair (middle), or fishing chair (right) in a patient with orthostatic hypotension. Orthostatic symptoms were present initially when standing and disappeared on crossing legs and sitting on the fishing chair. Sitting on a Derby chair caused the least rise in blood pressure and did not relieve the patient's symptoms completely (From Smith AAJ, Hardjowijono MA, Wieling W (1997). Are portable folding chairs useful to combat orthostatic hypotension? *Annals of Neurology* **42**, 975–8.)

In the Riley–Day syndrome (familial dysautonomia) there is a history of consanguinity, usually in the Ashkenazi Jewish population. A family history often is elicited in vasovagal syncope, and is expected in familial amyloid polyneuropathy. A drug history including exposure to chemicals, toxins, and poisons is important.

A detailed clinical examination is necessary. Pupillary and associated ocular abnormalites occur in Horner's syndrome. To assess orthostatic hypotension, blood pressure should be measured with the patient lying flat, and after standing (or sitting if not possible). A fall in systolic blood pressure of less than 20 mmHg in the prescence of appropriate symptoms does not exclude autonomic failure. Indeed, orthostatic hypotension may be unmasked, or enhanced, by factors such as food ingestion and exercise. Furthermore, in the presence of vascular disease (such as carotid artery stenosis) even a small fall in blood pressure results in cerebral ischaemia. Lack of additional neurological features favour pure autonomic failure (with a good prognosis) while associated parkinsonism or cerebellar dysfunction is suggestive of multiple system atrophy. Several disorders causing a peripheral neuropathy result in autonomic impairment. Basic bedside testing for glycosuria (in diabetes mellitus), or proteinuria (in systemic amyloidosis), provides important information.

Investigation

When an autonomic disorder is suspected, the first step is to determine if autonomic function is normal or abnormal. Autonomic screening tests (Table 6) have their value, but also limitations. The majority are directed towards cardiovascular assessment and to exclude autonomic underactivity. Tests of other systems increasingly are being made available. Normal screening results do not necessarily exclude an autonomic disorder, as on the basis of the history and clinical examination, additional tests such as carotid sinus massage may be needed in patients with syncope. If autonomic tests are abnormal, further evaluation will determine the site and

extent of the autonomic lesion, the functional deficit, and whether it results from a primary or secondary disorder, as an accurate diagnosis is essential for prognosis and for appropriate management. Thus, a 24-h ambulatory blood pressure profile and the effects of stimuli in daily life (such as food and exercise) aid management of orthostatic hypotension; while plasma catecholamine measurements (Fig. 5) and the clonidine growth-hormone stimulation test may separate the different primary autonomic failure syndromes. Investigations may be needed to diagnose underlying diseases, and include neuroimaging studies (MRI or CT scanning), sural nerve biopsy (with specific staining with monoclonal antibodies), and genetic testing. These tests should be combined with non-neurological investigations depending on the suspected diagnosis.

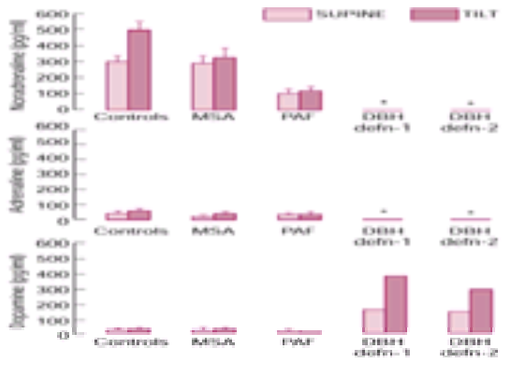

Fig. 5 Plasma noradrenaline, adrenaline, and dopamine concentrations (measured by high-pressure liquid chromatography) in normal subjects (controls), patients with multiple system atrophy (MSA), patients with pure autonomic failure (PAF), and two individual patients with dopamine b-hydroxylase deficiency (DbH defn) while supine and after head-up tilt to 45° for 10 min. The asterisk indicates levels below the detection limits for the assay, which are less than 5 pg/ml for noradrenaline and adrenaline and less than 20 pg/ml for dopamine. Bars indicate ± SEM. (Adapted from Mathias CJ, Bannister R (1999). Investigation of autonomic disorders. In: Mathias CJ, Bannister R, eds. *A textbook of clinical disorders of the autonomic nervous system*, 4th edn, pp. 169–95. Oxford University Press, Oxford.)

Management

This varies depending upon the autonomic disease, the systems affected, the functional autonomic deficit, and whether the disorder is primary or secondary. Treatment should take account of the underlying condition, for example in parkinsonian syndromes, where autonomic features may be worsened by antiparkinsonian therapy. In some diseases simple intervention is effective, such as unblocking a urinary catheter to resolve autonomic dysreflexia in high spinal cord lesions. Complex procedures such as hepatic transplantation are needed to reduce variant transthyretin levels in familial amyloid polyneuropathy. Multidisciplinary expertise may be needed, as in the Riley–Day syndrome and multiple system atrophy, to prevent complications, enhance survival, and improve quality of life. A combined approach is needed to reduce orthostatic hypotension, overcome urinary incontinence, alleviate gastrointestinal disturbances, and treat sexual dysfunction.

The management of orthostatic hypotension is outlined in Table 7 and Table 8; in individual disorders modification is needed.

Individual autonomic disorders

Primary autonomic failure

The onset is usually slow and insidious (chronic autonomic failure) unlike the acute–subacute dysautonomias.

Chronic autonomic failure

The most common is multiple system atrophy where there is additional neurological disease, unlike pure autonomic failure. Patients usually are middle aged at presentation although, with increasing awareness, diagnosis is being made in younger patients.

In pure autonomic failure, diagnosis usually is considered because of orthostatic hypotension. Nocturia (rather than incontinence) is frequent, presumably because fluid shifts from the peripheral to the central compartment elevate blood pressure and improve renal perfusion. Constipation often occurs. In temperate climates, hypohidrosis may not be recognized, unlike tropical areas where heat intolerance and collapse may occur. In the male, impotence is common. The clinical and laboratory findings indicate widespread sympathetic failure, usually with parasympathetic deficits. Physiological and biochemical tests, along with limited neuropathological data, indicate a peripheral autonomic lesion. Management is directed predominantly towards reducing orthostatic hypotension. Although recovery does not occur, the overall prognosis in pure autonomic failure is good.

The most common neurodegenerative disease affecting the autonomic nervous system is multiple system atrophy. It is a non-familial and sporadic disorder with autonomic features and additional neurological (parkinsonian, cerebellar, and pyramidal) features (Table 5) that occur at any stage and in any combination, in an unpredictable manner. Thus, patients initially may consult a range of specialists. It is randomly progressive, which adds to the difficulty of diagnosis. It is synonymous with the previously used term, Shy–Drager syndrome.

In multiple system atrophy the additional neurological features are predominantly parkinsonian; in a smaller number they are cerebellar and as the disease advances there is usually a mixture of features (Fig. 6). The neuropathological findings include striatonigral degeneration in multiple system atrophy (parkinsonian) and olivopontocerebellar degeneration in multiple system atrophy (cerebellar), with both changes often seen in either form. There is cell loss in various brainstem nuclei (that include the vagal nuclei), in the intermediolateral cell mass in the thoracic and lumbar spinal cord, and in Onuf's nucleus in the sacral spinal cord that accounts for the various autonomic and allied abnormalities. The paravertebral ganglia and visceral (enteric) plexuses are spared. A specific feature is the presence of intracytoplasmic argyrophyllic oligodendrocyte inclusion bodies, within the brain and spinal cord. Most patients with multiple system atrophy have parkinsonian features and distinguishing multiple system atrophy from idiopathic Parkinson's disease, especially in the early stages, is difficult. Thus, the true prevalence and incidence of multiple system atrophy is not known. At autopsy up to a quarter of patients previously considered to have Parkinson's disease, have the characteristic neuropathological features of multiple system atrophy.

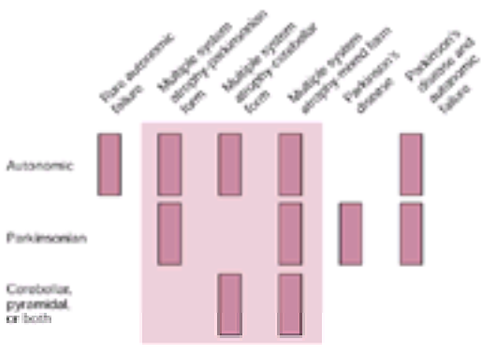

Fig. 6 Schematic representation of the major clinical features of primary chronic autonomic failure syndromes that include the three major neurological forms of multiple system atrophy (adapted from Mathias CJ (1997). Autonomic disorders and their recognition. *New England Journal of Medicine* **310**, 721–4).

In multiple system atrophy (parkinsonian), bradykinesia and rigidity is often bilateral, with minimal or no tremor, unlike Parkinson's disease; however, this may not be a

useful discriminator in an individual. Lack of a motor response to L-dopa is not indicative of multiple system atrophy, as two-thirds respond initially, although refractoriness and side-effects eventually reduce the benefit. The presence of autonomic failure (especially orthostatic hypotension) and unexplained genitourinary symptoms with sphincter disturbance should alert one to the possibility of multiple system atrophy in patients with parkinsonian or cerebellar signs. Oropharyngeal dysphagia and respiratory abnormalities favour multiple system atrophy, although these often occur later. The combination of cardiovascular autonomic failure and an abnormal urethral/anal sphincter electromyogram, with characteristic clinical features are virtually confirmatory of multiple system atrophy. Additional evaluation includes neuroimaging studies using MRI, positron emission tomography, and proton magnetic resonance spectroscopy of the basal ganglia, which are abnormal, at least in established cases. Clonidine growth-hormone testing, based on a $_2$-adrenoceptor stimulation of the hypothalamus with release of human growth-hormone releasing factor, distinguishes central from peripheral autonomic failure and separates Parkinson's disease from multiple system atrophy (Fig. 7); whether this is the case in the early stages of parkinsonism and in patients on dopaminergic agents (that are growth hormone secretagogues), remains to be resolved.

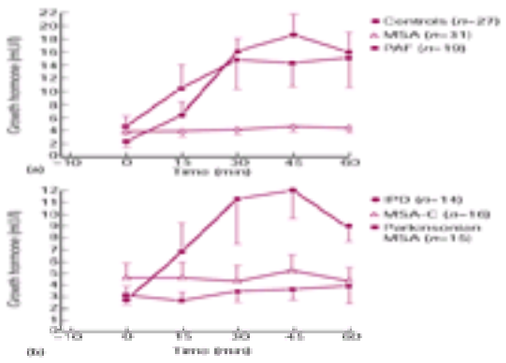

Fig. 7 (a) Serum growth hormone (GH) concentrations before (0) and at 15-min intervals for 60 min after clonidine (2 µg/kg.min) in normal subjects (controls) and in patients with pure autonomic failure (PAF) and multiple system atrophy (MSA). GH concentrations rise in controls and in patients with pure autonomic failure with a peripheral lesion; there is no rise in patients with multiple system atrophy with a central lesion. (From Thomaides T *et al.* (1992). The growth hormone response to clonidine in central and peripheral primary autonomic failure. *Lancet* **340**, 263–6.) (b) Lack of serum GH response to clonidine in multiple system atrophy (the cerebellar form and the parkinsonian form) in contrast to patients with idiopathic Parkinson's disease with no autonomic deficit (IPD), in whom there is a significant rise in GH levels. (From Kimber JR, Watson L, Mathias CJ (1997). Distinction of idiopathic Parkinson's disease from multiple system atrophy by stimulation of growth hormone release with clonidine. *Lancet* **349**, 1877–81.)

The prognosis in multiple system atrophy is poor compared with idiopathic Parkinson's disease and pure autonomic failure. Akinesia and rigidity often worsen, with increasing refractoriness and side-effects (including orthostatic hypotension), to antiparkinsonian therapy. As the disease advances there is often considerable immobility and difficulty in communication. In multiple system atrophy (cerebellar), worsening truncal ataxia causes falls and an inability to stand upright; orthostatic hypotension compounds the disabilities. Incoordination of the upper limbs, speech defects, and nystagmus result in further handicaps.

Respiratory complications include obstructive apnoea (due to laryngeal abductor cord paresis) and central apnoea may necessitate tracheostomy. Oropharyngeal dysphagia enhances the risk of aspiration, especially when vocal cord paresis is present; a percutaneous feeding gastrostomy may be needed. Urinary bladder dysfunction is distressing, and its management, together with that of constipation and, if appropriate, treatment of sexual dysfunction, is important in improving quality of life. There is often a need for specialist therapists, including speech therapists, physiotherapists, dietitians, and occupational therapists. As the neurological decline is inexorable, supportive therapy is crucial in management of multiple system atrophy, and should incorporate the family, carers, and community along with the primary care medical practitioner and therapists.

There is a smaller group of patients with Parkinson's disease, often successfully treated with dopaminergic therapy for many years, who develop severe orthostatic hypotension and other features of autonomic failure. They differ from most patients with Parkinson's disease in whom autonomic dysfunction, if present, is relatively mild and mainly compounded by drug therapy. In Parkinson's disease with autonomic failure, the autonomic lesions appear peripheral (and thus similar to pure autonomic failure)—a conclusion based on low plasma noradrenaline levels and other studies that suggest cardiac sympathetic denervation. Whether in patients with Parkinson's disease complicated by autonomic failure there is a coincidental association of a common condition with an uncommon disease (pure autonomic failure), vulnerability to autonomic degeneration in a subgroup of Parkinson's disease, a link with increasing age, chronic drug therapy, or an inherent metabolic susceptibility—or a combination of these factors—is unknown.

Acute/subacute dysautonomias

These disorders are relatively rare and consist of three main varieties: pure pandysautonomia (with features of both sympathetic and parasympathetic failure); pandysautonomia with additional neurological features usually indicative of a peripheral neuropathy; and pure cholinergic dysautonomia. The prognosis in pandysautonomias is variable, with substantial recovery in some. Recovery in two patients following immunoglobulin therapy favours an immunological basis, and the possibility of a Guillain–Barré syndrome variant. In pure cholinergic dysautonomia, described mainly in children and young adults, there is widespread parasympathetic failure with blurred vision, dry eyes, xerostomia, dysphagia with middle and lower oesophagus involvement, severe constipation, and urinary retention. Clinical findings include dilated pupils, an elevated heart rate, dry and warm skin, a distended abdomen, and a palpable urinary bladder. Anhidrosis may result in hyperthermia. The term 'cholinergic' is used because parasympathetic and also cholinergic sympathetic pathways (to sweat glands) are affected. Sympathetic vasoconstrictor function is preserved and orthostatic hypotension does not occur. Recovery is poor, but the prognosis is good if the condition is detected early. Management includes supportive therapy and adequate fluid and nutrient replacement of losses due to gastrointestinal and sudomotor failure. Barium studies should be avoided because contrast medium accumulates in the atonic colon. The differential diagnosis includes exposure to drugs, poisons, and toxins with anticholinergic effects. Similar autonomic features occur in thorn apple (*Datura stramonium*) seed poisoning; the poisoning is associated with hallucinations, hyperreflexia, and clonic jerking movements and recovery occurs in a few days. Botulism B affects cholinergic but spares motor systems and substantial recovery is expected within 3 months of the exposure.

Secondary disorders

Many disorders are associated with autonomic failure; a few are described.

Riley–Day syndrome (familial dysautonomia)

This is a recessive genetic defect characterized by absent lingual fungiform papillae, lack of corneal reflexes, absence of overflow emotional tears, decreased deep tendon reflexes, and a diminished response to pain and temperature; the disease occurs typically in children of Ashkenazi Jewish extraction. An abnormal intradermal histamine skin test (absent axon flare) and pupillary hypersensitivity to cholinomimetics provide diagnostic confirmation. Prenatal diagnosis is possible with the genetic markers linked to chromosome 9 (q31). Autonomic underactivity and overactivity include lability of blood pressure (hypertension and orthostatic hypotension), intermittent hyperhidrosis, periodic vomiting, dysphagia, constipation, and diarrhoea. The neurological abnormalities include emotional and behavioural disturbances, and sensory deficits that result in injury to skin and joints. Skeletal problems (scoliosis), respiratory (aspiration), and renal failure contribute to a poor prognosis. Anticipation of complications and adequate therapy has extended survival into adulthood.

