
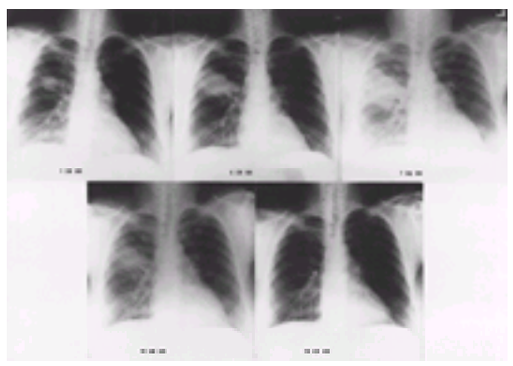

Fig. 2 Serial chest radiographs of a 35-year-old patient with Q fever pneumonia. The first radiograph (1 August 1989) shows a round opacity in the right upper lobe, which increases in size over the next 6 days. The pneumonia has completely cleared by 19 September 1989.

Fig. 3 Portable anteroposterior chest radiograph of a 72-year-old male with Q fever pneumonia. This radiographic picture is indistinguishable from pneumonia due to any other microbial agent.

The chest radiographic manifestations of Q fever pneumonia are usually indistinguishable from those of other bacterial pneumonias (Fig. 3). However, rounded opacities are suggestive of this infection (Fig. 2). Some investigators have reported delayed clearing of the pneumonia; however, in our experience resolution is usually complete within 3 weeks.

Hepatitis

The liver is probably involved in all patients with acute Q fever. There are three clinical pictures:

1. pyrexia of unknown origin with mild to moderate elevation of liver function tests;
2. a hepatitis-like picture—liver biopsy shows distinctive doughnut granulomas consisting of a granuloma with a central lipid vacuole and fibrin deposits;
3. 'incidental hepatitis'.

Neurological manifestations

Encephalitis, encephalomyelitis, toxic confusional states, optic neuritis, and demyelinating polyradiculoneuritis are uncommon manifestations of Q fever.

Rare manifestations

These include myocarditis, pericarditis, bone marrow necrosis, rhabdomyolysis, glomerulonephritis, lymphadenopathy, pancreatitis, mesenteric paniculitis, erythema nodosum, epididymitis, orchitis, priapism, and erythema annulare centrifugum.

Chronic fatigue may be a sequel of Q fever in some patients.

Chronic Q fever

The usual manifestation of chronic Q fever is that of culture-negative endocarditis. Some 70 per cent of these patients have fever and nearly all have abnormal native or prosthetic heart valves. Hepatomegaly and or splenomegaly occur in about half of these patients and one-third have marked clubbing of the digits. A purpuric rash due to immune complex-induced leucocytoclastic vasculitis and arterial embolism occurs in about 20 per cent of patients. Hyperglobulinaemia (up to 60 g/1) is common and is a useful clue to chronic Q fever in a patient with the clinical picture of culture-negative endocarditis.

Other manifestations of chronic Q fever include osteomyelitis, infection of aortic aneurysm, and infection of vascular prosthetic grafts.

The strains of *C. burnetii* that cause chronic Q fever do not differ from those that cause acute Q fever. Peripheral blood lymphocytes from patients with Q fever endocarditis are unresponsive to *C. burnetii* antigens *in vitro*, while responding normally to other antigens.

Diagnosis

A strong clinical suspicion based on the epidemiology and clinical features as outlined above is the cornerstone of the diagnosis of Q fever. This suspicion is confirmed by determining a fourfold or greater increase in antibody titre between acute and 2- to 3-week convalescent serum samples. A variety of serological tests are available: complement fixation, microimmunofluorescence, and enzyme immunoassay. The immunofluorescence antibody test is easiest to use. In acute Q fever the antibody titre to phase-II antigen is higher than that to phase-I antigen, while the reverse occurs in chronic Q fever. In chronic Q fever, antibody phase-I titres are extremely high, in the order of 1:8192 and higher. In acute Q fever, antibody titres to phase-I antigen are rarely in excess of 1:512, while peak antibody titres to phase-II antigen are between 1:1024 and 1:2048. The micro-organism can be isolated in embryonated eggs or in tissue culture; however, a biosafety level-3 laboratory is required. The polymerase chain reaction can be used to amplify *C. burnetii* DNA from tissues or other biological specimens.

Treatment

Acute Q fever is treated with a 2-week course of tetracycline or doxycycline. Chronic Q fever should be treated with two antimicrobial agents for at least 2 years. Some authorities recommend lifelong therapy for chronic Q fever. We use rifampicin, 300 mg twice a day, and ciprofloxacin, 750 mg twice a day, as agents of first choice. Rifampicin and doxycycline or tetracycline and trimethoprim–sulfamethoxazole have also been used to treat chronic Q fever. Another regimen for the treatment of

chronic Q fever is doxycycline 100 mg once daily and hydroxychloroquine 600 mg once daily to maintain a plasma level of between 0.8 and 1.2 µg/ml. This regimen is given for 18 months. Photosensitivity is a potential adverse reaction and patients should be warned to take preventive measures. In addition, an ophthalmologist must examine the optic fundus every 6 months for chloroquine accumulation. Antibody titres should be measured every 6 months for the first 2 years. A progressive decline in antibody titre reflects the successful treatment of chronic fever. Cardiac valve replacement may be necessary as part of the management of chronic Q fever.

Prevention

A formalin-inactivated *C. burnetii*, whole-cell vaccine is protective against infection and has a low rate of side-effects; 1 per cent of vaccinees developed an abscess at the inoculation site and another 1 per cent had a lump at this site 2 months after vaccination. The vaccine should be offered to those whose occupation places them at high risk for *C. burnetii* infection. Other measures to reduce Q fever infection are the use of only seronegative pregnant sheep in research facilities and the control of ectoparasites on livestock.

7.11.39 Bartonelloses, excluding *Bartonella bacilliformis* infections

James G. Olson

Background

Bacteria belonging to the genus *Bartonella* cause human diseases, including verruga peruana (discussed elsewhere), cat-scratch disease, trench fever, and bacillary angiomatosis–peliosis. During the last two decades, the aetiology of cat-scratch disease was discovered, bacillary angiomatosis was recognized, and the relationship of these diseases to trench fever, an epidemic scourge of soldiers in the First World War, was demonstrated. Because of recent microbiological and genetic evidence, the aetiological agents of these diseases have been included in the genus *Bartonella*. Recent progress has lead to an improved understanding of the aetiology, diagnosis, and epidemiology of infections with *Bartonella*, and some improvements in patient care and prevention.

Cat-scratch disease

Introduction

Cat-scratch disease, in most patients, is an acute, self-limiting infection characterized by development of a papule at the site of inoculation by a cat, followed by regional adenopathy that may persist for 1 to 4 months. In a small percentage of patients, serious systemic complications may arise, including involvement of the central nervous system, liver, spleen, lung, bone, eyes, and skin.

Epidemiology

Cat-scratch disease occurs world-wide in all races, more often in males than in females. Most cases of cat-scratch disease occur in children, but the disease is rare in infants. Estimates of the proportion of cases occurring before the age of 18 years range from 55 to 87 per cent. In the United States, the estimated incidence of cat-scratch disease in ambulatory patients is nine cases/100 000 population. Some 0.8 cases/100 000 population are discharged from hospital with a diagnosis of cat-scratch disease. These data support earlier estimates and suggest that cat scratch disease affects about 24 000 people each year in the United States, resulting in approximately 2000 hospital admissions. Incidence in the United States is highest in humid southern states and lowest in arid western states. Most reported cases occur in the fall and winter, but patients can be infected during any season. About 90 per cent of patients have a history of exposure to cats. Cat-scratch disease is strongly associated with owning a kitten, particularly one with fleas, and the presence of a scratch or bite by a kitten. Although they remain asymptomatic, domestic cats serve as major persistent reservoirs for *B. henselae*. Blood samples cultured from pet and impounded cats suggest that more than 40 per cent of cats are bacteraemic. *B. henselae* was also detected in fleas taken from an infected cats by both direct culture and PCR. Cat fleas from infected cats readily transmit *B. henselae* to uninfected cats. *B. henselae* is readily transmitted to uninfected cats by the subcutaneous inoculation of infectious flea faeces. The cat flea certainly plays an indirect role in human disease by increasing the size of the feline reservoir, and a direct role by producing infectious faeces that are inoculated into the human via the scratch of the cat.

Aetiology

Serological, epidemiological, and molecular findings indicate that *B. henselae* is responsible for cat-scratch disease. *B. henselae* is a small, curved, pleomorphic, fastidious, Gram-negative rod that is oxidase and catalase negative, and X-factor dependent. Colony morphology is varied, ranging from small, dry, grey-white colonies to smooth, creamy-yellow colonies. Its slow-growing sensitivity to a broad range of commonly used antimicrobials (including ampicillin, tetracycline, trimethoprim–sulfamethoxazole, and aminoglycosides) does not always correlate with *in vivo* efficacy. It is most closely related to *B. quintana*, the louse-borne agent of trench fever. There are many newly described species in the genus *Bartonella* that have been recovered from animals, but only four, *B. henselae*, *B. quintana*, *B. elizabethae* (which was isolated from a single patient with endocarditis), and *B. bacilliformis* have been associated with human disease. *Afipia felis* was claimed to be the aetiological agent of cat-scratch disease but was probably a soil contaminant.

Pathology

Examination of the primary inoculation lesion demonstrates dermal necrosis with variable numbers of histiocytes and occasional multinucleate giant cells accompanied by scattered microabscesses with mixed inflammatory cells, including neutrophils, eosinophils, lymphocytes, and plasma cells. The epidermal changes are non-specific with parakeratosis, hyperkeratosis, oedema, and exocytosis of inflammatory cells.

Adenopathy

Early in the course of infection lymph nodes show reactive lymphoid follicular hyperplasia with initial minute microabscesses adjacent to the subcapsular sinus. As the disease progresses, characteristic histopathology is necrotizing granulomas with central microabscesses and palisading histiocytes. Most of the necrotic centres have a stellate configuration. Multinucleated giant cells in lymph nodes are either rare or absent. A perivascular neutrophilic infiltrate may be present. The Warthin–Starry or Steiner silver impregnation stains may reveal pleomorphic bacilli in clusters or short chains within the areas of central necrosis or around small vessels (Fig. 1). Although these histopathological features are characteristic of cat-scratch disease, they are not diagnostic and must be correlated with clinical findings and serological studies. Other infections, such as tularaemia, lymphogranuloma venereum, and fungal and mycobacterial infections, may have a similar histology.

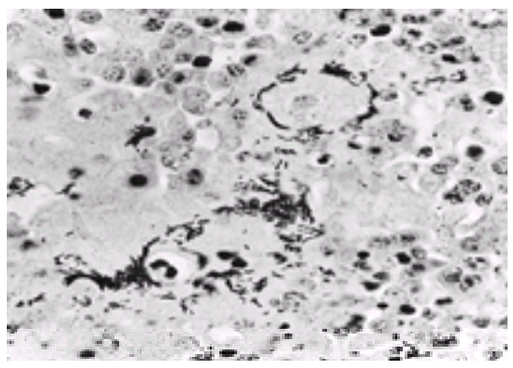

Fig. 1 Bacilli in tissue. Photomicrograph of Warthin–Starry silver impregnation stained section of an inguinal lymph node from a patient with a skin test positive for cat scratch disease. A vessel containing erythrocytes is cut in cross-section, bacilli are seen singly and in chains outlining the vessel (× 630). (Reproduced from Wear *et al*. (1983). *Science* **221**, 1403–5, Armed Forces Institute of Pathology negative 82–11271, with permission).

Clinical presentation

The typical course of cat-scratch disease begins with an erythematous papule or pustule at the inoculation site of a scratch or contact with a cat which usually persists for 1 to 3 weeks (Fig. 2). An inoculation site may be detected in over two-thirds of patients. Within 2 weeks, lymph nodes draining the site of inoculation become enlarged and tender. Lymphadenopathy occurs in more than 90 per cent of patients; it usually resolves spontaneously within a period of several months. In about 50 per cent, regional lymphadenitis is the only manifestation of the disease. Usually a single node or group of nodes is affected. The most common sites of lymphadenopathy are axillary, cervical, inguinal/femoral, and epitrochlear lymph nodes. Affected nodes are often tender and suppurate in about 10 per cent of the patients. Constitutional symptoms of fever, anorexia, malaise, and headache accompany the lymphadenitis in 75 per cent of patients, but in the vast majority these symptoms are mild. About one-third of patients complain of fever and one-quarter have malaise or fatigue. Other non-specific clinical features are headache, anorexia, weight loss, vomiting, sore throat, rashes (maculopapular and rarely erythema nodosum), and splenomegaly. Although considered to be a self-limiting illness, signs and symptoms of cat-scratch disease often persist for 2 to 4 months, and adenopathy for longer.

Fig. 2 Crusted erythematous papules at the site of a cat scratch above the umbilicus with bilateral inguinal lymphadenopathy, which developed 10 days later, in a 7-year-old boy (Copyright D.A. Warrell).

Atypical presentations occur in up to 15 per cent of patients. The most common, Parinaud's oculoglandular syndrome, was first described by Henri Parinaud in 1889. It is characterized by ocular granuloma or conjunctivitis with preauricular lymphadenopathy and fever. The affected eye is painless and non-pruritic and shows no evidence of discharge. Most patients recover spontaneously without any sequelae in 2 to 4 months. Other atypical manifestations include encephalopathy, aseptic meningitis, seizures, neuroretinitis, transverse myelitis, osteolytic lesions, hepatic and splenic granulomas, thrombocytopenic purpura, haemolytic anaemia, endocarditis, atypical pneumonia, pleural effusion, pulmonary nodules, breast mass, multiple granulomatous skin lesions, and recurrent adenopathy. In patients with central nervous system involvement, encephalopathy is the most commonly reported manifestation, occurring in 2 to 3 per cent of patients. Typically, 1 to 6 weeks after onset of lymphadenopathy, patients become abruptly confused and disoriented, rapidly progressing to coma. Cranial computed tomography is generally normal, and cerebrospinal fluid shows minimal pleocytosis or elevation of protein. Electroencephalography is frequently abnormal. Neurological recovery is almost always complete over 1 week, but persistent deficits have been reported. There have also been reports of patients presenting with recurrent fever, malaise, fatigue, and weight loss without obvious focal infection. The symptoms may persist for weeks to months before the diagnosis is made. Hepatic granulomas, osteomyelitis, and pulmonary involvement have also been reported as rare complications. All parts of the respiratory tract may be affected; bilateral hilar lymphadenopathy and primary atypical pneumonia have been reported. Severe manifestations have been described in an immunocompromised patient. Fatalities are extremely rare.

Diagnosis

The diagnosis of cat-scratch disease has evolved from a diagnosis by exclusion to one based on the laboratory confirmation of infection with the aetiological agent, *B. henselae.* The current case definition includes lymphadenopathy, with a serum IgG antibody titre more than 64 when tested by indirect immunofluorescence using *B. henselae* antigen; or PCR product specific for *B. henselae* as determined by RFLP or sequence analyses. Isolation of *B. henselae* is not practicable as viable bacteria are seldom present when the patient seeks medical care.

Differential diagnoses include lymphogranuloma venereum, syphilis, typical or atypical tuberculosis, other forms of bacterial adenitis, sporotrichosis, tularaemia, brucellosis, histoplasmosis, sarcoidosis, toxoplasmosis, infectious mononucleosis, and benign or malignant tumours.

Treatment

In the majority of patients, cat-scratch disease resolves spontaneously in 1 to 2 months. Azithromycin, rifampin, ciprofloxacin, trimethoprim–sulfamethoxazole, and gentamicin may benefit some patients. Antimicrobials should be considered for severe cases of cat-scratch disease but for uncomplicated cases of classical cat-scratch disease, treatment should be directed toward relief of discomfort. Application of moist soaks, local heat, analgesics, limitation of activity, and aspiration of suppuration may help to relieve the pain and resolve the inflammation. Aspiration is preferred to surgical drainage, which may lead to fistula formation or scarring. Spontaneous resolution of the infected node is common, but aspiration or surgical removal may be necessary. Healing is usually rapid. Treatment with erythromycin or doxycycline—either alone or in combination with rifampin—at standard doses but for longer duration (4 to 6 weeks) have been reported as effective and safe in both immunocompetent and immunosuppressed patients. Currently, the role of systemic steroid therapy, including in patients with neuroretinitis, is not clear.

Complications are uncommon and the prognosis is excellent. Recurrent attacks are rare and systemic sequelae are unusual.

Prevention

Isolation of patients is unnecessary. No vaccines are available, however, cat vaccines to protect cats from infection are under development. Treatments that prevent flea infestations in cats may be an effective means of preventing human infections. Cat owners should be encouraged to take their pets to routine veterinary visits and prevent ectoparasite infections, and to avoid cat scratches and bites. Cats implicated in transmission need not be destroyed.

Trench fever

Introduction

Trench fever is a febrile illness first described among British soldiers in 1915. From 1915 to 1918 it was thought to account from 40 to 60 per cent of all illnesses among soldiers. There were no deaths but much morbidity. By 1918 it was concluded that trench fever was an infectious disease and that the aetiological agent was transmitted by the human body louse. In 1961, *B. quintana* was isolated from the blood of a patient with trench fever and Koch's postulates for the causation of trench fever by *B. quintana* were fulfilled in 1969. Since the end of the Second World War, reports of trench fever have been rare but recent data suggest that cases may have escaped recognition; clusters of cases in homeless alcoholic men have been identified in the United States and France.

Epidemiology

Endemic foci of trench fever have been identified in Poland, the former Soviet Republics, Mexico, Bolivia, North Africa, Ethiopia, and Burundi, but its true incidence and geographical distribution are unknown.

B. quintana is transmitted by inoculation of contaminated louse faeces through a break in the skin from a louse bite or other injury. The incubation period is 7 to 30 days. It is not transmitted directly from person-to-person. The human body louse becomes infected by ingesting infected human blood.

In the 1980s, *B. quintana* re-emerged as an opportunistic pathogen among HIV-infected people in whom it causes bacillary angiomatosis, endocarditis, and bacteraemia. It has been isolated from AIDS patients in France and the United States. *B. henselae* is probably a more common cause of bacillary angiomatosis and bacteraemia among HIV-infected people.

More recently, *B. quintana* has been identified as a cause of invasive infection among HIV-seronegative, inner-city, homeless, alcoholics in Seattle, Washington, and Marseilles, France. A seroprevalence study conducted one year after the *B. quintana* outbreak among patients at a downtown Seattle clinic serving a primarily indigent and homeless population found that 20 per cent of patients had microimmunofluorescence titres at or greater than 64. Interpretation of these results is limited by the high cross-reactivity of the assay to *B. henselae*. The results suggest, however, that exposure to the organism was common in that population and that many cases of infection may have been asymptomatic or minimally symptomatic.

The mode of transmission of *B. quintana* among homeless persons is not well defined. Lice were detected on one patient at the time of presentation and five patients were reported to have been previously diagnosed with scabies. Transmission via a louse or other ectoparasitic vector is therefore a plausible hypothesis. Currently, the human body louse is the only known vector of *B. quintana*. No non-human vertebrate reservoir is known.

Clinical presentation

High fever is the most common clinical feature. Headache and myalgia are common prodromal symptoms. Fever starts acutely or insidiously and is often associated with headache, dizziness, and pains in the back, eyes, and legs, especially in the shins. Splenomegaly is common and a red macular rash (lesions 2–4 mm in diameter) may appear transiently. Complete recovery usually occurs within 5 to 6 weeks without antimicrobial therapy. Trench fever is not fatal but about half of the patients will have relapse of illness with fever and myalgia. Endocarditis has been described.

Four clinical patterns have been recognized:

1. asymptomatic or minimally symptomatic infection;
2. a single, acute, febrile attack lasting 3 to 4 days;
3. a periodic form, with multiple febrile paroxysms; and
4. a continuous form with weeks of fever.

Studies involving inoculation of humans with *B. quintana* from infected louse faeces suggest that the incubation period ranges from 5 to 20 days depending on the size of the inoculum. *B. quintana* may circulate in the blood for weeks after resolution of symptoms and infection may last as long as a year.

The clinical spectrum of infection among HIV-negative, alcoholic and homeless people has varied. Of these 13 cases of 'urban trench fever', five developed left-sided endocarditis which required valve replacement in four despite antibiotic therapy. One patient died 4 months after valve replacement surgery and one patient who had a concurrent positive blood culture for *Streptococcus pneumoniae* also died, presumably due to pneumococcal sepsis. Many of the patients with *B. quintana* bacteraemia presented with a subacute course of chronic fever, fatigue, and weight loss. Two patients had splenomegaly; however, other symptoms associated with classical trench fever, such headache, rash, and bone pain, were not reported.

Diagnosis

Bartonella quintana are slow growing bacteria which require special culture methods for isolation. The use of Isolator (lysis–centrifugation) tubes improves the yield from blood cultures. Specimens should be plated on enriched media (blood or chocolate agar) incubated at 35 to 37°C in 5 per cent CO_2 and high humidity and held for at least 4 weeks. The organism can also be isolated from blood using Bac Tec or resin-containing culture media if the contents are stained with acridine orange after 1 week of incubation. All stain-positive bottles are then subcultured onto enriched media and processed as above. Cocultivation of blood samples with endothelial cells has also been used for isolation of *Bartonella* species. With more widespread use of culture methods appropriate for the isolation of *Bartonella* species in clinical laboratories, the spectrum and apparent extent of infections due to this organism may be expanded.

Enzyme-linked immunosorbent (ELISA) and immunofluorescence (IFA) assays are available for serological diagnosis. Both exhibit substantial cross-reactivity between *Bartonella* species. The use of paired sera obtained four or more weeks apart is recommended. PCR amplification from infected tissues of DNA specific to *Bartonella* species has also been used.

Treatment

Optimal treatment has not been established. Erythromycin has been the drug of choice, although doxycycline, tetracycline, or azithromycin appear to be acceptable alternatives. At least 14 days of oral therapy is recommended for uncomplicated infection and for bacteraemia at least 4 weeks of therapy is indicated. Most of the few patients identified with *B. quintana* endocarditis have required cardiac valve replacement. Parenteral therapy for 2 to 3 months should therefore be considered for cases of suspected or confirmed *B. quintana* endocarditis.

Relapsing disease is well described, especially if therapy is terminated prematurely. In the Seattle outbreak one patient who was non-compliant with therapy had documented bacteraemia over an 8-week period. It is not known whether extended therapy will prevent relapses.

In immunocompetent hosts, infection with *B. quintana* is usually self-limited unless complicated by endocarditis. The disease is more severe in immunocompromised hosts and may progress to death.

Prevention

Control of the human body louse will prevent transmission of trench fever.

Bacillary angiomatosis–peliosis

Introduction

Bacillary angiomatosis was described in 1983 in an HIV-infected patient with fever and skin nodules. Since then it has been seen in many other HIV-infected patients

and in a few apparently immunocompetent individuals. Bacillary angiomatosis represents one aspect of a spectrum of infections due to the fastidious organisms *Bartonella quintana* and *B. henselae*. A similar disorder known as verruga peruana, caused by *B. bacilliformis*, is restricted to Peru and several neighbouring countries. More reliable diagnostic and identification methods are providing a better understanding of the ubiquitous distribution of both organisms and of the expanding spectrum and overlap of disease they cause. Like *B. bacilliformis*, *B. quintana* and *B. henselae* cause acute febrile illnesses (trench fever, Oroya fever), recurrent asymptomatic bacteraemias, skin lesions, and aseptic meningitis, while ocular involvement (Leber's stellate neuroretinis) appears to be limited to *B. henselae* infections. *B. elizabethiae* has been associated with endocarditis.

Epidemiology

Most cases of bacillary angiomatosis–peliosis have been reported from the United States but its incidence and global distribution are unknown. Epidemiological information is based on case reports, small case series, and a single case–control study. In the largest reported series of cases (*n* = 49), 45 (92 per cent) were HIV infected, one was HIV negative and immunodeficient, and three (6 per cent) were HIV negative and apparently immunocompetent.

Patients infected with *B. henselae* but not *B. quintana* were more likely than controls to own cats, to have been bitten or scratched by cats, to have been exposed to a household cat with fleas, and to have been bitten by cat fleas. The cat flea serves as an arthropod vector for *B. henselae.* Patients with *B. quintana* infections were more likely than controls to be homeless, to have a low annual income, and to be infested with head or body lice. The human body louse is the most likely the vector of *B. quintana.* Neither those infected with *B. henselae* or *B. quintana* were more likely than controls to be alcoholic or to use intravenous drugs.

Aetiology

B. quintana and *B. henselae* have recently been isolated from cutaneous lesions of bacillary angiomatosis. Their aetiological role is also supported by serological and molecular assay data. The morphological and staining characteristics, biochemical and antimicrobial sensitivity profiles, and phylogenetics of *B. quintana* are similar to those of *B. henselae* in cat-scratch disease.

Clinical presentation

Bacillary angiomatosis derives its name from the vascular proliferation and presence of numerous bacillary organisms in affected tissues. It has been reported to involve numerous tissues including skin, lymph node, muscle, bone, bone marrow, brain, liver, and spleen. Bacillary angiomatosis affecting the liver (also 'bacillary peliosis hepatis) and spleen has been referred to as 'bacillary peliosis'. Bacillary angiomatosis most commonly presents as single or clustered, reddish, papular lesions on the skin, but may also occur as brownish patches or subcutaneous nodules and may be confused with Kaposi's sarcoma or disseminated fungal infections, such as *Cryptococcus neoformans*, in the HIV-infected individual. Rarely, diffuse or isolated lymph node involvement can be seen without the characteristic rash. Systemic involvement may also occur, causing lytic bone lesions, peliosis hepatis, or disseminating to other visceral organ in more severe cases. Although descriptions of the disease were in patients with immune deregulation due to neoplastic processes, HIV-1 infection, or immunosuppressive therapy, bacillary angiomatosis has also been described in essentially immunocompetent individuals.

Diagnosis

Biopsy and histological examination of affected tissue is needed for diagnosis of bacillary angiomatosis. It is not possible to distinguish bacillary angiomatosis clinically from Kaposi's sarcoma or other diseases that may affect the skin, spleen, liver, and other tissues, especially in HIV-infected or other immunocompromised persons. Histological criteria for the diagnosis of bacillary angiomatosis include characteristic vascular proliferation on routine haematoxylin-and-eosin staining, and of demonstration of bacillary organisms by silver staining (Warthin–Starry, Steiner, or Dieterle) or electron microscopy.

B. henselae and *B. quintana* have been isolated from cutaneous lesions of bacillary angiomatosis after cultivation of tissue homogenates with endothelial cell monolayers, followed by plating of the supernatants on to solid agar. These organisms can also be isolated from the blood using a lysis–centrifugation method. Serological responses with an indirect immunofluorescence assay for antibodies to *B. quintana* and*B. henselae* may indicate recent infection and provide supporting evidence in a clinical syndrome compatible with diseases. While the duration of antibody responses is not known, IFA reactivity has been documented to last for over 1 year in several longitudinally followed cases. Tissue and blood for culture may also be useful—a positive culture is conclusive, but elusive. PCR of the 16s ribosomal subunit or the citrate synthase gene with restriction fragment length polymorphisms may also be employed.

Treatment

Most *Bartonella* infections are self limiting, particularly when associated with cat-scratch or isolated lymphadenopathy. However, with more disseminated disease such as bacillary angiomatosis, systemic antimicrobial therapy is necessary, particularly when it is an opportunistic infection in AIDS patients. Antimicrobial agents which achieve high intracellular concentrations, such as doxycycline, rifampin, erythromycin, and the macrolides, and possibly trimethoprim–sulfamethoxazol are the most effective in treating and clearing infection. In severe cases, combination therapy with doxycycline or a macrolide and rifampin have been used with success. Fluoroquinolones and cell-wall-active agents, including penicillins and cephalosporins, and aminoglycosides are ineffective. There is no clearly defined duration of therapy, although relapses have been seen when less than 4 weeks of antimicrobial treatment has been given both in HIV-infected and immunocompetent patients.

Prevention

Macrolide antibiotic (erythromycin, clarithromycin) prophylaxis is effective in preventing bacillary angiomatosis–peliosis. Both *B. henselae* and *B. quintana* can be transmitted by arthropod vectors to humans. Elimination of body louse infestations among human populations and cat flea infestations among domestic cats provide a potential means for preventing infections. The domestic cat is the zoonotic reservoir for *B. henselae*, and despite the fact that infected cats show no or mild clinical signs, effective clearance of infection may be achieved through the use of a variety of oral antibiotics.

7.11.39.1 *Bartonella bacilliformis* infection

A. Llanos Cuentas

Definition

Bartonellosis (Carrión's disease, verruga peruana, Oroya fever, Guaitará fever) is a non-contagious infectious disease that is endemic in the western Andes and inter-Andean valleys of Peru and occasionally has been reported in Colombia and Ecuador. The acute stage is characterized by infection of red blood cells leading to anaemia; in the late stage the patients develop dermal nodules, which are called 'verrugas'. This disease produces a temporary, reversible immunosuppression in the host, which explains why secondary opportunistic infections are common.

Aetiological agent

Barton, a Peruvian physician, described the causative organism in 1905. *Bartonella bacilliformis* is a small, motile, aerobic, Gram-negative bacillus that stains deep red or purple with Giemsa (Fig. 1). This facultative intracellular haemotrophic bacterium varies in morphology and quantity during various stages of the disease. In spite of being a pleomorphic organism, two essential types are distinguishable: bacilli or rod-shaped forms and coccoid forms. Rod-shaped forms predominate in the acute stage of the disease and coccoid in the convalescent stage. *B. bacillifomis* may infect red blood cells (Fig. 2), endothelial cells of capillaries, and sinusoidal lining cells. The organism is 2 to 3 µm long and 0.2 to 2.5 µm thick. In cultures, 1 to 10 flagella 3 to 10 µm long may originate from one end of the organism. Bartonella can be cultured in Columbia agar supplemented with 5 per cent defibrinated human blood or other supplemented media containing rabbit serum and haemoglobin at 28°C under aerobic conditions for up to 6 weeks.

Epidemiology

The disease has occurred since pre-Columbian times, as proved by artistic representations in pre-Inca potteries as well as lesions in a mummy. Bartonellosis is an endemic disease mainly in narrow river valleys and canyons usually in west Andean, and increasingly frequently in inter-Andean, valleys of the central and east Andes of Peru and high jungle areas (Fig. 3). Bartonellosis is a re-emergent disease that is extending its range in Peru. During the last two decades the disease has become endemic in new areas of Ayacucho, Huancavelica, Amazonas, Huanuco, Junín, and Cusco departments and important outbreaks have been reported in recent years. Outbreaks have been described in similar areas in Nariño, Colombia (in 1939) and in Loja and Chichipe areas, Ecuador (Fig. 4). It occurs between 500 and 3200 m above sea level. There are annual high and low transmission seasons and the transmission is greatest towards the end of the rainy season (March to May). Interepidemic periods occur every 10 to 15 years, influenced by climate, environmental, and ecological changes such as El Niño phenomenon.

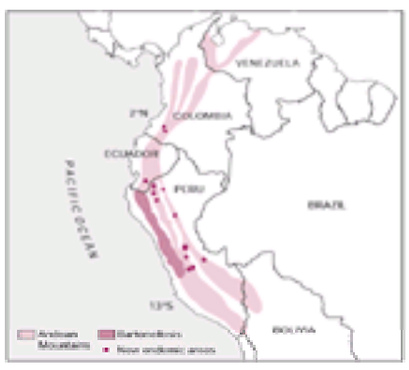

Fig. 4 Geographical distribution of bartonellosis. Coloured spots represent endemic areas of bartonellosis.

In recent years, other human infections by haemotrophic bacteria have been included in the genus *Bartonella: B*. (formerly *Rochalimaea*) *quintana*, the agent of trench fever, *B. henselae*, the major cause of cat-scratch disease, *B. elizabethae*, an aetiological agent of infective endocarditis, and *B*. (formerly *Rochalimaea*) *vinsonii*, until recently not considered to be a pathogen. In immunocompromised people, especially those with AIDS, *B. henselae* and *B. quintana* cause opportunistic infections, frequently manifested as cutaneous bacillary angiomatosis, resembling verruga peruana.

In endemic areas the disease appears in childhood and usually produces few symptoms. Outsiders generally develop acute severe forms of the disease (Oroya fever). Large epidemics have occurred when large groups of non-residents have entered endemic areas. In 1870 an epidemic involved workers building the railroad from Lima to Oroya (Fig. 5); the estimated mortality was 7000. Infection results from the bite of female sandflies of the genus *Lutzomyia*, the most important species being *L. verrucarum*. The vectors are closely associated with human dwellings and, because they are active during twilight hours, people acquire bartonellosis in the hours around sunrise and sunset. Although the reservoir is unknown, there is increasing evidence that humans are the major host. Asymptomatic infection by *B. bacilliformis* has been demonstrated in people of endemic areas. However, since bartonellosis can be acquired in several Andean areas uninhabited by humans, other reservoirs for the disease may exist. Some domestic animals, including horses, donkeys, mules, dogs, and cats, are susceptible and develop lesions similar to verrugas. *Bartonella*-like isolates have been obtained from a *Phyllotis* mouse.

Pathogenesis

After inoculation of *B. bacilliformis* through a sandfly bite, the bacteria multiply in endothelial cells of small vessels, and phagocytic cells near the skin. Systemic invasion and multiplication in endothelial cells and red blood cells follows. In the most serious cases, 95 to 100 per cent of red cells are infected with numerous bacteria. The hallmark of the disease is the severe anaemia caused by massive infection of red blood cells and subsequent erythrophagocytosis. Several mechanisms contribute to anaemia: increased fragility, form and size alteration, and reduced half-life of infected and non-infected red cells. Some inhibition of haemoglobin synthesis, probably induced by toxic factors, has also been invoked, since production of red cells increases dramatically with reduction of bacteraemia. Erythrophagocytosis contributes to lymphadenopathy and hepatosplenomegaly. Blockade of the mononuclear phagocytic system and the presence of the circulating iron leads to superinfection, usually by enterobacteria, during the anaemia stage or early recovery from it. Transient depression of cellular immunity has been reported. During the anaemic phase, mild lymphopenia with a reduction of OKT4, a mild increase of OKT8, and decrease of the polyclonal stimulation of the lymphocytes occurs.

A few weeks to months after the acute illness has subsided, the cutaneous form 'verruga peruana' may develop (Fig. 6). The vascular skin lesion shows endothelial proliferation and histiocytic hyperplasia (the cells contain degenerate organisms; Fig. 7), with later fibrosis and necrosis. Electron microscopy of verrucous tissue shows *B. bacilliformis* in the interstitial tissue, indicating that the presence of the bacteria is important for this unusual vascular response to occur. Verruga peruana results from persistent infection, a probably insufficient immune response, and a peculiar vascular reaction, which could be caused by bacterial products acting as an angiogenic factor. In 1885, D.A. Carrión, a Peruvian medical student, linked both phases of the disease by self-experimentation and died.

Fig. 6 Histological section of miliary skin lesion of 'verruga peruana', a sessile or partly pedunculated molluscum-like lesion. (Armed Forces Institute of Pathology photograph negative no. 77355.)

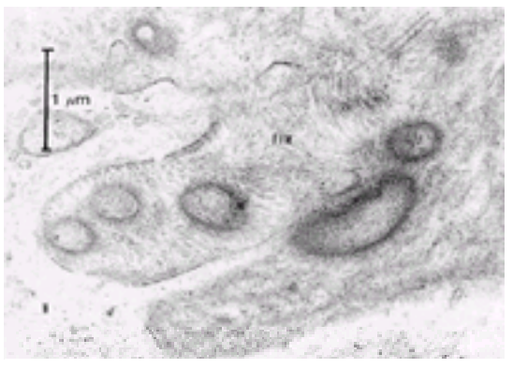

Fig. 7 Electron micrograph of a vascular skin lesion (verruga peruana) showing six *B. bacilliformis* in the fibrillar intertitial matrix (FIM). The cell wall, cell membrane, and internal structure of the bacteria can be seen. The clear cytoplasm of a histiocyte (H) can also be seen. Clinical features

The disease has two stages, anaemic and eruptive, with an asymptomatic intermediate period. After an incubation period of around 60 days (range 10 to 210 days), non-specific prodromal symptoms appear: onset is usually gradual with malaise, mild chills, fever, and headache. Occasionally, high fever may develop rapidly or build up over a few days. It is accompanied by sweating and rigors. Common symptoms include weakness, aching of the head, back, and extremities, prostration, and depression. The clinical picture is dominated by severe (haemolytic) anaemia: the patient rapidly become pale, dyspnoeic, and jaundiced. There may be hepatosplenomegaly, generalized lymphadenopathy, myocarditis, pericardial effusion, exudates, and retinal haemorrhages in the fundus; sometimes there is generalized oedema, a fine vesicular or petechial rash, and exceptionally, meningoencephalomyelitis. The duration of this state is variable (generally 2 to 4 weeks). In pregnant women the disease in this phase may cause abortion, fetal death, and be transmitted transplacentally; maternal death is common.

In the intermediate period the patients are asymptomatic and recover from the anaemia through great bone marrow activity. This pre-eruptive period varies from weeks to months.

In the eruptive stage, many nodular lesions of varying size appear on the face, trunk, and limbs during a period of one or more months and usually persist for 3 or 4 months. There is accompanying mild arthralgia, myalgia, and sometimes fever. The red or purplish skin lesions vary from papules a few millimetres across. Most often the eruption is miliary (miliary form) with many haemangioma-like lesions of the dermis (Plate 1). Nodular lesions (modular form) are larger but fewer and more prominent on the extensor surfaces or arms and legs (Plate 2). They are painless and prone to bleeding, secondary infection, and ulceration. The appearance may resemble haemangioma, granulome pyogenicum Kaposi's or fibrosarcoma, leprosy (hystioid form), or yaws. Occasionally, one to a few, large, deep-seated lesions that often ulcerate (mular form) develop. These tend to appear near joints, where they may be painful and limit motion. Apart from skin, the mucous membranes of the mouth, conjunctiva, and nose, serous cavities, and the gastrointestinal and genitourinary tracts may be involved. The eruptive phase tends to heal spontaneously, although the course is often prolonged. Inhabitants of endemic areas usually develop the eruptive stage as the sole manifestation of the disease.

The principal complication is superinfection, leading to septicaemia, which occurs at different stages of the disease but generally in the later part of the anaemic stage and during the intermediate stage. Formerly, *Salmonella typhi*,*S. typhimurium*,*S. dublin*,*S. anatum*,*S. enteritidis*, *Mycobacterium tuberculosis*, and *Enterobacter* spp. were the most frequent pathogens. Reactivation of toxoplasmosis, histoplasmosis, pneumocystosis, and sta-phylococcal infections are some of the other infections that are now frequent.

Diagnosis

Two elements must be considered: visiting or residence in an endemic area and a compatible clinical picture with demonstration of the bacteria in the blood film. Fluorescence antibody test, indirect haemagglutination, immunoblot, and enzyme-linked immunosorbent assay (ELISA) are the new serological tests, but they are not generally available.

Laboratory features

Bartonella can be isolated from the blood during the anaemic stage and sometimes during the eruptive stage. The enriched media may be positive in 4 to 28 days at 28 °C. As fever develops, intraerythocytic bacteria are visible in thick and thin films stained with Giemsa, Wright, or other variants of the Romanovsky stain. Organisms can also be seen and cultivated in the skin lesion of verrucous tissue. The haemolytic anaemia is Coombs' test negative. The blood picture is a macrocytic and hypochromic anaemia with polychromasia, anisocytosis, and poikilocytosis. The reticulocytosis is marked (average 11 per cent). The marrow is hyperactive and megaloblastic with erythrophagocytosis. The white cell count is not markedly elevated unless there is a secondary infection. Thrombocytopenia is quite common. After the crisis, the intracellular organisms ecome coccoid and later disappear, the white cell count rises, and there is lymphocytosis. Eosinophils, which are usually absent during the acute stage, reappear in differential counts of peripheral blood.

Prognosis and treatment

Death is usually during the anaemic phase, and in the preantibiotic era varied between 20 and 95 per cent. At present it varies between 1.1 and 2.4 per cent in endemic areas and around 9 per cent in patients admitted to hospital. During outbreaks, especially when the disease in not promptly recognized and treated, the mortality can reach 88 per cent. Alterations of consciousness (excitement, stupor, and coma) and progressive or focal neurological features, biochemical evidence of hepatic dysfunction (increased serum aspartate and alanine transaminases and alkaline phosphatase), pulmonary complications (non-cardiogenic pulmonary oedema), anasarca (severe hypoalbuminaemia), and pregnancy are associated with a higher mortality.

Chloramphenicol, penicillin, erythromycin, co-trimoxazole, tetracycline, and ciprofloxacin are dramatically effective, usually eliminating the fever in less than 48 h. Because of the common association with salmonellosis, chloramphenicol is the treatment of choice in a dose of 50 mg/kg per day for 10 days. An alternative is ciprofloxacin in a dose of 500 mg twice a day for 10 days. Supportive treatment includes transfusion of packed red cells and dexamethasone (if there is severe neurological involvement). Rifampicin (300 mg twice a day in adults or 10 mg/kg per day in children, orally for 14 to 21 days) is indicated for treatment of the verrucous form.

Prevention

When transmission is around dwellings, sandflies can be temporarily eliminated by spraying inside and outside with DDT or pyrethroids. Bites usually occur after dusk. They can be prevented by insect repellents, impregnation of clothes with pyrethroids, sleeping inside fine-meshed or impregnated nets, or by avoiding sleeping in highly endemic areas.

7.11.40 Chlamydial infections including lymphogranuloma venereum

D. Taylor-Robinson and D. C. W. Mabey

Trachoma is discernible as a cause of blindness in ancient Chinese and Egyptian writings. However, it was not until 1907 that L. Halberstaedter and S. von Prowazek first described intracytoplasmic inclusions in conjunctival scrapings from patients with trachoma and recognized the involvement of an infectious agent. In 1930, the first isolation of a chlamydial agent (*Chlamydia psittaci*) from psittacosis was made, that is about 27 years before the genomically and biologically different agent, *Chlamydia trachomatis*, was isolated in fertile hens' eggs from trachoma. The advent of the cell-culture technique in the late 1950s paved the way for the isolation of *C. trachomatis* in 1965 by this means and, together with immunological developments, made it possible to explore the nature, range, prevalence, and pathogenesis of clinical conditions associated with chlamydial infection.The complete sequencing of the chlamydial genome, accomplished recently, provides an even greater opportunity to define many unfathomed aspects of the biology and pathogenesis of chlamydial infections.

Classification

Chlamydial organisms, or chlamydiae, are ubiquitous pathogens infecting many species of mammals and birds. The genus *Chlamydia* comprises at least four species, of which three can infect humans. *C. trachomatis* is pathogenic for humans and causes ocular, genital, and systemic infections that affect millions of people worldwide. *C. pneumoniae* causes mainly human respiratory disease, has been associated with atherosclerosis, and equine and koala strains exist. *C. psittaci* infects birds and other animals, resulting in major economic losses and occasionally is transmitted to humans The fourth chlamydial species, *C. pecorum*, causes pneumonia, polyarthritis, encephalomyelitis, and diarrhoea in cattle and sheep.

Taxonomic reclassification based on 16S RNA analysis has been proposed recently. In this, the order Chlamydiales contains four families, the first of which, Chlamydiaceae, comprises two genera, namely *Chlamydia* (for example, *Chlamydia trachomatis*) and *Chlamydophila*(for example, *Chlamydophila pneumoniae*). This proposal has generated considerable debate.

Growth cycle, serovars, and protein profile

Chlamydiae probably evolved from host-independent, Gram-negative ancestors that contained peptidoglycan in their cell wall. The chlamydial envelope, like that of Gram-negative bacteria, has inner and outer membranes. Indeed, chlamydiae are best considered as bacteria that are specialized for an intracellular existence. The infectious elementary body is electron dense, deoxyribonucleic acid rich, and approximately 300 nm in diameter. Elementary bodies of *C. pneumoniae* often, but not always, have a wide periplasmic space and appear pear shaped, whereas those of the other chlamydial species have a narrow periplasmic space and are spherical. The elementary body begins its eukaryotic intracellular lifecycle by binding to the host cell and entering by 'parasite-specified' endocytosis. Inside the host cell, fusion of the chlamydia-containing endocytic vesicle with lysosomes is inhibited and the elementary body begins its unique developmental cycle. After about 10 h it has differentiated into the larger (800 to 1000 nm), non-infectious, metabolically active, reticulate body. This divides by binary fission and by 20 h there is the beginning of reorganization into a new generation of elementary bodies (Fig. 1), which reach maturation 20 to 30 h after entry into the cell. Their rapid accumulation within the endocytic vacuole precedes release from the cell between 30 and 48 h after the start of the cycle.

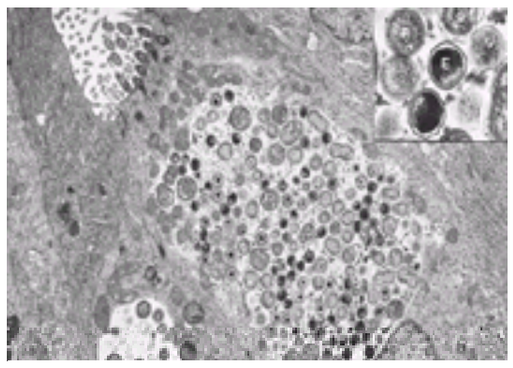

Fig. 1 Elementary bodies (E) and reticulate bodies (R) of *C. trachomatis* forming an inclusion in oviduct cell shown by transmission electron microscopy.

All species within the genus *Chlamydia* contain a common, heat-stable, lipopolysaccharide antigen, which is exposed on the surface of the reticulate body, but not on that of the elementary body. The major outer membrane protein (**MOMP**) is immunodominant in the elementary body and it contains epitopes that exhibit genus, species, and serovar specificity.The serovar-specific epitope is the basis of the microimmunofluorescence test by which *C. trachomatis* has been separated into 15 serovars: A, B, Ba, and C are responsible mainly for endemic trachoma, and D to K for oculogenital infections. Serovars L1, L2, and L3 of *C. trachomatis* cause the genital disease, lymphogranuloma venereum. At present, only one *C. pneumoniae* serovar has been identified, although minor geographical serovar variations have been described. The loosely defined *C. psittaci* species is likely to contain a wide variety of host-related serovars. Amino acid sequences of the MOMPs of all *C.*

trachomatis serovars are now known and epitope maps of different antigenic domains have been elucidated. It appears that the MOMP genes consist of five highly conserved regions punctuated by four short variable sequences. Serovar-specific epitopes have been demonstrated in variable sequence in I and II, while species-specific epitopes have been found in variable sequence IV. It is also probable that these variable sequences have some role in chlamydial pathogenesis. *C. trachomatis*, *C. psittaci*, and *C. pneumoniae* species have been compared and, although there is only 10 per cent DNA homology between each of them, MOMP gene analysis of the respective species reveals up to 65 per cent amino acid homology, indicating a probable common ancestor. A common chlamydial 57-kDa protein has been described and its possible role in disease pathogenesis is considered below.

Trachoma

Trachoma is a chronic keratoconjunctivitis believed to affect some 500 million people, of whom 7 million are blind and 10 million have some visual impairment. After cataract, it is the most common cause of blindness worldwide, but is now confined largely to developing countries. Trachoma is a disease of poverty rather than of hot climates, and in some respects the relation between genital and ocular chlamydial infections resembles that between syphilis and non-venereal treponematoses. In poor communities where hygienic standards are low, there is direct transfer of chlamydiae from eye to eye (compare with skin to skin for non-venereal treponematoses), and trachoma is endemic. As standards of hygiene improve, this mode of transmission is no longer possible and trachoma becomes less of a problem.

Clinical features

The active (inflammatory) stage of the disease, a follicular conjunctivitis, affects chiefly the subtarsal conjunctiva, but follicles occur elsewhere on the conjunctiva and at the limbus, where on resolution they leave characteristic shallow depressions known as Herbert's pits. New vessels (pannus) may be seen at this stage in the cornea, usually at the superior margin, and punctate keratitis may also be a feature. Since symptoms are mild or absent, the disease may not be suspected unless the upper eyelid is everted. Active trachoma affects mainly children in endemic areas. Among older children and adults in such areas, conjunctival fibrosis often develops as the follicles resolve and, if severe, it may distort the upper lid margin, turning it inward (entropion). Lashes rubbing against the globe (trichiasis) cause continuous discomfort and sometimes blindness due to corneal damage.

The World Health Organization (**WHO**) has proposed criteria for the clinical diagnosis of active trachoma and its potentially blinding sequelae and for grading their severity as follows:

1. trachomatous inflammation—follicular (**TF**): five or more follicles, each at least 0.5 mm in diameter, in the upper tarsal conjunctiva;
2. trachomatous inflammation—intense (**TI**): pronounced inflammatory thickening of the tarsal conjunctiva that obscures more than half the normal deep tarsal blood vessels;
3. trachomatous conjunctival scarring (**TS**): easily visible scarring in the tarsal conjunctiva;
4. trachomatous trichiasis (**TT**): at least one eyelash rubbing on the eyeball—evidence of recent removal of inturned eyelashes also graded as trichiasis; and
5. corneal opacity (**CO**): easily visible corneal opacity over the pupil, so dense that at least part of the pupil margin is blurred when viewed through the opacity.

Epidemiology

The reservoir of infection in endemic areas is the eye and possibly the nasopharynx of children with active disease. Active cases tend to cluster by household where there is prolonged intimate contact within the family. The higher prevalence of active disease and scarring in women than in men is probably due to the closer contact between women and children. *C. trachomatis* may be transferred from the eye of one individual to that of another via fingers, fomites, coughing, and sneezing, and by eye-seeking flies. Severe conjunctival scarring probably occurs only among individuals repeatedly exposed to reinfection. The availability and use of water are important determinants of the development of trachoma. When living conditions improve trachoma tends to disappear.

Diagnosis

In trachoma-endemic areas the diagnosis is generally made on clinical grounds, as most cases of follicular conjunctivitis are due to trachoma and laboratory facilities are usually lacking. Trachomatous follicles may be confused with the giant papillas of vernal conjunctivitis, in which pannus may also be seen. A number of viruses, notably adenoviruses, can cause follicular conjunctivitis. Intense cases of trachoma (TI), in which follicles may not be visible, should be distinguished from bacterial conjunctivitis. The diagnosis of trachomatous scarring is usually obvious, as few other conditions cause conjunctival scarring of the upper lid.

Laboratory diagnosis depends on the detection of *C. trachomatis*, which may be found in about 50 per cent of cases of active disease (TF or TI), but in only a minority of cases of scarring disease (TS). The microbiological diagnostic procedures are discussed later in this chapter.

Treatment

Inflammatory trachoma (TF and TI) responds to treatment with antimicrobial agents active against *C. trachomatis* (see Table 2). Until recently, the WHO has recommended 1 per cent topical tetracycline ointment, to be applied to both eyes daily for 6 weeks. This has proved impractical on a wide scale in trachoma-endemic communities. More recently, a single oral dose of azithromycin (20 mg/kg, to a maximum of 1 g) has been shown to be equally effective. When only individual cases are treated, reinfection is usually rapid; treatment of whole communities may reduce the rate of reinfection. Trichiasis and entropion require surgical correction. Several lid operations have been described, but few have been evaluated prospectively. Tarsal rotation is probably the operation of choice.

Prevention

The WHO has launched an initiative for the global elimination of blinding trachoma by the year 2020. The recommended strategy is based on the acronym 'SAFE': Surgery for trichiasis; Antibiotics for the treatment of inflammatory disease and the elimination of the reservoir of infection; promotion of Face washing, and Environmental improvement, to reduce fly populations, both of which are likely to reduce the rate of transmission of ocular *C. trachomatis* infection. In Mexico, children who washed their faces seven or more times per week were less likely to have trachoma than those who washed less often, and this intervention was also effective among rural villagers in Tanzania.

Genital tract infections

Infections of the genital tract due to *C. trachomatis* (Table 1) occur worldwide and, at least in developed countries, are much more common than gonococcal infections. The economic burden on health services due to genital chlamydial infections is enormous; for example, more than 3 billion dollars per year for pelvic inflammatory disease in the United States, based on 1994 incidence data. In Sweden, widespread and effective diagnostic testing, coupled with aggressive contact tracing and treatment, has greatly reduced genital chlamydial infections. This has not been achieved in other developed countries, but screening programmes are being or have been developed and implemented in some.

Non-gonococcal urethritis

C. trachomatis is detectable in the urethra of not more than 50 per cent of men with non-gonococcal urethritis and in up to 25 per cent of those with asymptomatic urethral infections. It is also likely that chlamydiae are a cause of some cases of chronic non-gonococcal urethritis

In women, there is no doubt that chlamydial urethral infection may cause urethritis but, in contrast to men, infection and inflammation are almost always asymptomatic. Thus, the dysuria and frequency of the urethral syndrome are rarely of chlamydial origin.

Prostatitis and epididymo-orchitis

There is no evidence that *C.trachomatis* causes acute symptomatic prostatitis. In chronic abacterial prostatitis diagnosed by the Stamey procedure, biopsy tissues taken transperineally to avoid the urethra have shown chronic inflammation, but chlamydiae have not been detected in them by culture and direct immunofluorescence techniques, although about 10 per cent have proved positive using polymerase chain-reaction technology. These largely negative observations, and the failure to

detect chlamydial antibody, suggest that chlamydiae are not often implicated directly in the chronic disease. However, the possibility cannot be excluded that a portion, at least, of chronic disease is chlamydial in origin, maintained perhaps by immunological means. A predominance of CD8 cells in the tissues is consistent with this notion.

C. trachomatis is responsible for epididymitis primarily in young men (35 years of age or less) in developed countries, being detected in at least one-third of epididymal aspirates. Furthermore, there is a strong correlation between IgM and IgG chlamydial antibodies, measured by microimmunofluorescence, and chlamydia-positive disease. In developing countries, although chlamydiae are important, *Neisseria gonorrhoeae* is still the major cause of acute epididymitis. In patients older than 35 years, an age boundary that, of course, is not strict, epididymo-orchitis tends to be caused by urinary-tract pathogens.

Convincing evidence that chlamydiae have been detected in the testes or that a previous chlamydial urethral infection or asymptomatic chlamydial infection causes male infertility has not been forthcoming.

Bartholinitis, vaginitis, and cervicitis

C. trachomatis has been weakly associated with bartholinitis, but is not regarded as a major cause. Chlamydiae are often detected more frequently in women with bacterial vaginosis than in those without this condition, but there is no evidence that they are causally associated or in any way contribute to the disease. It is apparent that the squamous epithelium of the vagina is not susceptible to chlamydial infection and that the cervix is the primary target for *C. trachomatis*. Indeed, it is a well known cause of mucopurulent/follicular cervicitis, although infection often may be asymptomatic. Women younger than 25 years, unmarried, using oral contraceptives, and who have signs of cervicitis are the most likely to have a chlamydial infection.

An association between cervical chlamydial infection and cervical intraepithelial neoplasia has been seen, but a causal link has not been established.

Pelvic inflammatory disease

Canalicular spread of chlamydiae to the upper genital tract leads to endometritis, which is often plasma-cell associated and sometimes intensely lymphoid. Further spread causes salpingitis, perihepatitis (the Curtis Fitz-Hugh syndrome), sometimes confused with acute cholecystitis in young women, in addition to periappendicitis and other abdominal complaints. Surgical termination of pregnancy or insertion or removal of an intrauterine contraceptive device may predispose to dissemination of the organisms.

Chlamydiae are the major cause of pelvic inflammatory disease in developed countries. Infertility is the outcome in about 10 per cent of such disease and may be the first indication of asymptomatic tubal disease. Fertility is influenced adversely by an increasing number and severity of upper genital tract chlamydial infections and infertility could result from endometritis, blocked or damaged tubes, or perhaps abnormalities of ovum transportation. Other consequences of salpingitis are ectopic pregnancy and chronic pelvic pain.

Other diseases associated with *C. trachomatis*

Adult paratrachoma (inclusion conjunctivitis) and otitis media

Adult chlamydial ophthalmia is distinguished from trachoma because it is caused by serovars D to K of *C. trachomatis* and commonly results from the accidental transfer of infected genital discharge to the eye. Chlamydiae can be detected in conjunctival specimens and in this respect the condition is different from the 'reactive' conjunctivitis seen in Reiter's syndrome (see below), where isolation from the conjunctiva is extremely unusual. Adult chlamydial ophthalmia usually presents as a unilateral follicular conjunctivitis of acute or subacute onset, the incubation period ranging from 2 to 21 days. The features are swollen lids, mucopurulent discharge, papillary hyperplasia due to congestion and neovascularization and later, follicular hypertrophy, and occasionally punctate keratitis. About one-third of patients have otitis media, complaining of blocked ears and hearing loss. The disease is generally benign and self-limited, but pannus formation and corneal scarring may occur unless systemic treatment is given. Patients and their sexual contacts should be investigated for the existence of genital chlamydial infections and managed accordingly.

Arthritis

Arthritis occurring with or soon after non-gonococcal urethritis is termed sexually acquired reactive arthritis (**SARA**); in about one-third of cases, conjunctivitis and other features characteristic of Reiter's syndrome are seen. At least one-third of cases of such disease are initiated by chlamydial infection and *C. trachomatis* elementary bodies and chlamydial DNA and antigen may be detected in the joints. *C. trachomatis* has also been associated in the same way with 'seronegative' arthritis in women. Viable chlamydiae have not been detected in the joints of patients with SARA and the pathogenesis of the disease is probably immunologically based (see below). Despite this, early tetracycline therapy is advocated by some investigators.

Immunocompromised states

C. trachomatis has been isolated from the lower respiratory tract of a few immunocompromised adults with pneumonia, some after renal transplantation, but its role has been obscured by the recovery of other agents from some. However, neither *C. trachomatis* nor *C. pneumoniae* is an important respiratory-tract pathogen in patients with AIDS. Nor does genital chlamydial disease seem to be more widely prevalent or severe in HIV-infected patients and hypogammaglobulinaemic patients do not appear to be especially prone to infection with any of the chlamydial species.

Neonatal infections

Although intrauterine chlamydial infection can occur, the major risk of infection to the infant is from passing through an infected cervix. The proportion of neonates exposed to infection depends, of course, on the prevalence of maternal cervical infection, which varies widely. However, between one-fifth and one-half of infants exposed to *C. trachomatis* serovars D to K infecting the cervix at the time of birth develop conjunctivitis, which occurs usually 1 to 3 weeks after birth. A mucopurulent discharge and occasionally pseudomembrane formation occur, but it is usually self-limited, resolution occurring without visual impairment. If complications do arise, however, they tend to be in untreated infants.

About half of the infants who develop conjunctivitis develop pneumonia, although the latter is not always preceded by conjunctivitis. A history of recent conjunctivitis and bulging eardrums is found in only about half of the cases. Chlamydial pneumonia occurs usually between the fourth and eleventh week of life, preceded by upper respiratory symptoms, and has an afebrile, protracted course in which there is tachypnoea and a prominent, stacatto cough. Hyperinflation of the lungs with bilateral, diffuse, and symmetrical interstitial infiltration and scattered areas of atelectasis are the radiographic findings. The occurrence of serum IgM antibody to *C. trachomatis* in infants with pneumonia is pathognomonic. Children so affected during infancy are more likely to develop obstructive lung disease and asthma than are those who have had pneumonia due to other causes.

The vagina and rectum also may be colonized by *C. trachomatis* at birth. However, vaginal colonization has not been associated with clinical disease, nor has there been evidence for chlamydial gastroenteritis in infants.

Lymphogranuloma venereum

This is a systemic, sexually transmitted disease caused by serovars L1, L2, L2a, and L3 of *C. trachomatis*. These chlamydiae are more invasive than the other serovars and cause disease primarily in lymphatic tissue. Although a small papule or necrotic genital lesion may be the first sign of infection, with the rectosigmoid colon also a primary site, the chlamydiae are soon carried to regional lymph nodes. These enlarge rapidly and inflammation of the capsule causes them to mat together. Multiple minute abscesses form in the parenchyma and in the absence of treatment they may coalesce and form sinus tracts, which rupture through the overlying skin. Scar tissue may obstruct lymphatic flow causing lymphoedema and elephantiasis of the genitalia and strictures, ulcers, and fistulas may develop.