Amyloid neuropathy

Deposition of amyloid into autonomic nerves can occur in reactive systemic amyloidosis (in chronic inflammatory disorders) or in immunoglobulin light chain (AL) amyloidosis (with lymphomas). In familial amyloid polyneuropathy, sensory, motor, and autonomic abnormalities result from deposition in peripheral nerves of mutated variant transthyretin, produced mainly in the liver. Symptoms of a sensory and motor neuropathy often begin in adulthood in the lower limbs in Portuguese, Japanese, and Swedish forms (familial amyloid polyneuropathy I), and in upper limbs in Indian/Swiss and German/Maryland forms (familial amyloid polyneuropathy II). These and other forms are now classified by the chemical and molecular nature of abnormal fibrillary protein, immunologically related to transthyretin. The most common is based on the first point mutations in the transthyretin gene associated with familial amyloid polyneuropathy—methionine 30 is the Portuguese form. The

cardiovascular system, gut, and gastrointestinal and urinary systems are affected at variable stages, with the disease progressing relentlessly. Autonomic symptoms and signs may be dissociated, leading to underrecognition of the autonomic deficit. Hepatic transplantation reduces variant transthyretin levels and prevents progression of neuropathy. Its ability to reverse neuropathy is unclear, emphasizing the need for intervention before nerve damage occurs.

Dopamine b-hydroxylase deficiency

This rare disorder (with seven patients reported, two of which are siblings) was recognized in the 1980s. Enzymatic deficiency probably occurs at birth but presentation is often in childhood. Orthostatic hypotension has been the clue to recognition. The clinical features indicate sympathetic adrenergic failure, with sparing of sympathetic cholinergic and parasympathetic function; thus sweating is preserved and urinary bladder and bowel function appear normal. In the male, erection is possible but ejaculation difficult to achieve. Basal levels of plasma noradrenaline and adrenaline are undetectable but dopamine is abnormally elevated. Sympathetic nerve terminals, except for the enzymatic and functional defect, are otherwise intact, as demonstrated by electron microscopy, immunohistochemistry, and sympathetic microneurography. Effective treatment is with the prodrug l-dihydroxyphenylserine, that has a structure similar to noradrenaline and is converted by the enzyme dopa-decarboxylase (abundantly present in extraneuronal tissue such as liver and kidneys) to noradrenaline (Fig. 2(a)).

Diabetes mellitus

In patients with long-standing diabetes, especially those on insulin, there is a high incidence of peripheral and autonomic neuropathy. Vagal denervation occurs earlier, impairing heart rate variability. Reduced sympathetic activity, for example in the feet, may increase blood flow substantially at an early stage before detection of neuropathy. Orthostatic hypotension may be enhanced by insulin. There may be sweating abnormalities (gustatory sweating), delayed stomach emptying (gastroparesis diabeticorum), impaired urinary bladder function (diabetic cystopathy), and impotence. Diarrhoea may be extremely distressing.

Spinal cord injuries

Autonomic dysfunction affecting many systems occurs in spinal injuries, depending upon the lesion level and the degree of completeness. Cardiovascular dysfunction may be life threatening, especially in high lesions, in the acute phase in spinal shock, since lack of sympathetic activity with increased vagal tone may cause bradycardia and cardiac arrest (Fig. 8). After a few weeks, spinal shock passes and isolated spinal reflex activity returns; in cervical and high thoracic lesions, abnormal spinal activation results in the syndrome of autonomic dysreflexia. This is induced by cutaneous, skeletal muscle, or visceral stimuli below the level of the lesion. Thus, severe muscle spasms, an anal fissure, or a blocked urethral catheter can result in paroxysmal hypertension (due to increased spinal sympathetic nerve activity, independent of normal cerebral pathways) with associated bradycardia (because of preserved baroreceptor afferents and vagal efferent pathways (Fig. 9). Patients with lesions below T6 are spared. Patients with high lesions also are prone to orthostatic hypotension which compounds difficulties in management, especially shortly after injury.

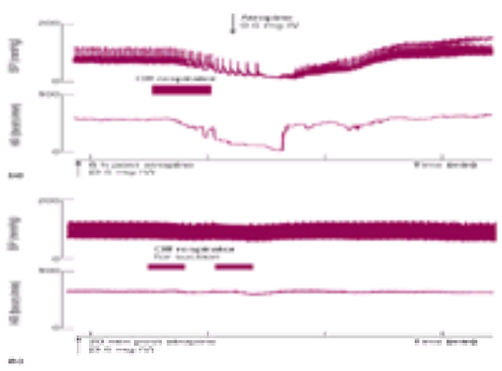

Fig. 8 (a) The effect of disconnecting the respirator (as required for aspirating the airways) on the blood pressure (BP) and heart rate (HR) of a recently injured tetraplegic patient (C4/5 lesion) in spinal shock, 6 h after the last dose of intravenous atropine. Sinus bradycardia and cardiac arrest (also observed on the electrocardiograph) were reversed by reconnection, intravenous atropine, and external cardiac massage. (From Frankel HL, Mathias CJ, Spalding JMK (1975). Mechanisms of reflex cardiac arrest in tetraplegic patients. *Lancet* **ii**, 1183–5.) (b) The effect of tracheal suction 20 min after atropine. Disconnection from the respirator and tracheal suction did not lower either heart rate or blood pressure (From Mathias CJ (1976). Bradycardia and cardiac arrest during tracheal suction—mechanisms in tetraplegic patients. *European Journal of Intensive Care Medicine* **2**, 147–56.)

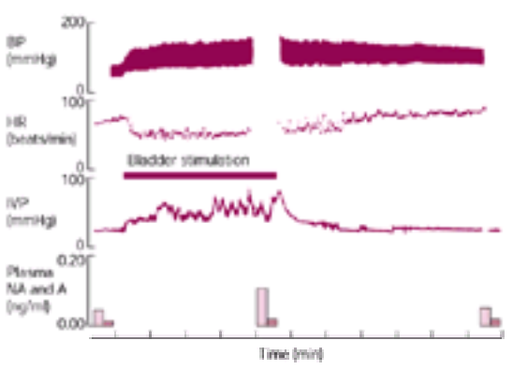

Fig. 9 Blood pressure (BP), heart rate (HR), intravesical pressure (IVP), and plasma noradrenaline (NA) and adrenaline (A) concentrations in a tetraplegic patient before, during, and after bladder stimulation induced by suprapubic percussion of the anterior abdominal wall. The rise in BP is accompanied by a fall in heart rate as a result of increased vagal activity in response to the rise in blood pressure. The level of plasma noradrenaline (open histograms), but not adrenaline (filled histograms), rises suggesting an increase in sympathetic neural activity independently of adrenomedullary activation. (From Mathias CJ, Frankel HL (1986). The neurological and hormonal control of blood vessels and heart in spinal man. *Journal of the Autonomic Nervous System* **Suppl.**, 457–64.)

Drugs

Dysfunction may result from an autonomic neuropathy (as induced by alcohol, vincristine, and perhexiline maleate) or through pharmacological effects. The latter may be expected with the sympatholytic agents, or may be a minor unexpected effect in susceptible individuals. An example of this is the anticholinergic bladder effects of disopyramide, which may cause urinary retention in patients with prostatic hyperplasia. A variety of toxins and poisons, including mushroom toxicity and botulism, as well as nerve gases such as sarin, affect the autonomic nervous system. The first-dose effect of ACE-inhibitors and prazosin may be mediated by the Jarisch–Bezold reflex. Autonomic overactivity occurs during withdrawal of clonidine, alcohol, and opiates.

Neurally mediated syncope

This is an intermittent abnormality with increased cardiac parasympathetic (causing severe bradycardia, cardio-inhibition) and sympathetic withdrawal (causing hypotension vasodepression) that results in fainting. The episodes may be cardio-inhibitory, vasodepressor, or mixed (Fig. 10(a) and Fig. 10(b)). Between episodes, screening autonomic tests usually reveal no abnormalities. In the young, a common cause is vasovagal syncope. This is often familial and more likely in females; it often presents in the early teenage years and is induced by stimuli such as fear, sight of blood, and venepuncture, and at times even discussion of venepuncture. Hypotension is more likely in the upright position and may occur whilst standing still, especially in warm weather when salt and fluid depletion occurs. Testing includes prolonged head-up tilt, or a provocative stimulus such as venepuncture during head-up tilt. A variety of physiological (head-up tilt plus lower body negative pressure) or pharmacological (isoprenaline infusions) stimuli have been used to unmask an episode. Cardiac conduction disorders and other causes of syncope (such as

neurological or metabolic) should be excluded. Treatment includes reducing or preventing exposure to precipitating causes and behavioural psychotherapy in patients with phobias. Added salt, fluid repletion, and exercise are often useful. Drugs such as fludrocortisone, vasopressor agents, and antidepressants such as the serotonin-uptake release inhibitors have been used. The long-term prognosis is favourable.

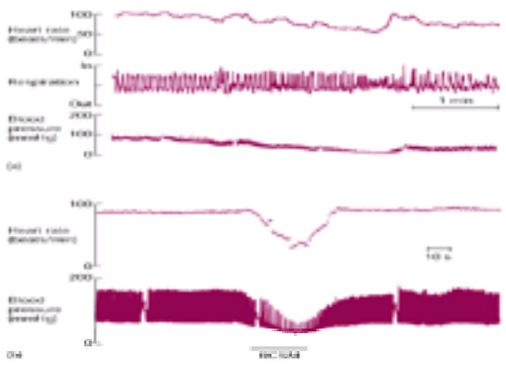

Fig. 10 (a) Blood pressure changes towards the end of a period of head-up tilt in a patient with recurrent episodes of vasovagal syncope. Blood pressure that was previously maintained begins to fall. There is also a reduction in heart rate. Initially there are relatively minor changes in respiratory rate. The patient was about to faint and was replaced to the horizontal (indicated by elevated time signal below) and then to 5° head-down tilt. Blood pressure and heart rate recover but still remain lower than previously. This patient had no other autonomic abnormalities on detailed autonomic testing. Blood pressure was measured non-invasively by the Finapres. (From Mathias CJ, Bannister R (1999). Investigation of autonomic disorders. In: Mathias CJ, Bannister R, eds. *Autonomic failure: a textbook of clinical disorders of the autonomic nervous system*, 4th edn, pp 169–95. Oxford University Press, Oxford.) (b) Heart rate and blood pressure before, during, and after right carotid sinus massage (RCSM) in a patient with syncopal episodes. There is a fall in heart rate and blood pressure during carotid sinus massage, typical of the mixed (cardio-inhibitory and vasodepressor) form of this disorder. The breaks in the record indicate interval calibration by the Finapres machine. (From Mathias CJ (2000). Autonomic dysfunction. In: Grimley-Evans J *et al.*, eds. *Oxford textbook of geriatric medicine*, 2nd edn, pp 833–52. Oxford University Press, Oxford.)

In the elderly, carotid sinus hypersensitivity is increasingly recognized, especially in those with falls of otherwise unknown cause. A classic history of syncope induced by head movements or collar tightening may be provided, although in many the precipitating factors are unclear. Carotid sinus massage should be performed in the laboratory with requisite precautions, ideally using continuous blood pressure and heart rate recordings, with the subject also tilted head-up, because hypotension is more likely to occur when sympathetic activation is needed. Treatment, especially of the cardio-inhibitory forms, includes a cardiac demand pacemaker; vasodepressor forms may require pressor agents. Surgical denervation of the carotid sinus has been used successfully, especially where unilateral hypersensitivity occurs.

A variety of other stimuli, acting through short-lived autonomic mechanisms, also can cause syncope. This may be in conjunction with factors such as heat or drugs that cause vasodilatation or reduce intravascular volume, thus increasing the tendency to hypotension and syncope. Examples include syncope associated with glossopharyngeal neuralgia (caused by swallowing), or induced by micturition, defaecation, coughing, laughing, and playing wind instruments.

Orthostatic intolerance without hypotension

This disorder is increasingly recognized, mainly in women below the age of 50 years. Dizziness on postural change or with modest exertion occurs usually without syncope. The symptoms appear to disrupt their lives, almost disproportionately. There is a substantial rise in heart rate (over 30 beats/min or to 120 beats/min) without orthostatic hypotension, hence the term postural (orthostatic) tachycardia syndrome. Associated features may include those of a partial autonomic neuropathy, chronic fatigue syndrome, mitral valve prolapse, and hyperventilation. It is unclear whether other factors such as vestibular dysfunction contribute. The relationship of this syndrome to previously described psychosomatic disorders such as Soldier's heart (da Costa's syndrome) is not known. Treatment includes salt and fluid repletion, exercise, and b-adrenergic blockers. Many recover within a year.

24.13.15 Disorders of cranial nerves

P. K. Thomas

The olfactory nerve

Loss of the sense of smell (anosmia) is most commonly encountered as a sequel to head injury and is probably related to severance of the central processes of the neurones of the olfactory mucosa as they pass through the cribriform plate to the olfactory bulb. It is usually permanent. Distortion of olfaction (parosmia) may occur and may be persistent. The sense of smell is occasionally congenitally absent or may be acutely and permanently lost after a coryzal infection. Bilateral anosmia is frequently accompanied by impairment of taste related to reduced detection of the volatile substances that impart flavours to foods. Unilateral anosmia may occur in olfactory groove meningiomas or other subfrontal tumours. This is usually not detected by the patient.

The central connections of the olfactory pathways are complex and include projections to the temporal lobes, hypothalamus, the septal region, and the amygdaloid nuclei. Olfactory hallucinations are well known to occur as a manifestation of temporal lobe epilepsy. Identification of odours may be impaired after bilateral medial temporal lesions and may be defective in multiple sclerosis, possibly as the result of demyelination in the olfactory tracts. Complaints of hypersensitivity of the sense of smell commonly have a psychoneurotic basis and persistent olfactory hallucinations may be reported by psychotic patients. Persistent parosmia is sometimes produced by lesions of the temporal lobe.

Third, fourth, and sixth cranial nerves

The third, or oculomotor, nerve supplies all the external ocular muscles with the exception of the superior oblique and lateral rectus. It also carries the parasympathetic innervation of the preganglionic pupilloconstrictor fibres of the iris. A complete third nerve lesion produces a dilated and unreactive pupil, complete ptosis, and loss of upward, downward, and medial movement of the eye. The eye becomes deviated downwards and laterally. Diplopia is only experienced when the lid is held up.

The fourth or trochlear nerve supplies the superior oblique muscle. Following a lesion of this nerve, there is extorsion of the eye when the patient looks outwards. When the patient looks downwards and medially, diplopia is experienced. This is particularly disturbing because of its occurrence on looking downwards and produces difficulty in walking and in descending stairs. The patient may compensate for this by tilting the head to the opposite side.

The sixth or abducens nerve supplies the lateral rectus. A lesion of this nerve causes convergent strabismus, inability to abduct the affected eye, and diplopia which is maximal on lateral gaze to the affected side.

The third, fourth, and sixth nerves may be affected singly or in combination, and the paralysis may be complete or partial. In some instances, the lesion is within the brainstem, where it may affect either the nuclei or intramedullary portion of the nerve fibres. In older patients, the commonest causes are vascular disease and neoplasms of the brainstem.

Extramedullary lesions of the third, fourth, and sixth nerves are more frequent and may occur at any point along their course, either intracranially or within the orbit. A third nerve palsy may develop in the region of the tentorial hiatus as a false localizing sign related to displacement of the brainstem produced by supratentorial space-occupying conditions. Unilateral or bilateral sixth nerve palsies may also arise as a consequence of raised intracranial pressure, probably caused by traction, again secondary to brainstem displacement. These nerves can be involved singly or together in conditions such as chronic basal meningitis or carcinomas of the skull base. Gradenigo's syndrome comprises a sixth nerve palsy and pain of trigeminal distribution. It is produced by a lesion at the apex of the petrous temporal bone. As this syndrome was most commonly infective in origin and related to chronic middle ear disease, it is now encountered considerably less frequently.

The third, fourth, and sixth nerves traverse the cavernous sinus, as do the first and second divisions of the trigeminal nerve. In this situation, they are most commonly damaged by an intracavernous aneurysm of the internal carotid artery. The third nerve is affected more often than the fourth and sixth. The consequent internal and external ophthalmoplegia is frequently accompanied by pain, and sometimes sensory loss and paraesthesiae, in the corresponding frontal region related to compression of the first division of the trigeminal nerve, and occasionally in the cheek from damage to the maxillary division. In the superior orbital fissure syndrome, caused for example by a tumour invading the fissure, a total ophthalmoplegia may result, associated with pain and sensory loss in the distribution of the first division of the trigeminal nerve. The eye is often proptosed because of obstruction of the ophthalmic vein. The Tolosa–Hunt syndrome consists of a painful external ophthalmoplegia related to a granulomatous angiitis. Within the orbit, the third, fourth, and sixth nerves may be affected by conditions such as tumours and granulomas. They may be damaged as a result of trauma at any point along their course and may be affected singly or in combination or as part of a cranial neuropathy, of which diabetes, the Miller–Fisher syndrome, Lyme borreliosis, and sarcoidosis are the most important examples. Internal and external ophthalmoplegias are common and this list of causes is by no means exhaustive.

Pupillary abnormalities

Constriction of the pupil (miosis) occurs as a result of paralysis of the sympathetic innervation of the pupillodilator fibres of the iris and may be accompanied by the other features of Horner's syndrome, namely mild ptosis and vasodilatation and anhidrosis of the face on the same side. The ocular manifestations may be encountered alone if the damage is restricted to the intracranial portion of the sympathetic plexus around the carotid artery. Raeder's syndrome consists of these components of Horner's syndrome together with involvement of the first division of the trigeminal nerve. It may be caused by tumours of the skull base. Miosis may also be produced by the local action of cholinergic drugs and by morphine and related compounds.

Pupillary dilatation may be caused by lesions of the third nerve, although it is of interest that the isolated third nerve palsies of presumed vascular origin that may occur in diabetes mellitus, in contradistinction to compressive lesions of the nerve, characteristically spare the pupil. Anticholinergic drugs such as atropine and related substances give rise to pupillary dilatation, as does cocaine.

The Argyll–Robertson pupil is small, fails to react to light, but constricts on ocular convergence, and, if bilateral, the pupils are frequently unequal in size (anisocoria). The pupil may be irregular in outline and it does not dilate fully in response to mydriatics. Argyll–Robertson pupils are almost always related to neurosyphilis but somewhat similar pupils are occasionally encountered in diabetic neuropathy and in some hereditary neuropathies.

The myotonic pupil (Holmes–Adie syndrome) reacts abnormally slowly both to light and on convergence, but particularly so for the response to illumination. A very bright light may be required to demonstrate any pupillary constriction, or if the patient remains in a dark room for some minutes, the pupil slowly dilates. The condition may be unilateral or bilateral and is commoner in women than men. Myotonic pupils may be associated with absence or depression of the tendon reflexes and

occasionally with anhidrosis in the limbs.

Trigeminal nerve

The fifth cranial nerve is predominantly sensory in function, but also innervates the muscles of mastication. It emerges from the pons and runs forwards to the Gasserian ganglion which is situated in Meckel's cave near the apex of the petrous temporal bone. The three sensory divisions of the nerve run anteriorly from the ganglion. The first or frontal division passes through the cavernous sinus and the superior orbital fissure. Its branches supply sensation to the anterior part of the scalp, the forehead, and the eye, including the conjunctiva and cornea. The second or maxillary division leaves the skull through the foramen rotundum, traverses the infraorbital canal, and supplies the cheek. The mandibular division emerges from the skull through the foramen ovale to reach the infratemporal fossa with the motor root with which it unites to form a single trunk. It is distributed to the lower lip, chin, and the lower part of the cheek, and its auriculotemporal branch supplies part of the ear and temporal area. It also supplies the inner aspect of the cheek and the anterior two-thirds of the tongue, and its lingual branch carries taste fibres from the anterior two-thirds of the tongue which leave it in the chorda tympani to join the facial nerve. It is important that the skin over the angle of the jaw is supplied from the second cervical nerve root, and the absence of this 'trigeminal notch' may be useful in distinguishing hysterical or feigned loss of sensation on the face which usually follows the angle of the jaw. The motor root innervates temporalis, masseter, pterygoids, mylohyoid, the anterior belly of the digastric, and also tensor tympani and tensor palati muscles. With unilateral paralysis of the masticatory muscles, the jaw deviates towards the affected side on opening because of the action of the unopposed external pterygoid on the unaffected side.

The trigeminal nerve may be affected by intramedullary lesions, it may be damaged during the intracranial part of its course, or its branches may be compromised extracranially. An acoustic neurinoma may compress the nerve in the posterior fossa or the nucleus of the descending root may be affected by direct compression of the brainstem by this tumour. Loss of corneal sensation is usually the earliest feature. Reference has already been made to involvement of the nerve in association with damage to the sixth nerve at the apex of the petrous temporal bone (Gradenigo's syndrome), as has involvement of the first and second divisions in the cavernous sinus, or the first division in the superior orbital fissure.

Trigeminal neuralgia

Symptoms

This condition is characterized by paroxysms of intense pain strictly confined to the distribution of the trigeminal nerve. In most cases the cause is unknown. It is generally encountered in individuals over the age of 50 years. In younger patients it may be due to multiple sclerosis. Rarely, compression of the nerve, for example by tumours in the cerebellopontine angle, is responsible.

The salient feature of the disorder is pain which is usually unilateral and is felt either within the territory of one division of the nerve only, or may involve two adjacent divisions or affect the whole territory of the nerve. Less commonly it is bilateral.

The pain occurs in brief searing paroxysms, each attack lasting only a matter of seconds. The pain is often described as piercing or knife-like. Its intense quality may cause the patient to screw up their face in agony, hence the use of the term 'tic douloureux' to describe the condition. The paroxysms may be spontaneous or provoked by movements of the face and jaw, by touching the skin, or by draughts of cold air on the face. Eating and speaking may become extremely difficult. 'Trigger spots' on the skin of the face may be present, the touching of which provokes the paroxysms. The attacks may be followed by less severe pain of a dull, boring character and by tenderness of the skin in the affected area. Fortunately the attacks usually cease at night.

The quality of the pain is characteristic, and when trigeminal neuralgia is present, the diagnosis is not usually missed, especially if a paroxysm is witnessed. The usual mistake is to regard as trigeminal neuralgia pain that is due to some other cause, and since there are many conditions that give rise to facial pain, the opportunities for error are numerous. Pain that is of a continuous character is not trigeminal neuralgia and some other cause must be sought. Absence of provocation by eating, talking, or the touching of trigger spots also makes the diagnosis unlikely. Once the diagnosis is accepted, it is essential to exclude compressive lesions affecting the nerve.

In the early stages, remissions lasting for months or years are usual, but in older patients remissions, if they occur, are likely to be brief. In all cases the remissions tend to become shorter as time goes on, and without treatment the condition persists for the rest of the patient's life.

The distribution of the pain is usually in one or two divisions of the nerve. The first division is rarely affected primarily, but pain may spread into it from the second division. If the pain begins in the second division it may, after a time, affect the third, and vice versa.

Treatment

The introduction of carbamazepine revolutionized treatment of this distressing condition. In a high proportion of cases, the paroxysms can be abolished or reduced. A dosage of 200 mg three to five times per day is employed. Ataxia and drowsiness may be troublesome side-effects with higher dosages, and aggravation of ataxia even with modest dosages may impede treatment in cases of multiple sclerosis. Hypersensitivity reactions producing skin rashes or, rarely, bone marrow depression may develop but are, fortunately, uncommon.

If carbamazepine is not successful, or if the patients fail to tolerate it, other drugs such as phenytoin or clonazepam can be tried, but they are rarely effective. In this event, thermocoagulation of the ganglion may have to be considered. This should be undertaken only if the disorder is established so that a prolonged natural remission is unlikely to occur. It should also not be undertaken unless the patient is completely unable to tolerate the disorder, despite analgesics and sedation, and if they are fully aware of the consequences. The persistent analgesia and sometimes dysaesthesiae may subsequently be troublesome, and when the first division is made anaesthetic, damage to the conjunctiva leading to corneal scarring has to be avoided. It may be possible to limit the anaesthesia to the affected area, sparing, for instance, the eye if the first division is not involved by the pain. If thermocoagulation fails, section of the sensory root by a posterior fossa approach employing a microsurgical technique is indicated.

Ophthalmic herpes zoster

In elderly individuals, the fifth nerve is prone to involvement in herpes zoster, the first division being most vulnerable, giving rise to the distressing condition of ophthalmic herpes. The clinical features and treatment of herpes zoster are considered elsewhere (see Section 7). An unfortunate sequel may be visual impairment from residual corneal scarring. Particularly in older subjects, post-herpetic neuralgia may also be a sequel. This gives rise to persistent and unremitting spontaneous pain associated with cutaneous hyperaesthesia in the affected area. Treatment is difficult. Analgesics, sedation, and antidepressive preparations to combat the secondary depression that is frequently present may be of some assistance.

Isolated trigeminal neuropathy

Rarely, a chronic isolated unilateral or bilateral affection of the trigeminal nerve may occur as a manifestation of Sjögren's sicca syndrome, or progressive systemic sclerosis or amyloidosis, although most cases are idiopathic. Extensive nasal scarring and tissue loss may occur secondary to repeated injury from picking and scratching.

Facial nerve

The seventh cranial nerve is largely motor. The nerve traverses the facial canal in the petrous temporal bone in close relationship to the middle ear and emerges at the stylomastoid foramen. Its branches pass forward through the parotid gland to be distributed to the muscles of the face, including the platysma. Within the petrous bone, a branch is given to the stapedius muscle. The chorda tympani, carrying the taste fibres from the anterior two-thirds of the tongue, joins the nerve within the facial canal and a small branch supplies cutaneous sensation to the region of the external auditory meatus. The nerve also carries preganglionic parasympathetic fibres destined for the lachrymal gland.

The distinction between upper and lower motor neurone lesions of the facial muscles is usually easy. In general, with upper motor neurone lesions there is a relative

preservation of power in the upper facial muscles, because these have a bilateral innervation from the cerebral hemispheres. There is no loss of tone with upper motor neurone lesions, so that the sagging of the face that is an unsightly feature of lower motor neurone palsy does not occur.

In common with the trigeminal nerve, the facial nerve may be affected by tumours in the cerebellopontine angle. In the past, it was often involved in middle ear infections. It may be involved in meningeal carcinomatosis, fractures, and tumours of the skull base, in a variety of cranial neuropathies, and cephalic herpes zoster, but the most common lesion by far is Bell's palsy. More peripherally, the nerve may be implicated in tumours of the parotid gland.

Bell's palsy

This term describes a usually unilateral facial paralysis of relatively rapid onset related to a lesion of the nerve within the facial canal. Taste may also be affected. It may develop at any age, most commonly between 20 and 50 years, and affects both sexes equally. Its causation is unknown. In the acute stage, the nerve is swollen and compression within the facial canal may contribute to the damage to the nerve fibres.

The onset is rapid and is frequently heralded or accompanied by aching pain below the ear or in the mastoid region. This clears within a few days and is not present in every case. The paralysis usually reaches its maximum severity after 1 or 2 days but occasionally progresses over the course of several days. Complete paralysis may occur. In the lower face, this may cause a mild dysarthria and some difficulty in eating because of food collecting between the gums and the inner sides of the cheek and the escape of fluid when drinking. The face sags and on smiling is drawn across to the unaffected side. Paralysis of orbicularis oculi renders voluntary eye closure impossible and, particularly in the older subject, ectropion develops. This can result in conjunctival injury from foreign bodies or conjunctivitis. If the paralysis is partial, the lower face is usually affected to a greater extent than the upper.

In the more severe cases, loss of taste over the anterior two-thirds of the tongue is often present, and paralysis of the stapedius muscle may result in a lack of tolerance for high-pitched or loud sounds.

Bell's palsy has to be distinguished from selective lesions of the facial nerve within the brainstem, in which instance taste will not be affected. A facial paralysis superficially resembling Bell's palsy may occur in multiple sclerosis, in which event evidence of more widespread neurological disease may well be detected on examination, or the history may indicate episodes of neurological disturbance in the past. With respect to peripheral lesions, middle ear disease requires exclusion. Facial paralysis related to cephalic herpes zoster is discussed above. A lesion of the facial nerve may represent a mononeuropathy from some generalized disorder of which diabetes, Lyme borreliosis, and sarcoidosis are the most important. Bell's palsy is rarely bilateral and the occurrence of bilateral facial paralysis would raise the possibility of Guillain–Barré syndrome. This may begin with facial weakness, or the weakness may remain restricted to the facial musculature. The occurrence of bilateral facial weakness would also raise the possibility of sarcoidosis.

In approximately 85 per cent of cases of Bell's palsy, the paralysis is the result of a local conduction block within the facial canal without axonal degeneration and this is effectively the situation in all instances of mild weakness. The conduction block is presumably the consequence of segmental demyelination. Providing that such cases do not progress to more severe weakness, all recover fully within a few weeks. In cases where there is total paralysis, a proportion of these will be the result of a conduction block, but in about 15 per cent axonal degeneration will have occurred. Those with a conduction block will again recover satisfactorily within a few weeks. In patients with a degenerative lesion, recovery has to take place by axonal regeneration. Evidence of reinnervation does not appear in under 3 months and the ultimate recovery is often incomplete or may fail to occur altogether. Synkinesis is frequent after reinnervation so that blinking, for example, results in a simultaneous contraction of the angle of the mouth. Aberrant parasympathetic reinnervation may also occur, leading for instance to gustatory lachrymation ('crocodile tears').

Axons remain excitable distal to the lesion for 3 or 4 days after interruption. It is therefore not possible to be certain from electrodiagnostic tests whether axonal degeneration has taken place until after this time. At that stage, electrical stimulation of the facial nerve at the stylomastoid foramen with brief pulses will still elicit a muscle contraction if the paralysis is due to conduction block, whereas none will be obtained if axonal degeneration has taken place.

In the early stages, the main endeavour of treatment should be to prevent either a partial lesion, or complete paralysis related to a conduction block, progressing to a degenerative lesion. There is some evidence that corticosteroids may be advantageous by reducing oedema in the nerve. Thus it is justifiable to treat all cases with corticosteroids if seen within a few days of onset, providing no contraindication to such treatment exists. A course of a week's duration with an initially high dosage is recommended.

Surgical decompression of the nerve has been advised. To be effective, this would have to be performed at the outset, which is not justifiable as 85 per cent of cases will recover satisfactorily without treatment. So far there are no means of predicting which cases will progress to a degenerative lesion. If this were available, decompression could be undertaken selectively in such cases.

It is helpful to perform electrodiagnostic studies at about 1 week after the onset. If this reveals a degenerative lesion, it is then known that recovery will be delayed. A prosthesis attached to the teeth to elevate the angle of the mouth to reduce facial deformity may be helpful. In patients with severe ectropion, a lateral tarsorrhaphy to protect the eye may be required. Electrical stimulation of the paralysed facial muscles has no effect on the ultimate prognosis.

In those cases in which regeneration fails to occur, operation may be desirable for cosmetic reasons to counteract the facial deformity. The angle of the mouth may be elevated by a fascial sling attached to the temporalis fascia, but the result is never highly satisfactory. Restoration of facial tone may be achieved by anastomosis of the hypoglossal nerve to the facial, but at the expense of denervation of the tongue on that side. Any operation should not be contemplated before an adequate length of time has been allowed for regeneration. This should be of the order of 9 months.

Facial paralysis related to 'geniculate' herpes zoster (Ramsay–Hunt syndrome)

Facial paralysis of rapid onset accompanied by severe pain in and around the external auditory meatus and in the throat may accompany 'cephalic zoster'. Vesicles may be detectable in the ear and ulceration in the fauces, or anywhere on the head. Occasionally there is concomitant vertigo, tinnitus, and some deafness with involvement of the eighth nerve ('otic herpes zoster'). Prognosis for recovery of the facial paralysis is stated to be less good than in Bell's palsy.

Hemifacial spasm

This consists of a unilateral disturbance affecting the facial muscles, producing irregular clonic or twitching movements of the facial muscles, usually of insidious onset. It most commonly occurs in middle-aged women. There may be a mild degree of facial weakness, but severe paralysis does not occur. Usually no underlying cause is demonstrable. The condition selectively affects the facial nerve, within the brainstem or in the posterior fossa.

It begins with intermittent twitching of the facial muscles such as around the eye or at the angle of the mouth. These movements gradually become more frequent and extend to involve the rest of the facial muscles, often gradually advancing over the course of some years. If they become severe, the face is contorted by irregular clonic spasms which may keep the eye closed for prolonged periods. The facial distortion is often a considerable embarrassment to the patient, who finds that the spasms tend to be aggravated by emotional stress.