Clinical features

Three stages of infection are usually recognized. After an incubation period of 3 to 21 days, a small, painless, papular, vesicular, or ulcerative lesion develops and disappears spontaneously within a few days without scarring. In men the lesion is on the penis, and in women most commonly on the fourchette, often going unnoticed, especially if it is in the rectum of homosexual men. Extragenital primary lesions on fingers or tongue are rare.

The secondary stage is conventionally separated into inguinal and genitoanorectal syndromes. The former is more common and is usually seen in men as an acute painful inguinal bubo. The lymphadenopathy is unilateral in two-thirds of cases, and rarely may be so extensive that the inguinal mass is cleaved by the inelastic Poupart's ligament—the almost pathognomonic 'groove sign' of the disease. Buboes are accompanied by fever, malaise, chills, arthralgia, and headache and about 75 per cent of them suppurate and form cutaneous draining sinus tracts. In women, the external and internal iliac lymph nodes and the sacral lymphatics are involved more often than are the inguinal lymph nodes. Signs include a hypertrophic suppurative cervicitis, backache, and adnexal tenderness. In both sexes, but more frequently in women, a genitoanorectal syndrome characterized by a haemorrhagic proctitis or proctocolitis may occur. Inflammation is limited to the rectosigmoid colon and is accompanied by fever, a mucopurulent or bloody anal discharge, tenesmus, and diarrhoea. Histopathological changes in such cases may mimic Crohn's disease. The process usually resolves spontaneously after several weeks but, rarely, anal, rectovaginal, rectovesical, and ischiorectal fistulas occur and, late in the disease, a rectal stricture. Rare manifestations of the secondary stage are acute meningo-encephalitis, synovitis, pneumonia, cardiac involvement, and follicular conjunctivitis, which is self-limited.

Lesions of the tertiary stage appear after a latent period of several years. They include genital elephantiasis, occurring predominantly in women as a sequel to the genitoanorectal syndrome and often accompanied by fistula formation, and rectal stricture, which is found almost exclusively in women or homosexual men. Gross ulceration and granulomatous hypertrophy of the vulva ('esthiomene') is very rare. Indeed, all late complications are rare today because of broad-spectrum antibiotics.

Epidemiology

Lymphogranuloma venereum is found worldwide, but its major incidence is limited to endemic foci in sub-Saharan Africa, South-East Asia, South America, and the Caribbean. All races are equally susceptible to infection, but the reported sex ratio is usually greater than 5:1 in favour of men because early disease is recognized much more easily in them. In North America and Europe, the disease is usually diagnosed in travellers, seamen, and military personnel returning from endemic areas, and in male homosexuals. The reservoir of infection is presumed to be asymptomatically infected women and male homosexuals.

Diagnosis

The differential diagnosis of lymphogranuloma venereum includes genital herpes, syphilis, chancroid, donovanosis, extrapulmonary tuberculosis, cat-scratch disease, plague, filariasis, lymphoma, and other malignant diseases. Of these, primary genital herpes can be the most difficult to distinguish. Lymphadenitis of the deep iliac nodes may mimic appendicitis or pelvic inflammatory disease and tuberculosis and certain parasitic and fungal infections of the genital tract cause lymphoedema and elephantiasis of the genitalia that may cause confusion.

The classic Frei skin test is no longer used for diagnosis. Staining of infected tissues to detect elementary bodies or inclusions (see later section on diagnosis) is not often used because the frequent bacterial contamination makes detection difficult. The use of cell culture is preferable, but only 25 to 40 per cent of patients with lymphogranuloma venereum have positive cultures of bubo aspirate, endourethral or endocervical scrapings, or of other infected material. The much more sensitive DNA amplification methods are being used with increasing frequency.

Of the serological tests (see later section on diagnosis), complement fixation is not specific for lymphogranuloma venereum. The microimmunofluorescence test is also not entirely specific, but is the method of choice and antibody titres of 1:1024 or more are not uncommon and can be regarded as diagnostic, particularly in a patient with typical signs and symptoms.

Treatment

Of the several antimicrobial drugs available, oral tetracycline is usually recommended (Table 2) although azithromycin is finding a place. Fever and bubo pain rapidly subside after antibiotic treatment is started, but buboes may take several weeks to resolve. Suppuration and rupture of buboes with sinus formation is usually prevented by antibiotic treatment. Surgical incision and drainage is neither necessary nor recommended. How long treatment needs to be continued to prevent relapse or progression of disease is debated but a minimum of 2 weeks is recommended. Fistulas, strictures, and elephantiasis may require plastic repair but surgery should not be attempted until the patient has had weeks or months of antimicrobial treatment to reduce inflammation and necrosis.

Chlamydia pneumoniae infections

It is interesting that the prototype strains of *C. pneumoniae* were isolated from conjunctival material collected in the mid-1960s from patients in trachoma-endemic areas. It was not until 1983, however, that a third *C. pneumoniae* strain was isolated, this time from the throat of a patient with acute pharyngitis. The two original isolates (TW-183 and IOL-207) were found to be identical serologically and distinct from *C. trachomatis* and *C. psittaci* and, in 1989, *C. pneumoniae* was defined as the third species of the genus *Chlamydia*. At present only one serovar of *C. pneumoniae* has been identified, although minor geographical serovar variations have been described.

Clinical features

Respiratory tract disease

At the outset of acute disease, pharyngitis is often present, more than 80 per cent of patients with lower respiratory-tract disease developing a sore throat. A cough may take some time to develop and fever is uncommon. Bronchitis is associated with some infections and in young adults about 5 per cent of primary sinusitis is associated with *C. pneumoniae*. Mild respiratory infections are probably frequent but, overall, pneumonia has been the most common feature; in mild cases, radiographs usually reveal a unilateral pneumonia, whereas in patients needing hospital care, bilateral pneumonia is quite common. This is often difficult to distinguish clinically from that caused by other micro-organisms, for example *Mycoplasma pneumoniae*.

Arthritis

An exaggerated synovial lymphocyte response to *C. pneumoniae* has been found in some adults with reactive arthritis and *C. pneumoniae* DNA and high titres of specific antibody have been detected in the joints of a few children with juvenile chronic arthritis, suggesting the possibility of a causal role.

Atherosclerosis

Patients with chronic coronary heart disease and acute myocardial infarction were noted first by Finnish investigators and later by others to have antibody to *C. pneumoniae* significantly more often than age-matched controls. The possibility that *C. pneumoniae* infection might be a risk factor for such disease was enhanced by detection of the organisms or their DNA in at least 40 per cent of atheromatous coronary and other major arteries of adults and subjects as young as 15 years. In addition, specific DNA has been found in at least 40 per cent of peripheral blood mononuclear cells, raising the possibility that they transmit the organisms to the arterial wall, atheromatous or otherwise, from the respiratory tract. Inoculation of mice and rabbits with *C. pneumoniae* has initiated or potentiated atherosclerotic-like changes, observations that are provocative but insufficient to determine the significance of the human findings.

Epidemiology

C. pneumoniae organisms are transmitted from person to person, apparently without any intermediate host. Serological evidence indicates that *C. pneumoniae* is widespread and endemic in many areas, although localized epidemics have been recorded in both military and civilian groups in Scandinavia, the United States, the United Kingdom, and elsewhere. *C. pneumoniae* probably causes many mild respiratory infections that were previously thought to be viral in origin and it is also likely that many infections labelled 'human psittacosis/ornithosis' in the past were in reality due to *C. pneumoniae*.

Chlamydia psittaci infections

The *C. psittaci* species comprises a diverse group of organisms that have been isolated from a variety of mammals and frogs and many avian species. Nine serovars have been proposed from mammals and seven from birds, and two biovars from koala bears. The relatively low degree of homology between serovars exhibited in DNA–DNA hybridization analyses signals the possibility of further speciation among organisms currently assigned to the species. This, in fact, has happened with the separation of strains causing pneumonia, polyarthritis, encephalomyelitis, and diarrhoea in cattle and sheep and the constitution of the fourth chlamydial species, *C. pecorum*.

The spectrum of animal diseases caused by *C. psittaci* species includes enteritis, abortion, sterility, pneumonia, and encephalitis, all of which cause economic loss. Occasionally, the organisms are transmitted to humans through contact with infected animals or birds or from contact with faecal materials from an infected source. Psittacosis may be a hazard to those who keep pet birds or who work in poultry processing plants, or in animal husbandry. Many birds are known to harbour the organisms, but psittacine species (parrots), poultry, and pigeons are probably the major sources of human infection.

Clinical features

Human respiratory infection with *C. psittaci* (psittacosis) is equally common in either sex. It is uncommon and mild in childhood and usually affects adults, particularly those in the 30- to 60-year age group. After an incubation period of 1 to 2 weeks, the clinical presentation can vary from a mild influenza-like illness to a fulminating toxic state with multiple organ involvement. The disease may be insidious in onset over a few days or start abruptly with high fever, rigors, and anorexia. Headache occurs in most, a cough, often dry, in over two-thirds, and arthralgia and myalgia in over one-third. Inspiratory crepitations are more common than classic signs of consolidation. Chest radiographs usually show patchy shadowing, most often in the lower lobes. Homogeneous lobar shadowing is less common, and miliary and nodular patterns even less so. Hilar lymphadenopathy has been reported in up to two-thirds of patients and a pleural reaction in more than half, but significant pleural effusions are infrequent. Extrapulmonary complications, mostly rare, include endocarditis, myocarditis, pericarditis, a toxic confusional state, encephalitis, meningitis, tender hepatomegaly, splenomegaly, pancreatitis, haemolysis, and disseminated intravascular coagulation. The advent of superior laboratory tests should not allow disease caused by *C. psittaci* to be confused with that due to *C. pneumoniae*, as occurred in the past.

Ovine *C. psittaci* strains have caused abortion, albeit rarely, in pregnant women, often farmers' wives, after exposure to sheep suffering from enzootic abortion during the lambing season. The feline keratoconjunctivitis agent, isolated from the genital tract of female cats, has caused follicular conjunctivitis in humans similar to that caused by *C. trachomatis* serovars D to K.

Diagnosis of chlamydial infections

The laboratory diagnosis of chlamydial infection depends on detection of the organisms or their antigens or DNA and to a much lesser extent on serology. The procedures mentioned, with some of their advantages and disadvantages, are summarized in Table 3. Certain swabs, for example those that are cotton tipped, are superior to others, and swabs provided in commercial enzyme immunoassay kits may be toxic if used for collecting specimens for culture. Examination of two or more consecutive swabs from patients rather than one improves the chlamydial detection rate and this may be achieved in women by pooling cervical and urethral specimens. However, in recent times attention has turned to the use of 'first-catch' urine specimens, which were ignored for years because they were found not to be suitable for chlamydial culture. Nevertheless, they are unquestionably valuable samples from both men and women, provided that the centrifuged deposits are tested by molecular methods. The same comment applies to the use of meatal samples in men and of vulvar/vaginal samples.

Culture and staining of chlamydia

The growth of chlamydiae about 40 years ago in cultured cells, rather than in embryonated eggs, revolutionized both their detection and chlamydial research. *C. pneumoniae* is particularly difficult to isolate and this may be facilitated by using a line of human lung cells. The method of detection used widely for *C. trachomatis* involves the centrifugation of specimens on to cycloheximide-treated McCoy cell monolayers. Inoculation of cell cultures is followed by incubation and staining with a fluorescent monoclonal antibody or with a vital dye, usually Giemsa, to detect inclusions; one blind passage may increase sensitivity. However, the cell-culture technique is no more than 70 per cent sensitive and is slow and labour intensive, drawbacks that have hastened the development of non-cultural methods .

Staining of epithelial cells in ocular and genital specimens with vital dyes was used first to detect chlamydial inclusions, but the method is insensitive and often non-specific. Papanicolaou-stained cervical smears provide an excellent example of these drawbacks. In contrast, detection of elementary bodies by using species-specific fluorescent monoclonal antibodies is rapid and, for *C. trachomatis* oculogenital infections, sensitivities ranging from 70 to 100 per cent and specificities from 80 to 100 per cent have been achieved. Skilled observers, capable of detecting a few elementary bodies, even one, provide values at the top of these ranges. However, the test is most suited for dealing with a few specimens and for confirming positive results obtained with other tests.

Enzyme immunoassays and DNA amplification techniques

The popularity of enzyme immunoassays that detect chlamydial antigens is due to their ease of use and not to their sensitivity. Indeed, it is rarely possible to detect small numbers of chlamydial organisms (less than 10) of whatever species. Since at least 30 per cent of genital swab specimens and a larger proportion of urine samples from women contain such small numbers, some chlamydia-positive patients are misdiagnosed. Despite this, immunoassays still occupy a diagnostic niche largely because of cost saving.

By enabling enormous amplification of a DNA sequence specific to the chlamydial species, polymerase chain reaction (PCR), ligase chain reaction (LCR), transcription mediated, and some other molecular assays have overcome the problem of poor sensitivity and may provide evidence for the existence of chlamydiae in chronic or treated disease when viable or intact organisms no longer exist. These sensitive assays have replaced culture as the 'gold standard' and have a place not only in research, but also in routine diagnosis and in promoting and maintaining effective screening programmes.

Serological tests

The complement fixation test tends not to distinguish between the chlamydial species and, therefore, is used infrequently. Most of the pertinent diagnostic information has come through the use of the microimmunofluorescence test by which class-specific antibodies (IgM, IgG, IgA, or secretory) may be measured. However, a fourfold or greater increase in the titre of antibody (IgM and/or IgG) is detected infrequently so that the value of serology in the diagnosis of chlamydial infections in individual patients is limited. A good correlation has been found between the presence of IgG and/or IgA antibody in tears and the isolation of *C. trachomatis* from the conjunctiva in endemic trachoma and adult ocular paratrachoma. In genital infections, serum antibodies are found frequently in the absence of a current chlamydial infection of the cervix, so that reliance cannot be put on a single serum or local IgA-specific antibody titre to denote a current infection. In pelvic inflammatory disease, especially in the Curtis Fitz-Hugh syndrome, antibody titres tend to be higher than in uncomplicated cervical infections. A very high IgG antibody titre, for example 512 or greater, suggests causation in pelvic disease, but high titres do not always correlate with detection of chlamydiae and are associated more with chronic or recurrent disease. However, specific *C. trachomatis* IgM antibody in babies with pneumonia is pathognomonic of chlamydia-induced disease.

In primary respiratory infections with *C. pneumoniae*, IgM antibody is considered to develop within a few weeks and IgG antibody by 2 months. In repeat infections, IgG but not IgM antibody develops more rapidly and to a greater titre than before. However, when only a single serum is available, it may be difficult to interpret information complicated by cross-reacting antibodies to the other species. Only in children is the finding of *C. pneumoniae* antibody in a single serum sample an assurance of infection with this species. Although the complement fixation test has been used in the past to diagnose lymphogranuloma venereum and psittacosis, as indicated above it is unwise to do so because of its lack of specificity.

Treatment of chlamydial infections

Chlamydiae are particularly sensitive to tetracyclines and macrolides, but also to a variety of other drugs. The rifampicins are probably more active than the tetracyclines *in vitro* but there is evidence for chlamydial resistance to the rifampicins which, in any case, are usually reserved for mycobacterial infections. Tetracycline resistance has been reported but is insufficiently widespread to cause a problem clinically. However, vigilance should be kept for resistant strains that might jeopardize clinical practice, particularly as the move away from cultural diagnostic procedures has made their detection less easy. Of the macrolides,

erythromycin is used most often, particularly to treat chlamydial infections in infants, young children, and in pregnant and lactating women. Azithromycin in a single dose has gained popularity because it seems to be effective and enhances compliance. Other alternatives, such as some of the quinolones, particularly ofloxacin, are effective but have not found regular use.

More detailed recommendations for dose and duration of antibiotic treatment are presented in Table 2. The principle of giving systemic treatment as well as topical to eradicate nasopharyngeal carriage in trachoma applies also in neonatal chlamydial conjunctivitis, where topical treatment provides no additional benefit. Oral erythromycin should be given to treat the conjunctivitis and to prevent the development of pneumonia. Azithromycin in a single oral dose (20 mg/kg) has been shown to be as effective as 6 weeks of topical tetracycline for active trachoma and may well be the drug of choice. Azithromycin as a single 1-g oral dose has also been shown to be effective in treating non-gonococcal urethritis. In complicated genital tract infections such as epididymo-orchitis and pelvic inflammatory disease, treatment will almost certainly be needed before a microbiological diagnosis can be established, following which additional broad-spectrum antibiotic cover may be required. In the case of *C. pneumoniae* and *C. psittaci* infections, treatment follows the same principles as for *C. trachomatis* infections. Finally, it should be kept in mind that treatment is likely to be most effective when given over a long rather than short time, suboptimal doses are avoided, compliance is strict, and when, in the case of genital infections, partners of patients are also treated.

Immune response and pathogenesis

The immune response to chlamydial infections may be protective or damaging, much of the pathology being immunologically mediated. The hallmark of chlamydial infection, whatever the anatomical site, is the lymphoid follicle. Follicles contain typical germinal centres, consisting predominantly of B lymphocytes, with T cells, mostly CD8 cells, in the parafollicular region. Between follicles the inflammatory infiltrate contains plasma cells, dendritic cells, macrophages, and polymorphonuclear leucocytes in addition to T and B lymphocytes. The late stage of chlamydial infection is characterized by fibrosis, seen typically in trachoma and pelvic inflammatory disease. T lymphocytes are also present and outnumber B cells and macrophages. Biopsies taken from patients with cicatricial trachoma and persisting inflammatory changes show a predominance of CD4 cells, but those from patients in whom inflammation has subsided contain mainly CD8 cells.

Repeated ocular infection by chlamydiae induces progressively worse disease with a diminished ability to isolate the organisms, features noted both naturally and experimentally. There is also experimental evidence that such events occur in the genital tract. For example, primary inoculation of the oviducts of pig-tailed macaques with *C. trachomatis* produced a self-limiting salpingitis with minimal residual damage, whereas repeated tubal inoculation caused hydrosalpinx formation with adnexal adhesions. In the cynomolgus monkey model, a similar exaggerated inflammatory response was effected by the genus-specific 57-kDa protein that has sequence homology with the GroEL heat-shock protein of *Escherichia coli*. It is thought that the damaging sequelae of chlamydial infections, such as scarring in trachoma, tubal adhesions following pelvic inflammatory disease, and reactive arthritis consequent to urethritis, may result from soluble mediators of inflammation in response to the 57-kDa protein. Thus, it is possible that interferon-g secreted by lymphocytes from immune subjects, together with other cytokines, particularly those that stimulate fibroblast activity, such as interleukin 1 and tumour necrosis factor-b, may play a part in the scarring process.

The epidemiology of trachoma suggests that protective immunity follows natural infection, as active disease is uncommon in adults in endemic areas, and *C. trachomatis* can rarely be isolated from them. Similarly, the chlamydial isolation rate for men with non-gonococcal urethritis is lower in those who have had previous episodes. Furthermore, women who have had cervical chlamydial infections accompanied by IgM and IgG antibodies to *C. trachomatis* are less likely to develop salpingitis than those without such antibodies. These observations and the results of animal experiments indicate that chlamydial infection of the eye, the genital tract, and also the respiratory tract provides moderate resistance to reinfection. Nevertheless, attempts to develop an effective vaccine against any of the chlamydial species have, so far, been unsuccessful, although DNA vaccines hold out some hope.

Mycoplasmas

D. Taylor-Robinson

Characteristics of mycoplasmas

Mycoplasmas, originally called pleuropneumonia-like organisms (**PPLO**), are the smallest free-living micro-organisms. They lack a rigid cell wall seen in other bacteria so that they are resistant to penicillins and other antimicrobials which act on this structure. Instead, they are bounded by a pliable unit membrane (Fig. 1), which encloses the cytoplasm, DNA, RNA, and other metabolic components necessary for propagation in cell-free media. Despite their general similarity, mycoplasmas comprise a heterogeneous group of micro-organisms that differ from one another in DNA composition, nutritional requirements, metabolic reactions, antigenic composition, and host specificity. Taxonomically, mycoplasmas are divided into four orders, namely the Mycoplasmatales, the Entomoplasmatales comprising those from insects and plants, the Acholeplasmatales, which do not require sterol for growth, and the oxygen-sensitive, strictly anaerobic Anaeroplasmatales, one genus of which also does not need sterol. The mycoplasmas isolated commonly from humans belong to the family Mycoplasmataceae within the order Mycoplasmatales. This family comprises the genus *Mycoplasma*, which contains organisms that metabolize glucose or arginine or both, but not urea, and the genus *Ureaplasma*, the organisms of which hydrolyse urea uniquely. The latter originally were termed T-strains or T-mycoplasmas because of the tiny (T) colonies they form on agar medium, in contrast to the larger characteristic 'fried-egg'-like colonies produced by most other mycoplasmas (Fig. 2).

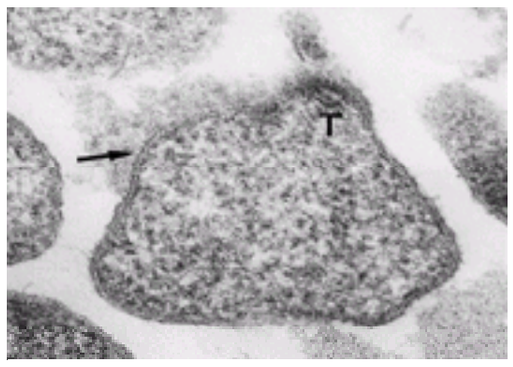

Fig. 1 Electron micrograph of *M. pulmonis* (murine origin), illustrating that the organism does not have a bacterial cell wall but has a trilaminar unit membrane (arrow); also note what appears to be a terminal structure (T). × 66 000.

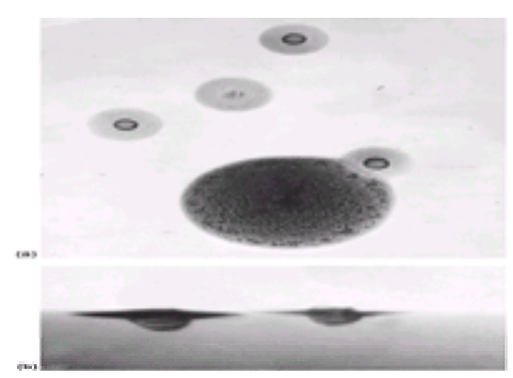

Fig. 2 (a) 'Fried-egg'-like mycoplasma colonies (one not well formed) and a larger bacterial colony. Transmission light microscopy, × 43. (b) Section through mycoplasma colonies illustrating growth in the depth of the agar. × 78.

The small size of the mycoplasma genome restricts their metabolic capabilities. Nevertheless, apart from their importance in humans, certain mycoplasma species are of economic importance because of the pneumonia, arthritis, keratoconjunctivitis, and mastitis they cause among livestock and poultry in Africa, Australia, and other parts of the world. Furthermore, a number of species are a laboratory nuisance as occult contaminants of cell cultures.

Occurrence of mycoplasmas in man

Sixteen mycoplasma species have been isolated from humans, but only 14 constitute the normal flora or behave as pathogens (Table 1). Most of them are found in the oropharynx. There is little information, as yet, about the distribution or significance of *M. penetrans*, *M. pirum*, and *M. spermatophilum*.

Respiratory infections

The relation between mycoplasmas and respiratory disease

M. pneumoniae is the most important mycoplasma found in the respiratory tract (see below), most of them behaving as commensals (Table 1). *M. genitalium* was found originally in the male genitourinary tract but was subsequently isolated from a few respiratory specimens, which also contained *M. pneumoniae*. However, the significance of *M. genitalium* in the respiratory tract remains to be determined. *M. fermentans* has been detected in the throat more often than hitherto because of the use of the polymerase chain reaction (**PCR**) (see later) and has been recovered from adults with an acute influenza-like illness, which sometimes deteriorates rapidly with development of an often fatal respiratory distress syndrome. *M. hominis*, on the other hand, shows little virulence. Despite it causing a mild exudative pharyngitis in adult male volunteers given large numbers of organisms orally, it has not been shown to cause naturally occurring sore throats in children or adults.

In the late 1930s, non-bacterial pneumonias were first recognized and brought under the heading of primary atypical pneumonia to distinguish them from typical lobar pneumonia. Gradually, primary atypical pneumonia was recognized to be aetiologically heterogeneous and, in one variety, cold agglutinins often developed. It was from this form of disease that an infectious agent was isolated in embryonated eggs. This micro-organism, the 'Eaton agent', produced pneumonia in cotton rats and hamsters, and was thought first to be a virus. However, this was seriously doubted when it was found to be affected by chlortetracycline and gold salts, and its mycoplasmal nature was established finally by cultivation on a cell-free agar medium. The agent was subsequently called *M. pneumoniae* and its ability to cause respiratory disease was established fully by studies based on isolation, serology, volunteer inoculation, and vaccine protection.

M. pneumoniae disease manifestations

M. pneumoniae produces a spectrum of effects ranging from inapparent infection and mild, afebrile, upper respiratory-tract disease to severe pneumonia. Clinical manifestations are often not sufficiently distinctive to permit an early definitive diagnosis of mycoplasmal pneumonia. Indeed, this shares the features of other non-bacterial pneumonias in that general symptoms, such as malaise and headache, often precede chest symptoms by 1 to 5 days, and radiographic examination frequently reveals evidence of pneumonia before physical signs, such as rales, become apparent. Usually, only one of the lower lobes is involved and the radiograph most often shows patchy opacities. About 20 per cent of patients suffer bilateral pneumonia, but pleurisy and pleural effusions are unusual. The course of the disease is variable but often protracted. Thus, cough, abnormal chest signs, and changes in the radiograph may persist for several weeks and relapse is a feature. The organisms may also persist in respiratory secretions despite antibiotic therapy, particularly in patients with hypogammaglobulinaemia, where excretion may continue for months or years rather than weeks. Although a few very severe infections have been reported, occurring usually in patients with immunodeficiency or sickle-cell anaemia, death has been rare. In children, infection has been characterized occasionally by a prolonged illness with paroxysmal cough followed by vomiting, thus simulating the features of whooping cough.

Extrapulmonary manifestations

Disease caused by *M. pneumoniae* is limited usually to the respiratory tract, but various extrapulmonary conditions may occur during the course of the respiratory illness or as a sequel to it. These complications and an estimation of their frequency are shown in Table 2. Whether any of them might be due to *M. genitalium* is a moot point. Haemolytic anaemia with crisis is brought about by the development and action of cold agglutinins (anti-I antibodies), the organisms apparently altering the I antigen on erythrocytes sufficiently to stimulate an autoimmune response. It is possible that some of the other clinical conditions, such as the neurological complications, may arise in a similar way. However, invasion of the central nervous system cannot be discounted as *M. pneumoniae* has been isolated from cerebrospinal fluid.

Microbiological diagnosis of *M. pneumoniae* infection

This depends on detection by culture or molecular methods and/or serology. The usual medium employed for isolation of *M. pneumoniae* consists of PPLO broth, 20 per cent horse serum, and 10 per cent (v/v) fresh yeast extract (25 per cent w/v). However, a more sensitive medium (SP4) is that used first for the isolation of spiroplasmas, comprising a conventional mycoplasma broth medium with fetal calf serum and a tissue-culture supplement. Either medium is supplemented with a broad-spectrum penicillin, and glucose, with phenol red as a pH indicator. The fluid medium, inoculated with sputum, throat washing, pharyngeal swab, or other specimen, is incubated at 37 °C and a colour change (red to yellow), which occurs usually within 4 to 21 days, signals the fermentation of glucose (Table 1), with production of acid, owing to multiplication of the organisms. This preliminary identification may be confirmed after subculturing to agar medium, usually by demonstrating inhibition of colony development around discs impregnated with specific antiserum (Fig. 3) or by immunofluorescence of colonies with an *M. pneumoniae*-specific antibody.

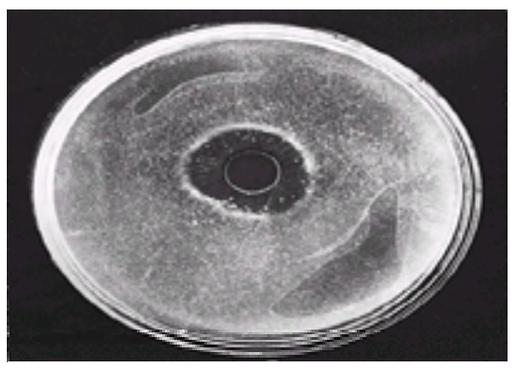

Fig. 3 Mycoplasma identification by agar growth inhibition. Colony development inhibited around a filter-paper disc impregnated with specific antiserum. Note also antibody–antigen precipitation at edge of inhibition zone.

Culture and identification are slow, but rapid PCR determination of *M. pneumoniae* positivity and then continued culture of only those specimens that are PCR-positive makes for a speedier diagnosis. However, this approach, or the use of the PCR to test specimens directly, is not routine, reliance still being placed on serology for diagnosis. Testing by complement fixation is undertaken in many laboratories and a fourfold or greater rise in antibody titre with a peak at about 3 to 4 weeks after the onset of disease is said to occur in about 80 per cent of cases and be indicative of a recent infection. A titre of 1:128 or greater in a single serum is suggestive but not proof of infection in the previous few weeks or months; a fourfold or greater fall in antibody titre, perhaps over 6 months, may be helpful but, sometimes, may be difficult to relate to a particular prior illness. It must be remembered that the complement-fixation test does not distinguish between *M. pneumoniae* and *M. genitalium* and the occasional occurrence of the latter in the respiratory tract may jeopardize a specific diagnosis of *M. pneumoniae* infection. More specific, perhaps, is the microimmunofluorescence test in which IgM antibody is sought; its presence provides some confidence in making an accurate diagnosis of a current infection or one within the previous few weeks. The same comment applies to a commercially available enzyme immunoassay specific for IgM. Cold agglutinins, detected by agglutination of O Rh-negative erythrocytes at 4 °C, develop in about half the patients and a titre of 1:128 or greater is suggestive of a recent *M. pneumoniae* infection. However, such agglutinins are occasionally induced by a number of other conditions, but the ability of *M. genitalium* to do so is unknown.

Epidemiology of *M. pneumoniae* infections

The consequence of infection depends on age, about a quarter of infections in persons 5 to 15 years old resulting in pneumonia, with about 7 per cent of infections in young adults doing so. Thereafter, pneumonia is even less frequent, but generally is more severe the older the patient.