The condition must be distinguished from benign fasciculation of the face, which usually occurs around the eyes, related to fatigue or emotional tension, and from the myokymic twitching that is occasionally encountered as a manifestation of multiple sclerosis. The latter consists of a persisting irregular rippling movement of the facial muscles that usually subsides after a week or two. These conditions can be distinguished by electromyography (see Chapter 24.2.5).

No satisfactory treatment is available. If exaggeration by emotional factors is evident, the administration of diazepam or a similar preparation may produce a marginal improvement. In severe cases, injections of botulinum toxin may be helpful, although these have to be repeated. Neurosurgical intervention to relieve compression of the nerve by aberrant vessels in its intracranial course has been advocated and may be helpful in selected cases.

Glossopharyngeal nerve

The ninth cranial nerve leaves the skull through the jugular foramen, closely related to the tenth nerve. It supplies the stylopharyngeus muscle and the constrictor

muscles of the pharynx. Parasympathetic fibres are supplied to the parotid gland. Sensory fibres are carried from the posterior third of the tongue, the ear, the fauces, and the nasopharynx, and chemoreceptor and baroreceptor afferents from the carotid sinus.

The glossopharyngeal nerve is rarely affected in isolation. Lesions usually occur in conjunction with involvement of the vagus and give rise to some dysphagia, impaired pharyngeal sensation, and loss of taste over the posterior third of the tongue. It may be affected in the jugular foramen syndrome (Vernet's syndrome), along with the tenth and eleventh nerves, of which glomus tumours or metastatic carcinoma are the commonest causes. The nerve may also be involved in diphtheritic neuropathy and in a polyneuritis cranialis.

Glossopharyngeal neuralgia is a rare form of neuralgia within the distribution of the glossopharyngeal nerve. Its features are otherwise strictly comparable with those of trigeminal neuralgia in the quality and severity of the pain, its occurrence in brief paroxysms, its provocation by actions such as speaking or swallowing, and the remissions in its course. As with trigeminal neuralgia, it is most often encountered in elderly subjects, and the pain may initially be confined to individual branches. Thus it may be felt deep in the ear, related to the tympanic branch, or in the throat, related to the pharyngeal branches. It also usually responds to treatment with carbamazepine.

In treatment, carbamazepine may be effective. In instances of severe pain unrelieved by this preparation, surgical treatment, usually avulsion of the nerve, may be required.

Vagus nerve

The tenth cranial nerve is structurally complex. Within the skull it is joined by the cranial division of the eleventh nerve. It leaves the skull through the jugular foramen. Cutaneous sensory fibres are carried from the external ear and visceral afferent fibres are carried from the pharynx, larynx, trachea, oesophagus, and the thoracic and abdominal viscera. Motor fibres are supplied to the striated musculature of the palate and pharynx and through the external and recurrent laryngeal nerves, to the muscles of the larynx. Parasympathetic fibres are provided to innervate the parotid gland (through the glossopharyngeal nerve), the heart, and the abdominal viscera.

The important symptoms of damage to the vagal nerve are those relating to pharyngeal and laryngeal innervation. The cells of origin in the nucleus ambiguus of the medulla may be damaged in the lateral medullary syndrome, in motor neurone disease, and in acute bulbar poliomyelitis, leading to dysphagia and dysphonia. Involvement along with the glossopharyngeal nerve in the jugular foramen syndrome has already been mentioned. The recurrent laryngeal nerve may be damaged during operations on the thyroid gland or by tumours within the neck, or within the thorax, usually by carcinoma of the bronchus. The nerve on the left is vulnerable to damage from aneurysm of the aortic arch. Isolated and unexplained lesions of the recurrent laryngeal nerve are not uncommon.

Nuclear or high vagal lesions, as well as involving the larynx, cause palatal and pharyngeal paralysis. If unilateral, there are no symptoms from palatopharyngeal paralysis. The uvula is pulled up to the opposite side on phonation and pharyngeal sensation is impaired on the affected side. With bilateral paralysis, the palate is paretic leading to nasality of the voice and nasal regurgitation of liquids on attempts at swallowing. Bilateral palatopharyngeal paralysis may be encountered in motor neurone disease, bulbar poliomyelitis, diphtheritic neuropathy, and polyneuritis cranialis.

Unilateral intrinsic laryngeal paralysis from lesions of the recurrent nerve may be asymptomatic or give rise to hoarseness of the voice. If the superior laryngeal nerve is also involved leading to paralysis of the cricothyroid muscle, the affected cord lies in a paramedian or cadaveric position. The effects of bilateral lesions of the recurrent laryngeal nerves depend upon the degree of approximation of the vocal cords. Lesions of insidious onset tend to give rise to dysphonia and also to stridor on exertion. In partial lesions, close approximation of the cords may result from selective paralysis of the abductor muscles, giving rise to limitation of the airway and sometimes necessitating tracheostomy. With bilateral lesions involving both the recurrent and superior laryngeal nerves, both cords are paralysed and in the cadaveric position. Phonation is impossible.

Spinal accessory nerve

The spinal accessory portion of the eleventh cranial nerve arises from the upper cervical cord and the lower medulla. The nerve passes through the foramen magnum and joins the cranial portion of the nerve before emerging from the skull through the jugular foramen. The spinal accessory nerve then separates and supplies the sternomastoid and trapezius muscles, the latter also receiving an innervation from the cervical plexus.

The nerve may be affected by lesions in the region of the jugular foramen, but more commonly it is damaged by injuries to the neck or by operations for the removal of cervical glands, particularly as it crosses the posterior triangle of the neck. Isolated and unexplained lesions of the nerve are occasionally encountered.

Unilateral paralysis of the sternomastoid usually passes unnoticed by the patient. The muscle does not stand out when the head is turned to the opposite side. Paralysis of the trapezius, on the other hand, causes difficulty in lifting the arm above the horizontal, in shrugging the shoulder, and in approximating the scapula to the midline and therefore also in carrying the extended arm backwards. The shoulder droops when the arm is hanging at the side and there is moderate winging of the scapula which is accentuated when the patient attempts to elevate the arm laterally.

The hypoglossal nerve

The twelfth cranial nerve supplies all the muscles of the tongue, both intrinsic and extrinsic. It leaves the skull through the anterior condyloid foramen. A unilateral lesion of the hypoglossal nerve causes weakness and atrophy of the tongue on the affected side. When protruded, the tongue deviates to the affected side. Articulation is unaffected. The nerve may be affected by tumours in the region of the anterior condyloid foramen, or by tumours or penetrating injuries in the neck. If the lesion is the result of a unilateral lower brainstem lesion, it may be combined with a crossed hemiplegia.

Bilateral lesions give rise to generalized atrophy of the tongue. Protrusion becomes impossible and articulation is disturbed. The commonest cause is motor neurone disease (progressive bulbar palsy variant). The wasting of the tongue is usually accompanied by fasciculation.

24.13.16 Diseases of the spinal cord

L. D. Blumhardt

Anatomy

The spinal cord extends from its junction with the brainstem (medulla oblongata) at the foramen magnum (opposite the odontoid peg at C1) to the lower border of the first lumbar vertebra. It is enclosed within the arachnoid and dura mater, which extend below the termination of the spinal cord (conus medullaris) into the sacral canal.

The clinically important upper motor neurones run in the corticospinal tract which crosses at the level of the pyramids and then runs caudally in the lateral white matter of the cord. The uncrossed sensory fibres in the posterior columns of the cord convey the sense of joint position and two-point discrimination. Fibres transmitting pain and temperature sensation enter the cord in the posterior spinal roots and ascend three or four segments in the dorsolateral funiculus before decussating through the central grey matter to the contralateral side, where they ascend in the spinothalamic tracts of the anterior and lateral columns. Ascending and descending autonomic fibres involved in sphincter control are in close proximity to the spinothalamic pathways.

The blood supply of the spinal cord is made up of an arterial plexus that is supplied mainly from the anterior spinal artery in the anterior fissure and the two posterior spinal arteries in close proximity to the posterior columns. The anterior plexus is the most extensive and supplies the majority of the cord including the anterior and lateral columns, the corticospinal and spinothalamic tracts, and the anterior grey matter. The posterior system supplies the posterior columns and grey matter. The plexus receives variable supplies from the vertebral arteries, thyrocervical trunk, and multiple spinal medullary arteries arising from the intercostal arteries. The most constant and important contribution to the anterior spinal artery arises from the tenth left intercostal artery ('artery of Adamkiewicz').

Anatomical localization

The sensory and motor pathways of the cord can be damaged by disease anywhere in their long spinal course. Clues to the segmental level of a lesion may be provided by sensory or motor levels, or by involvement of the spinal and superficial cutaneous reflexes. Spastic upper motor neurone weakness in all four limbs arises from involvement of the motor pathways at the cervical level and of the lower limbs at the thoracic level. Loss or reduction of a deep tendon reflex may indicate damage to a particular arc within a segment of the cord, or the appropriate spinal root. By convention, the biceps and supinator jerks are considered C5–C6, the triceps jerk C7, the knee jerk L(3)4, and the ankle jerk S1. Sensory loss, muscle wasting and weakness, or pain within a spinal segment, may also have localizing value. In addition, the loss of superficial reflexes (abdominal D7 to D12, cremasteric L2, plantar S1) has potential localizing value: thus the superficial abdominal reflexes will be abolished by lesions at D6 or above, whereas the upper abdominal reflexes should be retained when the lesion is at D10 or below.

If there is complete transection of the cord, motor power and all sensation is lost below the level of the segment involved. In addition, there will be retention of urine with overflow incontinence. If the condition develops suddenly a state of spinal shock occurs in which there is flaccid paralysis of both skeletal and smooth muscle with loss of sensation and reflex activity below the level of the lesion. Partial lesions result in a variable syndrome of motor and sensory signs. There is often loss of coordination of bladder contraction and sphincter relaxation with consequent urgency and incontinence. If the cord damage is unilateral, the Brown–Séquard syndrome will result in ipsilateral loss of posterior column function combined with contralateral upper motor neurone signs and symptoms and spinothalamic irritation, or impairment. There is a level on the trunk usually several segments below the lesion. Light touch sensation is generally relatively preserved. Superficial abdominal reflexes are generally lost below the level of the lesion. The syndrome is often partial or incomplete.

A spastic paraparesis (upper motor neurone weakness and spasticity in the lower limbs) may be associated with loss of reflexes in the arms, typically asymmetric C5–C6 loss or reduction in cervical spondylotic myelopathy, Damage to the C5–C6 reflex arc may be associated with weakness of shoulder abduction and elbow flexion, reduced biceps and supinator jerks, and enhanced triceps jerks, with spastic weakness below this level. Syringomyelia is usually associated with general upper limb areflexia with a spastic paraparesis and dissociated sensory loss (see below). Lesions at the level of the foramen magnum (meningioma or developmental abnormalities) that involve the cervical enlargement may be confusingly associated with wasting of the small muscles of the hands. Respiratory involvement may complicate high cervical lesions through paralysis of the muscles of the thoracic wall or diaphragm.

Symptoms of spinal cord disease

Lesions of the upper and lower motor neurones cause characteristic patterns of symptoms. Lower motor neurone weakness and wasting often goes unnoticed by patients in the early stages when it will already be obvious to an examiner. By contrast, in the earliest stages of upper motor neurone involvement, symptoms may be present in the absence of signs. Upper motor neurone weakness, which is usually responsible for the first symptoms of a myelopathy, may be described as involving sensations of heaviness, dragging, 'numbness', stiffness, tripping, scuffing, lack of control, clumsiness, or loss of dexterity. Rapid repetitive movements are particularly impaired. Associated spasticity may cause extensor spasms and clonus, which may be described as a vibration of the foot usually noticed when negotiating stairs or kerbs. Lesions of the spinothalamic tracts result in a sensory level on the trunk with loss or reduction of pain and temperature sensation on the opposite side below the lesion (usually two or three segments below, because of the ascending course of the fibres prior to sensory decussation). Partial or irritative spinothalamic lesions cause a variety of unpleasant sensory symptoms, including burning pains, increased sensitivity to touch, feelings of wetness, or the sensation of movements under the skin (formication). Posterior column involvement can lead to tingling paraesthesiae and tight constricting feelings around joints, as well as sensory ataxia. Stretching or movement of the cervical cord on neck flexion may cause shooting paraesthesiae ('electric shocks') down the back into the lower limbs ('Lhermitte's symptom'). This can be associated with any pathology in the cervical canal but is most often seen with multiple sclerosis. Autonomic involvement may cause hesitancy, urgency, and urge incontinence of bladder and bowel.

Acute and subacute myelopathy

Rapidly developing weakness in the lower limbs (over minutes, days, or weeks) requires immediate referral to a neurological unit for diagnosis and management. The urgent problem is to establish the site of the weakness (spinal cord or peripheral nerve) and the cause (intrinsic or extrinsic spinal cord disease or acute polyneuritis). It is essential to exclude a compressive cause requiring emergency decompression. An acute transverse myelopathy, with absent deep tendon reflexes, non-elicitable plantar responses, and paralysed, flaccid limbs (so-called 'spinal shock'), may superficially mimic acute Guillain–Barré syndrome, but retention of urine and a sensory level on the trunk will indicate the correct pathological localization in the spinal cord.

An acute or subacute spinal cord syndrome may be due either to extrinsic cord compression (Table 1) or to intrinsic pathology. If compressive, the prognosis for recovery may depend on how rapidly the spinal cord can be decompressed. There are many intrinsic causes of an acute myelopathy, including multiple sclerosis, acute disseminated encephalomyelitis, viral myelitis, systemic lupus erythematosus, sarcoidosis, Behçet's disease, paraneoplastic syndrome, and spinal cord infarction or haemorrhage. Unless there are other clues from the history, or from general or neurological examination, it is not usually possible to make a reliable distinction between intrinsic and extrinsic causes. It is vitally important to relieve bladder retention and to search for a primary focus of infection or underlying neoplasia that may have led to metastasis. Neuroimaging of the spinal cord (preferably magnetic resonance imaging) must be carried out as an emergency procedure. Lumbar puncture should be avoided until compression has been excluded, as worsening of the myelopathy may be precipitated by reduction of cerebrospinal fluid pressure below an obstruction.

Chronic progressive myelopathy

The first symptoms of a slowly progressing spinal cord lesion, particularly a compressive lesion, are often due to the insidious development of upper motor neurone weakness. There may be a barely noticeable deterioration in ambulation with the onset of subtle difficulties (heavy limbs, dragging foot or leg), at first only apparent when running or during long walks. At first there may be little in the way of objective signs, and symptoms may progress very slowly over months or years A careful history and examination in anyone who complains of walking difficulties is mandatory. Upper motor neurone weakness is frequently missed by incomplete examination as it primarily involves flexor movements in the legs and extensors in the arms. As for acute myelopathy, the cause may be intrinsic or extrinsic, and neuroimaging is indicated without delay. Common compressive causes are cervical spondylotic myelopathy, prolapsed intervertebral dorsal disc, neurofibroma, meningioma, and ependymoma. Multiple sclerosis is the most common intrinsic cause in the United Kingdom, but motor neurone disease, hereditary spastic paraplegia, HTLV-I myelopathy, vitamin B_{12} or folate deficiency, and, rarely, thyroid disease may present in this way and require exclusion.

Cervical spondylotic myelopathy

This is a spinal cord compression syndrome that typically occurs in the sixth decade or later. It usually presents as a chronic progressive spastic paraparesis, but an acute or subacute ascending myelopathy can also occur. Radicular symptoms (pain and sensory impairment or paraesthesiae) may or may not be present, but typically, there is coexisting radiculopathy and the C5–C6 reflexes are found to be depressed or absent and the C7 reflexes brisk ('inverted supinator jerk'). Magnetic resonance imaging of the cervical spine is the investigation of choice. Those affected have constitutionally narrower cervical canals. Coexisting ischaemic demyelination due to compression is often present in the centre of the cord, but a statistical association with multiple sclerosis has also been described.

Spinal epidural abscess

Pain with signs of spinal cord compression may occur acutely with a spinal epidural abscess, and often with little in the way of systemic disturbance. Staphylococcal and streptococcal organisms are frequently responsible and septicaemia may be present. Treatment is with appropriate antibiotics and surgical drainage procedures.

Tuberculosis

Tuberculosis is primarily an infection of the spinal vertebral bodies and intervertebral discs. Compression of the cord often results from vertebral collapse. Infection may spread through the meninges to involve the spinal cord directly, or there may be associated arterial occlusions. Management is by antituberculous drugs and, where appropriate, surgery for decompression or spinal stabilization.

Syringomyelia

A rare condition (prevalence approximately 7 per 100 000) in which an irregular fluid-filled cavity (syrinx) causes a central cord syndrome. The cavity usually begins in the cervical area, initially localized to a segment or two, but may extend the whole length of the cord. Adjacent structures including the decussating fibres destined for the spinothalamic tracts, the anterior horn cells, and the pyramidal tracts may become involved, although the posterior columns are characteristically spared.

Typically in early adult life the patient notices weakness and wasting of an upper limb and/or loss of the sensation of pain. Painless injuries often occur and may lead to dramatic symptoms (one of the author's patients was a butcher who lost the ends of his fingers in a mincer before noticing). There is usually areflexia in the arms, a spastic paraparesis, and a 'dissociated' sensory loss (retention of common touch and proprioception sense with loss of pain and temperature sensation) in the upper limbs with extension on the trunk in the forequarter ('cape') area. Associated features may include Horner's syndrome, upper limb pain, and a mild dorsal scoliosis. The syrinx and the presence of any associated abnormality at the foramen magnum are now easily established by magnetic resonance imaging, sometimes before a typical clinical syndrome develops. Tumours and Tangier's disease can also result in a central cord syndrome. The condition can be static for years, but often progresses irregularly. Rostral extension into the brainstem (syringobulbia) may cause dysarthria, dysphagia, wasting of the tongue, and sensory loss in the face (sparing the central areas such as the mouth and nose until last).

A syrinx is often associated with an Arnold–Chiari malformation, but can be secondary to an intrinsic spinal cord tumour or spinal cord injury. Treatment by surgery is controversial and outcomes are complicated by the variable natural history. If there is an associated cerebellar ectopia and hypodevelopment of the posterior fossa, decompression of the foramen magnum may successfully relieve pain and halt progression. Drainage of the syrinx by various shunt procedures may also be helpful if it is carried out before moderate or severe disability has resulted.

Spinal arachnoiditis

Any inflammatory process can result in a progressive fibrosis of the subarachnoid space. The most common causes include myelographic contrast media, subarachnoid haemorrhage, surgery, trauma, and infection. Complications include cystic compression and ischaemic damage to the spinal cord and/or spinal nerve roots, often with intractable pain and blockage of cerebrospinal fluid pathways. Once initiated, arachnoiditis can be progressive and there is no effective treatment. Attempts at surgical correction may cause further fibrosis and deterioration.

Schistosomiasis (bilharziasis)

A chronic infection with a trematode worm (in South America, Asia, and Africa) occasionally causes spinal cord or root compression or a transverse myelitis due to a granulomatous inflammatory reaction to the parasite's eggs. Granulomas may be intrinsic or extrinsic and there may be associated meningoencephalitis and intracranial granulomas. Treatment is with praziquantel. Other worms including cysticercosis and echinococcus may also (rarely) cause spinal cord compression.

Demyelinating diseases

Involvement of the spinal cord is almost invariable in multiple sclerosis. In the early stages of the disease, acute or subacute episodes of partial myelopathy often occur with partial or complete recovery (relapsing–remitting disease). Lhermitte's symptom is common, but non-specific for demyelination. In the later stages (secondary progressive multiple sclerosis) a chronic progressive myelopathy associated with spasticity, sensory loss, and ataxia is characteristic. Eighty five per cent of patients with primary progressive multiple sclerosis present as an insidious progressive myelopathy, mostly in middle age. Diagnosis is established by clinical history and examination, magnetic resonance imaging of the spinal cord and brain, evoked potentials, examination of the cerebrospinal fluid (intrathecal oligoclonal bands), and blood tests to exclude other causes of myelopathy.

Perivenous inflammation and demyelination also occur in the white matter of the brain and spinal cord following vaccination or an acute childhood viral infection such as measles, mumps, rubella, or chicken pox (acute disseminated encephalomyelitis), but the triggering infection is not always identifiable. The illness is usually monophasic, but recurrent symptoms indicate that the initial bout was the onset of multiple sclerosis.

Acute/subacute transverse myelitis

An acute or subacute spinal cord syndrome may occur as a monophasic, spontaneous illness with no obvious cause, or may follow a viral infection or vaccination. It is characterized by a sensory level on the trunk (usually thoracic) to all modalities with retention of urine and faeces and severe symmetrical paraplegia. The myelogram

may be normal or show a swollen cord. The spinal fluid shows an inflammatory reaction with an excess of white cells and raised protein. High-dose intravenous steroids are usually administered. There may be a full or partial recovery, or permanent paraplegia may result.

Many conditions can give rise to a similar clinical picture, including infections (sarcoidosis, syphilis, Lyme disease, spinal tuberculosis, brucellosis), collagen vascular diseases, viruses (Epstein–Barr, herpes zoster, herpes simplex, rubella), and multiple sclerosis. However, unlike the acute or subacute partial spinal cord syndromes, multiple sclerosis develops in only a small proportion and the cause most often remains obscure, even after many years of follow-up.

Paralytic poliomyelitis

After an incubation period of 1 to 2 weeks, a viraemia is associated with fever, vomiting, and headache. Replication of the virus in the anterior horn cells of the spinal cord and the motor nuclei of the brainstem is usually associated with signs of meningitis and pains in the spine and limbs ('preparalytic phase'). Recovery may then occur, but some patients may go on to develop a highly variable, asymmetric, patchy muscle weakness. Reflex loss, fasciculation, and muscle wasting are early features, but sensation remains normal. A minority of patients develop bulbar complications including respiratory failure. A variable degree of recovery may occur. Management is supportive with control of frequently associated infections. Widespread vaccination has virtually eliminated this condition.

Human immunodeficiency syndrome (AIDS) myelopathy

A subacute to chronic progressive myelopathy characterized by vacuolar changes in myelin sheaths with relative axonal preservation and an emphasis on the dorsolateral thoracic spinal cord is the most common form of myelopathy in AIDS. Spasticity, weakness, loss of the sense of joint position, and sphincter dysfunction develop over weeks or months. Magnetic resonance imaging usually shows the spinal cord to be normal or non-specifically atrophic. There may be coexisting dementia or neuropathy. Treatment is limited to management of symptoms.

Myelitis in AIDS may result from a variety of causes including infection with herpes simplex, cytomegalovirus, varicella zoster, HTLV-I and -II, syphilis, or tuberculosis. Vitamin B_{12} deficiency, lymphoma, and spinal epidural abscess may also cause an acute or subacute myelopathy in this situation.

HTLV-I associated myelopathy ('tropical spastic paraparesis')

Retroviral infection results in a chronic slowly progressive myelopathy characterized by paraesthesiae (often painful) in the lower limbs, sphincter dysfunction, and spastic paraparesis. Some cases may also have cerebellar ataxia, optic neuritis, and signs of a peripheral neuropathy. There is positive HTLV-I serology in the blood and cerebrospinal fluid.

Nutritional deficiencies

Subacute combined degeneration of the spinal cord due to vitamin B_{12} deficiency has become rare with the early diagnosis and treatment of pernicious anaemia. Presenting complaints are persistent paraesthesiae in the feet and later in the hands with unsteadiness of gait. There may be signs of peripheral nerve damage (distal sensory loss and loss of ankle jerks). Unless treatment is initiated early, weakness in the lower limbs becomes more marked with extensor plantar responses and ataxia indicating largely irreversible damage to the pyramidal tracts and posterior columns. There may be additional loss of memory and cognition, reduced vision with central scotomas, and sphincter disturbance. The patients are usually middle aged and there may be no evidence of anaemia or changes in the blood film. The serum level of vitamin B_{12} is almost invariably markedly reduced. Treatment with hydroxycobalamin should be started immediately to prevent irreversible damage. Motor symptoms usually respond better than sensory symptoms, and paraesthesiae may persist indefinitely. Rarely, a similar syndrome may be associated with folate deficiency.

Low levels of vitamin E may cause a spinocerebellar syndrome with pyramidal signs, with or without peripheral nerve involvement and ophthalmoplegia. Patients present with an unsteady gait and weakness with limb ataxia, and loss of reflexes, proprioception, and vibration sense. The cause is often malabsorption due to gastrointestinal disease (see also Section 14).

Vascular disease

Haemorrhage into the parenchyma of the spinal cord is rare and may be spontaneous, or a complication of arteriovenous malformations, trauma, and clotting abnormalities, including anticoagulant therapy . Infarction of the spinal cord may result from aortic disease (atherosclerosis, dissecting aneurysm, surgery), thoracic or cardiac surgery, or cardiac arrest (hypotension). The resulting paraplegia is often ushered in by acute pain at the level of the infarction. As the anterior spinal artery is most often involved, loss of pain and temperature sensation occurs below the level of the infarction with preservation of common sensation and proprioception. Infarction of one-half of the cord results in the Brown–Séquard syndrome. Rarely, the whole cord can be infarcted below the occlusion. Recovery from infarction is variable and unpredictable. Embolism may occur in decompression sickness or bacterial endocarditis and ischaemic damage in the context of autoimmune vasculitic diseases such as systemic lupus erythematosus and Sjögrens disease. Spinal arteries may be secondarily involved during bacterial meningitis or syphilitic leptomeningitis, or by neoplasia.

Drug abuse, particularly of heroin or cocaine, may cause an acute myelopathy. The clinical picture resembles an anterior spinal artery occlusion with paraplegia, sensory level and bladder dysfunction, and sparing of posterior column function. The causes include particulate emboli, vasculitis, and watershed infarction from hypotension.

Decompression sickness arising from bubbles of gas in the bloodstream caused by too rapid decompression following exposure to high atmospheric pressures (usually due to diving) may cause ischaemic damage to the spinal cord. Generally within minutes of a return to normal atmospheric pressure a widely variable syndrome of paraesthesiae, sensory loss, pain, and weakness in the limbs develops, that either recovers on rapid recompression, or progresses to a permanent spastic paraparesis.

Venous thrombophlebitis may cause a patchy, asymmetric, and rapidly ascending subacute necrotic myelitis. This may occur as a result of intra-abdominal or pelvic sepsis, but often no cause can be found. The prognosis is poor.

Spinal arteriovenous malformations are congenital abnormalities of blood vessels supplying the spinal cord and may cause either an acute or chronic progressive spinal cord syndrome. There may be various combinations of spinal cord compression, venous infarction, vascular 'steal' due to shunting, haemorrhage, or progressive fibrosis. Pain may worsen with exercise. Haemorrhage into the cerebrospinal fluid can cause sudden confusion, headaches, and neck stiffness. Cord compression may result from a secondary haematoma. Auscultation over the spine should be performed in all patients with undiagnosed myelopathy, although bruits are only present in a minority. The arteriovenous malformation may be demonstrated by magnetic resonance imaging or myelography and its vascular supply established by spinal angiography, which is not without risk. They may be inoperable, or amenable to embolization or surgical removal in expert hands.

Subacute necrotizing myelitis is a rare condition in which a flaccid paraplegia results from extensive cord involvement below the highest segment. There may be a stepwise development with ascending levels. The lesion can be associated with vascular abnormalities, but no cause can usually be identified, treatment is not effective, and the prognosis is poor.

Spirochaetal infections

Acute vascular cord lesions including an anterior spinal artery occlusion may be the presentation of meningovascular syphilis. Damage to the spinal cord can also arise from chronic inflammatory changes in the cervical meninges (leptomeningitis) involving spinal nerve roots and spinal cord. Symptoms and signs of wasting of the small hand muscles (C8–T1) with and without upper motor neurone signs may be present.

The diagnosis is often suspected when high cell and protein levels are found and confirmed by serology in the blood and cerebrospinal fluid.

The classical chronic progressive neurological disorder tabes dorsalis has become very rare due to improved recognition and early treatment of syphilis. Clinical features may include an ataxic steppage gait, lancinating pains in the legs, skin ulcers, hypotonicity, and painless arthritis. Damage starts in the dorsal root ganglion

cells and particularly involves the central processes extending into the posterior columns. Classic 'lightning' pains or electric shock-like sensations in the lower limbs and eventually loss of deep pain sensation usually occur. Further damage to the spinal roots leads to loss of reflexes and hypotonicity of the limbs. Hypermobility of joints with loss of pain sensation may lead to a progressive painless destruction of knee, ankle, or elbow joints ('Charcot's joints'). Damage to the pyramidal tracts eventually results in extensor plantar responses ('taboparesis'). Additional findings may include analgesic patches on the trunk and inner arms, loss of sphincter control with a dilated atonic bladder, optic atrophy, small light near-dissociated pupils (Argyll–Robertson pupils), and ptosis. Painful autonomic attacks ('crises') affecting the bladder, rectum, stomach, or larynx, may also be a feature.

Toxic damage

X-ray therapy to the thorax or neck, particularly directed at the bronchi or oesophagus, may occasionally result in damage to the spinal cord (radiation myelopathy). The risk is dose related. An acute transient form of myelopathy characterized by paraesthesiae and Lhermitte's symptom comes on soon after exposure and usually remits. The mechanism is probably demyelination of the posterior columns. The delayed myelopathy that comes on 6 months to several years after treatment is due to a vasculopathy with cord necrosis and atrophy leading to a progressive spinothalamic sensory loss and disabling paraplegia. Magnetic resonance imaging excludes other possibilities, including compression from metastases and paraneoplastic subacute necrotizing myelitis.

The neurotoxin b-*N*-oxalylamino-L-alanine, a glutamine receptor agonist, contained in the pulse *Lathyrus sativus* (chickling pea) may cause an acute or chronic paraparesis, often with prominent muscle spasms, which usually occurring in outbreaks during periods of famine (lathyrism). Chronic cyanide poisoning from ingesting the roots of the cassava plant may result in pyramidal signs, usually combined with a painful peripheral neuropathy.

Neuronal degenerations

Hereditary spastic paraplegia

This is a relatively rare condition, in which degeneration of the pyramidal tracts and posterior columns causes a slowly progressive spastic paraparesis of varying severity. It is essential to take a family history and examine relatives carefully, as mild cases may be asymptomatic, causing misdiagnoses and an underestimate of the true prevalence. There are dominant (70 to 80 per cent of cases) and recessive forms. Genetic studies of the autosomal dominant variant have identified loci on at least three chromosomes that account for about half the cases. Type I hereditary spastic paraplegia comes on in childhood or adolescence with clumsiness and poor athletic performance caused by spasticity. Weakness is usually slight or absent. Sensory loss tends to be mild and late and usually involves proprioception. Abdominal reflexes are often retained and significant bladder involvement is relatively uncommon until the later stages. Pes cavus is often present. Type II hereditary spastic paraplegia has similar clinical features, but an onset after the age of 35 years. Recessive forms tend to be more rapidly progressive and are often misdiagnosed. Other causes of spastic paraparesis must be excluded.

Motor neurone disease

The full-blown picture of amyotrophic lateral sclerosis with mixed lower and upper motor neurone features is unmistakeable, but individual cases can sometimes resemble other diseases, particularly cervical spondylotic myelopathy and primary progressive multiple sclerosis. A minority of cases present with a pure upper motor neurone spinal cord syndrome with a spastic paraparesis ('primary lateral sclerosis') and no evidence of lower motor neurone wasting or weakness. The clinical picture is of a slowly progressing spastic paraparesis or quadraparesis. The differential diagnosis is extensive and many of the conditions listed in Table 2 need to be considered and excluded. Investigations may include magnetic resonance imaging, electromyography, muscle biochemistry, evoked potentials, and examination of the cerebrospinal fluid. Prolonged clinical follow-up may be required to clarify the diagnosis.

Friedrich's ataxia

This is a rare, progressive, autosomal recessive condition that begins in childhood or adolescence and leads, usually by the third decade, to limited mobility and death a few years later. Presentation is usually with unsteadiness and clumsiness. Features include dysarthria, inco-ordination of the limbs, gait ataxia, impaired proprioception, and areflexia.

Adrenomyeloleucodystrophy

This is an X-linked recessive disorder in which demyelination in the brain and spinal cord occurs as a result of the accumulation of very long chain fatty acids. Adult males develop a spastic paraparesis with or without mild sphincter involvement and sensory loss. A very slowly progressive mild spastic paraparesis with sphincter and sensory loss may also be found in heterozygote females. Associated adrenal insufficiency may be very mild. The condition may be mistaken for multiple sclerosis, although the magnetic resonance abnormality, when present, usually shows widespread symmetrically distributed lesions often in the posterior white matter more appropriate to a leucodystrophy. A locus has been demonstrated at chromosome Xq28. There are increased levels of very long chain fatty acids in the serum.