Although *M. pneumoniae* causes inapparent and mild upper respiratory-tract infections more commonly than severe disease, it is responsible for only a small proportion of all upper respiratory-tract disease, most of it being of viral or streptococcal aetiology. It plays a relatively greater part in producing lower respiratory-tract disease together with *Chlamydia pneumoniae* and various other bacteria. Thus, in the United States, it has been calculated that in a large general population, the proportion of all pneumonias due to *M. pneumoniae* is about 15 to 20 per cent, and in certain populations, for example military recruits, it has been responsible for as much as 40 per cent of acute pneumonic illness.

M. pneumoniae infections have been reported from every country where appropriate diagnostic tests have been undertaken. Infection is endemic in most areas and occurs during all months of the year, with a predilection for late summer and early autumn. However, epidemic peaks have been observed about every 4 to 7 years in some countries. The incubation period ranges from 2 to 3 weeks and spread from person to person occurs slowly, usually where there is continual or repeated close contact, for example in a family.

Immunopathological factors in the development of *M. pneumoniae* pneumonia

Adherence of *M. pneumoniae* organisms to respiratory mucosal epithelial cells (Fig. 4) is a crucial factor in the pathogenesis of disease. After cytadsorption, mediated by P1, P30, and possibly up to seven other proteins on the surface of the organisms, immune mechanisms are important in the development of *M. pneumoniae* pneumonia in humans, which rarely causes death. Thus, the histopathological picture is derived mainly from infection in other animals. The pneumonic infiltrate is predominantly a peribronchiolar and perivascular accumulation of lymphocytes, most of which are thymus dependent (Fig. 5). The importance of cell-mediated immune mechanisms is indicated by the fact that immunosuppression in hamsters results in ablation of the pneumonia or a decrease in its severity. The development of a cell-mediated immune response to *M. pneumoniae* has been shown further by positive lymphocyte transformation, macrophage migration inhibition, and delayed-hypersensitivity skin tests. A polysaccharide–protein fraction of the organisms is involved in this response rather than the glycolipid that is the main antigenic determinant in complement-fixation and other serological reactions. The initial lymphocyte response is followed by a change in the character of the bronchiolar exudate, with polymorphonuclear leucocytes and macrophages predominating. The rather slow development of these events on primary infection contrasts with an accelerated and often more intense host response seen on reinfection. To at least some extent, therefore, the pneumonia caused by *M. pneumoniae* is an immunopathological process. Children of 2 to 5 years of age often possess mycoplasmacidal antibody, suggesting infection at an early age and the notion that the pneumonia that occurs in older persons is an immunological over-response to reinfection, the lung being infiltrated by previously sensitized lymphocytes.

Treatment

M. pneumoniae, like other mycoplasmas, is sensitive to the tetracyclines and apparently more sensitive to erythromycin than the other mycoplasmas of human origin. It is also inhibited by the newer macrolides, such as clarithromycin and azithromycin, and the newer quinolones, such as sparfloxacin. The value of tetracyclines was shown first in a controlled trial of dimethylchlortetracycline in United States marine recruits, a dose of 300 mg three times daily for 6 days significantly reducing the duration of fever, pulmonary infiltration, and other signs and symptoms. Planned trials are the most favourable for determining the value of antimicrobials but in civilian practice they prove less effective, probably because disease is often well established before treatment is instituted. Despite this, treatment with an antimicrobial is worthwhile. For pregnant women and children it is advisable to use erythromycin rather than a tetracycline, and the former has sometimes proved more effective than a tetracycline in adults. Successful treatment of clinical disease, however, is not always accompanied by early eradication of the organisms from the respiratory tract, probably because they can become intracellular and the drugs only inhibit their multiplication and do not kill them. These are possible reasons for relapse in some patients and plausible ones for recommending a 2- to 3-week course of treatment. It is a moot point whether early treatment prevents some of the complications but, nevertheless, it should commence as soon as possible. As laboratory confirmation of *M. pneumoniae* infection sometimes may be slow, it would seem wise to start antimicrobial treatment on the basis of the clinical evidence and a suggestive antibody titre in a single serum sample despite the drawbacks, mentioned previously, of making a diagnosis serologically.

The true value of corticosteroids is in doubt, although, in conjunction with antimicrobials, they appear to have been helpful in patients with severe pneumonia and erythema multiforme.

Prevention

M. pneumoniae infection or disease may occur despite high titres of serum mycoplasmacidal antibody. Furthermore, mycoplasmal infection of the respiratory tract of laboratory animals may stimulate only a weak antibody response and yet induce greater resistance to reinfection and disease than parenteral inoculation with organisms that stimulate much higher titres of serum antibodies. Such observations have led to the belief that local immune factors are crucial in resistance. The correlation between the resistance of adult volunteers to *M. pneumoniae* disease and the presence of IgA antibody in respiratory secretions is consistent with this contention. This antibody could provide the first line of defence by preventing attachment of the organisms to respiratory epithelial cells.

So far as vaccination is concerned, the efficacy of formalin-inactivated *M. pneumoniae* vaccines in preventing pneumonia caused by this mycoplasma has ranged from 28 to 67 per cent in field trials. The failure of some killed *M. pneumoniae* vaccines to protect fully may have been due to poor antigenicity, but others induced serum antibody levels similar to those that develop after natural infection. This suggests that the relatively poor protection afforded by the killed vaccines may have been due to their inability to stimulate cell-mediated immunity and/or local antibody. With local antibodies in mind, live attenuated vaccines, particularly those based on temperature-sensitive mutants of *M. pneumoniae*, were developed. The organisms could multiply at the temperature of the upper, but not the lower, respiratory tract and some vaccines produced pulmonary infection in hamsters without causing pathological changes, and induced significant resistance to subsequent challenge with virulent wild strains of *M. pneumoniae*. However, because the same mutants produced some disease in human volunteers they were considered unacceptable for general human use. Recombinant DNA vaccines involving P1 and other proteins, or a recombinant vaccine developed by cloning a component of the *M. pneumoniae*

P1 gene into an adenovirus vector may offer greater success.

Chronic respiratory disease

As mycoplasmas of animals are frequently involved in chronic illnesses, the possible role of mycoplasmas in human chronic respiratory disease, particularly chronic bronchitis, is worthy of consideration.

M. pneumoniae frequently persists in the respiratory tract long after clinical recovery and occasionally the respiratory disease it causes has a protracted course. Furthermore, tracheobronchial clearance is very much reduced soon after infection and there is a tendency for slower clearance, in comparison with that in healthy subjects, even 1 year later. Despite this, there is no evidence that *M. pneumoniae* is a primary cause of chronic bronchitis, or that it is responsible for maintaining chronic disease other than by possibly causing some acute exacerbations. This is perhaps the case in some patients, experiencing an acute exacerbation of chronic bronchitis, from whom *M. pneumoniae* has been isolated and in whom a serological response has been seen.

There is no doubt that *M. salivarium*, *M. orale*, and perhaps other mycoplasmas present in the oropharynx of healthy persons spread to the lower respiratory tracts of some who suffer from chronic bronchitis. There is no substantial evidence that these mycoplasmas are a cause of acute exacerbations, but antibody responses to them occur in association with such exacerbations more frequently than at other times, which suggests that the organisms are more antigenic during exacerbations. It is tempting to think that this is probably due to increased mycoplasmal multiplication and participation in tissue damage brought about primarily by viruses and bacteria, and that in this way the mycoplasmas may play some part in perpetuating a chronic condition.

Mycoplasmas in the vagina are transmitted rarely to the infant *in utero*, but often during birth and *U. urealyticum* organisms (ureaplasmas), in particular, may be isolated from the throats and tracheal aspirates of some neonates. Ureaplasma-infected infants of very low birth-weight (under 1000 g), have died or have developed chronic lung disease twice as often as uninfected infants of similar birth weight or those of over 1000 g. *M. hominis* has also been implicated in pneumonia soon after birth, albeit even more rarely. However, whether these organisms are a cause of the disease in their own right or only together with the various bacteria that are associated with maternal bacterial vaginosis is unresolved. It remains to be seen whether *M. genitalium* might be involved, a possibility that exists because it has been detected in the vagina and cervix.

Genitourinary and related infections

Clinical conditions in which there is evidence strongly suggesting that mycoplasmas have an aetiological role, at least in part, will be considered in some detail. Other diseases in which the role of mycoplasmas is minimal, or the evidence for a mycoplasmal cause is weak and/or contentious, are mentioned briefly. All are summarized in Table 3.

Non-gonococcal urethritis and complications

There have been many studies concerned with the role of large-colony-forming mycoplasmas. It is clear that most of them cannot be considered as causes of non-gonococcal urethritis because they are isolated so rarely from the genitourinary tract either in health or disease (Table 1). However, *M. genitalium* (Fig. 6a) is associated strongly with acute non-gonococcal urethritis, having been detected by use of the PCR in about 25 per cent of such cases compared with a significantly smaller proportion (about 6 per cent) of healthy controls, and almost independently of *Chlamydia trachomatis.* Experimentally, it also causes urethritis in male chimpanzees and, like *M. pneumoniae*, adheres to and enters epithelial cells (Fig. 6b). Such a location could, at least, partially protect *M. genitalium* from antimicrobials and account for its occurrence in about one-quarter of men with persistent or recurrent non-gonococcal urethritis, in some of whom it may be a cause. Although *M. hominis* has been isolated from about 20 per cent of patients with acute non-gonococcal urethritis, it has not been implicated as a cause. Nevertheless, the fact that some cases are associated with bacterial vaginosis in sexual partners in whom *M. hominis* organisms are found in large numbers should not be overlooked. The role of ureaplasmas in non-gonococcal urethritis has been contentious for many years and is discussed below.

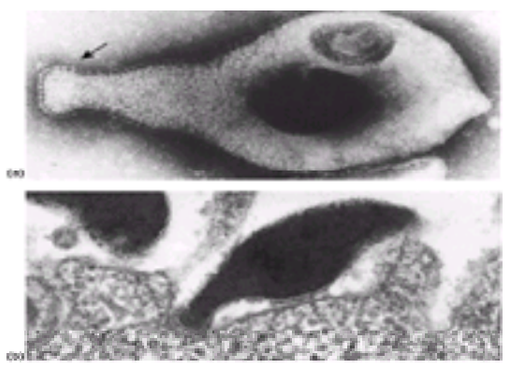

Fig. 6 (a) Electron micrograph of *M. genitalium*, negatively stained, to show flask-shaped appearance and terminal specialized structure (arrow). × 90 000. (Reproduced from Tully *et al.*, 1983, *International Journal of Systematic Bacteriology* **33**, 387, with permission.) (b) Electron micrograph of *M. genitalium* adhering to Vero cell by the terminal structure. × 60 000. (Reproduced from Tully *et al.*, 1983, *International Journal of Systematic Bacteriology* **33**, 387, with permission.)

The results of most studies, based on qualitative estimations, have failed to demonstrate a significant difference between the prevalence of ureaplasmas in men with or without acute non-gonococcal urethritis. However, if ureaplasmas are involved in the pathogenic process, it would be reasonable to expect them to be present in larger numbers in men with disease than if they were behaving only as commensals; a few workers have provided quantitative data to support this idea. In addition, some patients with hypogammaglobulinaemia develop a prolonged urethrocystitis in which persistent ureaplasmal infection seems to be responsible. In support of ureaplasmal pathogenicity in non-gonococcal urethritis are the results of several antimicrobial trials. For example, in one of these a larger proportion of patients responded to minocycline (active against ureaplasmas and *C. trachomatis*) than to rifampicin (active against *C. trachomatis* only), and those infected with ureaplasmas failed to respond to rifampicin significantly more often than those who were not infected. Although these findings might be difficult to explain if ureaplasmas had no involvement in non-gonococcal urethritis, the failure to take *M. genitalium* into account tends to jeopardize this conclusion. About 10 per cent of ureaplasmas are resistant to tetracyclines and the urethritis of patients infected by them sometimes responds only to treatment with antimicrobials, such as erythromycin, to which the organisms are susceptible.

Finally, some ureaplasma strains, unpassaged in the laboratory, produced a mild urethritis and an antibody response in male chimpanzees inoculated intraurethrally, the disease responding to tetracycline therapy. Furthermore, four investigators inoculated themselves intraurethrally and each developed urethritis. In one detailed study, two of them received cloned *U. urealyticum*, serotype 5, which had been isolated from a patient with acute non-gonococcal urethritis in whom no other potentially pathogenic micro-organisms could be detected, although *M. genitalium* was not sought at that time. Both developed symptoms and signs of urethritis which responded to treatment with minocycline. The results of the most recent volunteer experiment suggest that ureaplasmas may cause disease the first few times they gain access to the urethra but later insults result in colonization without disease, accounting perhaps for their frequent occurrence in the urethra of healthy men.

Ureaplasmas have been recovered from the urethra and directly from epididymal aspirate fluid, accompanied by a specific antibody response, in a patient with acute non-chlamydial, non-gonococcal epididymitis, and they may be a rare cause. *M. genitalium* has not been sought. Information suggesting that the prostate becomes infected during the course of an acute ureaplasmal infection of the urethra is scanty, although ureaplasmas have been isolated more frequently and in greater numbers from patients with acute urethroprostatitis than from controls, and most of those with more than 10^3 organisms in expressed prostatic fluid responded to tetracycline therapy. In contrast, ureaplasmas have not been found, and *M. genitalium* only rarely, in prostatic biopsy specimens from patients with chronic abacterial prostatitis, and, in most studies, *M. hominis* has not been associated with prostatitis of any kind.

Pyelonephritis

M. hominis has been isolated, sometimes in pure culture, from the upper urinary tract of almost 10 per cent of patients with acute pyelonephritis. In addition, antibody

to *M. hominis*, measured by indirect haemagglutination, has been demonstrated in serum and urine of some of these patients. In contrast, the mycoplasma has not been found in the upper urinary tract of patients with non-infectious urinary-tract diseases, nor has antibody been detected in their urine. These data have not been confirmed recently, but they suggest that *M. hominis* causes a few cases of acute pyelonephritis or acute exacerbations of chronic pyelonephritis and that ureaplasmas are involved less often if at all.

Pelvic inflammatory disease

Micro-organisms in the vagina and lower cervix may ascend to and cause inflammation of the fallopian tubes and adjacent pelvic structures. Like non-gonococcal urethritis, non-gonococcal pelvic inflammatory disease does not have a single cause and the possibility that infection by genital mycoplasmas might be one cause has engaged the attention of numerous investigators.

M. hominis has figured prominently among reports of the isolation of large-colony-forming mycoplasmas from inflamed fallopian tubes, tubo-ovarian abscesses, and pelvic abscesses or fluid. Swedish workers collected specimens by laparoscopy and found *M. hominis* in the tubes of about 10 per cent of women with salpingitis but not in those of women without signs of the disease, an observation that has found some support with investigators in the United Kingdom.

It is likely, but not certain, that this happens mostly when large numbers of *M. hominis* organisms occur in the vagina as a consequence of bacterial vaginosis. The same comment applies to hysterosalpingography, which may occasionally stimulate inflammation of the fallopian tubes in women who carry *M. hominis* in the lower genital tract.

Ureaplasmas have been studied less intensively, but they have been isolated directly from the fallopian tubes of a very small proportion of patients with acute salpingitis, from pelvic fluid, and from a tubo-ovarian abscess. *M. pneumoniae* is reported to have been isolated also from such an abscess and from the cervix. The significance of these findings is unclear but it would seem that ureaplasmas, at least, are of little importance . Examination of specimens for *M. genitalium* by PCR technology is needed to establish whether it is involved in pelvic inflammatory disease, which is possible since it has been found in the cervix.

Antibody to *M. hominis*, measured by the indirect haemagglutination technique, was found by Swedish workers in about half the patients they studied with salpingitis, but in only 10 per cent of healthy women. Furthermore, a significant rise or fall in antibody titre occurred during the course of disease in more than half of the women who had *M. hominis* in the lower genital tract. Others found that patients with gonococcal pelvic inflammatory disease responded serologically to *M. hominis* more often than those without such disease; they suggested that damage incurred by the gonococci was a factor in the serological response and questioned the primary role of *M. hominis*. However, a response to *M. hominis* has been seen quite often in women in whom gonococci are not the cause of pelvic inflammation. In addition, a significant antibody response to *M. genitalium* has been detected in about one-third of women with pelvic inflammatory disease in whom antibody responses to *M. hominis* and *C. trachomatis* could not be detected. In contrast, antibody responses to *U. urealyticum* have been detected rarely, consistent with the impression that ureaplasmas are of little importance in acute pelvic inflammatory disease.

Fallopian-tube organ cultures, in which the tissues are maintained in a condition similar to that *in vivo*, are particularly useful in assessing the effect of micro-organisms. In such cultures, gonococci destroy the epithelium, and *M. genitalium* causes some damage, whereas *M. hominis* organisms, although multiplying, produce no more than swelling of some of the cilia. No damage has been caused by ureaplasmas of human origin. This differential effect may be a true reflection of the pathogenic potential of these micro-organisms *in vivo*. However, failure to demonstrate damage does not mean necessarily that the organisms are avirulent, because organ-culture studies do not account for the role of the immune system in pathogenesis. Studies in intact animals may be helpful in elucidating this aspect. It is of interest, therefore, that the introduction of *M. hominis* into the oviducts of grivet monkeys and *M. genitalium* into the oviducts of these monkeys, as well as those of marmosets, resulted in a self-limited acute salpingitis and parametritis with an antibody response, whereas ureaplasmas had no effect.

These various data indicate that *M. hominis* and perhaps *M. genitalium* are likely to have a role in some cases of acute pelvic inflammatory disease.

Postabortal fever

The results of various studies suggest a role for *M. hominis* in fever after abortion (see Section 13), the mycoplasma having been isolated from the blood of about 10 per cent of women who had such fever but not from aborting women without fever, nor from normal pregnant women. However, the key point of whether the mycoplasma was isolated in pure culture was not always clear. A rise in the titre of antibody to *M. hominis* has been detected in half the women who become febrile but in only a small proportion of those who have abortions and remain afebrile. Thus, despite the caveat mentioned, on balance the evidence seems in favour of *M. hominis* causing some cases of postabortal fever, whereas there is none to suggest that ureaplasmas do likewise, possibly because studies have not been focused on this micro-organism.

Postpartum fever

Genital mycoplasmas found transiently in maternal blood a few minutes after normal vaginal delivery are not associated with postpartum fever. However, *M. hominis* isolated from the blood a day or more after delivery has been associated in 5 to 10 per cent of women who develop fever, often with an antibody response. As the organisms are seldom isolated from the blood of afebrile postpartum women, the inference is that *M. hominis* induces postpartum fever, assuming they are recovered in pure culture. Whether fever occurs predominantly in women who have bacterial vaginosis in pregnancy, in which there is proliferation of *M. hominis* together with various bacteria in the vagina, has not been resolved. Patients with postpartum or postabortal fever recover usually without antibiotic treatment.

Microbiological diagnosis of genitourinary and related infections

Swabs from the urethra or vagina provide a slightly more sensitive means of collecting specimens for mycoplasmal isolation than urine specimens. The basic medium is similar to that described for the isolation of *M. pneumoniae*, SP4 medium, mentioned previously, being best for *M. genitalium*. Advantage is taken of the metabolic activity of the mycoplasmas (Table 1) in order to detect their growth. Clinical material is added to separate vials of liquid medium containing phenol red and 0.1 per cent glucose, arginine, or urea. *M. genitalium* metabolizes glucose and changes the colour of the medium from red to yellow. *M. fermentans* does this also but, in addition, converts arginine to ammonia, as do *M. hominis* and *M. primatum*. Ureaplasmas possess a urease that breaks down urea to ammonia too. In each case, the pH of the medium increases and there is a colour change from yellow to red. Ureaplasmas change the colour usually within 1 to 2 days, while *M. genitalium* may take 50 days or longer. Indeed, it soon became clear that attempts to culture this mycoplasma failed and detection was salvaged only by the implementation of PCR technology. Introduction of specimens into Vero cell cultures with subculture to mycoplasmal medium when the PCR signifies multiplication is laborious but has been a successful strategy. A PCR assay is also useful for the detection of *M. fermentans* and *U. urealyticum.* Conventionally, however, when colour changes have occurred in liquid medium, subculture to agar medium results in the formation of colonies of about 200 to 300 µm diameter by most genital mycoplasmas; those of *M. genitalium* are usually smaller. Ureaplasma colonies are very small (15 to 60 µm) (Fig. 7(a)) and on medium containing manganous sulphate are brown in colour and, therefore, are detected more easily (Fig. 7(b)). On ordinary blood agar, *M. hominis*, but not ureaplasmas, produces non-haemolytic pinpoint colonies, the nature of which can be established by the methods outlined above. The metabolism-inhibition technique may be used to detect antibodies to *M. hominis* and the ureaplasmas. Antibody inhibits multiplication and metabolism of homologous organisms, thus preventing a change in colour of the medium due to organism multiplication. The indirect haemagglutination technique has been used to detect antibody to *M. hominis* and the microimmunofluorescence test to detect antibody to *M. genitalium*, but these and other tests, such as the enzyme immunoassay, tend to be used as research tools only.

Joint infections

Rheumatoid arthritis

The fact that mycoplasmas cause several animal arthritides, and that gold salts inactivate mycoplasmas and have had a beneficial effect on rheumatoid arthritis, provided the impetus to search for mycoplasmas in the joints of persons suffering from this disease. However, numerous attempts over the second half of the twentieth century failed to detect mycoplasmas in rheumatoid joints or produced inconsistent or unrepeatable results, those mycoplasmas (*M. hyorhinis*,*M. hominis*) that were recovered by means of cell-culture techniques being nothing more than culture contaminants. The case made in the late 1960s and early 1970s, based on apparent isolation and immunological observations, that *M. fermentans* was important in rheumatoid arthritis was not substantiated in the next 30 years. However, renewed interest has been generated because this mycoplasma, and ureaplasmas, have been found by PCR technology in the joints of more than 20 per cent of patients with rheumatoid arthritis and other chronic inflammatory disorders, that is significantly more than in those with non-inflammatory disorders. The significance of the findings needs to be deter-mined.

M. pneumoniae and other mycoplasmal infections

A feature of the mycoplasmal arthritides of animals is that the mycoplasmas isolated from the joints are found often in the respiratory tract. The question arises, therefore, of whether the known human respiratory pathogenic mycoplasma, namely *M. pneumoniae*, causes arthritis. There is no doubt that respiratory infection is often accompanied by non-specific arthralgia or myalgia (Table 2) during the acute phase, and occasionally it leads to migratory polyarthritis affecting middle-sized joints in adults. A fourfold or greater rise in the titre of antibody to *M.pneumoniae* has been seen occasionally in juvenile chronic arthritis, but an aetiological association has not been demonstrated.

M. hominis has been isolated from septic joints, usually hip, that have developed in mothers after childbirth. The arthritis responds to tetracycline therapy and the diagnosis should be considered in a postpartum arthritis which is unaffected by penicillin.

Reiter's disease (see also Section 21)

Arthritis may occur soon after or concomitant with non-gonococcal urethritis (sexually acquired reactive arthritis; **SARA**) or the arthritis may be associated with conjunctivitis and urethritis (Reiter's disease). In defining the role of mycoplasmas, a difficulty is that the patients have often been treated with antimicrobials before microbiological investigation. However, the possible role of *M. genitalium* and ureaplasmas should not be ignored in view of the strong involvement of the former and the weaker involvement of the latter in uncomplicated non-gonococcal urethritis. *M. genitalium* has been detected in the synovial fluid of a patient with SARA, but further evidence is required to establish a causal link in the case of this mycoplasma, and ureaplasmas too. The latter have not been isolated from involved joints but synovial lymphocytes from some patients have been shown to proliferate *in vitro* in response to ureaplasmal antigens.

Arthritis in patients with hypogammaglobulinaemia

Arthritis of mycoplasmal aetiology (Fig. 8(a) and Fig. 8(b)) should be considered in patients with hypogammaglobulinaemia (see Section 5) who develop an abacterial septic arthritis. Thus, *M. pneumoniae* (together with *M. genitalium* in one instance), *M. hominis*, *M. salivarium*, and, in particular, ureaplasmas have been isolated from synovial fluids of at least two-fifths of these patients. Furthermore, in view of diminished immunity, vigilance should be kept for infection by mycoplasmas of non-human origin. The arthritis usually responds to tetracyclines or other antimicrobials to which the organisms are sensitive, an indication that they are a cause of the disease. Intravenous therapy may be required and administration of antiserum prepared specifically against the mycoplasma in question may be helpful in the few patients whose disease does not respond to antimicrobial therapy.

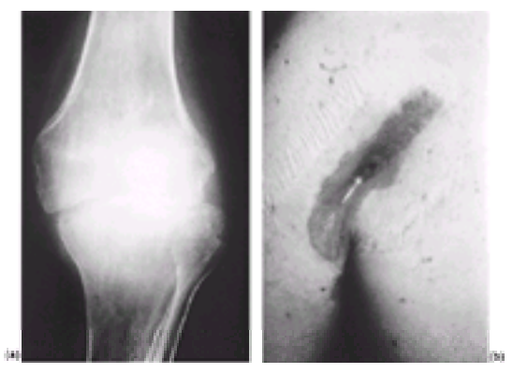

Fig. 8 (a) Damage to the knee joint of a hypogammaglobulinaemic patient caused by *U. urealyticum* infection. (b) Sinus connected with the shoulder joint of a patient with hypogammaglobulinaemia; ureaplasmas were isolated repeatedly from the sinus exudate. (By courtesy of A.D.B. Webster.)

Conditions of rare or equivocal mycoplasmal aetiology

The occurrence of *M. hominis* or ureaplasmas in cerebrospinal fluid from cases of neonatal meningitis or brain abscess is due presumably to infection *in utero* or to colonization at birth with subsequent invasion. This is a rare event but should be considered in cases of neonatal disease of the central nervous system in which the results of bacteriological staining and culture are negative.

M. hominis organisms, apart from inducing fever after abortion or childbirth, have been associated with fever attributed to burns and trauma, and have been implicated in some wound infections. Whether they have any role in the pathogenesis of bacterial vaginosis in which they occur in large numbers is difficult to define because they do so together with a variety of bacteria, which are found also in profusion. *M. hominis* has been associated with premature labour, but in view of this pregnancy outcome being associated strongly with bacterial vaginosis, the involvement of the mycoplasma would seem to be as part of the latter condition.

Data on ureaplasmas in urinary calculi suggest that they could be involved aetiologically, and these organisms have been associated also with infertility, chorioamnionitis, spontaneous abortion, and low birth weight. It is noteworthy, however, that like *M. hominis* organisms, ureaplasmas are found in larger numbers in the vagina of women with bacterial vaginosis than in those without disease. Thus, it cannot be ignored that, in the reproductive problems referred to, ureaplasmas may be involved, at least in part, as a component of bacterial vaginosis and to attribute the problems to ureaplasmas alone may sometimes be misleading.

Association of mycoplasmas with AIDS

The idea that mycoplasmas might act as a cofactor, enhancing human immunodeficiency virus type 1 (**HIV-1**) replication and accelerating progression to AIDS, was fuelled initially by studies *in vitro*. In these, treatment of HIV-infected cell cultures with tetracyclines or fluoroquinolones, active against mycoplasmas, inhibited cell killing without affecting virus replication. In other studies, certain mycoplasmas (*M. fermentans*, *A. laidlawi*i) enhanced cytopathic changes by HIV-1. Such *in vitro* observations, however, were preceded by attempts to identify a virus in Kaposi's sarcoma tissue which culminated in the recovery of a mycoplasma in cell culture, possibly a cell-culture contaminant. This was termed initially ' *M. incognitus*', but identified later as *M. fermentans*, and was found to be distributed widely in tissues

taken at autopsy from patients with AIDS. Subsequently, it was shown to be linked strongly with AIDS-associated nephropathy. In addition, some investigators, who used PCR technology, detected *M. fermentans* in peripheral blood monocytes, throat, and urine of 10, 23, and 8 per cent of HIV-seropositive patients, respectively, almost all of whom were homosexual men. They probably had the mycoplasma before acquiring the virus because the former was detected with similar frequency in samples taken from HIV-seronegative patients, a large proportion of whom were homosexual men, attending a sexually transmitted disease clinic. The interaction of mycoplasmas with the immune system could induce cytokines and so enhance HIV replication with increased loss of CD4+ cells, in this way the mycoplasma acting as a cofactor. Nevertheless, no association was found between infection by *M. fermentans* and the stage of the disease, the patients' CD4+ count, or the viral load. This does not eliminate the possibility that a mycoplasmal infection could influence the speed of disease progression. However, this seems unlikely as no significant difference has been found between the proportion of non-progressors, slow progressors, or rapid progressors of HIV-associated disease who have peripheral blood monocytes that are positive for *M. fermentans*.

A recently discovered mycoplasma of human origin, *M. penetrans*, was isolated from urine sediments of a small number of homosexual men infected with HIV-1, most of whom had AIDS. This mycoplasma avidly invades eukaryotic cells, and antibody to it, detected by an enzyme-linked immunosorbent assay, was found in the sera of 40 per cent of patients with AIDS, but in only a very small proportion of HIV-seronegative subjects, or subjects attending sexually transmitted disease clinics, and in none of a group of patients with other immune dysfunctions. However, the mycoplasma has not been found by PCR technology in the peripheral blood monocytes of a large number of HIV-positive homosexual men. Thus, despite its ability to penetrate cells and its apparent association with HIV infection and AIDS, there is no evidence that *M. penetrans* behaves as a cofactor in the development of AIDS.