24.13.17 Spinal cord injury and its management

M. P. Barnes

Introduction

Spinal cord injury is a prime example of the improvement in survival and quality of life that can follow from the application of modern rehabilitation techniques. In the early part of the last century around 9 out of 10 people with a spinal cord injury died within 1 year and only 1 per cent survived in the long term. The situation greatly improved with the advent of spinal cord injury centres, particularly pioneered in the United Kingdom by Sir Ludwig Guttmann at Stoke Mandeville. The co-ordinated, multidisciplinary care provided at these centres significantly reduced mortality and improved quality of life. However, even in the 1960s there was still a 35 per cent mortality associated with tetraplegia, and it has only been in the last decade or so that modern rehabilitation techniques have reduced mortality to less than 5 per cent. Life expectancy has improved such that the major causes of late death in spinal injury are now those experienced by the general population, such as cancer and myocardial infarction. However, there is no room for complacency. Deaths from renal failure or respiratory infection in those with tetraplegia are still too common. Although life expectancy in those with paraplegia is only modestly reduced, people with tetraplegia still have a significantly reduced survival rate. A 20-year-old male would normally be expected to have a further 56 years' life expectancy, but this is reduced to about 45 years in those with paraplegia, and those with tetraplegia only have an expected survival of a further 33 years.

Although this chapter will concentrate on the medical management of spinal cord injury and its complications, it would be incomplete without a mention of the acute and emergency management.

Epidemiology

The annual incidence of spinal cord injury, at least in Western Europe, is around 10 to 15 cases per million of the population per annum. The mean age of injury is about 33 years, although the mode is 19 years. Most injuries occur in males (around 82 per cent). The commonest cause is road traffic accidents (about 40 per cent). Regrettably, spinal cord injury from violence (either self-harm or criminal assault) is increasing, particularly in the United States. In the older age group, falls become a more common cause. Table 1 summarizes the leading causes in the United Kingdom and United States.

The proportion of injuries from road traffic accidents has seen a modest reduction in recent years, probably due to the introduction of seat-belt legislation and improved safety features on cars. Hopefully, the improved safety of vehicles and improved traffic regulation, particularly speed control in urban areas, will further reduce the incidence in coming years. There is some evidence in the last decade that the incidence of spinal injury has plateaued, having been increasing in previous decades. Regrettably, the commonest result of injury is tetraplegia (around 60 per cent), which, compared to paraplegia, is still increasing.

Early acute management

The appropriate management of the individual at the scene of an accident is vital to avoid unnecessary worsening of a spinal cord injury. If the individual is unconscious then it should be assumed there is an injury to the cervical spine until proven otherwise. Until this diagnosis can be ruled out the head and neck should, as far as possible, be held firmly in a neutral position. This is normally achieved at the scene of an accident by immobilization in a semi-rigid collar, but if this is not available alternative improvised methods of stabilizing the head and neck should be initiated. The individual should not be placed in the coma position as this will rotate the cervical spine, but is best placed, if other injuries allow, in a lateral position with the head kept in line with the spine by the underlying arm. If any movement is necessary the person should be 'log rolled' to ensure their spine is kept in a straight and neutral position at all times. Usually, transportation is on a spinal board with a head immobilizer. Speed of evacuation is important, particularly if there are other life-threatening injuries. Preferably, the individual should be transferred to the Regional Spinal Injuries Unit; but obviously the individual may need to be resuscitated, and other life-threatening injuries may need treatment at the nearest casualty department. It is worth recalling that the diagnosis of intra-abdominal injury can be very difficult in people with spinal cord injuries. The initial phase of spinal shock will tend to give rise to paralytic ileus and abdominal distension, which can further confuse the situation if an abdominal injury is suspected.

Obviously, a general and neurological examination is vital—particularly to determine the neurological level of the lesion. Figure 1 illustrates the myotomes, dermatomes, and reflexes as an *aide mémoire*. Table 2 summarizes the likely functional outcome according to lesion level.

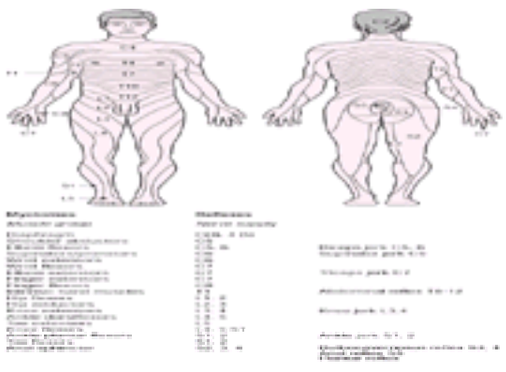

Fig. 1 An *aide mémoire* to examination—summary of the dermatomes, myotomes, and associated reflexes.

Spinal injury, however, can not be determined solely by examination and often there are very few local signs. There may be some bruising, tenderness, or deformity, but equally there may be no clue on examination as to the actual nature and extent of the underlying bone injury. Thus, although radiological investigation is essential, it should preferably only be undertaken in a unit familiar with the management of those with spinal injury. In a radiology department it is still important to remember that spinal movement must be minimal. Usually, radiography will clearly reveal the fracture or dislocation, although bony abnormalities are occasionally minimal or absent. This is particularly true in older people with underlying cervical spondylosis when tetraplegia can result from a hyperextension injury without fracture or dislocation. Radiological examination can also be normal in children when a spinal traction injury can occur without evidence of bony damage.

Initial management of people with injuries to the cervical spine usually consists of skeletal traction applied through skull callipers. Traction will help to stabilize and splint the spine and can also reduce fractures and dislocations. A number of different callipers are available, of which the Gardner–Wells calliper is but one type (Fig. 2).

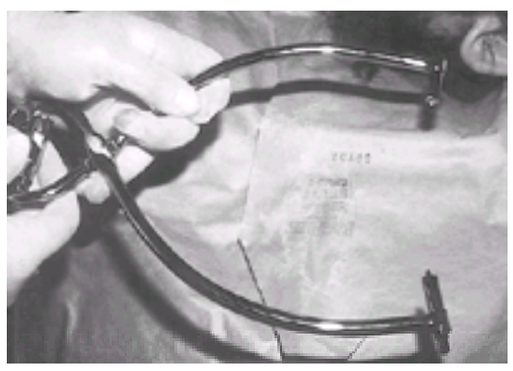

Fig. 2 Skull traction using Gardner–Wells calliper.

The amount of traction applied will vary according to the type and extent of injury, but it will be in the order of 2 kg for upper cervical injuries and somewhat more, around 4 kg, for lower cervical spinal injuries. Sometimes, if the spine is dislocated, reduction is achieved by incrementally increasing the weight of traction every few hours. Once the neck has reduced, a halo brace is a useful alternative to skull traction in many people and will allow early mobilization.

The standard treatment for thoracic and lumbar injuries is simple support of the individual in the correct posture, usually with a pillow under the lumbar spine to maintain the normal lordosis.

Surgical versus conservative treatment

In most cases, skull traction for cervical injuries and conservative postural treatment for thoracolumbar injuries is quite sufficient and operative intervention is unnecessary. It has long been a source of controversy whether operative intervention and fusion aids neurological recovery. Practice varies from country to country and indeed from centre to centre. In a broad-based survey in the United States 60 per cent of people underwent spinal surgery. Most individuals underwent fusion and internal fixation, but increasing numbers also now undergo anterior or posterior decompression of the spinal cord with or without internal fixation and fusion. However, practice in the United States tends to be more oriented towards surgical intervention than in the United Kingdom and other parts of Western Europe. In the United Kingdom, surgical intervention will tend to be reserved for those with unstable displaced fractures, whereas conservative management would be the normal practice for stable and/or undisplaced fractures. However, if the neurological symptoms are deteriorating then many spinal centres would now recommend surgical intervention.

Use of steroids

Another treatment intervention that can be considered in the very early stages after injury is a short course of high-dose methylprednisolone. There is some evidence that such intervention, started within 8 h of injury, improves the neurological outcome. However, this is not totally accepted and such practice not uniform. The results of further trials are awaited.

Management in the spinal cord injury centre

Initial management will consist of resuscitation, treatment of associated injuries, and stabilization of the spine, either conservatively or by surgical intervention. However, the individual should be transferred to a recognized spinal injury centre as soon as possible. There is clear evidence that the outcome is maximized, both physically and psychologically, if individuals are managed in such centres as opposed to a less co-ordinated and less experienced approach in another hospital setting.

Management of the spine

As mentioned above, the injured person will either be managed conservatively or surgically. The advantage of surgery is that the individual can be mobilized more quickly. If a conservative approach is adopted, mobilization and active rehabilitation is obviously difficult in the first few weeks. Cervical spine traction is normally maintained for around 6 weeks and then monitored for signs of bony union and stability. Once the fracture site is stable the individual can be gradually sat up in bed whilst continuing with cervical support. A profiling bed, which enables a more natural seated position to be adopted, is most useful. In the early few weeks a halo brace can be used instead of skull traction. The advantage of this brace (see Fig. 3) is to allow early mobilization. The halo brace is kept on for between 10 and 12 weeks until the site is stable. In those with thoracolumbar injuries, who are usually managed conservatively, the period of bed rest will usually last from 8 to 12 weeks followed by bracing and gradual mobilization, assuming that the fracture site is stable.

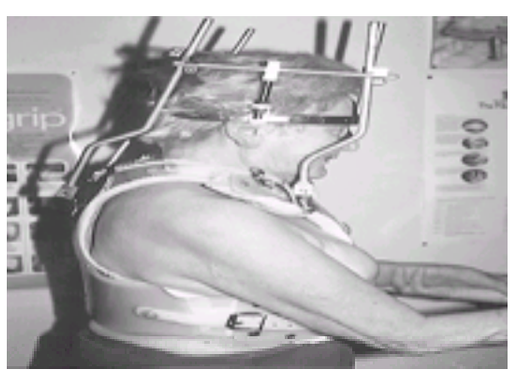

Fig. 3 Illustration of a halo brace.

A number of medical problems can occur over this initial period of immobilization.

Management of medical problems

Respiratory problems

Respiratory insufficiency can occur in people with cervical cord injuries. Intercostal muscles may be paralysed, and in high cervical lesions the diaphragm can also be paralysed. However, even in people with lower lesions, respiratory problems can still occur from associated injuries such as rib or sternal fractures. Since respiratory function can decline several hours or even days after injury, probably due to the development of spinal cord oedema, respiratory function should therefore be monitored carefully and ventilation provided if required. Regular chest physiotherapy is vital at this time. Since pulmonary embolism is also a risk, particularly in those immobilized, anticoagulation is advisable prior to mobilization.

Pressure sores

Regrettably, the development of pressure sores still occurs even with high-quality care. Sores are commonest where there are bony prominences near the skin: such as the ischial tuberosity, greater trochanter, sacrum, heel, and sometimes at the back of the head in those with skull traction. A key to prevention is awareness of the potential problem, with vigilance, regular changes of position in bed, and regular lifting in the wheelchair. A large range of commercial mattresses and wheelchair cushions are available that relieve pressure. Shear forces should be avoided as far as possible when lifting or positioning the patient; and obviously the individual should never be dragged over sheets or from the wheelchair. The skin should be kept clean, with particular care taken to avoid any urine or faecal soiling. If a sore does occur then the area must be kept clean, any dead tissue be removed, and there should be complete relief of pressure from that area until it is fully healed. Occasionally, surgery is indicated for larger or deeply infected sores that otherwise would take too long to heal. Education of the injured person and their family is essential. Despite awareness of the problem around 25 per cent of people still develop a pressure sore during the rehabilitation phase. About 15 per cent of people will develop a pressure sore in the first year following discharge—a figure that increases still further with time, such that by year 10 about 15 per cent of those with incomplete lesions and 28 per cent of those with complete lesions will have developed at least one pressure sore. Septicaemia from pressure sores is still responsible for around 10 per cent of deaths in people with spinal injury.

Bladder problems

In the early part of this century, problems, usually infection, of the urinary system were responsible for at least half the deaths of those with spinal injury. Although very significant progress has been made in the management of bladder and kidney problems, nevertheless urinary tract complications are still the leading residual cause of mortality and morbidity.

During the period of spinal shock the bladder is usually non-contractile, so that catheterization may be appropriate at this time. Once spinal shock begins to wear off the commonest problem is of detrusor hyperreflexia, which usually gives rise to the frequent passage of small quantities of urine associated with urgency. However, other possibilities include detrusor sphincter dyssynergia and detrusor hyporeflexia. The latter will tend to occur when there is damage to the S2, 3, and 4 sacral nerves.

The management of urinary problems usually involves obtaining satisfactory answers to three questions:

- Is there impairment of renal function?
- Is there a failure of bladder emptying?
- Is there detrusor hyperreflexia?

Is there impairment of renal function?

Screening of the upper urinary tract is important both in the short and long term. Intravenous urography should be used in the early months after injury, but long-term follow-up can often be carried out by renal ultrasound scanning or plain abdominal radiography. Late complications are possible, such as renal calculi. Cystometrography is also vital for determining the exact nature of the underlying bladder and sphincter problems.

Is there a failure of bladder emptying?

A residual urine volume greater than 100 ml is generally accepted as the level at which intervention is necessary. Residual urine can predispose to infection and stone formation, and contributes to impairment of renal function, particularly if the failure to empty is associated with a high intravesical pressure and back-pressure up to the kidney. Occasionally, failure of emptying can be managed by artificial stimulation such as suprapubic tapping or perineal stimulation. However, in most cases failure of bladder emptying requires mechanical drainage. The most useful method is intermittent, clean self-catheterization. This is carried out by the disabled person, or sometimes by a carer, four or five times every 24 h such that volumes in the bladder are kept to less than 500 ml. Intermittent self-catheterization has revolutionized the management of bladder problems in those with spinal injury. Anticholinergic drugs, such as propantheline, oxybutynin, or imipramine, may sometimes help to reduce detrusor activity. Condom drainage in the male is helpful in preventing leakage between catheterizations. A silastic indwelling catheter might need to be used if intermittent self-catheterization is impossible. However, suprapubic catheterization is far better in the long term and is associated with less problems. Regrettably, there are many problems of catheterization, including leakage, blockage, stone formation, and infection.

Is there detrusor hyperreflexia?

A small number of people can control minor problems with the detrusor hyperreflexia by rigid bladder drill, emptying the bladder at frequent and regular intervals. However, most people need some form of oral medication and, as above, anticholinergics are the most effective, and oxybutynin the most common—propantheline and imipramine are alternatives. Once again, protection against the embarrassment of leakage is often necessary and is more readily achieved in men with the use of condom drainage. A variety of absorbent pads can be worn by women. Advice from a specially trained nurse continence advisor can be invaluable whatever the nature of the problem.

A whole variety of surgical techniques may be applicable in particular circumstances. An endoscopic distal sphincterotomy can be useful for those with reflex bladder emptying. The technique of bladder augmentation with an ileocystoplasty can also be helpful to allow for sufficient capacity for intermittent, clean self-catheterization. Fortunately, urinary diversion techniques are now needed less frequently. Recent advances include artificial urinary sphincters for treating neuropathic incontinence. Some centres also now employ sacral anterior nerve root stimulators that can be used in some people with suprasacral cord lesions. For instance, the bladder can be emptied by activating a radio-linked implant to stimulate the S2, S3, and S4 anterior nerve roots. Occasionally, a similar implant can also be used to assist in defecation and in obtaining a penile erection.

Incontinence can be a major disability and handicap, and, indeed if not treated properly, the complications can be life-threatening. Long-term follow-up is essential, and proper management can make significant reductions in long-term risks and produce major improvements in the quality of life.

Bowel care

During the initial period of spinal shock the bowel remains flaccid and should not be allowed to overdistend, with the attendant risk of constipation and overflow incontinence. Manual evacuation is usually carried out until bowel activity returns. Eventually, reflex emptying can occur in those with predominant upper motor neurone lesions, but the bowel can remain flaccid in those with lower motor neurone involvement. In the former, bowel evacuation can usually be triggered by glycerin suppository or by anal digital stimulation. In those with flaccid bowel there is a continuing need to evacuate manually or by straining using abdominal muscles. Advice on proper diet is also required, with a good-quality, high-fibre diet being the most helpful.