Specialists in clinical microbiology and infectious diseases aim, among other things, to detect and characterize novel pathogens and their disease associations and to refine our knowledge regarding the natural history and treatment of known infections. At the time of writing, at least 890 species of bacteria, with names which have standing in nomenclature, in 193 genera, plus a number of other less well characterized taxa, have been reported to be associated in some way with human disease (Table 1). The list includes a core assemblage of bacteria long known to be associated with infection, some of which are widely known (e.g. *Staphylococcus aureus*), others of which are of restricted geographical distribution (e.g. *Bartonella bacilliformis*, the agent of Oroya fever) or seldom encountered (e.g. *Erysipelothrix rhusiopathiae*, the cause of erysipeloid). Advances in laboratory methods have made it possible to associate novel pathogens with well-known clinical conditions (e.g. *Tropheryma whippelii* and *Arthrobacter* spp. with Whipple's disease; and *Bartonella henselae* and *Afipia felis* with cat scratch disease). Members of the human commensal flora from various body sites have been associated with localized infections (e.g. *Acidaminococcus fermentans*, *Bilophila wadsworthia*, and *Buttiauxella agrestis* from the faecal flora with abdominal sepsis; *Catonella morbi*, *Centipeda periodontii*, and *Cryptobacterium curtum* with periodontal disease). In such cases it is difficult to distinguish between aetiological agents and colonists of pre-existing disease foci. In addition to well-known zoonotic agents (e.g. *Mycobacterium bovis*, the agent of bovine tuberculosis), increasing numbers of species have been associated with contact with animals or animal products (e.g. *Capnocytophaga canimorsus* from dog bites). Some rarely encountered conditions have been associated with exposure to environmental organisms (e.g. humidifier fever following inhalation of *Parachlamydia acanthamoebae*; actinomycetoma following inoculation injury with *Actinomadura* spp.). Invasive medical procedures and devices and immunosuppressive therapies have allowed relatively non-pathogenic organisms (e.g. *Acinetobacter* spp. and *Staphylococcus epidermidis*) to cause infection, making it harder to distinguish between contaminants and isolates of clinical significance.

Clinicians cannot be expected universally to be familiar with more than a small proportion of the known potentially pathogenic bacteria. Hence, it is necessary to develop strategies that allow assessment of the likely significance of bacterial names encountered in the literature and laboratory reports. Table 1 lists genera in alphabetical order. Within genera, species are grouped according to associated clinical features, alongside which are given reported antimicrobial susceptibilities and treatments, concise notes, and selected references. The names used are those which have standing in nomenclature at the time of writing; that is to say, names that appear in the *Approved lists of bacterial names*(Skerman VBD, McGowan V, Sneath PHA (1989) American Society for Microbiology, Washington DC; amended edition), or the *Index of the bacterial and yeast nomenclature changes* (Moore WEC, Moore LVH (1992) American Society for Microbiology, Washington DC), or have been validated by publication in the *International Journal of Systematic Bacteriology*. Issues up to and including Part 4 of Volume 49 (October 1999) have been consulted. To check a taxon's standing in nomenclature, an extremely useful reference source is the *List of bacterial names with standing in nomenclature* (http://www.bacterio.cict.fr/). The use of correct names allows accurate communication between specialists, but name changes resulting from reclassification (e.g. the splitting of *Pseudomonas* into several genera) or from the correction of Latin (e.g. *Streptococcus sanguinis* instead of *S. sanguis*) may cause confusion. Table 1 includes some recently used synonyms (stated in parentheses) and CDC alphanumeric groups (e.g. CDC group DF-3) which await designation of scientific names. A useful list of such terms may be found in the *Summary of current nomenclature, taxonomy and classification* in *Clinical Infectious Diseases* 1999,**29**, 713–27. Names not validly published are stated in inverted commas (e.g. '*Flexispira rappini*'). An updated version of this chapter is available at (http://homepages.pavilion.co.uk/tetrix/).

The antimicrobial susceptibility and treatment notes are based on a wide range of sources and are no more than a rough guide. In the absence of well-established regimens for particular situations, treatment should take into account susceptibility data from the strain causing the infection and the monitoring of treatment response. Caution should be exercised in interpreting the significance of unusual isolates, especially from normally non-sterile sites.

7.12.1 Fungal infections

*R. J. Hay**

Introduction

Fungi are saprophytic or parasitic organisms that are normally assigned to a distinct Kingdom. As eukaryotes, they have the complex subcellular organization and highly organized genetic material seen in both animal and plant cells. The cell wall is a distinctive feature of fungi and has a complex skeleton based on mannan and glucan subunits. The arrangement and reproduction of individual cells is also characteristic. Most fungi form new cells terminally, which remain connected to form long, branching filaments or hyphae (the mould fungi). Some reproduce in a similar manner but each new cell separates from the parent by a process of budding (the yeast fungi). It is a feature of certain fungi to be yeast-like during one phase of their life history but hyphal at another, a phenomenon known as dimorphism. In culture, mould fungi usually form a cottony rowth on laboratory media while yeasts normally have a smooth, shiny appearance.

Fungi adversely affect humans in a number of ways. They cause disease indirectly by spoilage and destruction of food crops with subsequent malnutrition and starvation. Many of the common moulds produce and release spores, which may act as airborne allergens to produce asthma or hypersensitivity pneumonitis. Fungi elaborate complex metabolic by-products, some of which are useful to humans, such as the penicillins. However, others are toxic. Disease caused by the ingestion of fungal toxins includes both poisoning by eating certain mushrooms (mycetism) and damage caused by the ingestion of minute quantities of toxin (mycotoxicosis), for instance in contaminated grain. The contribution of the latter mechanism to human disease remains largely unexplored and, in addition, whether inhalation of toxic fungal spores may cause pathology. Finally, fungi may invade human tissue. Medical mycology is largely concerned with this last group. Invasive fungal diseases are normally divided into three groups: the superficial, subcutaneous, and deep mycoses. In superficial infections, such as ringworm or thrush, fungi are confined to the skin and mucous membranes. Extension deeper than the surface epithelium is rare. Subcutaneous infections are usually tropical: the main site of involvement is within subcutaneous tissue, although secondary invasion of adjacent structures such as bone or skin may occur. In deep or systemic infections, deep organs such as the lung, spleen, or brain are invaded. This classification of mycoses is based on the main 'sphere of involvement' by the causal organisms, but there are exceptions. For instance, brain involvement has been recorded in patients with chromoblastomycosis, which is normally a subcutaneous infection.

The fungi causing systemic mycoses are often classified in two groups: the opportunists and the endemic pathogens. The former cause disease in overtly compromised individuals. These contrast with the true pathogens, which cause infection in all subjects inhaling airborne spores.

---

*Dr M.A.H. Bayles prepared the chapter on Chromoblastomycosis for the third edition of this textbook. Much of her text has been included in this chapter and we acknowledge her contribution with grateful thanks.

Superficial fungal infections

The main superficial mycoses are the dermatophyte infections, superficial candidosis, and tinea versicolor (see Section 23). These are both common and widespread. Rare superficial infections include tinea nigra, and black or white piedra.

Dermatophyte infections (dermatophytoses)

Aetiology

The dermatophyte or ringworm infections are caused by a group of organisms capable of existing in keratinized tissue such as stratum corneum, nail, or hair. The mechanism of invasion is thought to be linked to production of extracellular enzymes, such as the three distinct keratinases produced by *Trichophyton mentagrophytes*, but other proteases may also be involved.

Epidemiology

Some dermatophyte fungi have a worldwide distribution; others are more restricted. The most common and most widely distributed is *Trichophyton rubrum*, which causes different types of infection in different parts of the world. It is commonly associated with athlete's foot (tinea pedis) in temperate areas as well as tinea corporis or tinea cruris in the tropics. This distinction is not based solely on climatic factors, as immigrants from tropical countries, particularly the Far East, may still have tinea corporis caused by *T. rubrum* when living in northern Europe. Certain dermatophytes are limited to defined areas. For instance, tinea imbricata caused by *Trichophyton concentricum*, is found in hot, humid areas of the Far East, Polynesia, and South America. Scalp ringworm tends to occur in well-defined endemic areas in Africa and elsewhere. In different regions, different species of dermatophytes may predominate. Thus, in North Africa, the most common cause of tinea capitis is *Trichophyton violaceum*; in southern parts of the continent, the major agents may be *Microsporum audouinii*, *Microsporum ferrugineum*, and *Trichophyton soudanense*. Not all dermatophyte infections are endemic and dominant species may disappear to be replaced by others. *M. audouinii*, once endemic and common in the United Kingdom, is now infrequent, probably because of improved treatment and detection of carriers. By contrast *Trichophyton tonsurans* is now established as a major cause of tinea capitis in urban areas in both the United Kingdom and the United States. Dermatophytes may be passed from person to person (anthropophilic infections), from animal to person (zoophilic), or soil to person (geophilic). Sources of zoophilic organisms in Europe include cats and dogs, cattle, hedgehogs, and small rodents. Rarer sources include horses, monkeys, and chickens. Lesions produced by zoophilic species may be highly inflammatory.

Factors governing the invasion of stratum corneum are largely unknown, but heat, humidity, and occlusion have all been implicated. Susceptibility to certain infection, such as tinea imbricata, may be genetically determined.

Clinical features

The clinical features of dermatophyte infections are best considered in relation to the site involved. Often the term tinea, followed by the Latin name of the appropriate part (such as *corporis*—body) is used to describe the clinical site of infection.

Tinea pedis

Scaling or maceration between the toes, particularly in the fourth interspace, is the most common form of dermatophytosis seen in temperate countries. Itching is variable, but may be severe. Sometimes blisters may form both between the toes and on the soles of the feet. The causative organisms are commonly *T. rubrum* and *Trichophyton interdigitale*, the latter being responsible for the vesicular forms. Similar appearances can be caused by *Candida albicans* and in the bacterial infection, erythrasma. Gram-negative bacterial infection causes erosive interdigital disease associated with discomfort.

'Dry type' infections of the soles and palms

These are normally caused by *T. rubrum*. Palms or soles have a dry, scaly appearance, which in the soles may encroach on to the lateral or dorsal surfaces of the foot. The palmar involvement is often unilateral, an important diagnostic feature (Plate 1). Nail invasion is often seen (see below). Itching is not prominent, and infections are usually chronic.

Tinea cruris

Infections of the groin, most often caused by *T. rubrum* or *Epidermophyton floccosum*, are relatively common. They occur in both tropical and temperate climates, although in the former the infection may spread to involve the whole waist area in both males and females. Tinea cruris in females is uncommon in Europe. An erythematous and scaly rash with a distinct margin extends from the groin to the upper thighs or scrotum. Itching may be severe. Coincident tinea pedis is common, and patients should be examined for this. The rash of crural erythrasma shows uniform scaling without a margin, whereas in candidosis, satellite pustules occur distal to the rim.

Onychomycosis (caused by dermatophytes)

Invasion of the nail plate is most often seen with *T. rubrum* infections. The plate is invaded distally and becomes thickened and friable with terminal loss of the nail plate. Onycholysis may be seen. More rarely, and most often with *T. interdigitale*, the dorsal surface of the plate is invaded, causing superficial white onychomycosis.

Tinea corporis (body ringworm)

Dermatophyte or ringworm infection on the trunk or limbs may produce the characteristic annular plaque with a raised edge and central clearing (Plate 2). Scaling and itching is variable. Lesions caused by zoophilic organisms may be highly inflammatory and in certain cases, particularly those caused by *Trichophyton verrucosum*, intense itching, oedema, and pustule formation (kerion) may develop. This reaction is seldom secondarily infected by bacteria but is a response to the fungus on hairy skin. Infections of the beard, tinea barbae, are often highly refractory to treatment. Facial dermatophyte infections may mimic a variety of non-fungal skin diseases, including acne, rosacea, and discoid lupus erythematosus. However, the underlying annular configuration can usually be distinguished. The term tinea incognito is used to describe such atypical lesions.

Tinea capitis (scalp ringworm)

In the United Kingdom as in the United States, the most common cause of scalp ringworm is *Trichophyton tonsurans*, an anthropophilic fungus which mainly occurs in inner cities, particularly in black Caribbean or African children. This has now replaced *Microsporum canis*, originating from an infected cat or dog, although this dermatophyte is dominant elsewhere. Scalp ringworm is mainly a disease of childhood, with rare infections occurring in adult women. Spontaneous clearance at puberty is the rule. *M. canis* causes an 'ectothrix' infection where spores form on the outside of the hair shaft and the scalp hair breaks above the skin surface. Scaling, itching, and loss of hair occur. Other causes of ectothrix infection include *M. audouinii*, which is becoming more common in Europe, and is still seen in the tropics. This infection can be spread from child to child and causes serious social handicap. The infection may occur in epidemic form, particularly in schools. By contrast, infections with *M. canis* are acquired from a primary animal source rather than by spread from human lesions. In endothrix infections where sporulation is within the hair shaft, scaling is less pronounced and hairs break at scalp level (black dot ringworm). Examples include *T. tonsurans* and *T. violaceum*, the latter being most prevalent in the Middle East, parts of Africa, and India, although it also is being recognized with increasing frequency in Europe.

Favus, now most often seen in isolated foci in the tropics, is a particularly chronic form of ringworm where hair shafts become surrounded by a necrotic crust or scutulum. Individual crusts coalesce to form a pale, unpleasant-smelling mat over parts of the scalp. Such infections may cause extensive and permanent hair loss.

Tinea imbricata (tokelau)

This infection is endemic in parts of the Far East, West Pacific, and Central and South America, and is caused by *Trichophyton concentricum*. In many cases the trunk is covered with scales laid down in concentric rings producing a 'ripple' effect. Alternatively, large, loose scales (tiled, Latin— *imbricata*) may form. The infection is often chronic, and may constitute a serious social handicap. There is some evidence that susceptibility of this disease in Papua New Guinea may be inherited as an autosomal recessive trait.

Infection in HIV and immunocompromised patients

While dermatophyte infections are no more common in the immunocompromised patient, they may differ clinically. In patients with HIV infections there may be (i) more tinea facei, (ii) more widespread and atypical skin lesions, and (iii) a distinct pattern of nail infection characterized by white discoloration spreading rapidly through the nail plate from the proximal nail fold.

Laboratory diagnosis

The mainstays of diagnosis are direct microscopy of skin scales mounted in potassium hydroxide (20 per cent) to demonstrate hyphae, and culture. Scalp hairs may also be examined in a similar way, and the site of arthrospore formation, inside or outside the shaft, determined. Fluorescent whitening agents (Calcofluor) or chlorazol black stain have been used to highlight fungi in scales. Further tests, such as the ability to penetrate hair, may be used to separate similar cultures. Identification of organisms is important, as it will indicate the source of infection in scalp ringworm, for example. When large numbers of children are involved, screening of scalp infections with a filtered ultraviolet (Wood's light) lamp is useful. Certain species, including *M. canis* and *M. audouinii*, cause infected hair to fluoresce with a vivid greenish light. Scalps can also be screened for infection by passing a sterile brush or scalp massager through the hair and plating this directly on to an agar plate.

Treatment

The treatment of dermatophyte infections depends to an extent on the nature and severity of infection. Topical therapy is reserved for circumscribed infections such as athlete's foot and tinea corporis, not involving hair or nail keratin. Scalp and nail infections, severe or widespread ringworm, and failures of topical therapy are usually treated orally with griseofulvin, itraconazole, or terbinafine.

Specific antifungal drugs in topical form are effective and well tolerated. The important compounds in this group are miconazole, clotrimazole, ketoconazole, and econazole, which are imidazole derivatives, undecenoic acid, and tolnaftate and the allylamine, terbinafine. Generally treatment is given for 7 to 30 days. They are all very similar in their clinical efficacy, but topical terbinafine is particularly rapid in foot infection (7 days or less). Adverse reactions are rare.

For oral therapy the main alternatives are terbinafine, itraconazole, or fluconazole. Terbinafine (250 mg daily) is rapidly effective in most forms of dermatophytosis that require oral therapy and also produces rapid responses in toe nail (12 weeks) and sole infections (2 to 4 weeks), without a high rate of relapse. Side-effects include headache and nausea, but loss of taste may also occur. Itraconazole is somewhat similar in its profile, but is given intermittently (200 mg twice daily for 7 days). This course is given once for sole infections but repeated three times at monthly intervals for toe nail infections, as pulsed therapy. Side-effects include nausea and abdominal discomfort. Fluconazole is also active and is given in a dose of 150 mg weekly; 300 mg may be necessary for toe nail infections. This side-effect profile is similar to itraconazole. All three drugs are extremely rare causes of hepatic toxicity. Griseofulvin is still used for tinea capitis in a dose of 10 to 20 mg/kg daily. Treatment should be continued for at least 6 weeks in tinea capitis. Side-effects are not common, but include headache, nausea, and urticaria. The drug can also precipitate acute intermittent porphyria and systemic lupus erythematosus in predisposed subjects.

Scytalidium infections

The organisms, *Scytalidium dimidiatum* (*Hendersonula toruloidea*) and *Scytalidium hyalinum*, can cause a superficial scaly condition that resembles the 'dry type' of dermatophyte infection on the palms or soles. Nail plate destruction may also occur, the lateral border of the nail being the initial site of invasion. The disease has been seen in Europe, almost invariably in immigrants from the tropics, particularly the Caribbean, West Africa, and India or Pakistan. Its prevalence in the tropics is unknown, although in some surveys it has been shown to be relatively common. In skin scrapings the tortuous hyphae may resemble those of a dermatophyte, but the organisms do not grow on media containing cycloheximide, which is often incorporated into agar for routine dermatophyte isolation.

Treatment is difficult, but some improvement may follow the use of keratolytic compounds such as salicylic acid. Nail infections do not respond to terbinafine, griseofulvin, or azoles.

Further reading—*Scytalidium*

Hay RJ, Moore MK (1984). Clinical features of superficial fungal infections caused by *Hendersonula toruloidea* and *Scytalidium hyalinum*. *British Journal of Dermatology* **110**, 677–83.

Miscellaneous nail infections

Occasionally, fungi other than dermatophytes or *Scytalidium* species are isolated from dystrophic nails. These include *Scopulariopsis brevicaulis*, *Onychocola canadensis*, *Acremonium*, and *Fusarium* species, and certain types of *Aspergillus*. These infections are usually seen in the elderly. It is often difficult, particularly with *Aspergillus* species, to establish that the organism is playing a pathogenic role.

Pityriasis versicolor (tinea versicolor)

Aetiology

Pityriasis versicolor is a superficial infection caused by *Malassezia* species. Although most common in tropical countries, it has a worldwide distribution. Dermal penetration does not occur.

There are six species of *Malassezia* that can be found on normal skin, the commonest of which are *M. sympodialis* and *M. globosa*. In pityriasis versicolor there is transformation of yeast cells to produce hyphae. It is likely that the state of host immunity plays some part in pathogenesis and depression; for instance, endogenous or exogenous corticosteroids potentiate the disease in some individuals. However, it is also commonly seen in normal individuals, and climatic factors or sun exposure are believed to trigger the infection in many cases. There is no effective animal model for studies of this disease.

Epidemiology

Pityriasis versicolor is very common in the tropics, where it may be widespread on the body. Its incidence in temperate climates has increased over the last 20 to 30 years. It is not more common in HIV infected subjects.

Clinical features

The rash of pityriasis versicolor is asymptomatic or mildly pruritic. Its presents with scaling, confluent macules on the trunk, upper arms, or neck. These may be hypopigmented or hyperpigmented. In some individuals and in the tropics, other areas including face, forearms, and thighs may be involved.

The diagnosis is rarely confused with other complaints, although eczema or ringworm infections are sometimes considered. Patients are often anxious to exclude leprosy, but the two are unlikely to be mistaken. In vitiligo, depigmentation is complete and there is no scaling.

Laboratory diagnosis

P>The diagnosis is made by demonstration of the yeasts and hyphae of *Malassezia* in skin scales removed by scraping. Culture is difficult and unnecessary.

Treatment

Topical ketoconazole, miconazole, clotrimazole, or econazole are effective. Oral itraconazole may be used in recalcitrant cases. Alternatives include 2 per cent selenium sulphide or 20 per cent sodium hyposulphate lotions. Whatever the treatment, relapse is common.

Other *Malassezia*-associated conditions

Malassezia yeasts have been implicated in the pathogenesis of a number of other skin diseases such as seborrhoeic dermatitis and a form of itchy folliculitis, *Malassezia* folliculitis. The evidence connecting seborrhoeic dermatitis, one of the most common of skin diseases, and *Malassezia* is largely concerned with the response of antifungal drugs and the observation that improvements in the rash mirror disappearance of organisms from the skin. Severity of the skin condition does not appear to reflect the numbers of yeasts on the skin surface.

Superficial candidosis (candidiasis)

Aetiology

Superficial candidosis is a term used to describe a group of infections of skin or mucous membranes caused by species of the genus *Candida*. They range in severity from oral thrush to chronic mucocutaneous candidosis, a chronic infection refractory to conventional antifungal treatment.

Candida albicans is the species most frequently involved. It is a saprophytic yeast often found as a commensal in the mouth and gastrointestinal tract, and is commonly present in the vagina. Several factors may influence the incidence of carriage. For instance, oral colonization is more common in hospital staff than in equivalent non-hospital subjects. Vaginal carriage is more common in pregnancy. Other factors (Table 1) are known that predispose to conversion from a commensal to a parasitic role with the causation of disease—candidosis. The list includes factors that influence host immunological response, such as carcinoma, AIDS, or cytotoxic therapy; those that disturb the population of other micro-organisms, such as antibiotics; and those that affect the character of the epithelium, such as dentures.

Other species of *Candida* may also cause superficial infections, but are less common. They include *C. glabrata*, *C. dubliniensis*, and *C. parapsilosis.* There is evidence that the first two species are more common now in oral infection in patients with HIV and *C. glabrata* in vaginal candidosis.

Epidemiology

Superficial *Candida* infections are seen in all countries.

Clinical features

There are a number of clinically distinct types of superficial infection caused by *Candida* species, as follows.

Oral candidosis (thrush)

Oral infection by *Candida* is fairly common, particularly in infancy and old age, or in association with antibiotic or cytotoxic therapy, or in diseases where the neutrophil or T-lymphocyte responses may be impaired. In the older age group, the wearing of dentures is a predisposing factor. The lesions present with discomfort both in the mouth and at the corners of the lips. The mouth and buccal mucosa show patchy or confluent, white adherent plaques; less commonly the mucosa and tongue are sore and glazed—erythematous candidosis. Angular cheilitis usually accompanies the oral lesions. In long-standing cases, the plaque may become hypertrophic, with oedema of the mucosal surfaces, or the mucosa may appear glazed and raw.

There is a significant correlation between leucoplakia and oral candidosis, and it has been suggested that the infection may lead to epithelial dysplasia.

The diagnosis is made by the demonstration of yeasts and hyphae of *Candida* in smears, and by culture.

Vaginal candidosis (thrush)

See Chapter 21.3 for further details.

Paronychia

Infection around the nail fold is seen in people whose occupations involve frequent wetting of the hands (such as cooks) or in those with eczema or psoriasis. The aetiology is complicated and there may be a mixture of bacterial infection and irritant or allergic contact dermatitis as well as *Candida* infection. The condition presents with painful, red swelling of the nail fold. Pus may be discharged. Secondary invasion of the lateral border of the nail plate by *Candida* may occur from this site.

Candida intertrigo

Infection of the moist folds of the skin in the groin or under the breasts causes itching and discomfort. The area becomes macerated and erythematous. Candida may contribute to this condition, but is certainly not the only factor. It may also superinfect the napkin area in infants. The presence of satellite pustules (see above) is a useful indicator of involvement by *Candida* in the disease process.

Direct invasion of toe-web folds by *Candida* closely resembles 'athlete's foot' caused by dermatophytes. A similar erosive infection may occur in the finger webs—interdigital candidosis—and is seen most commonly in the tropics.

Chronic superficial candidosis

Chronic *Candida* infections of the mouth, vagina, and nail present problems in management. Chronic oral candidosis, for instance, is associated with leucoplakia. Predisposing causes should be searched for. The most serious of this group of infections is chronic mucocutaneous candidosis, a rare condition in which chronic skin, nail, and mucosal infection coexist (Plate 3). A series of underlying genetic, endocrine (hypoparathyroidism, hypoadrenalism, or hypothyroidism), and immunological abnormalities has been found. Extensive human papilloma virus (wart) or dermatophyte infections may also be present in these patients, whose condition is normally diagnosed in childhood.

Oral candidosis is one of the earliest signs of untreated AIDS, occurring in a high proportion of patients. The appearances are similar to those seen with other groups,

although plaque formation may be very extensive. Oesophageal infection is common in this group.

Laboratory diagnosis

All these infections are diagnosed by microscopy and culture. When associated with the condition, *Candida* cells are always evident on microscopy. Culture establishes the specific identity and is important particularly where non- *albicans Candida* species may be involved.

Treatment

Two groups of drugs are effective in superficial candidosis. The polyenes such as nystatin and amphotericin B are topically active in many forms of candidosis. They are often less effective in oral candidosis in immunodeficient patients including those with AIDS. Likewise, topical azole drugs such as miconazole and clotrimazole are usually effective in superficial candidosis. For resistant cases, oral therapy with fluconazole, itraconazole, or ketoconazole may be necessary.

For vaginal infections, topical creams or vaginal preparations should be used—many requiring only a single treatment. Single-dose oral fluconazole is an alternative. In recalcitrant cases it may be necessary to use longer courses of fluconazole or itraconazole.

Miscellaneous superficial mycoses

There are a number of relatively rare, superficial fungal infections such as tinea nigra, and black or white piedra. They never cause invasive disease, and are mainly confined to the tropics.

Tinea nigra

Tinea nigra is a superficial infection confined to the epidermis of the palms or soles, and more rarely elsewhere. The initial lesion is a dark macule without scaling, which resembles a brown stain on the skin and spreads slowly over the palmar or plantar surface. The disease is normally asymptomatic.

On scraping the skin, brown pigmented hyphae can be seen by direct microscopy, and the causative organism, *Phaeoanellomyces werneckii*, isolated.

The lesion responds to Whitfield's ointment.

Black piedra

Black piedra is a disease of the tropics in which small, dark nodules form on hair shafts in the scalp or, less commonly, elsewhere. There are no symptoms. Each nodule consists of a dense mat of hyphae containing the sexual spores (ascospores) of the fungus.

The diagnosis is made by direct microscopy of infected hair, and the isolation of *Piedraia hortae*. Treatment using formalin solution or amphotericin B lotion is usually effective.

White piedra

White piedra occurs in both temperate and tropical climates, and is rare. It produces pale nodules on the hair of the beard, groin, or scalp. The hair shaft may fracture. The nodule consists of hyphae, arthrospores (spores formed by fragmentation of hyphae), and blastospores (budding yeast cells). The organism *Trichosporon beigelii* can be readily cultured. The treatment is similar to that for black piedra.

The subcutaneous mycoses

Subcutaneous infections caused by fungi are rare, and are mainly seen in the tropics. The organisms gain entry via the skin; in mycetoma, organisms may be implanted subcutaneously via a thorn. The majority of the causative organisms in this group of infections can be isolated from vegetation or soil. Involvement of deep viscera is rare. Attempts to establish experimental infections that resemble the human diseases have been largely unsuccessful. A clearer understanding of the pathogenesis therefore awaits such a model system. These infections tend to be chronic, chemotherapy may be lengthy, and in the case of mycetoma, often unsuccessful.

Mycetoma (Madura foot)

Aetiology

Mycetoma is a chronic infection involving subcutaneous tissue, bone, and skin, in which colonies of infecting fungi or actinomycetes (grains) are found within a network of burrowing abscesses and sinuses (Plate 4).

A list of the more common organisms that cause mycetoma is shown in Table 2. The organisms are divided into two groups, the actinomycetomas and the eumycetomas, caused by actinomycetes and fungi, respectively. The size and colour of the grains (red, pale, or dark) are important clues to their identification. The organisms can be found in the natural environment, and some have even been identified in association with acacia thorns in an endemic area. The infection is initiated when an infected thorn is implanted in deep tissue. However, many years may elapse before the formation of a clinically apparent mycetoma.

Epidemiology

The disease is seen primarily in the tropics, although rare cases, apart from imported ones, may occur in temperate areas. Countries with the most reported cases include Sudan, India, Senegal, Mexico, and Venezuela. However, the disease is widely distributed in the tropics, particularly to the south and east of the Sahara Desert in Africa.

The pattern of prevalence of infections caused by certain organisms differs strikingly in different parts of the world. For instance, *Streptomyces somaliensis* is most common in the Sudan and Middle East. *Madurella grisea* is mainly found in the New World. Altogether about 60 per cent of reported infections are caused by actinomycetes, of which *Nocardia brasiliensis* is the most common (Chapter 7.11.27).

Clinical features

Early mycetomas may present with a circumscribed area of hard subcutaneous swelling (Plate 5). Later, sinus tracts open on to the skin surface and visible grains may be discharged, along with serosanguinous fluid (Plate 6). Bone erosion and destruction, leading to deformity, may occur. However, severe pain is rarely a problem. Local lymph node invasion may occur, but more widespread involvement is very rare.

Feet and lower legs are the areas most commonly involved, but the arms, buttocks, chest, and head may all be sites of infection. Mycetoma caused by *N. brasiliensis*

may occur in any site, but one favoured area is the chest wall.

The radiological features of mycetoma are cortical erosion, followed by the development of lytic deposits in bone. Periosteal proliferation and destruction, leading to deformity, may follow. MRI provides a clearer picture of bone involvement and may be positive earlier than radiography.

Laboratory diagnosis

The diagnosis is made by the demonstration and identification of grains obtained from the sinus openings by gentle pressure or curettage. If these measures are not successful, tissue should be obtained by deep surgical biopsy. Grains can be mounted in potassium hydroxide and examined microscopically. Those containing filaments of 3 to 4 µm in diameter or more are caused by true fungi (eumycetomas), and those with filaments of less than 1 µm by actinomycetes (actinomycetomas). These features can usually be distinguished by direct microscopy.

The morphology of grains fixed, sectioned, and stained with haematoxylin and eosin is typical. Special stains are less helpful. Grains can be used for culture, although several attempts at isolation may have to be made. Serology (such as immunodiffusion) can also be helpful, although the tests are not widely available.

Treatment

Actinomycetomas may respond to sulphones such as dapsone (50 to 100 mg daily) or sulphonamides such as sulphadiazine. The treatment of choice for many is long-term co-trimoxazole (two to three tablets twice daily) with an initial 2 to 3 months of streptomycin or rifampicin. Treatment may have to be continued for many months or years. Dapsone is an effective and cheaper alternative to co-trimoxazole. Extensive actinomycetomas may respond poorly and additional treatment with amikacin or fucidin may be necessary. The eumycetomas seldom respond to antifungal therapy. About 50 per cent of *Madurella mycetomatis* infections respond to ketoconazole. In other infections griseofulvin, amphotericin B, ketoconazole, and itraconazole have rarely produced remission or cure. A trial of therapy may be attempted, where the patient can be monitored closely in outpatient departments. Otherwise, radical surgery or amputation is usually necessary. Small, local excisions are rarely successful.

Mycetoma is slowly progressive and increasingly disabling. However, wider dissemination is very rare, and therefore cases are seldom fatal, except where the skull is involved. However, the deformity caused by the disease may be severely disabling.

Chromoblastomycosis

Aetiology

Chromoblastomycosis, one of the intermediate subcutaneous mycoses, is a chronic granulomatous fungal infection characterized histologically by the presence of brown, spherical fungal cells known as sclerotic cells or fumagoid bodies. In most cases, the lesions are confined to the skin and subcutaneous tissues. In the past there has been great confusion over nomenclature of the aetiological agents of chromoblastomycosis. At present, five agents assigned to four genera are recognized as causing chromoblastomycosis. They are:

1. *Fonsecaea pedrosoi*, which occurs in high rainfall areas and is found worldwide;
2. *Cladophialophora carrionii*, the sole cause of chromoblastomycosis in arid areas;
3. *Phialophora verrucosa*, the first agent to be described;
4. *Fonsecaea compactum*, an uncommon cause and isolated only a few times;
5. *Rhinocladiella aquaspersa*, the rarest cause.

Sporadic cases caused by other dematiaceous fungi such as *Cladosporium trichoides* and *Taeniolélla boppii* have been reported from Uganda and Brazil.

Epidemiology

The principal endemic areas for chromoblastomycosis are the tropical and subtropical countries including Central and South America, Costa Rica, Africa, Japan, Australia, Malagasy, and Indonesia. Curiously, sporadic cases have been reported from Finland and Russia.

Although soil itself does not seem to be a particularly good substrate, the various agents of chromoblastomycosis occur as saprobic fungi in the environment and have been isolated from soil, decaying vegetation and rotting wood. Strains of *F. pedrosoi* and *P. verrucosa* have been isolated from the atmosphere but proved less virulent than those isolated from human lesions or organic material.

Infection occurs as a result of trauma, however minor, the fungi gaining entrance through a cut, abrasion, or thorn prick. Farmers and labourers in agricultural areas are most likely to be exposed to contaminated material. Although lesions on exposed areas may be accounted for in this way it was suggested by Wilson in 1958 that lesions on non-exposed areas may result from a previously unrecognized pulmonary focus. Bacquero later demonstrated the presence of *F. pedrosoi* in bronchial washings and subsequently proved their pathogenicity by inoculating those strains into normal skin of human volunteers and recovering the fungus from the ensuing skin lesions. Other methods of transmission have included metal particles from automobiles, and acupuncture. Person-to-person and animal-to-man transmission have not so far been reported. Chromoblastomycosis has rarely been reported in children and it may be that factors other than trauma and exposure to contaminated material are necessary for its development.

Pathogenesis

Host resistance and virulence of the organism are the two main factors associated with the pathogenesis of this disease. Chromoblastomycosis occurs mainly in healthy individuals. However, it has been found in patients where immunosuppression has occurred either from underlying disabling disease or from chemotherapy. Although the mechanism of granuloma formation is not well understood, it appears that lipids extracted from these fungi and cell-wall constituents may be responsible for this reaction.

Clinical features

The initial lesion of chromoblastomycosis is a small papule at the site of trauma, which gradually enlarges. Nodules and tumours develop, producing a malodorous discharge; eventually, over a period of years, a wide variety of morphological patterns may emerge including dry, hyperkeratotic plaques, verrucose lesions, and large, cauliflower-like masses. Extensive cicatricial plaques, surrounded by peripherally spreading vegetative lesions, may also be present. Evolution is slow and lesions usually involve the lower limb. However, any part of the body may be involved and the sites may be multiple.

Dissemination occurs by (i) surface spread, (ii) the lymphatics, the most common method, (iii) autoinoculation from scratching, and (iv) haematogenously, resulting in subcutaneous lesions at sites distant from the primary. Visceral metastases are known to occur and involvement of the central nervous system, respiratory system, larynx, and vocal chords has been recorded. Therapeutically, therefore, early diagnosis is important.

Complications of long-standing chromoblastomycosis include lymphoedema, flexion deformity of joints, and development of squamous carcinoma.

Diagnosis

Although the history and clinical presentation may suggest the diagnosis, the varied clinical presentation of chromoblastomycosis necessitates consideration of other granulomatous diseases such as sporotrichosis, cutaneous tuberculosis, Hansen's disease, blastomycosis, candidosis, leish-maniasis, paracoccidioidomycosis, rhinosporidiosis, tertiary syphilis, squamous carcinoma, and even psoriasis, sarcoidosis, and discoid lupus erythematosus.

Therefore, to establish a definitive diagnosis, histological and mycological investigations are essential. Diagnosis is confirmed by the presence of the characteristic brown, sclerotic bodies in histological sections. From both epidemiological and therapeutic points of view, culture is necessary as *F. pedrosoi* is the most difficult of the causative fungi to eradicate whereas *C. carrionii* responds rapidly to treatment.

Treatment

Small, single, localized lesions are satisfactorily eradicated by cryosurgery, but long-term follow-up is needed to assess accurately the success of this treatment. Thermotherapy has been found effective by some, again principally in the management of small, single lesions, but here the possibility of a burn must be borne in mind. Rapid spread of the disease has been associated with inadequate surgery, curettage, and electrodesiccation.

Oral monotherapy has been unsuccessful in some cases and drug resistance remains a problem. However itraconazole and terbinafine have both been reported as effective agents. A combination of 5-flucytosine with either thiabendazole or itraconazole may also be efficacious., particularly in long-standing disease

Whatever method of treatment is used, chromomycosis although clinically healed, should be followed-up for at least 2 years before its total eradication can be assumed.

Sporotrichosis

Aetiology

The most common clinical form of sporotrichosis is a subcutaneous infection, which may spread proximally from its initial site in a series of nodules along the course of a lymphatic. More rarely, systemic involvement is seen, for example in the lung (see Systemic mycoses, below).

The causative organism *Sporothrix schenckii* can be found in soil, vegetation, or in association with plants or bark. People who develop the subcutaneous infection may have had contact with material that harbours the organism, such as moss or flowers (for example florists). It is assumed that the pathogen gains entry via an abrasion and in some endemic areas there is often a preceding history of a scratch or insect bite.

Epidemiology

Although sporotrichosis was once prevalent in Europe, particularly France, non-imported cases are now very rare in this area. However, the disease is seen in the United States, Mexico, Central and South America, and Africa. In the late 1930s, there was a remarkable epidemic of sporotrichosis in workers in the Witwatersrand gold mines. The source of infection was a large number of wooden pit props contaminated with the organism. Other, smaller 'epidemics' have been described in certain groups, such as Mexican pottery workers packing ceramics in straw. Normally, however, cases are sporadic in incidence. There are also 'hyperendemic' areas where there is an unexpectedly high incidence of this infection.

Systemic sporotrichosis is much rarer, and cases have mainly been described from the United States.

Clinical features

There are two main clinical types of subcutaneous sporotrichosis.

The first, the fixed type, presents with a solitary cutaneous ulcer or nodule. In this form of the disease, infection does not spread along lymphatics. It has been suggested that it is most common in children, and it has been described most frequently in Central and South America.

In the lymphangitic form, an initial nodule forms on a limb or extremity, such as a finger. This may break down and ulcerate. Subsequently, one or more secondary nodules develop along the draining lymphatic channel, which may ulcerate through the skin. Other variants include the psoriasiform or verrucous types or a superficial granuloma that resembles lupus vulgaris. These usually represent chronic infection.

Rarer forms include secondary spread via scratching, which may present with multiple widespread ulcers or multiple cutaneous lesions secondary to systemic disease. In HIV-positive individuals, widespread cutaneous lesions may develop.

Fixed-type sporotrichosis may resemble many other forms of cutaneous ulceration. However, in endemic areas a major source of confusion is cutaneous leishmaniasis. The lymphangitic variety may also resemble other infections, notably atypical mycobacterial infections, particularly fish-tank granuloma, or 'sporotrichoid' leishmaniasis.

Treatment

Some cases of sporotrichosis may heal spontaneously. However, treatment is usually advised to prevent scar formation. The cheapest treatment is potassium iodide, which is administered in a saturated aqueous solution. The starting dose is 0.5 to 1 ml, given three times daily, and this is increased drop by drop per dose to 3 to 6 ml, three times daily. The mixture is more palatable if given with milk. Treatment should be given for a month after clinical resolution. However, both itraconazole and terbinafine are also effective; minimal durations of treatment for these agents have not been defined.

Subcutaneous zygomycosis due to *Basidiobolus*

Subcutaneous zygomycosis is an infection primarily seen in children in Africa or the Far East (Indonesia). It is characterized by the development of localized woody swellings on the limbs or trunk. The swelling is rarely inflammatory, but has a well-defined leading edge, and is hard. Progression is slow. The causative organism *Basidiobolus haptosporus* can be cultured or demonstrated histologically in biopsy material. Although resolution has been recorded without treatment, therapy is normally given. Potassium iodide solution is the treatment of choice, and is given in as high a dose as possible (see Sporotrichosis, above). Itraconazole may also be effective.

Subcutaneous zygomycosis due to *Conidiobolus* (conidiobolomycosis or rhinoentomophthoromycosis)

Conidiobolomycosis is a similar infection confined to subcutaneous tissue and presenting with painless swelling. The infection is mainly seen in West Africa, but a case has been seen in the Caribbean. There are important differences from the subcutaneous zygomycosis caused by *Basidiobolus*. The disease is most common in young adults, and is confined to facial tissues around the nose, the forehead, and the upper lip. The initial site of infection is in the region of the inferior turbinate in the nose. The diagnosis is established by biopsy or culture. The causative organism is *Conidiobolus coronatus*. Treatment with itraconazole or ketoconazole is effective, but an alternative is high-dose potassium iodide. Relapse after treatment is common, and residual fibrosis may be severely disfiguring.

Lobo's disease (lobomycosis)

Lobo's disease is a subcutaneous infection. The organism, in tissue, appears to be a yeast. It has a tendency to form chains of four to six yeast cells with prominent nucleoli, joined by a narrow, intercellular bridge. However, the organism has never been cultured from human cases and can only be identified by biopsy and histology. The disease is seen in countries of South America around, and north of, the Amazon basin, and cases are also seen in Central America. Apart from humans the only other species affected are freshwater dolphins. Often, exposed sites (such as ear lobes) are invaded and small nodules containing the organisms develop. These may resemble keloids (Plate 7). More diffuse plaques may also be seen. Deep invasion has not been documented. The treatment is excision, and there is no effective chemotherapy.

Systemic mycoses

The systemic or deep visceral mycoses include some of the rare and more serious of the fungal infections. There are two main types of infection in this group, those caused by organisms which invade normal hosts, the endemic mycoses, and those which only cause disease in compromised patients, the opportunistic mycoses. The fungi associated with these two types of infection differ in their innate levels of pathogenicity, but an element of opportunism, depending on host susceptibility, is usually recognizable in all cases of systemic mycoses.

The endemic pathogens cause infections such as histoplasmosis or coccidioidomycosis. These diseases have well-defined endemic zones and the majority of those exposed remain symptomless but usually develop positive skin tests. However, in certain patients, chronic local or disseminated disease may occur. In the systemic infections caused by opportunistic fungi, there is usually a serious underlying abnormality in the patient affecting T lymphocytes (such as HIV) or neutrophils (such as cancer chemotherapy). Such infections are worldwide in occurrence: where tissue invasion occurs the mortality is high. Cryptococcosis, a systemic yeast infection, has features of both types of systemic disease and occurs in both normal and immunosuppressed subjects.

The systemic endemic infections are histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, and infections due to *Penicillium marneffei.* The significance of various laboratory tests in these infections is shown in Table 3.

Further reading—systemic mycoses

Histoplasmosis (see also Section 17)

There are two forms of histoplasmosis. In both types, the organism is present in tissue in its yeast phase. In small-form or classic histoplasmosis, the diameter of the yeast cells is between 3 and 4 µm. Infections are most common in the United States, but sporadic cases are reported widely from the New World, Africa, and the Far East. By contrast, large-form or African histoplasmosis is most common in Central Africa, south of the Sahara and north of the Zambezi river. Yeast forms in infected tissue are much larger, 10 to 15 µm in diameter. Both infections are clinically distinct (see below), but cultural isolates are indistinguishable.

Histoplasmosis (classic or small-form histoplasmosis)

Aetiology

Histoplasmosis is a systemic infection caused by *Histoplasma capsulatum*. The main route of infection is pulmonary. The majority of those exposed are sensitized without overt signs of infection, but more rarely chronic pulmonary or disseminated forms of the disease are seen.

The organism, *H. capsulatum*, can be found in soil in endemic areas. Its growth is facilitated by the presence of bird excreta, for instance in old chicken houses, bird roosts, and barns. In tropical and some temperate areas, bat guano plays a similar role. Exposure to a suitable source, such as a cave containing bats, is often recorded in acute epidemic histoplasmosis (see below). It is rarely identified in more slowly evolving cases.

The condition of the host is important in determining the clinical course and manifestations of histoplasmosis. Slowly evolving (chronic), disseminated disease may occur in normal individuals. However, infants, elderly people, or those with untreated AIDS appear to be more likely to develop the more rapidly progressive forms of disseminated infection.

Epidemiology

The major endemic area, as shown by skin testing, is in the central region of the United States around the Ohio and Mississippi valley basins. Prevalence is highest in the states of Tennessee, Kentucky, and Ohio. Up to 95 per cent of those skin tested in certain parts of these areas have positive delayed reactions to intradermal histoplasmin (compare Mantoux test). Scattered cases of active disease, healed calcified foci in chest radiographs, and foci found at autopsy representing inactive histoplasmosis also provide evidence of spread within this area. However, the disease also occurs in other parts of the United States, Mexico, Central and South America, Africa, the Far East, and Australia. Outside the major endemic areas in the United States, human cases are less frequent, and much of the evidence of the endemicity comes from positive skin tests or the presence of the organism in selected sites, such as caves. Although there has been considerable discussion on the nature of soil factors responsible for the growth of *H. capsulatum*, the conditions limiting its occurrence to certain areas are largely unknown.

Clinical features

The clinical forms of histoplasmosis can be placed in several groups:

1. asymptomatic;
2. acute symptomatic pulmonary:
    i. acute epidemic,
    ii. acute reinfection;
3. chronic pulmonary;
4. disseminated (acute, subacute, and chronic); and
5. primary cutaneous (by inoculation).

Asymptomatic infection

Over 99 per cent of patients becoming infected in endemic areas record no overt symptoms but develop a positive skin test. The incidence of positive skin tests declines in individuals above the age of 60 years.

Acute (symptomatic) pulmonary histoplasmosis

Acute epidemic histoplasmosis

Groups of individuals exposed to a source of infection, for instance during cave exploration, or those who may have inhaled a large infecting dose, often develop a symptomatic illness 12 to 21 days after exposure. The main features are pyrexia, cough, chest pain, and malaise. Flitting arthralgia and, less commonly, erythema nodosum or multiforme may occur. The radiological appearances may be much more severe than would be supposed from the symptoms, and enlargement of hilar lymph nodes and diffuse or patchy consolidation suggesting pneumonitis may occur (Plate 6).

These patients develop precipitating or complement-fixing antibody, but this often follows the peak of illness. About 50 per cent of those with symptoms do not develop positive antibody responses. Likewise, skin test conversion is often too late to be of diagnostic value, and its use is normally contraindicated, as a single histoplasmin test may cause the development of false-positive serological results. Cultures are often negative. The symptoms and history of exposure to a suitable source, combined with a rising antibody titre, are often the best evidence of infection.

The majority of cases require no specific therapy apart from rest. Those with severe or prolonged symptoms or impaired gas exchange require intravenous amphotericin B or itraconazole. The lung lesions often heal to leave multiple scattered pulmonary calcifications.

Acute reinfection histoplasmosis

Massive acute exposure to *H. capsulatum* in sensitized individuals is believed by some physicians to cause a less severe infection associated with bilateral pulmonary infiltrates. The incubation period is shorter than with acute epidemic histoplasmosis, namely 5 to 10 days.

Chronic pulmonary histoplasmosis

Chronic pulmonary disease caused by *H. capsulatum* is mainly seen in the United States. It is more common in males and smokers, and there is often underlying pulmonary disease such as emphysema. Early cases may present with pyrexia and cough, but malaise and weight loss occur later. Lesions may heal initially, but relapse is common, leading to established consolidation and cavitation. The most common radiological appearance of early lesions is of unilateral, wedge-shaped, segmental shadows in the apical zones. Subsequently, the disease may become bilateral, with fibrosis and cavitation. In some cases, extensive and progressive destruction of lung tissue may occur.

Culture and serology are both helpful methods of diagnosis in this form of histoplasmosis, but repeated attempts may be required before positive results are obtained.

In early cases, resolution may occur on rest alone. However, relapse occurs in at least 25 per cent of cases, and these patients may require amphotericin B therapy or itraconazole. Although chemotherapy may virtually sterilize lesions, fibrosis persists and relapse may occur. Surgical excision or lobectomy is sometimes effective.

Solid lung tumours may persist after the primary infection. These may be single (coin lesions) or multiple, and have to be distinguished from carcinomas. The diagnosis is normally made at surgery, although the presence of calcification may give a clue to the nature of the lesion (histoplasmoma). The organisms can be demonstrated by histopathology, but they are seldom viable.

Disseminated histoplasmosis

There is considerable variation in the rate of progression of histoplasmosis that has spread beyond the initial focus in the lung. In rapid or acutely disseminated cases, widespread infiltration of reticuloendothelial cells of bone marrow, spleen, and liver may occur. Gastrointestinal lesions, endocarditis, and meningitis are less common, and meningitis is more usually associated with a slower course of disseminated disease. Infants, elderly people, or immunosuppressed patients are more susceptible to acute dissemination. The most prominent symptoms are fever and weight loss, with accompanying hepatosplenomegaly. Extensive purpura and bruising secondary to thrombocytopenia may occur. The blood picture may reflect marrow infiltration with organisms, leading to pancytopenia. Disseminated histoplasmosis is also seen in patients with AIDS. The clinical manifestations are not significantly different, although skin papules and ulcers have been reported in many; isolation of *Histoplasma* from blood has also been reported more frequently in these patients. Cultures, including sputum or bone marrow, should be taken. Serology is often positive, with high titres of complement-fixing antibodies occurring in some patients. However, new antigen detection systems in serum or urine provide a better means of confirming the diagnosis and monitoring treatment.

A much more slowly progressive form of disseminated histoplasmosis may present with fewer localized lesions, such as persistent oral ulcers, chronic laryngitis, or adrenal insufficiency. Granulomas, few of which contain organisms, can be found in the liver in some patients. Such cases may present up to 30 years after the patient has left an endemic area. Outside endemic areas this form is the most widely recognized presentation of histoplasmosis, occurring in Europeans, for instance, who have worked in Africa or the Far East.

The diagnosis of disseminated histoplasmosis is made on culture or biopsy of affected areas. Antibodies may only be positive in low titres and in all cases adrenal involvement should be looked for.

Treatment is required in all forms of disseminated histoplasmosis. Itraconazole is preferred by most physicians, although amphotericin B may be necessary in some patients. Oral ketoconazole is an alternative. In patients with AIDS who are acutely ill, the disease is often controlled by a short (2 week) course of amphotericin B and thereafter patients receive continuous itraconazole indefinitely.

Primary cutaneous histoplasmosis

Primary infection sometimes follows accidental inoculation of viable organisms in a laboratory or autopsy room. This type of infection is normally associated with a chancre at the site of inoculation and regional lymphadenopathy. The condition is self-limiting.

African histoplasmosis

Overt pulmonary involvement is rare in this form of histoplasmosis, and the normal portal of entry of the pathogen is not known. The most common presenting features are skin lesions (papules, nodules, abscesses, or ulcers) (Plate 8) or lytic bone deposits. Solitary or multiple foci may be present, and in the latter instances rapid progression and death may occur. In such cases, gastrointestinal and lung lesions may develop.

The diagnosis is normally made by culture, smear, or biopsy. The organism *H. capsulatum* var. *duboisii* is identical to that causing classic histoplasmosis in culture, but in lesions the yeast forms are considerably larger (10 to 15 µm).

While local excision of skin nodules has been reported to be curative, treatment with itraconazole, ketoconazole, or amphotericin B is usual. Some patients will respond to co-trimoxazole. A skeletal scan should be made to detect occult foci of infection.

Blastomycosis (see also Section 23)

Blastomycosis (North American blastomycosis) caused by *Blastomyces dermatitidis* is a systemic fungal infection in which skin and lung involvement are common features.

The infective organism, *B. dermatitidis*, has only been isolated from the environment on rare occasions. Positive sites have included soil and rotten timbers. The organism infects humans and domestic animals, particularly the dog.

Epidemiology

Blastomycosis was originally thought to be confined to North America, where it occurs sporadically throughout the south and east-central area, and in areas of central Canada. 'Epidemics' of acute disease are rare, and where these occur a source of infection is rarely demonstrated. There is evidence that sources may include areas exposed to flooding.

More recently, cases have been found in Africa. Again, these are widely scattered from the north coast to the southern parts of the continent, and are rare in all areas. Patients with the disease have also been reported from the Middle East and Central Europe.

Clinical features

The clinical forms of blastomycosis differ from histoplasmosis in a number of important aspects. The existence of an asymptomatic form has not been proved conclusively, because there is no reliable skin test. Acute infections or infections in groups are rare, and the features are often similar to histoplasmosis (acute pulmonary). However, specific serological tests may be negative in 30 to 50 per cent of cases. The demonstration of the organisms in sputum and positive cultures are more reliable diagnostic criteria. Although some cases undoubtedly resolve without sequelae, some physicians advise chemotherapy, with a short course of amphotericin B in acute cases of blastomycosis.

Chronic pulmonary blastomycosis

Chronic consolidation or cavitation of the upper or mid-zones occur with chronic pulmonary infections. Fever, malaise, and cough with sputum are seen. Weight loss may be prominent. Culture is again the most reliable method of diagnosis.

The mainstays of treatment are itraconazole or amphotericin B.

Disseminated blastomycosis

Although generalized infiltration in skin, lungs, and liver may occur over a short period, leading to rapid death, signs of chronic extrapulmonary dissemination are more usual.

The skin is an area that is frequently involved (chronic cutaneous blastomycosis). The face or forearms and hands are common sites for skin lesions. These are slow, spreading, verrucose plaques with central scarring. The initial lesion is often a dermal nodule. Many such cases have underlying pulmonary consolidation, or cavities. The diagnosis is established by biopsy and culture. Bone deposits in the form of lytic lesions, and involvement of the genitourinary tract, particularly the epididymis, are also seen in chronic disseminated blastomycosis. Unlike tuberculosis, the kidneys are often spared.

In slowly progressive forms of blastomycosis, itraconazole (200 to 400 mg daily) has proved to be very effective. Alternatively, amphotericin B can be given intravenously and is indicated where there is rapidly progressive disease.

Coccidioidomycosis

See Chapter 7.12.3.

Paracoccidioidomycosis

See Chapter 7.12.4.

Systemic sporotrichosis

In addition to causing cutaneous disease, *Sporothrix schenckii* may be responsible for a systemic mycosis. The infection is rare and has been mainly reported from the United States. Involvement may be confined to a single site such as a lung or a joint, or it may be multifocal. Cavitation in the lung associated with weight loss and pyrexia is probably the most common variety of systemic sporotrichosis. Unlike cutaneous forms of the disease, systemic sporotrichosis responds poorly to potassium iodide, and amphotericin B is the treatment of choice.

Rare systemic infections

These include pulmonary invasion by *Geotrichum candidum* (geotrichosis) and adiaspiromycosis, a respiratory infection caused by *Emmonsia crescens* or *Emmonsia parva*. Isolated examples of human disease caused by fungi are consistently reported and almost always occur in the immunosuppressed host. In these patients many fungi that are normally saprophytes in the environment may invade and cause disease.

Systemic mycoses caused by opportunistic fungi

The opportunistic mycoses are a worldwide problem, although fortunately rare in most countries. In recent years they have been recognized more frequently with the increase in transplantations of organs such as heart or bone marrow and in the more effective but immunocompromising regimes of cancer chemotherapy. Opportunistic invasion by organisms such as *Candida* or zygomycetes (*Mucor*, *Absidia*) may also occur in cases of malnutrition. One of the recent trends in the management of the patient with neutropenia has been the emergence of new pathogens such as non-*albicans* species of *Candida* or other organisms such as *Fusarium*, *Trichosporon*, or *Hansenula* species.

The opportunists present particular problems in diagnosis and management. Because many of the organisms are normally saprophytic, it has to be positively established that they have assumed an invasive role. Mere isolation may not provide sufficient evidence and in some instances low titres of antibody may be present

even in normal hosts. The significance of various laboratory tests in these infections is shown in Table 3. Treatment is also difficult and it is important in most cases to attempt to reverse the process that led to the establishment of the infection.

Systemic candidosis

Aetiology

In addition to their role in superficial infections, yeasts of the genus *Candida* may also cause invasive systemic disease. The clinical forms described range from bloodstream isolation or candidaemia to disseminated invasive disease, sometimes with involvement of a single organ, site, or body cavity (deep focal candidosis) as may occur in peritonitis or meningitis. Urinary tract infections may also be caused by *Candida* species.

The factors underlying systemic *Candida* infections are shown in Table 4. All these factors are important in disrupting the balance by which *Candida* is maintained as a saprophyte. Intravenous or central venous pressure lines may serve as a portal of entry or as a nidus for circulating yeasts in a candidaemia. Antibiotic therapy may upset the balance by inhibiting a potentially competitive bacterial flora.

Candida albicans is the most common species involved but other species may be isolated, particularly in cases of endocarditis, for example *Candida parapsilosis*. *Candida tropicalis* has been implicated in infections of patients with neutropenia. These non- *albicans Candida* species are now more frequent causes of systemic infection and are important to recognize as their antifungal susceptibility may differ from *C. albicans*. Portals of entry include the gastrointestinal tract (common), skin, and urinary tract (rare). However, superficial candidosis or saprophytic colonization of mouth, skin, or airways may also occur in compromised patients and does not necessarily indicate systemic invasion.

Epidemiology

Systemic infections caused by *Candida* species are worldwide in distribution. However, they are particularly associated with a number of predisposing factors such as neutropenia, antibiotic usage, indwelling lines, and abdominal surgery.

Clinical features

Candidaemia

The isolation of *Candida* in blood culture may be linked to any of the factors listed in Table 4. Common predisposing features are the presence of intravenous lines, previous surgery (mainly gastrointestinal), antibiotic therapy, hepatic failure, or neutropenia. Patients develop a swinging fever and feel generally unwell. Clinical shock may occur.

Some such cases resolve following removal of predisposing factors, particularly the intravenous lines. Generally, however, all such patients receive treatment and a careful investigation should be made to identify the presence of established invasive disease. Other sites should be searched for evidence of infection; for example urine by culture or the presence of white cells. Signs of muscle invasion (tenderness) or metastatic skin nodules should be excluded (Plate 9). Other signs of invasion include the development of new cardiac murmurs or of soft, white, retinal plaques caused by *Candida*. Persistently positive blood cultures or serum *Candida* antigen levels or high antibody titres may also indicate possible deep invasion.

Disseminated candidosis

Although multiorgan invasive candidosis may follow candidaemia, at least 50 per cent of disseminated infections develop in patients without initially positive blood cultures. The features of some forms of invasive candidosis are listed above (under Candidaemia). Although *Candida* may be isolated from the sputum in these patients, there is rarely objective evidence of lung invasion. Moreover, there is no radiological appearance that is diagnostic of pulmonary candidosis and, indeed, chest radiographs may even appear normal. General localizing signs may be a late feature of disseminated candidosis.

Laboratory diagnosis of disseminated candidosis

The diagnosis may be made by culture and repeated attempts to isolate should be made where cultures are initially negative. Numerous techniques have been used to detect antibody or antigen in disseminated candidosis. However, in many patients, particularly those with neutropenia, it may not be possible to confirm the diagnosis using laboratory tests and treatment is often initiated on the basis of clinical suspicion (empirical therapy) as the risk of delaying antifungal therapy is great.

By themselves, positive cultures, particularly from sputum, or the presence of antibodies do not necessarily prove the existence of deep-seated candidosis. A positive isolation may simply indicate the presence of colonization and normal individuals may have low titres of antibody to *Candida*. If there is a readily accessible lesion from which to take a biopsy, such as a skin nodule or even a pulmonary infiltrate, this may provide the best evidence of invasion, although such procedures may carry their own risk (Plate 8).

Treatment of disseminated candidosis

Untreated disseminated candidosis is normally progressive and fatal. The signs must be separated from, for instance, bacterial septicaemia, which may coexist with the *Candida* infection.

The treatment of invasive candidosis is intravenous amphotericin B or intravenous or oral fluconazole given until there is a clinical and mycological response. This may take between 2 and 20 weeks depending on the site of infection and the underlying state of the patient. Fluconazole is usually used in infections where the patient is not neutropenic. Lipid-associated forms of amphotericin B are also useful and carry a lower risk of renal impairment. An alternative approach is to add flucytosine in doses of 150 to 200 mg/kg body weight daily to amphotericin B in serious infections or where cure may be hampered by poor penetration of amphotericin B, such as in the eye.

Deep focal candidosis

Candida infections in the peritoneum or meninges most often follow direct implantation after dialysis or surgery. Alternatively, secondary invasion from the middle ear or a perforated bowel is also possible. The signs and symptoms are similar to bacterial meningitis or peritonitis but *Candida* is isolated. Sometimes these infections clear spontaneously, but normally treatment is instituted with fluconazole, which penetrates areas such as peritoneum, or amphotericin B.

Candida endocarditis

Invasion of heart valves, mainly the mitral or aortic valves, most commonly follows homograft replacement, but it may occur also in patients with neutropenia or drug addicts. The symptoms are similar to bacterial endocarditis. However, *Candida* vegetations may reach considerable size. Embolic phenomena may involve obstruction of large vessels including the femoral artery or large cerebral vessels. The detection of large vegetations using an echo scanning device, particularly in cases with negative blood cultures, should raise the possibility of fungal endocarditis. Blood cultures are usually positive at some stage in the illness but repeated sampling may be necessary. High antibody titres are usually seen in such cases and serological tests are therefore of considerable value.

Untreated *Candida* endocarditis is uniformly fatal. There is also a high mortality associated with cases in which early surgical intervention is precipitated by impending heart failure. Normally, treatment consists of amphotericin B given intravenously and, where possible, valve replacement. There is no evidence to suggest that the addition of flucytosine to the regimen increases the effectiveness of treatment. However, the relapse rate is high and combination therapy may therefore be a reasonable approach on theoretical grounds.