Autonomic dysreflexia

This is a potentially fatal problem most commonly seen in those with cervical cord injuries above the sympathetic outflow, but it can occur in those with high thoracic lesions above T6. Autonomic dysreflexia is characterized by an exaggerated autonomic response to a stimulus below the level of the lesion. Stimuli can include

distension of the pelvic organs such as the bladder, colon, and rectum: such distension induces sympathetic activity resulting in vasoconstriction and hypertension. Other stimuli include catheterization, urinary infections, sexual intercourse, pressure sores, and even tight clothing; surgical procedures can also induce the reflex. Symptoms include headaches, sweating, vasodilatation, nasal obstruction, paraesthesia, and anxiety. Significant hypertension also occurs. The problem occurs in around 50 to 80 per cent of those at risk, with most cases occurring between 2 and 12 months' postinjury. Other than awareness of the problem and avoidance of the necessary stimuli, attention is directed to reducing blood pressure. Sublingual nifedipine can be used, or intravenous hydralazine in more severe cases. Chlorpromazine, nitroprusside, and diazoxide are also possibilities. Occasionally, the sympathetic reflex activity may have to be blocked by spinal epidural anaesthetic.

Spasticity and contractures

Spasticity occurs in an upper motor lesion with intact spinal reflex arcs below the level of the lesion. It is usually worse in those with incomplete lesions. Spasticity can be functionally useful and the individual can sometimes use flexor or extension spasms as an aid to dressing. However, spasticity usually produces functional problems as well as causing pain. In the long term there is a significant risk of muscle contractures. Initial management focuses on removing any unnecessary exacerbating factors such as pressure sores, tight catheter leg bags, or even urinary infections and constipation. Treatment should always involve an expert neurological physiotherapist who will advise on appropriate positioning and seating. In the early stages, passive stretching of the spastic muscles and regular standing regimes can be helpful; in the longer term, such regimes can often be taken on by the disabled person and their carers. Although antispastic drugs should always be used with care as they induce significant tiredness and weakness, they can provide some useful background antispastic effect. Baclofen, dantrolene, and tizanidine are the commonest prescribed. The latter is a more recently introduced drug, at least in the United Kingdom, and is an effective antispastic agent that appears to produce less weakness than the other available drugs. However, spasticity is often localized and focal treatment is more appropriate. Nerve blocks with phenol and alcohol can be used, but intramuscular botulinum toxin has recently proved very useful in the management of spasticity. The toxin is injected directly into the muscle and blocks the release of acetylcholine from nerve endings, which, over 2 or 3 days, produces a muscle relaxation that lasts for 2 to 3 months. Occasionally, more severe spasticity will need other treatment measures, such as the use of intrathecal baclofen. If contractures have resulted, surgical correction by tenotomy, tendon lengthening, or muscle division is often the only way to get the limb back into a functionally useful position. Aggressive early management of spasticity is important in order to maximize any neurological recovery and prevent unnecessary complications.

Heterotopic ossification

This term is used when bone develops in an abnormal anatomical position in soft tissues. The prevalence in spinal cord injury is reported to vary between 5 and 50 per cent. Heterotopic ossification commonly occurs around the hips and knees, causing a decrease in the range of movement as well as localized swelling and joint effusion. It normally occurs during the first few months after the injury and will only rarely begin later than 1-year postinjury. Unfortunately treatment is difficult. Etidronate disodium (Didronel) is probably the most useful treatment. Surgical intervention can be required in severe cases, but is usually unsatisfactory. Some centres now use prophylactic etidronate disodium for about a year.

Deep venous thrombosis

Deep venous thrombosis still remains a significant complication after spinal injury, with a small risk of death from pulmonary embolism. Heparin is generally used as a prophylactic but some centres now use external pneumatic calf compression.

Pain and dysaesthesia

Peripheral pain is quite common in the early weeks after injury. Although, burning pain can, unfortunately, also continue for some months, it usually responds reasonably well to the use of carbamazepine, tricyclic antidepressants, or gabapentin. Pain from other sources such as osteoarthritis can also occur. It should be remembered that people with spinal cord injury do not always appreciate pain or that it is manifested in different ways, such as autonomic dysreflexia or worsening of spasticity. Treatment modalities—for example, transcutaneous nerve stimulation, acupuncture, and psychological techniques, such as relaxation and hypnotherapy or alleviation of depressive illness—can all help. Spinal cord stimulation is occasionally used, as are surgical techniques, such as dorsal-root, entry-zone radiofrequency coagulation. Other causes of pain such as nerve root compression should also be borne in mind.

Rehabilitation

There is no evidence that rehabilitation can promote natural recovery, but there is ample evidence that a co-ordinated multidisciplinary team can improve functional outcome for the person with a spinal cord injury. The team can ensure that functional abilities are maximized and that physical and psychological complications are kept to a minimum. The co-ordinated team input is vital during the early weeks and months after injury, but it is equally important that the team maintains contact over the period of discharge and indeed into the longer term.

Principles of rehabilitation

There is no room in this chapter to dwell on the basic principles of rehabilitation. However, it is important to state that modern rehabilitation practice is somewhat different from other medical specialties. It is based on the principles of education and is a process in which the disabled person and the family must be involved for it to have any meaning. Rehabilitation should go beyond the narrower confines of physical disease to also deal with the psychological consequences of physical disability and with the social milieu in which the disabled person has to operate.

Rehabilitation is based around the concepts of impairment, disability, and handicap as outlined by the World Health Organization in 1980. 'Impairment' is simply a term that describes a loss or abnormality of psychological, physiological, or anatomical structure or function. Rehabilitation must go beyond impairment and should place such impairment within a functional context—the 'disability'. 'Handicap' describes the social context of disability. Rehabilitation can be defined as an active and dynamic process by which a disabled person is helped to acquire knowledge and skills in order to maximize physical, psychological, and social function.

The basic nature of rehabilitation is to work with the disabled person and their family in partnership. The professional should impart accurate information and advice, give guidance on prognosis and natural history, and help the individual to establish realistic goals in an appropriate social context.

A key to successful rehabilitation is goal-setting. The first goal should be a long-distance strategic aim. In the context of spinal cord injury this could, for example, include enabling the person to return to their previous home fully competent in wheelchair use. The overall strategic goal can also have a number of long-term subgoals in different spheres of life such as employment, home, and leisure. Once the long-term goal has been determined, steps will need to be defined to achieve that goal, which in turn will involve setting a number of short- and medium-term goals. These shorter term aims should be clearly stated. A useful mnemonic is SMART: that is, the goals should be specific, measurable, achievable, relevant, and time-limited. The implication of goal-setting is that the team, and indeed the disabled person, should know when the goals have been achieved. Thus, valid and reliable outcome measures are important tools; but it is neither possible nor desirable to outline such tools. The outcome measures will depend on the goals set. However, it is often useful to employ a general disability measure such as the Functional Independence Measure or, in the short term, the more physically oriented Barthel Score. Some of the standard scales employed in the field of spinal cord injury are frankly of little value in monitoring progress. First to be developed was the Frankel Score. This has now been largely superseded, at least in the United States, by the 1992 revised American Spinal Injury Association Classification (see Table 3). Although this scale is now widely quoted in the spinal cord literature (mainly in terms for helping to determine natural history and prognosis), it is not a tool for monitoring goal attainment.

Rehabilitation team

Medical input is obviously vital to the team, particularly during the early acute stages of management. Spinal cord injury consultants are now trained rehabilitation specialists who do not necessarily have surgical qualifications. However, spinal cord injury centres will always need input from spinal surgeons, as well as assistance from urologists and a variety of other medical consultants. Because of their 24-h daily contact with the injured person, nursing staff on the ward are clearly vital team members, many of whom possess additional spinal cord injury or other specialist qualifications; for example, in giving continence advice or in the management of sexual problems.

The physiotherapist's role during the very early stages of management is to minimize chest complications, particularly in those with high cervical cord lesions. Physiotherapy advice is helpful to ensure the patient is correctly positioned in bed and to prevent the complication of spasticity. Once a patient is beginning to

mobilize the physiotherapist is the key person to advise on the choice of wheelchair and for teaching the individual to become familiar with all aspects of its control. A number of advanced wheelchair skills will eventually be learnt, such as back-wheel balancing, to allow manoeuvrability over rough ground and up kerbs, and sideways jumping for manoeuvrability in a limited space. In people with lower cord lesions the physiotherapists can be involved in providing limited gait training using callipers and crutches. Orthotic devices, such as the reciprocating-gait orthosis (**RGO**) and hip-guidance orthosis (**HGO**), may be considered in some cases. The physiotherapist can also help in the context of handicap by encouraging and assisting with the development of sporting activities. However, this assistance clearly overlaps with the role of the occupational therapist.

The occupational therapist is usually concerned with assisting people to reach their highest level of physical and psychological independence, particularly with regard to personal care and appropriate adaptation of the home, work, and leisure environments. For example, the occupational therapist will be involved in the design of appropriate splinting (for example, writing or typing splints and feeding straps) to assist those with high cord lesions. Many increasingly sophisticated assistive technology devices are now available to enable even those with profound disabilities to remain reasonably independent. For instance, environmental control equipment will enable an individual to operate a door intercom, turn lights on and off, turn the pages of a book, control the television, and use a telephone and computer, etc. Even people with high tetraplegia can control these devices using mouth sticks or breath control. The occupational therapist will often be involved in giving such advice, particularly at the time of discharge back into the home environment.

If necessary, a psychologist may be particularly useful in enabling the person to make an emotional adjustment to their new disability.

The social worker is likely to be involved with the family as a whole, and only a small part of the job is to advise on disability benefits. Most of the social worker's task is to ensure that the disabled person and family integrate and adapt to the new disability as smoothly as possible.

At some point, others, such as vocational advisors, specialist nurses, and dieticians, will all need to be part of the comprehensive spinal injury team.

Long-term issues in spinal cord injury

Discharge home

A particularly difficult time for the injured person is discharge home. Often the person will have spent several weeks or months in a spinal cord centre and returning home can be a traumatic process both for the injured person and their family. Brief, trial home visits will almost certainly have been carried out beforehand. These visits are particularly important for ensuring that the house is appropriately adapted. Obviously in some cases a new house or bungalow will need to be purchased. A number of adaptations regarding access, both internal and external, hoisting gear, adaptations to the toilet, bathroom, and kitchen may all be required before the individual can return home. Environmental control equipment may need to be prescribed and installed. Psychological support is also vital over this period not only for the injured person but for their family. Anxiety and depressive illness are both quite common and will need active intervention. The community services and the primary care team will need to be involved. Planned discharges are vital and should involve a case conference between the hospital and community staff to ensure a smooth hand-over. However, at this time many spinal cord injured people will wish to move away from the more paternalistic hospital care that was important during the first few weeks' postinjury. Most will choose to live as independently as possible, albeit with the help of their family or a personal assistant. Advice on the available financial support is important. If financial compensation from a personal injury claim is ongoing then a solicitor can be helpful at this point to arrange interim payments from the Court towards the costs of home adaptations, transport, and personal care.

Emotional problems

Obviously there are profound changes in one's life following spinal cord injury. The refocusing of life ambitions can be a frustrating, anxious, or depressing time. The attitude of family and friends will have a further bearing over the period of adjustment. Regrettably, clinical depression is common and occurs at some point in at least 50 per cent of individuals. Suicide can also occur. Whilst such problems are not always preventable, anxiety, depression, and adjustment problems can be alleviated by appropriate intervention. Although the role of medication, at least in the short term, can be helpful, probably most assistance can be provided by cognitive therapy or other forms of counselling and psychological support. Contact with others in similar circumstances can often be helpful and may be facilitated through the various peer support groups.

Sexual life

Sexual ability depends on the level and completeness of the spinal lesion. Sexual readjustment is an important part of the rehabilitation process both for the injured person and their partner, regardless of gender. Self-image and self-confidence can be severely affected. Individuals should be counselled about the totality of sexuality as there is a tendency for discussions to focus on penetrative sexual intercourse. In both sexes, absence of genital sensation can be compensated for by the use of other erogenous zones such as the breasts, neck, and mouth. Orgasm is sometimes possible even in those with complete spinal cord lesions. In women, problems can result from the lack of vaginal lubrication. In men, various techniques and devices are available to restore erectile capacity. Most people with complete upper motor neurone lesions will have reflex but not psychogenic erections; however, these are often not always sustained or strong enough for intercourse. Reflex erections are usually impossible in those with parasympathetic lesions. A satisfactory erection can often be achieved either by the use of intracavernosal drugs or mechanical means such as vacuum erection aids and compressive retainer rings. However, the recent introduction of sildenafil (Viagra) is beginning to reduce the need for mechanical or injected assistance.

Fertility

Fertility is not usually reduced in women, although some can go through a time of amenorrhoea. However, fertility is generally reduced in men who have low sperm counts with diminished motility. Sometimes if ejaculation is not possible during intercourse it can be induced by direct stimulation or by electroejaculation. Fertility can also be improved by some of the modern assistive conception techniques such as *in vitro* fertilization and intracytoplasmic sperm injection. Women with spinal cord injury who become pregnant may have some problems in labour, particularly if the lesion is complete above T10. Autonomic dysreflexia is also a risk during labour. However, spinal cord injury is not by itself an indication for caesarean section.

Later medical complications

All the complications listed above in the acute phase can, of course, occur later. This is why it is so important for the multidisciplinary team to keep an overview of the individual in the long term. However, a few other problems are more likely to occur in the long term:

- Pathological fractures—there is a higher risk of osteoporosis in paralysed limbs and thus pathological fractures may occur with minimal trauma. For example, a minor fall from a chair or even a flexor spasm secondary to spasticity can result in a fractured leg. Treatment should usually be conservative.
- Post-traumatic syringomyelia—this occurs in about 4 per cent of people and consists of an ascending myelopathy due to secondary cavitation in the central part of the spinal cord. The problem is commonly delayed several years' postinjury. It presents with pain in the arm with a characteristic disassociated sensory loss: reduced pain and temperature sensation but preservation of proprioception. Motor loss of the lower motor neurone type occurs and occasionally sensory loss can spread up to the face (syringobulbia). Surgical treatment including decompression and drainage of the cavity may be necessary.
- Respiratory management—those with high cervical cord lesions with lost diaphragmatic function obviously require long-term ventilatory support. Modern portable ventilators can be readily mounted on a wheelchair. Speech is entirely possible with an uncuffed tracheostomy tube that allows air to escape to the larynx. In some people it is possible to implant a phrenic nerve stimulator to achieve diaphragmatic ventilation. Regrettably, it is still the case that individuals with long-term, ventilator-dependent requirements have significantly more morbidity and mortality than those with lower lesions.

Leisure pursuits

A wide variety of leisure pursuits are now possible for those with spinal cord injury. Although integration to able-bodied clubs and pursuits is obviously to be encouraged, a reasonable range of sports and other clubs exists for those with spinal injuries. Wheelchair skills can be finely tuned to develop expertise in a variety of sports. Physical access to leisure and social outlets is improving, albeit very slowly. Recent legislation, such as the Disability Discrimination Act in the United Kingdom, should further improve the situation.

Driving

Access to a motor vehicle is vital in modern society. Driving should be entirely possible for people with spinal cord injury, with the probable exception of those with very high cervical cord lesions. Automatic transmission is vital and hand controls are usually essential. Hand controls enable the individual to control the accelerator and brake functions from a lever or other device near the steering wheel. A variety of infrared devices to control secondary functions such as windscreen wipers, lights, and horn are now available. Very light-powered steering makes life easier for those with weak grip. Those with higher cord lesions who can still retain some useful shoulder and upper arm function can still drive a car using a variety of commercial devices attached to the steering wheel. A number of techniques can be taught to stow wheelchairs safely for those with paraplegia, and for those with higher lesions there are a number of mechanical wheelchair stowage devices. It is also quite possible to adapt a suitable vehicle to enable people to drive from their wheelchair. Financial advice is often required, combined with advice on the range and type of possible adaptations. The United Kingdom now has a number of driving assessment centres, often attached to rehabilitation centres.

Employment

Between 25 and 35 per cent of people with spinal cord injuries return to work, either in their original occupation or, after a period of retraining, to a new job. The chances of employment are higher in the younger population and in those who already had a job at the time of injury. There is also a positive correlation with the number of years of education. Fortunately, employment should become more prevalent as the ability to work at home becomes more readily acceptable. The individual should be encouraged to contact disablement employment advisors who can provide both advice and financial help for a return to work. In other cases, careers' advice or retraining to obtain new qualifications may be more appropriate.