Urinary tract candidosis

Candida species may be isolated from the urine, particularly in conditions associated with urinary stasis such as neurogenic bladder or where there is an indwelling catheter. Maturity-onset diabetes mellitus is another predisposing factor. There is no value in using the presence of pyuria or quantitative yeast-colony counts to assess the significance of infection. Treatment is normally given where there are symptoms such as dysuria or frequency or where there is a potential risk of invasion such as in immunosuppressed patients. Fluconazole is very useful in these patients as urinary levels are above inhibitory concentrations.

Aspergillosis (see Section 8.4)

Cryptococcosis

Aetiology

Cryptococcosis is a systemic infection caused by *Cryptococcus neoformans*. Its most common clinical feature is meningitis, but pulmonary, cutaneous, and widely disseminated forms of the infection are also recognized. There are two varieties of *C. neoformans* called *C. neoformans neoformans* and *C. neoformans gattii*. They differ in their geographical range and ecology. The *neoformans* variety is the most common in patients with AIDS.

C. neoformans neoformans is a yeast that can be isolated from the environment, although it is most often found in pigeon excreta. Its growth from soil appears to be enhanced by certain nitrogenous compounds, such as creatinine in the pigeon droppings. The birds are not infected, although their crops may be heavily colonized. Very large numbers of organisms (1×10^7 yeasts/g of droppings) may be found in densely populated urban areas. *C. neoformans gattii* has been detected in leaf and bark debris of certain eucalyptus species.

The portal of entry is usually the lung, from where the organism spreads to involve other organs or sites such as the meninges. Although many isolates from natural sources have small cells, one sequel to tissue invasion is the development of a large, mucoid capsule *in vivo*, a feature that may confer some protection to the organism. Infections with *C. neoformans* are seen in both normal and immunocompromised hosts. The main underlying processes are sarcoidosis, Hodgkin's disease, collagen disease, carcinoma, and the administration of systemic corticosteroid therapy, but AIDS is the commonest predisposition.

Epidemiology

Cryptococcosis has been recorded from most countries, although it is most prevalent in the United States and Australia. Before the AIDS epidemic in the United States approximately 50 per cent of cases were said to occur in normal persons. By contrast, in the United Kingdom, 85 per cent of cases were found in patients with underlying disorders. There is no skin-test reagent widely available, but some pilot studies in the United States suggest that workers exposed to the organism (for example in laboratories) are more likely than other groups to have a positive skin test without any overt sign of infection. It is probable, therefore, that there is an asymptomatic form of cryptococcosis (compare histoplasmosis). Additional evidence for the existence of subclinical infection is provided by the repeated isolation of *C. neoformans* in sputum from individuals without evidence of disease.

Clinical features

Pulmonary cryptococcosis

Acute or subacute respiratory disease caused by *C. neoformans* is seen in both HIV-positive and healthy individuals. The disease consists of a chest infection with fever and cough and scattered, often well-circumscribed, areas of pulmonary infiltration seen on radiographs. Pleural involvement can occur and sometimes massive pulmonary infiltrates may occur. Before the advent of the azoles, in some patients the whole process resolved without treatment, although it is probably advisable to give fluconazole to those with isolated pulmonary disease. More often, lung lesions accompany disseminated cryptococcosis or cryptococcal meningitis and the treatment is discussed below. The laboratory diagnosis is made by biopsy or culture. Isolated cryptococcal granulomas (cryptococcoma) may present as coin lesions and are removed surgically to exclude carcinoma. Once the correct diagnosis is made, many workers advise a short course of amphotericin B or fluconazole as there is a small risk of dissemination to other organs following surgery.

Disseminated cryptococcosis

The best-recognized form of extrapulmonary cryptococcosis is meningitis. This may present with signs of acute meningism. However, more usually the features are less specific. Pyrexia, headache, and mental changes such as confusion or drowsiness occur. The mental changes probably follow the development of hydrocephalus. Blurring of vision and papilloedema may also occur. Cranial nerve involvement is less common. Patients with AIDS often present with widely disseminated disease. The signs of meningeal involvement may be very subtle and the infection has often spread to other sites such as liver and spleen as well as skin.

The cerebrospinal fluid shows pleocytosis that is highly variable. Often there are excessive numbers of lymphocytes, but sometimes polymorphonuclear leucocytes abound. In some cases only small numbers of white cells (4 to 10/ml) are seen. Characteristically, but not invariably, the glucose concentration falls and protein rises. Cryptococci can be seen in some cases in an India ink or nigrosin preparation, which is used to highlight the capsule. A spun sediment is best for this purpose. The organism can also be cultured from the cerebrospinal fluid. The latex test for antigen is usually positive for cerebrospinal fluid, but on rare occasions this is negative. The antigen titre has both diagnostic and prognostic value. Initial high (> 100) titres are likely to correlate with relapse following therapy and with a poor prognosis. In patients with AIDS, antigen titres over 1:1000 convey poor prognosis and blood cultures are often positive. Extrameningeal disease should be looked for by sputum or urine culture and serology in patients presenting with meningitis.

Other sites

Cryptococci may disseminate to other sites including liver and spleen, kidney, skin, or bone. Infection in skin and bone are most often seen in patients with sarcoidisis. In every case, underlying deep disseminated lesions (such as meningitis) may be found. The methods of diagnosis and treatment are similar to those seen with meningitis. Only a small proportion of cases with solitary disseminated lesions of cryptococcosis, such as bone or skin, may have detectable antigen (15 to 30 per cent), and this may occur late in the course of therapy. In patients with AIDS the organism spreads widely involving bone marrow, liver, and spleen as well as other sites. Positive blood cultures are not uncommon. The serum antigen titres are often very high, for example over 500, and may not return to normal even during antifungal treatment.

It is important in all cases where cryptococcosis presents with lesions in an extrameningeal site to exclude occult meningitis by lumbar puncture.

Treatment

In the patient without AIDS the combination of flucytosine (150 to 180 mg/kg daily) and intravenous amphotericin B (0.3 to 0.6 mg/kg daily) is the most widely used treatment. It is possible to induce recovery with this approach and treatment is generally continued for at least 6 weeks or longer if necessary. The clinical response and antigen levels are useful for monitoring progress.

The situation is different in patients with AIDS because in patients not receiving combination antiretrovirals it is impossible to achieve complete recovery. The object of therapy is to induce the most rapid remission possible, followed by long-term suppressive therapy. There are various regimens used for induction of remission. The use of amphotericin B with or without flucytosine is favoured by many. This is given for 2 weeks and is then followed by indefinite treatment with fluconazole to prevent

relapse. Itraconazole is an alternative. In patients on highly active antiretroviral therapy (MAART) it may be possible to discontinue treatment but guidelines are awaited.

Invasive zygomycosis (mucormycosis, phycomycosis)

Aetiology

Invasive disease caused by mucor-like (zygomycete) fungi is rare. In the compromised host it may lead to paranasal destruction, necrotic lung or skin lesions, and disseminated disease.

The causative organisms commonly belong to three genera, *Absidia*, *Rhizopus*, and *Rhizomucor*. More rarely other organisms such as *Cunninghamella* or *Saksenaea* have been implicated. Most of the agents are associated with decaying vegetable matter and are common airborne moulds. The route of infection is highly variable: they may invade via the lungs, paranasal sinuses, gastrointestinal tract, or damaged skin. The predisposing illness may in some way determine the site of clinical invasion. Underlying factors include diabetic ketoacidosis (rhinocerebral involvement), leukaemia and immunosuppressive therapy (lung and disseminated infection), malnutrition (gastrointestinal infection), and burns or wounds (cutaneous invasion). These patterns are not always strictly followed.

Epidemiology

Invasive zygomycosis is rare but has a worldwide distribution. Its invasive nature, particularly the tendency to involve blood vessels and its selection of compromised hosts, distinguishes this form of infection from subcutaneous zygomycosis, which is also caused by zygomycete species.

Clinical features

The most characteristic features of this type of infection are the extensive necrosis and infarction that may follow blood vessel invasion leading to thrombosis. A similar type of invasion may occur with invasive aspergillosis, but is usually less prominent. Invasive zygomycosis follows a number of different patterns.

The infection may initially localize in one of several sites. The most common is in the paranasal sinuses and this is most often seen in diabetic patients with ketoacidosis. The patient presents with fever and unilateral facial pain. Subsequently, there may be facial swelling with nasal obstruction and proptosis. There may be invasion into the orbit leading to blindness, into the brain, and the palate. Palatal ulceration should be searched for. Widespread dissemination with infarction of major organs or limbs may occur subsequently. A similar pattern of invasion of surgical wounds or burns may occur and has on occasions been associated with contamination of dressing packs. Infections are initially localized causing extensive necrosis around the original wound. Gastrointestinal invasion may be heralded by perforation of viscera, and diarrhoea or haemorrhage.

Alternatively, a patient may present with established pulmonary or widespread dissemination. Such patients are usually leukaemic or are severely immunosuppressed. Neutropenia is often seen.

Once infection has spread beyond the original site, invasive zygomycosis is almost invariably fatal with or without treatment.

Laboratory diagnosis

The diagnosis is suggested by the combination of infection and extensive infarction, particularly if it occurs in any of the sites mentioned. The organisms may be difficult to culture even from biopsy and histology is often the quickest way of establishing the diagnosis. Serology is frequently negative.

Treatment

Treatment should be initiated as soon as possible and extensive surgical debridement combined with intravenous amphotericin B in maximum daily dosage offers the best chance of success. Local instillations of amphotericin B may also be used where appropriate (such as nasal sinuses). Some physicians also recommend anticoagulation with heparin to forestall thrombosis. Despite therapy, the mortality remains high. Liposomal amphotericin B also has been used with some success is cases of mucormycosis.

Rhinosporidiosis

Rhinosporidiosis is an infection found in India, Sri Lanka, parts of East Africa, and South America. It is characterized by polypoid growth from the nose or conjunctiva. The causative organism can be demonstrated in tissue and consists of aggregates of large sporangia containing spores in various phases of development. However, they have never been successfully cultured and their fungal nature has only been assumed from their morphological appearance in histology.

The treatment is surgical excision.

Otomycosis and oculomycosis

External otitis is often multifactorial, but in some cases dense fungal colonization can contribute to the picture. In severe cases, the external ear may be plugged by a dense mat of mycelium. *Aspergillus* species are the most common organisms cultured, particularly *A. niger*, but *Candida*, *Penicillium*, and *Mucor* may all contribute. Intensive ear toilet may eradicate the infection without recourse to antifungal agents.

Infections of the eye, particularly the cornea, caused by fungi (oculomycosis) are rare. They often follow penetrating injuries to the globe or contamination of lacerations. An opacity develops within the cornea with associated pain and chemosis. An exudate is usually present in the aqueous humour. Prompt treatment with intensive topical instillation of drugs containing an antifungal drug such as miconazole or econazole is necessary every 2 to 4 h. Perforation of the eye may occur in advanced cases.

Approaches to management of fungal infections

Antifungal agents can be considered in four main groups: the polyenes, azoles, morpholines, and allylamines, and an assortment of drugs of specific activity that are not related.

The polyene antifungals are macrolide substances derived originally from species of *Streptomyces*. They include amphotericin B, natamycin, and nystatin. More recent additions to this group are partricin and mepartricin. Amphotericin B is the only one widely used as a parenterally administered drug. Nystatin and natamycin are purely topical. Amphotericin B is metabolized in the liver with low penetration of body cavities, cerebrospinal fluid, and urine. The polyenes have broad activity

against a wide range of fungi. The mode of action of the polyenes appears to involve inhibition of sterol synthesis in the fungal cell membrane.

The combination of an amphotericin B with a lipid, for instance a liposome, has been proposed as a means of reducing the nephrotoxicity of this drug. Three commercial lipid amphotericins are available: AmBisome (a true liposome), amphotericin B lipid complex—ABLC or Abelcet (a ribbon-like lipid binding amphotericin B), and amphotericin B colloidal dispersion (ABCD) (a dispersion of lipid discs).

The imidazoles are synthetic antifungal agents. They include miconazole, clotrimazole, econazole, isoconazole, ketoconazole, tioconazole, and bifonazole. The triazole series contains two potent oral agents, fluconazole and itraconazole. A third, voriconazole, is in clinical trial. Most are used topically except for ketoconazole (oral), itraconazole (oral), and miconazole (intravenous). These are metabolized in the liver and, like amphotericin B, affect fungal cell-membrane synthesis and penetrate cerebrospinal fluid and urine in low concentrations. The imidazoles have a broad spectrum of activity against many fungi, although neither miconazole nor ketoconazole are useful for aspergillus infections. By contrast, itraconazole is active *in vitro* against aspergilli. Fluconazole is less active against moulds and there are instances of both primary (*Candida krusei*, *C. glabrata*) and secondary resistance to this compound. The allylamines such as terbinafine are primarily active against superficial fungi, but *in vitro* appear to have fungicidal activity at low concentrations.

Other antifungal drugs include flucytosine, which is a synthetic pyrimidine analogue. Given either intravenously or orally it is mainly useful for chromomycosis and certain yeast infections. Drug resistance is a major problem with flucytosine, particularly with cryptococcus. The drug shows a number of modes of action including disruption of RNA transcription following uptake by the cell. Griseofulvin is derived from a species of *Penicillium*. It can be given orally and is only useful against dermatophytes. It is best absorbed when given with a meal and selectively accumulates in stratum corneum in concentrations approximately 10 times greater than serum levels. Griseofulvin acts by inhibiting intracellular microtubule formation. There are a large number of unrelated antifungal drugs, such as tolnaftate, haloprogin, and chlorphenesin, that are only used topically.

Management of superficial infections

Specific details of therapy are included under the separate diseases. Benzoic acid compound (Whitfield's ointment), which contains 2 per cent salicylic acid and 2 per cent benzoic acid, acts as a keratolytic agent by causing exfoliation of the superficial layers of the stratum corneum. Other topical agents with only eak antifungal activity include gentian violet (candidosis or dermatophytosis), Castellani's paint, which contains magenta and resorcinol (candidosis or dermatophytosis), and brilliant green (dermatophytosis). Two per cent selenium sulphide remains a highly effective method of treating pityriasis versicolor by application once daily for 2 weeks.

The more specific antifungals such as the polyenes, amphotericin B, nystatin, and natamycin (candidosis) or the imidazoles (candidosis, dermatophytosis, and pityriasis versicolor) are highly effective and probably quicker, although more expensive, than the keratolytics or dyes. Local irritancy can be a problem particularly with Whitfield's ointment, which is usually given as a half-strength preparation. Allergic contact dermatitis is rare but has been recorded from some imidazoles (miconazole, clotrimazole, tioconazole) and tolnaftate. Topical terbinafine is highly active in tinea pedis with cures being effected with less than 1 week of therapy.

Terbinafine or itraconazole are more effective in many forms of dermatophytosis requiring oral therapy than griseofulvin. In onychomycosis they are preferred. Terbinafine has occasional side-effects, mainly related to gastrointestinal intolerance, although it may also cause transient loss of taste. It is given in daily doses of 250 mg. Itraconazole is usually given in 'pulses', for example 200 mg twice daily for one week monthly. Itraconazole likewise can cause gastrointestinal discomfort and nausea. Both drugs rarely cause hepatic injury, with a frequency of less than 1 in 70 000–120 000. This is in contrast with ketoconazole, which also causes hepatitis but in around 1 in 8000 cases. Liver function tests should be monitored if ketoconazole is used extensively over any length of time. In high doses, ketoconazole may block human androgen biosynthesis causing side-effects such as gynaecomastia. Fluconazole is also effective in dermatophytosis and is given in weekly doses of 150 to 300 mg. Griseofulvin is still the principal treatment for tinea capitis (10 to 20 mg/kg per day).

In onychomycosis caused by dermatophytes both terbinafine and itraconazole lead to remission of toe-nail infections in only 3 months. Terbinafine is used on a daily basis, whereas itraconazole is given in a pulsed regimen, 200 mg twice daily for 1 week every month for 3 to 4 months. There is one study which shows better responses with terbinafine for toe-nail disease. Amorolfine, a morpholine drug, is used in the topical treatment of nail disease where there is less than complete involvement of the nails. It can be given together with other drugs, such as terbinafine.

Management of deep mycoses

There are very few drugs that are effective in systemic fungal infections and those that are used should always be accompanied by supportive measures and, if possible, an attempt to eliminate any predisposing conditions. For instance, if their condition permits, patients who have developed a candidaemia while a central venous line is in place should be managed by removal of the line. However, fluconazole is also usually given as well. In the patient with neutropenia, a positive blood culture would be regarded as evidence of dissemination and antifungal therapy would be required.

Amphotericin B is given intravenously in a 5 per cent dextrose infusion not containing additional drugs, if possible. A test dose of 1 to 5 mg is given over 2 h and this is followed by gradually increasing doses over the next 3 to 9 days to the normal maximum of 0.6 to 1.0 mg/kg body weight daily depending on the infection. In some cases this slow approach may help the patient to tolerate the drug better or may define the dose at which side-effects such as pyrexia start. In severely ill patients, half of the full dose may be given 4 h after a test dose of 5 mg, usually under hydrocortisone cover. The full dose is given 24 h later. Side-effects include thrombophlebitis, nausea, hypotension, and pyrexia. Renal clearance may fall in the initial period but this usually returns to normal after a temporary halt in therapy. More permanent renal tubular damage may follow a total dose of 4 g or more. Amphotericin B does not penetrate urine, cerebrospinal fluid, or peritoneal fluid in significant concentrations. Local instillations (such as the peritoneum) can be used, but can be highly irritant. Amphotericin B is normally given until clinical or mycological cure is induced. This is often difficult to judge accurately and in many of the mycoses caused by the systemic pathogens a course of at least 2 g is often used on an empirical basis. In the opportunistic infections, lower total doses are probably effective and the length of treatment should depend on the clinician's judgement.

This approach is not necessary with the lipid-associated amphotericin B formulations, which can be given without the slow build-up. The initial dose is usually 1 mg/kg but standard daily doses of 3 mg/kg are common. Patients are less likely to develop renal impairment although it can occur. There have been a few clinical trials comparing these formulations with amphotericin B and these show equal efficacy with less toxicity; however, these formulations are expensive. The main lipid-associated formulations are given above.

The azole drugs are also used in systemic mycoses. Fluconazole is given in systemic candidosis, urinary tract infections, and as a long-term suppressive, in addition to primary therapy, in cryptococcosis in patients with AIDS. Side-effects are uncommon, although it can cause nausea and vomiting. Fluconazole can be given orally or intravenously. It penetrates urine in effective concentrations. Its daily dosage varies from 100 to 200 mg for oropharyngeal infections to 600 to 800 mg for disseminated candidosis. It is highly active in *Candida* infections. It can also be used in some endemic mycoses such as histoplasmosis. Resistance to fluconazole has mainly been recorded with oropharyngeal candidosis, principally in HIV-positive patients, although it can occur with other *Candida* infections; *C. krusei* and *C. glabrata*, for instance, are often primarily resistant to this drug.

Itraconazole has been evaluated in a variety of systemic mycoses from aspergillosis to cryptococcosis. Its active range includes histoplasmosis, sporotrichosis, chromoblastomycosis, blastomycosis, coccidioidomycosis, and paracoccidioidomycosis. Itraconazole is used as an oral preparation, but a new intravenous formulation is now available. Oral absorption is often defective in individuals with AIDS and patients after bone marrow transplantion and in these groups the mean daily dosage is doubled (200 mg). An itraconazole suspension is also available for treatment of oral infections.

Flucytosine (5-fluorocytosine) is an effective oral and intravenous antifungal agent that is primarily active against yeasts such as *Candida* and *Cryptococcus*. It enters urine, cerebrospinal fluid, and peritoneal fluid. Its excretion is reduced in renal failure and the daily dose should be reduced accordingly and blood levels monitored. The main disadvantage of flucytosine is the development of either primary or secondary drug resistance in a significant number of isolates, and when given in toxic doses it may cause bone marrow depression. The serum level should not be allowed to rise above 100 to 120 µg/ml.

Combination amphotericin B and flucytosine therapy may offer an alternative but effective method of treatment. Theoretically, as the drugs synergize, the dose of amphotericin B may be reduced. In cryptococcal meningitis, combination therapy using a dose of 0.3 to 0.6 mg/kg body weight of amphotericin B with the normal dose of flucytosine is more effective at sterilizing the cerebrospinal fluid and preventing relapse. In other forms of systemic infection such as candidosis there is little evidence that it is more effective than amphotericin B alone, although this may be the case. Combinations of other drugs have not been evaluated *in vivo*.

The use of leucocyte growth factors has been reported to improve the recovery from fungal infections. The most effective combination has been a mixture of granulocyte and granulocyte–monocyte colony-stimulating factors. Further studies of these compounds in patients with neutropenia are warranted.

7.12.2 Cryptococcosis

William G. Powderly

Aetiology and epidemiology

Infection with the fungus *Cryptococcus neoformans* occurs mainly in patients with impaired cell-mediated immunity. It is the most common, systemic, fungal infection in patients infected with human immunodeficiency virus (HIV), and is also seen as a complication of solid organ transplantation, lymphoma, and corticosteroid therapy. *C. neoformans* is found world-wide as a soil organism; it is an encapsulated yeast measuring 4 to 6 µm with a surrounding polysaccharide capsule ranging in size from 1 to over 30 µm. Two varieties exist, distinguishable by serology—*C. neoformans* var. *neoformans* (serotypes A and D) and *C. neoformans* var. *gattii* (serotypes B and C). Virtually all HIV-associated infection is caused by *C. neoformans* var. *neoformans*. About 5 per cent of HIV-infected patients in the Western World develop disseminated cryptococcosis; the disease is more prevalent in sub-Saharan Africa and southeast Asia. *C. neoformans* var. *gattii* infection is more common in tropical and subtropical areas (Australia, New Guinea, the Philippines) in apparently immunocompetent people. It has rarely been reported in HIV-immunosuppressed patients.

The exact mechanism of infection is unknown. It is assumed that transmission occurs via inhalation of the organism leading to colonization of the airways and subsequent respiratory infection. Throughout the world, the excreta of birds such as pigeons is the richest environmental source of *C. neoformans* var. *neoformans*. The ecological association of *C. neoformans* var. *gattii* is with red river and forest river gum trees (*Eucalyptus camaldulensis* and *E. tereticonrnis*) and it has been suggested that infective basidiospores are released at flowering.

In the case of *C. neoformans* var. *neoformans*, the absence of an intact cell-mediated response results in ineffective clearance with subsequent dissemination. The polysaccharide capsule, composed mainly of glucuronoxylomannan, is thought to be its primary virulence factor. It is unclear whether cryptococcal infection in immunocompromised patients represents acute primary infection or reactivation of previously dormant disease.

Clinical features

The most common presentation of cryptococcosis is a subacute meningitis or meningoencephalitis with fever, malaise, headache, and altered behaviour and level of consciousness. Symptoms are usually present for 2 to 4 weeks before diagnosis. Classic meningeal symptoms and signs (such as neck stiffness or photophobia) occur in only about a quarter to a third of patients. Papilloedema and cranial nerve palsies (especially VI and VII) are common. Patients may present with encephalopathic symptoms such as lethargy, altered mentation, personality changes, and memory loss. Analysis of the cerebrospinal fluid (CSF) usually shows a mildly elevated serum protein, normal or slightly low glucose, and a lymphocytic pleocytosis. India ink staining of the CSF will usually reveal the yeast. Cryptococcal antigen is almost invariably detectable in the CSF. The opening pressure in the CSF is elevated in a majority of patients.

Infection with *C. neoformans* can involve sites other than the meninges. Isolated pulmonary disease has been well described and usually presents as a solitary nodule in the absence of other symptoms. Cryptococcal pneumonia also occurs. In immunocompromised patients, especially those with AIDS, subsequent dissemination is common but presentations such as cough or dyspnoea and abnormal chest radiographs may be the initial finding. Many patients have positive blood cultures. Skin involvement is common; several types of skin lesion have been described but the most common form is that resembling molluscum contagiosum. Osteolytic bone lesions and prostatic involvement have also been described.

In New Guinea, *C. neoformans* var. *gattii* is the commonest cause of chronic meningitis. Immunocompetent people are affected. Compared to *C. neoformans* var. *neoformans* meningitis in AIDS patients, victims of var. *gattii* have more aggressive retinal involvement with papilloedema and haemorrhagic papillitis in more than a half, leading to blindness in one-third of survivors.

Diagnosis

The latex agglutination test for cryptococcal polysaccharide antigen in the serum is highly sensitive and specific in the diagnosis of infection with *C. neoformans* and a positive serum cryptococcal antigen titre of greater than 1:8 is presumptive evidence of cryptococcal infection. Such patients should be evaluated for possible meningeal involvement. Culture of *C. neoformans* from any body site should also be regarded as significant and is an indication for further evaluation and initiation of therapy.

Treatment

Management of patients with cryptococcal infection depends on the extent of the disease and the immune status of the patient. The finding of a solitary pulmonary nodule in a normal host may not need treatment, provided patients have careful follow-up. Fluconazole, 200 to 400 mg/day can be given for 3 to 6 months in most patients with localized pulmonary disease. Extrapulmonary disease is generally managed in the same way as meningitis. In patients who are not known to be immunosuppressed, a search for underlying problems should be initiated. An HIV antibody test should be performed as cryptococcal meningitis may be the initial AIDS-defining event. Additionally, a CD4 lymphocyte count should be considered, as cryptococcal infection has been described as one of the manifestations of so-called 'isolated CD4 T-lymphocytopenia'.

Untreated, cryptococcal meningitis is fatal. In patients with AIDS, amphotericin B (0.7 mg/kg intravenously) given for 2 weeks followed by fluconazole 400 mg orally for a further 8 weeks is associated with the best outcome to date in prospective trials, with a mortality of less than 10 per cent and a mycological response of approximately 70 per cent. This regimen is also reasonable for treatment of meningitis in other circumstances. Concomitant use of flucytosine (100 mg/kg per day in four divided doses) with amphotericin B may be considered. In patients with AIDS, it does not improve immediate outcome but may decrease the risk of relapse. In other hosts, more prolonged use (4 to 6 weeks) of amphotericin B and flucytosine may be curative but is also toxic. The combination of fluconazole (400 to 800 mg/day) with flucytosine and liposomal formulations of amphotericin B are options for patients unable to tolerate the usual formulation of amphotericin B.

Clinical deterioration in patients with meningitis may be due to cerebral oedema, which may be diagnosed by a raised opening pressure of the CSF. All patients with cryptococcal meningitis should have the opening pressure measured when a lumbar puncture is performed, and if the opening pressure is high (>25 cm of water) pressure should be reduced by repeated lumbar punctures, a lumbar drain, or a shunt. In var. *gattii* meningitis, corticosteroid treatment is helpful in reducing intracranial pressure and reducing retinal damage.

Cryptococcal meningitis in AIDS requires life-long suppressive therapy unless the immunosuppression is reversed. In other immunocompromised patients, suppressive treatment for 6 to 12 months may be given. Fluconazole, 200 mg daily, is the suppressive treatment of choice. Fluconazole, in dosages ranging from 400 mg weekly to 200 mg daily, and itraconazole, 100 mg twice daily, are very effective in preventing invasive cryptococcal infections, especially in HIV-positive patients with CD4 counts less than 50 to 100 cells/mm^3. However, because of the relative infrequency of invasive fungal infections, antifungal prophylaxis does not prolong life and is not routinely recommended.

7.12.3 Coccidioidomycosis

John R. Graybill

Aetiology and epidemiology

Coccidioides immitis was initially named by Gilchrest in 1986, because its round spherule form appears similar to coccidia, which are protozoans. Although traditionally associated with the southwest United States, the pathogen was initially discovered by Alejandro Posadas in Buenos Aires. Although the Argentine Pampas remains an important focus for *Coccidioides*, the desert southwest of the United States and northern Mexico is better known as the endemic zone. Fifty years ago, German prisoners of war who were held in Arizona developed coccidioidomycosis, and were mistakenly thought to be the victims of 'medical research'. This illness still plagues German airmen who train in Arizona.

Coccidioides immitis is dimorphic, and grows as a mycelium in desert soil where winters are mild. After spring rains, mycelia form myriads of small barrel-shaped arthroconidia. The mycelium disrupts readily, and the conidia are wafted for many kilometres. Earthquakes and desert sandstorms in California have caused large epidemics. Infection follows inhalation of just a few conidia. Over the course of several days the fungus converts to the pathognomonic spherule. This enlarges to as much as 60 µm in diameter, and is commonly filled with maturing endospores. Endospores are released after several days of growth; they are chemoattractive to neutrophils, which ingest but cannot kill them. Endospores enlarge into spherules and the growth cycle repeats itself. Although the spherule does not directly transmit disease, it is important to destroy all contaminated materials to prevent this most infectious of the endemic mycoses from converting back to the mycelium and causing secondary infections.

Clinical features

In no mycosis is the interplay of pathogen and host defences more important than coccidioidomycosis. The uncomplicated infection progresses through 3 to 6 weeks in the lungs, during which time protective cell-mediated immune responses develop. A strong immune response may cause arthralgias, fever, eosinophilia, and various rashes, including erythema multiforme or erythema nodosum ('desert fever'). A rise in IgM precipitin antibodies is diagnostic. Initial pulmonary infiltrates are later replaced by granulomas, which may condense to cicatrices or nodules. Cavitation of nodules may occur within weeks, or be a much later consequence of smouldering disease. The skin test to either spherulin or coccidioidin antigens commonly converts to positive. Illness resolves over weeks or months, to leave lifelong immunity. Low titres of IgG 'complement-fixation' antibody are generated 1 to 2 months after infection, and may persist for months.

Immunity and dissemination

Although immune suppression (by steroids or AIDS) is associated with dissemination, there are subtle factors of race (Blacks, American Indians, Filipinos) and gender (pregnancy) which also favour dissemination. The course of the disease may be strung out over years, with responses to treatment being followed by relapses. If the host is severely immune depressed, the course may evolve rapidly over weeks to persistent worsening pulmonary infiltrates and haematogenous dissemination to almost any tissue. Favourite locations are the bones (especially vertebral osteomyelitis), the skin (papular verrucous or proliferative), the lymph nodes, and the central nervous system. Coccidiodal meningitis presents insidiously (or rarely acutely after exposure) with headache, nausea, vomiting, seizures, and focal signs. Hydrocephalus and brain infarcts may develop. In general the association of skin or deep tissue abscesses draining pus with neutrophils and coccidioides indicates a poor host immune response, while granulomas showing spherules in Langerhans giant cells suggest better control of the organism.