Information

The key to independence is access to good-quality information. In most countries there are now voluntary organizations that can provide such information and advice. These organizations can also act as pressure groups, many of which have been instrumental in promoting increased awareness and improved legislation for disabled people. The Internet now provides an excellent source of information and advice, and training in computer literacy should certainly be encouraged by the rehabilitation team.

Conclusions

The management of spinal cord injury can pose a range of challenges to the multidisciplinary rehabilitation team. Although we cannot yet promote natural recovery in spinal cord injury, such interventions may be possible in the future. However, our failure to influence the natural history of a spinal cord injury should certainly not inhibit active and dynamic rehabilitation to enable the individual to resume as normal a life as possible. The application of modern rehabilitation practice, together with greater social awareness and understanding, has led to significant improvements in the overall survival and quality of life of people with spinal cord injuries.

Useful addresses

Spinal Injuries Association, 76 St James Lane, London N10 3DF. Tel: +44 (0) 181 444 2121. This association, for spinal cord injured people and all involved in their care, produces an excellent quarterly newsletter.

24.13.18.1Intracranial tumours

Jeremy Rees

Introduction

Intracranial tumours comprise primary tumours that originate from the brain, cranial nerves, pituitary gland, or meninges and secondary tumours (metastases) that arise from organs outside the nervous system. These tumours present to many different specialists and their management is difficult because of their location and their variable clinical manifestations.

Aetiology

There are no known risk factors apart from prior irradiation to the skull and a few rare neurogenetic syndromes, such as neurofibromatosis (optic nerve glioma, meningioma, vestibular schwannoma) (Fig. 1), von Hippel–Lindau syndrome (haemangioblastoma), and Li–Fraumeni syndrome (glioma).

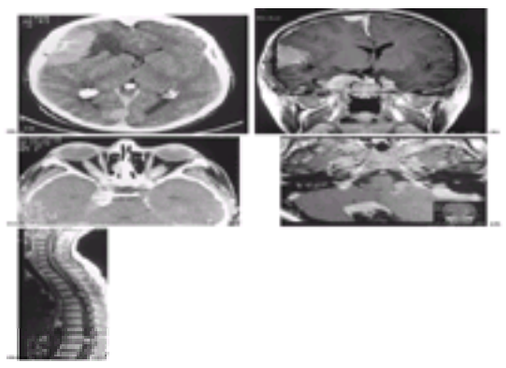

Fig. 1 Contrast-enhanced CT and MR scans of a patient with neurofibromatosis type 2 and multiple intracranial tumours. (a) CT of the brain with gadolinium enhancement showing a large right parietal convexity meningioma surrounded by vasogenic oedema exerting considerable mass effect. There is also a smaller falx meningioma in the right occipital region. (b) Coronal T_1-weighted MRI of the brain with gadolinium enhancement showing multiple meningiomas in the right temporoparietal region, right parafalcine region, and both cavernous sinuses. (c) Contrast-enhanced CT scan of the orbits showing bilateral optic nerve sheath meningiomas with intracranial extension into the right cavernous sinus causing a partial right third nerve and sixth nerve palsies. (d) Axial T_1-weighted MRI of the brain with gadolinium enhancement showing bilateral vestibular nerve schwannomas, and a large fourth ventricle tumour. (e) Sagittal T_1-weighted MRI of the spinal cord with gadolinium enhancement showing three discrete meningiomas encroaching on the spinal column at mid-cervical, mid-thoracic, and upper lumbar levels.

Epidemiology

Intracranial tumours represent the sixth most common neoplasm in adults (approximately 8 per cent of all primary neoplasms) and the second most common neoplasm in children. After stroke, intracranial tumours are the leading cause of death from neurological disease in the United Kingdom.

Based on a recent Scottish study, the crude annual incidence for primary intracranial tumours is 15.3 per 100 000 and for secondary tumours 14.3 per 100 000 population. There is evidence that the incidence is increasing, particularly in elderly patients. Different tumour types present at different ages. Supratentorial gliomas are uncommon below the age of 30 years but become increasingly prevalent thereafter. The most frequent tumours of middle life (third and fourth decades) are astrocytomas, meningiomas, pituitary adenomas, and vestibular schwannomas, while glioblastoma multiforme and metastases are more frequent in the fifth and six decades of life. In contrast, children tend to have infratentorial tumours: 70 per cent of childhood primary intracranial tumours originate below the tentorium cerebelli, whereas in adults the figure is only 25 per cent. There is a strong female preponderance of meningiomas and schwannomas, whereas slightly more men have astrocytomas.

Pathogenesis

Certain genetic lesions are associated with brain tumours. Chromosomal deletions—particularly chromosome 10, which contains multiple tumour suppressor genes—are found in astrocytic tumours, occurring in up to 70 per cent of glioblastomas. Mutations of a tumour suppressor gene *p53*, located on chromosome 17p, have also been reported in approximately 40 per cent of astrocytic tumours. In general the accumulation of predictable genetic alterations is associated with increasing malignant progression.

Clinical features

With increasing sophistication of neuroimaging, tumours are being detected at an earlier stage than before. Patients typically present with one or more of four clinical syndromes:

- progressive neurological deficit
- seizures
- raised intracranial pressure
- altered mental states.

The particular combination of clinical features varies depending on the location, histology, and rate of growth of the tumour. For instance, patients with low-grade gliomas present typically with a seizure disorder that may remain static for many years, while patients with malignant gliomas typically develop a rapidly progressive

neurological deficit and raised intracranial pressure

Progressive neurological deficit

Focal neurological symptoms due to brain tumour are typically subacute and progressive with over 50 per cent of patients having focal signs by the time of diagnosis. Cortical tumours produce contralateral weakness, sensory loss, dysphasia, dyspraxia, and visual field loss depending on their location. Posterior fossa tumours cause ataxia and cranial nerve palsies. Vestibular schwannomas cause progressive unilateral deafness followed by ipsilateral facial sensory loss. Pituitary tumours may cause a bitemporal hemianopia if there is chiasmal compression or endocrine disturbances due to either hypopituitarism or hypersecretion of specific hormones.

Seizure disorder

Brain tumours account for about 5 per cent of epilepsy cases although they are over-represented in cases of intractable epilepsy. Seizures are the presenting symptom in 25 to 30 per cent of patients with gliomas and are present at some stage of the illness in 40 to 60 per cent overall.Approximately half the patients have focal seizures and the other half have secondarily generalized seizures. Low-grade gliomas are associated with seizures in over 90 per cent of cases and these frequently remain the only complaint for many years. Conversely, malignant gliomas have a lower frequency of seizures, presumably because of their more rapid growth and destructive characteristics. In these patients, seizures are associated with a better prognosis. Seizures are also common initial manifestations of meningiomas (40 to 60 per cent) and metastases (15 to 20 per cent). Supratentorial tumours and those superficially located are particularly likely to cause seizures, particularly in the frontal and temporal lobes. A Todd's paresis, which may persist, is an uncommon but characteristic feature of tumour-associated epilepsy. About 10 per cent of patients presenting *de novo* in status epilepticus have an underlying tumour.

Raised intracranial pressure

Intracranial tumours increase intracranial pressure either by a direct mass effect, by provoking cerebral oedema, or by producing obstructive hydrocephalus. The most common symptom of raised intracranial pressure is headache, which is the presenting symptom in 25 to 35 per cent of patients; papilloedema is found in up to 50 per cent of patients with headache due to tumours. The classic picture of headache, vomiting, and visual obscurations (transient fogging of vision usually on rapid changes in posture) due to raised intracranial pressure is well known and easily recognized, but most patients present before this develops. Less than 1 per cent of patients presenting with isolated headache has a brain tumour.

Most brain tumour headaches are intermittent and non-specific and may be indistinguishable from tension headaches. Supratentorial tumours typically produce frontal headaches, while posterior fossa tumours usually result in occipital headache or neck pain. Certain features of a headache are suggestive but not pathognomic of raised intracranial pressure. These include headaches that wake the patient at night or are worse on waking and improve over the course of the day.

Mental state changes

These are an uncommon presentation of brain tumours occurring in about 20 per cent of patients at diagnosis. Personality changes may initially be quite subtle and may show themselves as an inability to cope at work. In these cases it is essential to obtain a collateral history from relatives or colleagues at work.

Pathology

Neuroepithelial tumours (predominantly gliomas) account for approximately 50 to 60 per cent of all primary brain tumours. The other common types are meningiomas (20 per cent), pituitary adenomas (15 per cent), vestibular schwannomas (5 per cent), and primary central nervous system lymphomas (5 per cent). The most common sites of origin of secondary tumours are lung (50 per cent), breast (15 per cent), melanoma (10 per cent), and unknown (15 per cent).

The gliomas are a family of neoplasms that arise from astrocytes, oligodendrocytes, and ependymal cells. Astrocytomas are the most common type of glioma and are infiltrating neoplasms composed of fibrillary astrocytes. Almost all of these tumours have the propensity to undergo anaplastic change to a more malignant lesion. Thus a fibrillary astrocytoma (Fig. 2) progresses to an anaplastic astrocytoma (Fig. 3) and then to the most malignant form, glioblastoma multiforme. This process occurs more often and more rapidly in older patients. The grading systems that have been used have attempted to describe degrees of anaplastic change and thereby correlate the histological appearances with prognosis. The most widely accepted classifications of gliomas are the World Health Organization three-tiered system and the St Anne–Mayo grading system as shown in Table 1. These systems have been retrospectively applied to large series of patients and have been shown to provide reproducible and prognostically useful information. A rare type of astrocytoma is the oligodendroglioma characterized by the presence of uniform round nuclei with small nucleoli. This also has the propensity to undergo anaplastic change but unlike anaplastic astrocytomas, oligodendrogliomas are frequently chemosensitive (see below).

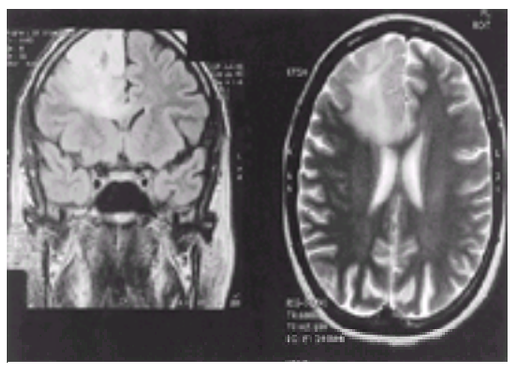

Fig. 2 Coronal and axial T_2-weighted MRI of the brain showing a diffuse lesion in the right frontal lobe which returns high signal. It is seen extending from the cortex into the deep white matter and infiltrating across the corpus callosum. There is mass effect causing compression of the frontal horn of the lateral ventricle. The tumour did not enhance with gadolinium. This patient presented with generalized seizures and has remained well after 3 years of follow-up. Biopsy revealed a fibrillary astrocytoma (WHO Grade II).

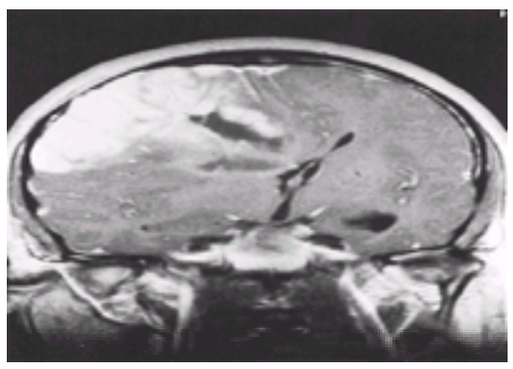

Fig. 3 Coronal T_1-weighted MRI of the brain with gadolinium enhancement showing a large heterogeneous enhancing tumour arising from the right frontal lobe exerting considerable mass effect in a patient presenting with a 2-month history of complex partial seizures, headaches, and papilloedema. The lesion was resected and shown to be an anaplastic astrocytoma.

Diagnosis

The diagnosis of a brain tumour is made by a combination of CT/MR scanning and pathological examination of either a biopsy or resection specimen. Newer techniques include magnetic resonance spectroscopy and metabolic imaging (single photon and positron emission tomography). These may permit a non-invasive method of differentiating between low-grade and high-grade gliomas and between tumour recurrence and radiation damage.

Treatment

The three methods of treatment for brain tumours are surgery, radiotherapy, and chemotherapy. The use of each is dictated by the location of the tumour, the likely histology, and the patient's age and general condition.

Surgery

Recent advances in tumour neurosugery include the use of computerized neuronavigation techniques, improved pre- and intraoperative mapping of eloquent brain areas using functional magnetic resonance imaging (fMRI), and cortical mapping. These have all contributed to improving the morbidity and mortality of neurosurgery but an effect on overall survival has not been demonstrated.

Surgery is indicated as a first-line treatment for meningiomas, non-secreting pituitary adenomas, and vestibular schwannomas. The role of surgery in the management of primary intracranial tumours, particularly gliomas, is more controversial. Some types of glioma, for example pilocytic astrocytomas, can be cured by surgical resection. For most types, however, removal is not curative. While surgery is of undoubted benefit in relieving the symptoms and signs of raised intracranial pressure or an evolving focal deficit, there are no prospective randomized data to support its use for prognostic purposes alone. However, it may be beneficial in a subgroup of patients who are young, fit, and who have a tumour in a non-eloquent region, such as the non-dominant frontal lobe. Overall, about 50 per cent of patients with medically refractory seizures derive considerable seizure reduction from surgery.

There is evidence that a combination of surgery and radiotherapy offers a survival advantage over radiotherapy alone for the treatment of solitary metastases in patients whose systemic cancer is well controlled.

Radiotherapy

Radiotherapy is the only treatment which has been proved to extend survival in patients with primary malignant brain tumours. Radiotherapy provides useful palliation in patients with low-grade gliomas, but there is no evidence to suggest that early radiotherapy prolongs overall survival compared with radiotherapy given at the time of tumour progression. Meningiomas are also partially radioresponsive and should be treated with radiotherapy where there is atypical or malignant histology or where there is recurrent tumour which is not surgically accessible.

Advances in technology have allowed greater accuracy of radiotherapy delivery and, in particular, the use of stereotactic frames which permit the focusing of radiation to a small tumour with minimal dosage to the surrounding normal tissue. This can be done either in a single high dose (stereotactic radiosurgery) or in smaller fractions (stereotactic radiotherapy) and is predominantly indicated for lesions less than 3 cm in diameter which are well circumscribed, extra-axial, and more than 5 mm away from vital structures.

Chemotherapy

There has been increased awareness of the chemosensitivity of certain tumours, particularly anaplastic oligodendrogliomas and primary lymphomas of the nervous system in adults and diencephalic gliomas in children. Approximately two-thirds of anaplastic oligodendrogliomas respond dramatically to a combination of treatment with procarbazine, lomustine, and vincristine, and this is now the first-line treatment for these tumours, particularly in the group who have combined deletions of chromosomes 1p and 19q. The addition of methotrexate-based chemotherapy to cranial irradiation markedly improves disease control and survival of patients with primary lymphomas. Adjuvant nitrosurea chemotherapy is used in patients with malignant gliomas although it offers only a marginal survival advantage. Recently, a new oral alkylating agent, Temozolomide, has been approved for use as a second-line treatment for recurrent malignant glioma. There is no chemotherapy that is effective for the treatment of meningiomas.

H3>Prognosis

Neither earlier diagnosis of tumours nor advances in treatment over the last decade have significantly changed the overall prognosis of primary brain tumours. The median survival of glioblastoma multiforme without treatment is 3 months and with radiotherapy about 1 year. Anaplastic astrocytomas are associated with a median survival of 18 months. Young age and good performance status are the most important prognostic factors.

The outlook for patients with low-grade gliomas is considerably better with a median survival of 5 to 10 years depending on age, performance status, and histology. Oligodendrogliomas are more chemosensitive than astrocytomas and have a more indolent course, so their prognosis is correspondingly better with patients surviving 10 to 15 years after diagnosis.

At least 40 per cent of primary intracranial tumours are extra-axial (not arising from within the brain substance itself) and are thus readily treatable, if not curable. Some tumours such as meningiomas and pituitary adenomas are associated with 10-year survival of over 90 per cent if diagnosed before irreversible neurological damage has occurred.