Diagnosis

The IgG antibodies tend to rise to levels associated with the severity of disease (titres of $\geq$ 1:16 suggest worsening disease), and may remain elevated for many months. The erythrocyte sedimentation rate also rises. Coccidioidal meningitis is associated with lymphocytic and eosinophilic pleocytosis, hypoglychoracchia, and positive cerebrospinal fluid culture and/or serology for IgG.

The diagnosis of coccidioidomycosis may be made by culture or histopathology of tissues showing the characteristic spherule, or may be inferred from positive IgM or IgG serum (or IgG cerebrospinal fluid) antibody titres. The oganism is biphasic and converts readily to the mycelium in most culture media. Coccidioides is susceptible *in vitro* to most polyene and azole antifungals. Nevertheless, coccidioidomycosis is the most difficult of the endemic mycoses to treat.

Treatment

Clinical response is assessed using a scoring system developed by the Mycoses Study Group. This includes clinical symptoms and signs, cultures, radiographic changes, and serology. For non-meningeal disease, amphotericin B is reserved for those patients with the most fulminant courses, and even then there may be only a 70 per cent response rate. One troubling site of disease is vertebral osteomyelitis. This site is commonly refractory to medical therapy alone, and usually requires surgical stabilization of the spine for cure. For most patients the treatment of choice may be itraconazole, with a loading dose of 800 mg followed by 400 mg per day (capsules) until the illness resolves and then 9 to 12 months more for consolidation. A solution of itraconazole improves absorption but is less well tolerated than capsules. Resolution may require months or years, and occurs in fewer than 70 per cent of patients. Post-treatment relapses occur in 30 to 40 per cent of patients and may require repeated courses or higher doses. Fluconazole at 400 to 800 mg per day is an alternative for non-meningeal coccidioidomycosis, and is the drug of choice for meningeal coccidioidomycosis. Fluconazole allows highly toxic intrathecal amphotericin B to be avoided, but for coccidioidal meningitis it must be administered for the rest of the patient's life. More than two-thirds of patients relapse if fluconazole is stopped, even after many years of therapy. Cerebrospinal fluid abnormalities normalize very slowly on fluconazole; chemistries may improve more rapidly with intrathecal amphotericin B. However, amphotericin B causes arachnoiditis, and patients may even have cerebrovascular accidents complicating this therapy.

Two recently developed thiazoles, voniconazole and posaconazole, may be superior to itraconazole. Posaconazole has shown very rapid improvement in most patients but there are still relapses when treatment is dropped.

7.12.4

Paracoccidioidomycosis

M. A. S. Yasuda

Definition

Paracoccidioidomycosis is a systemic granulomatous disease caused by a dimorphic fungus, *Paracoccidioides brasiliensis*, that involves mainly the lungs, phagocytic mononuclear system, mucous membranes, skin, and adrenals.

History

The disease was first described in 1908 by Lutz, a Brazilian scientist. In 1912, Splendore classified the organism as a yeast of the genus *Zymonema* and in 1928, Almeida and Lacaz suggested the name Paracoccidioides. In 1930, Almeida named the fungus *Paracoccidioides brasiliensis*. Formerly the disease was known as South American blastomycosis, or Lutz–Splendore–Almeida' s disease. In 1977 it was renamed paracoccidioidomycosis.

Epidemiology

Paracoccidioidomycosis is the most common endemic human mycosis in Latin America and is geographically restricted to Central and South America, ranging from Mexico to Argentina. The disease is prevalent in Brazil, Colombia, Venezuela, Argentina, Uruguay, Paraguay, Guatemala, Equador, Peru, and Mexico. No cases have been reported in Chile, Belize, Nicaragua, Guyana, Surinam, or French Guyana. Imported cases have been recorded in the United States, Europe, and Asia.

Prevalence, inferred from the result of intradermal paracoccidioidin testing, ranges from 6 to 60.6 per cent among rural and urban populations of endemic and non-endemic areas. It is equally prevalent in both sexes.

The disease occurs mainly among 20- to 50-year-olds, who are agricultural workers or who have lived in rural endemic areas. The sex ratio of clinical cases is 10 or more males to each female among adults, while it is equally distributed among prepubescent boys and girls. This may be explained by the ability of oestrogens to inhibit the transformation of mycelium or conidia to yeast. Spouses of patients are rarely affected by the disease, which suggests that hormonal and genetic factors play a part in the distribution of this mycosis. Transmission from one person to another has not been shown.

Ecology

The geographical regions in which paracoccidioidomycosis is most commonly found are humid areas where the soil is more frequently acidic and the temperature ranges from 15 to 30 °C.

P. brasiliensis has been isolated from soil, animals such as armadillos and bats, dog food, and penguin faeces. It has also been isolated from the intestinal contents of bats. Efforts to maintain the fungus in bat intestines have been unsuccessful. The saprophytic habitat of *P. brasiliensis* has yet to be discovered.

Aetiology

Mycology

P. brasiliensis is a dimorphic fungus, which can be cultivated either as a mould or a yeast. When cultured at 25 °C it appears after 15 to 30 days as white colonies. When Sabouraud's dextrose agar is used the mycelium shows hyaline septate hyphae with branches.

P. brasiliensis also grows as a yeast in human and animal tissues (Fig. 1) and in cultures maintained at 37 °C. Colonies can be observed after 7 to 20 days. Under direct microscopy, yeast forms can be observed as oval or spherical cells with doubly refractile walls; the cells vary in size from buds of 2 to 10 µm in diameter to mature cells of 20 to 30 µm. Mother cells may produce 10 to 12 uniform or variably sized buds (Fig. 2), forming the characteristic 'pilot wheel' shape observed in biological samples or in infected tissues.

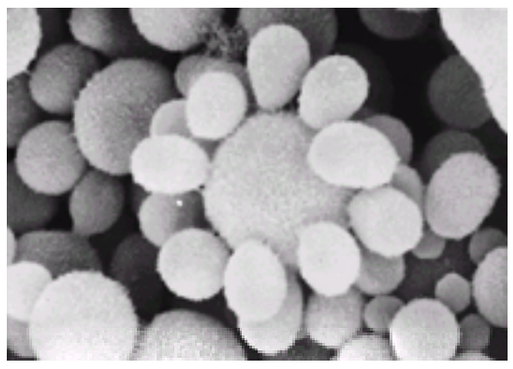

Fig. 2 Scanning electron micrograph of a multiple budding yeast cell of *Paracoccidioides brasiliensis*. (By courtesy of C. S. Lacaz.)

Genomic clones that encode a 70 kDa heat shock protein from this dimorphic fungus have been studied. A differential expression of this gene was observed between mycelial and yeast forms, with a higher level of expression in the yeast form.

Virulence

Virulence is defined as the ability to produce disseminated infection in experimental animals. Variation in the virulence of different fungal isolates has been documented but little is understood of the biochemical basis for these differences.

The presence of higher levels of a-1,3 glucan in virulent strains of *P. brasiliensis* compared with avirulent strains was initially related to virulence, but no correlation has been shown between glucans and virulence in experimentally induced infections.

Pathogenesis

Several experimental and clinicopathological observations provide evidence that the respiratory route is the main portal of entry and the lung is the primary site of infection.

The first fungus–host contact occurs through inhalation of airborne conidia. When mice are experimentally infected through the respiratory route, conidia have been observed in the alveoli soon after inoculation. Some 12 to 18 h after the exposure, yeast forms can be observed in the alveoli. There is an initial inflammatory response, which is mediated by polymorphonuclear cells, followed by granuloma formation.

The primary infective complex develops at the inoculation site and involves the surrounding lymphatic vessels and regional lymph nodes. The fungus spreads to other parts of the lung through peribronchial lymphatic vessels and drains into regional lymph nodes. Haematogenous dissemination to a variety of organs and tissues may occur at this time. The lesions usually undergo involution and the fungi remain dormant if the host's immune response can control their proliferation. A balanced host–fungus relationship is associated with the absence of symptoms, although in some children or young adults, acute disease may arise, primarily affecting the phagocytic mononuclear system. In adult life, previously quiescent lesions may become reactivated, especially in the lungs, leading to the adult or chronic form of the disease.

Pathology

The characteristic lesion is a granuloma containing *P. brasiliensis* cells. The infected tissue may exhibit a predominantly proliferative, granulomatous inflammatory response, and/or an exudative reaction, sometimes resulting in necrosis, with variable numbers of neutrophils and large numbers of extracellular yeast cells, leading to a chronic epithelioid granuloma.

Autopsy studies, mainly of adult patients, indicate that the organs most frequently involved are the lungs (42 to 96 per cent), adrenals (44 to 80 per cent), lymph nodes (28 to 72 per cent), pharynx/larynx (18 to 60 per cent), and skin/other mucosal surfaces (2.7 to 64 per cent).

Host–fungus interaction

Non-specific immune response

The influence of genetic factors on the individual susceptibility to this mycosis is suggested by the observation of higher rates of HLA phenotypes A9, B13, B40, and Cw3 among patients than in controls. In isogenic mice, resistance to *P. brasiliensis* is controlled by a single autosomal gene.

The ability of circulating human neutrophils obtained by bronchoalveolar washing to digest the yeast forms of fungi was impaired in severe cases, while this defect was absent in uninfected family members of patients.

Specific immune response

The relation of the severity of the human disease to deficient late hypersensitivity was established through intradermal testing for ubiquitous antigens and paracoccidioidin, or through lymphoblastic transformation tests to mitogens and to *P. brasiliensis* antigens, including the 43 kDa glycoprotein.

The different distribution of T-lymphocyte subpopulations according to the clinical form of the disease (decreased CD4 in chronic form and increased CD8 in acute form) suggests that different mechanisms might be involved in each form.

The deficient T-cell response is followed by a decreased ability of macrophages to control fungal multiplication and to kill the fungus. This capacity of murine pulmonary macrophages in intratracheal infection is increased *in vivo* and *in vitro* by treatment with interferon-g. Neutralization of endogenous interferon-g by monoclonal antibodies induced exacerbation of the pulmonary infection, earlier fungal dissemination to the liver and spleen, and impairment of the specific cellular immune response and increased levels of IgG1 and IgG2b specific antibodies.

In severe human disease there are decreased levels of T helper 1 type cytokines (interferon-g and interleukin 2 (**IL-2**)) and preserved T helper 2 type cytokines (IL-10 and IL-13 or IL-4). This pattern is associated with poor granuloma formation, spreading of the fungus and high levels of antibody production (immunoglobulins IgG1, IgG4, and IgE). The importance of late hypersensitivity in protection has been observed recently in patients receiving cytotoxic therapy for associated neoplasms and in those with AIDS.

Antibodies may enhance phagocytosis through opsonization of the fungus, but their role in resistance is not established.

Clinical features

The clinical picture ranges from an asymptomatic course to severe disseminated disease, which can lead to death. The incubation period is unknown except in a laboratory worker, who developed a skin lesion some days after an accidental inoculation. The disease has been reported in children 3 years of age or older who had lived for some years in the endemic area.

The following classification of clinical forms of paracoccidioidomycosis has been proposed:

1. paracoccidiodomycosis infection;
2. regressive (self-healing) paracoccidioidomycosis;
3. paracoccidioidomycosis disease;
    a. acute form (juvenile type): moderate or severe;
    b. chronic form (adult type): mild, moderate, or severe;
4. sequelae.

Localization in a particular tissue or organ and the degree of severity of the disease according to established criteria make this classification easily and uniformly applicable. General and nutritional debility and organ dysfunction (lung, brain, adrenals, bone marrow) indicate the severity of the disease.

Acute form (juvenile type)

Children, adolescents, and young adults (under 30 years old) are affected; males and females being afected in equal numbers. Only 1 to 20 per cent of the patients fall into this group. There is progression for 2 to 3 months or more, characterized by involvement of the phagocytic mononuclear system. Cervical, axillary, and inguinal nodes are the most commonly enlarged (Fig. 3). Nodes are initially hard but are sometimes fluctuant and drain pus rich in fungi. Less frequently, deep-seated lymph nodes may also be affected. When the hepatic perihilar lymph nodes are enlarged, they may produce symptoms of obstructive jaundice.

Fig. 3 Lymph node and skin involvement in a patient with the acute form of paracoccidioidomycosis. (Courtesy of C. S. Lacaz.)

The liver and spleen are usually moderately enlarged. Bones (clavicle, scapulae, ribs, skull, long, and flat bones) and, rarely, the bone marrow may be involved. Radiographs show lytic lesions without periosteal reaction. Involvement of the small bowel may be asymptomatic or produce abdominal pain, diarrhoea, constipation, and even intestinal obstruction. Radiological studies of the digestive tract reveal intestinal tract involvement in about 50 per cent of clinical cases.

Fever and weight loss are common. Multiple mucocutaneous lesions are more frequent in some geographical areas. High transient blood eosinophilia (up to 30 000/mm^3) has sometimes been described.

Clinical lung involvement is rarely described in this form of paracoccidioidomycosis. In some case reports either bronchopneumonia or primary complex-like disease was observed.

Chronic form

This form of the disease usually occurs in 30- to 50-year-old men who have worked in agricultural areas. The male:female ratio varies from 10:1 to 25:1. The evolution is insidious and in many cases clinically mild.

The organ most frequently involved is the lung, followed by skin and mucous membranes, mainly pharynx, larynx, and trachea. Lymph nodes and adrenals may be compromised. More than one organ or tissue is usually involved. Less frequently, intestine, spleen, bones, central nervous system (brain, cerebellum, meninges), eyes, genitourinary system, myocar-dium, pericardium, and arteries are involved.

The patients may be asymptomatic or complain of dyspnoea, cough, sometimes purulent sputum, and rarely haemoptysis. Fever is unusual. Physical examination is frequently normal or there may be scattered rales. In contrast, chest radiography commonly reveals bilateral, asymmetrical, reticulonodular infiltrates in the middle and lower parts of the lungs (Fig. 4). Apical cavities and pleural effusions are less frequently observed.

Fig. 4 Alveolar and interstitial infiltrates in both lungs in a patient with chronic paracoccidioidomycosis.

Cutaneous lesions include papules, pustules, ulcers, crusted ulcers, vegetations, tuberculoids, verrucoids, or acneiform lesions mainly on the face (Fig. 5) or limbs. Multiple, scattered lesions result from haematogenous dissemination. Subcutaneous cold abscesses, more commonly associated with bone lesions, can occur.

Fig. 5 Mucocutaneous lesions in a patient with chronic paracoccidioidomycosis. (By courtesy of C. S. Lacaz.)

Mucosal lesions are usually in the mouth and/or oropharynx, including the palate, uvula, and tonsils, or in the respiratory tract, involving mainly the larynx (vocal cords, glottis, and epiglottis) and trachea. Pain is usually intense, and may hamper mastication and swallowing. Hoarseness and dysphonia result from laryngeal lesions, and may lead to obstruction of the upper respiratory tract. Examination shows ulcerative, verrucous, vegetant, and infiltrative 'moriform' stomatitis, resembling a raspberry, with papules, vesicles, and haemorrhagic spots. The last is characteristic of this mycosis and appears as shallow ulcers, with a granular surface showing multiple, fine, haemorrhagic points.

Few lymph nodes may be involved, in contrast to the acute form of the disease.

Uni- or bilateral lesions in the adrenal glands have been found in about half of patients coming to autopsy. Partial adrenal insufficiency has been documented in about 40 per cent of the cases but only 7.4 per cent were symptomatic.

Concomitant tuberculosis is observed in about 10 to 15 per cent of cases of pulmonary paracoccidioidomycosis and has also been described in cases of lymph node involvement by *P. brasiliensis.* Carcinomas may arise in pulmonary or mucosal mycotic lesions.

Sequelae

Nowadays these constitute one of the most important problems in the management of paracoccidioidomycosis. Although fungal multiplication can been controlled by chemotherapy, impairment of vital functions might prove fatal.

Acute form

Lesions in the small intestine and mesenteric lymph nodes may fibrose causing lymphatic obstruction, intestinal malabsorption, or protein-losing enteropathy. A clinical picture of severe malnutrition and immunodeficiency has been reported (Fig. 6).

Fig. 6 Ascites, cachexia, and immunodeficiency due to malabsorption and protein-losing enteropathy as sequelae of acute paracoccidioidomycosis. (By courtesy of M. Shiroma.)

Chronic form

As the lesions usually tend to heal by fibrosis, sequelae such as microstomy and laryngeal, tracheal, or even bronchial stenosis may be observed. Corrective surgery is indicated.

Pulmonary emphysema, fibrosis, respiratory insufficiency, and, finally, cor pulmonale are frequent sequelae. Obstructive and restrictive patterns of ventilatory defect have been found in about 36 and 16 per cent of patients respectively. As many as 30 per cent of these patients may die as a result of respiratory or cardiorespiratory failure.

Diagnosis

Microbiological identification

Isolated or budding (single or multiple) mother cells are observed under direct microscopy in sputum, pus from lymph nodes, and material from the skin or mucous membrane lesions.

Specimens are cultured at 37 °C on blood, chocolate, or yeast extract agar. The colonies are produced after 7 days, usually in 10 to 20 days. Cultures can be maintained, at 25 °C, on Sabouraud's dextrose agar, where the colonies may be noticed after 15 to 30 days.

Histopathology

Silver or periodic acid-Schiff staining is required to detect the fungus on sputum. Diagnostic features are the variable size (1 to 30 µm) of the yeast cells, and their multiple budding. Proliferative or exudative reactions, as described in the section on pathology, may be observed.

Immunological test

Serological reactions

Immunodiffusion (Ouchterlony) and counterimmunoelectrophoresis are the best techniques initially. Sensitivities and specificities are as high as 95 per cent. Cross reactions are mainly with other deep mycoses such as histoplasmosis, aspergillosis, cryptococcosis, and candidiasis.

Complement fixation and indirect immunofluorescence are less reliable tests for diagnosis, but they can be employed in patients under treatment.

Recently, enzyme immunoassays employing *P. brasiliensis* antigens, including a 43 kDa glycoprotein have shown high sensitivity and specificity. Antibody titres tend to decrease about 3 to 6 months after starting specific therapy and to disappear after 9 months to 5 years or more.

Antigenaemia and antigenuria have been considered useful indications in patients presenting low levels of antibodies in the sera, both for diagnosis and follow-up after treatment, particularly in an immunocompromised host.

The correlation between immunological and histopathological findings and clinical forms is outlined in Table 1.

Therapy

Clinically active disease is treated for 3 to 6 months, followed by maintenance therapy with sulfamethoxipiridazine after the resolution of clinical signs and symptoms, continued for many months or until 1 to 2 years after antibody levels have fallen to normal.

Severe cases of acute or chronic disease should be treated with intravenous infusion of amphotericin B. The daily dose begins at 0.1 to 0.2 mg/kg, increasing up to 1.0 mg/kg. The total dose ranges from 1 to 3 g or more. Toxic reactions to amphotericin B include fever, chills, headache, anaemia, and nephrotoxicity characterized by tubular acidosis and potassium urinary excretion and resultant hypokalaemia and azotaemia. In most cases, these reactions can be controlled until the end of the course of therapy. Liposomal amphotericin has been used in severe cases of paracoccidioidomycosis, but this treatment was followed by relapses.

In milder cases, sulphonamides or imidazoles (ketoconazole 200 to 400 mg/day or itraconazole 100 to 200 mg/day) have been shown to be effective. In a randomized trial, sulphadiazine (150 mg/kg per day), itraconazole (50 to 100 mg/day), and ketoconazole (200 to 400 mg/day) were equally effective in patients with moderately severe disease. The combination of 160 mg of trimethoprim and 800 mg of sulfamethoxazole is also effective. Fluconazole has been used in a few cases and although it achieves high levels in cerebrospinal fluid, there is no conclusive experience in neuroparacoccidioidomycosis.

Prognosis

Even though the disease is easily controlled in the majority of cases, the course of treatment is long and in Brazil, for example, abandonment of treatment is the most important cause of therapeutic failure. Normalization of cellular specific responses, particularly of the skin test (paracoccidioidin) indicates a good prognosis.

Death may occur in severe acute or chronic cases and severe cases with sequelae.

7.12.5 Pneumocystis carinii

Robert F. Miller and Ann E. Wakefield

Who gets *Pneumocystis carinii* pneumonia?

Most patients have abnormalities of T-lymphocyte function or numbers, but rarely *Pneumocystis carinii* pneumonia develops in patients with isolated B-cell defects and in individuals without evidence of immunosuppression. In non-HIV immunosuppressed individuals, glucocorticoid administration is an independent risk factor for development of *P. carinii* pneumonia irrespective of the type or intensity of immunosuppression or the nature of the underlying disease process. In HIV-infected individuals, those at greatest risk have CD4+ T lymphocyte counts less than 200 cells/μl. *P. carinii* pneumonia in HIV-infected patients in Europe, United States, and Australasia is now largely confined to patients who are unaware of their HIV serostatus at presentation or to those who are non-compliant with, or intolerant of, prophylaxis and antiretroviral therapy. The incidence of *P. carinii* pneumonia in HIV-infected individuals in Africa is lower than in the West.

Aetiology

Until recently, *P. carinii* was regarded taxonomically as a protozoan, based on its morphology and lack of response to antifungal agents such as amphotericin B. *P. carinii* pneumonia cannot be cultured *in vitro*, but molecular biological techniques demonstrate clearly that it is a fungus. *P. carinii* from different mammalian host species show antigenic, karyotypic, and genetic heterogeneity. Cross infection between host species has not been successful, suggesting host specificity and that *P. carinii* infection in man is not a zoonosis. In the human host, *P. carinii* shows lower levels of genetic diversity than occurs between *P. carinii* from different mammalian hosts. Over 30 genotypes of human type *P. carinii* have been described; some types are associated with a mild pneumonia, others with severe hypoxic pneumonia.

The demonstration of antibodies against *P. carinii* in the majority of healthy children and adults has been regarded previously as supportive of the hypothesis that *P. carinii* arises in an immunocompromised individual by reactivation of a childhood-acquired, symptomless, latent infection. However, this hypothesis is challenged by the failure to demonstrate *P. carinii* in bronchoalveolar lavage (BAL) fluid or necropsy lung tissue of immune competent individuals, and the observation that *P. carinii*-specific DNA is detectable only at low levels in less than 25 per cent of HIV-infected individuals with low CD4+ T lymphocyte counts presenting with respiratory episodes and diagnoses other than *P. carinii* pneumonia. Human *P. carinii* infection is now thought to arise from *de novo* infection from an exogenous source. The finding of different *P. carinii* genotypes in each episode in patients with recurrent *P. carinii* pneumonia supports the reinfection model.

Pathogenesis

After inhalation of *P. carinii*, the organism reaches the alveoli where the trophozoite form attaches to type 1 pneumocytes. In an immune-competent individual the organism is eliminated, in the immune-deficient host *P. carinii* pneumonia will develop.

The major surface glycoprotein of *P. carinii* binds macrophages and induces T-lymphocyte proliferation and increases secretion of IL-1 and -2 and TNF-a. Monocytes respond to major surface glycoprotein by releasing IL-8 and TNF-a. *P. carinii* induces changes in the quantity and quality of pulmonary surfactant: total cholesterol, glycerol, and phospholipase A-2 are increased while phospholipid is reduced.

Clinical presentation

This is non-specific. Patients typically present with progressive exertional dyspnoea, a non-productive cough, and fever of several days or weeks duration. Patients often report an inability to take in a deep breath, not due to pleural pain. Purulent sputum, haemoptysis, and pleural pain are atypical for *P. carinii* and suggest a bacterial or mycobacterial pathogen. In HIV-infected patients, the presentation is usually more insidious than in patients immunosuppressed by other causes, however in a small proportion of HIV-infected patients the disease course of *P. carinii* is fulminant with an interval of 7 days or less between onset of symptoms and progression to respiratory failure. Occasionally *P. carinii* may have an indolent presentation with respiratory symptoms worsening almost imperceptibly over many months. Rarely, *P. carinii* may present as pyrexia of undetermined origin.

Examination of the chest is usually normal; occasionally fine bibasal end-inspiratory crackles are heard. Signs of focal consolidation or pleural effusion suggest an alternative diagnosis.

Pathology

Within the lung, *P. carinii* infection is characterized by an eosinophilic, foamy intra-alveolar exudate, associated with a mild plasma cell interstitial pneumonitis. Morphologically, two forms of *P. carinii* may be identified: thick-walled cysts (6–7 μm diameter) which lie freely within the alveolar exudate are demonstrated by Grocott's methenamine silver, toluidine blue O, or cresyl violet stains. The exudate consists largely of thin-walled, irregularly shaped, single-nucleated trophozoites (2–5 μm diameter) which are shown by Geimsa stain but lack distinctive features. Rarely, interstitial fibrosis, diffuse alveolar damage, granulomatous inflammation, nodular and cavitary lesions, and pneumatocoele formation may occur.

Rarely *P. carinii* infection extends beyond the air spaces; extrapulmonary pneumocystosis involving liver, spleen, gut, or eye may occur and is strongly associated with use of nebulized pentamidine for prophylaxis or treatment.

Investigations

The chest radiograph may be normal in early or mild pneumonia. With more severe disease or later presentation, diffuse perihilar interstitial infiltrates are seen. These may progress to diffuse bilateral alveolar (air space) consolidation that mimics pulmonary oedema. In the late stages the lungs may be massively consolidated and almost airless. Radiographic deterioration from near normal at presentation to being markedly abnormal may occur over 48 h or less. Up to 20 per cent of chest radiographs are atypical, showing intrapulmonary nodules, cavitary lesions, lobar consolidation, pneumatocoeles, or hilar/mediastinal lymphadenopathy. Predominantly apical change may be seen in patients who develop *P. carinii* pneumonia having received *P. carinii* prophylaxis with nebulized pentamidine. All these typical and atypical radiographic appearances may also be seen in bacterial, mycobacterial, and fungal infection, and in non-specific pneumonitis and Kaposi's sarcoma.

With treatment and clinical recovery the chest radiograph in some individuals may remain abnormal for many months in the absence of symptoms. In others

postinfectious bronchiectasis or fibrosis occurs.

Arterial blood gases/oximetry

Less than 10 per cent of patients with *P. carinii* pneumonia have a normal PaO_2 and a normal PAO_2–PaO_2. These measures are sensitive though not specific for *P. carinii* pneumonia and may also occur in bacterial pneumonia, Kaposi's sarcoma, and tuberculosis.

Computed tomography

High resolution computed tomography scanning of the chest may be useful in the symptomatic patient with a normal or equivocal chest radiograph. Areas of ground glass shadowing indicate active pulmonary disease. These appearances may be caused by *P. carinii*, cytomegalovirus, or fungal pneumonia.

Induced sputum

Spontaneously expectorated sputum is inadequate for diagnosis of *P. carinii* pneumonia. Sputum induction by inhalation of ultrasonically nebulized hypertonic (3N) saline may provide a suitable sample. *P. carinii* is usually found in clear 'saliva-like' samples. Purulent samples suggest an alternative diagnosis. The sensitivity varies between 55 and 90 per cent and a negative result for *P. carinii* should prompt further diagnostic tests.

Bronchoscopy

Fibreoptic bronchoscopy with BAL has a sensitivity of more than 90 per cent for detection of *P. carinii.* Immunoflourescence staining increases the diagnostic yield compared to conventional histochemical staining. Transbronchial biopsies add very little to the diagnostic yield and are associated with a relatively high complication rate (pneumothorax in » 8 per cent). As *P. carinii* persists in the lung for many days after the start of antimicrobial therapy, bronchoscopy may be performed up to 1 week after commencing anti-*P. carinii* therapy without a reduction in diagnostic yield.

Molecular diagnostic tests

Detection of *P. carinii*-specific DNA by the polymerase chain reaction (PCR) on BAL fluid and induced sputum is superior to conventional histochemical methods. Detection of *P. carinii* DNA by PCR may also be achieved on oropharangeal samples obtained by gargling with normal saline; this technique compared to conventional staining of BAL fluid has a sensitivity of 89 per cent and a specificity of 94 per cent for *P. carinii*. These molecular techniques are not widely available.

Empirical therapy

Many centres in the United Kingdom and North America seek to confirm a diagnosis in every suspected case of *P. carinii* pneumonia. Other centres treat HIV-infected patients empirically who present with symptoms, chest radiographic abnormalities, and hypoxaemia, features typical of *P. carinii* pneumonia. Bronchoscopy is reserved for those who fail to respond to empirical therapy by day five or those who have atypical presentations. Both strategies are equally effective in clinical practice.

Treatment

It is important to stratify *P. carinii* pneumonia as mild (PaO_2 (on air) > 11.0 KPa, SaO_2 > 96 per cent) moderate (PaO_2= 8.0–11.0 KPa, SaO_2 = 91–96 per cent), or severe (PaO_2< 8.0 KPa, SaO_2 < 91 per cent) as some drugs are unproven or ineffective in severe disease.

First choice treatment is high-dose co-trimoxazole (sulfamethoxazole 100 mg/kg per day and trimethoprim 20 mg/kg per day) in two to four divided doses, orally or intravenously. In HIV-infected patients with *P. carinii* pneumonia 21 days are given, in those with other causes of immunosuppression 14 to 17 days are frequently given. In mild disease oral medication may be given throughout, in moderate/severe disease intravenous therapy is usually given for the first 7 to 10 days, then orally.

Other treatments in patients with severe disease include clindamycin 450 to 600 mg orally or intravenously, four times daily, with primaquine 15 mg once daily orally, or trimetrexate 45 mg/m^2 intravenously, daily, with folinic acid 20 mg/m^2 four times daily. Despite its toxicity, pentamidine 4 mg/kg daily, intravenously, may be used if other treatments have failed. In patients with mild or moderate disease, alternatives to co-trimoxazole include clindamycin with primaquine (doses as above), dapsone 100 mg orally once daily, with trimethoprim 20 mg/kg per day, or atovaquone 750 mg orally twice daily.

Adjuvant steroids

HIV infected patients with moderate/severe *P. carinii* pneumonia benefit from adjuvant glucocorticoids which reduce the risk of respiratory failure, need for mechanical ventilation, and risk of death. Many non-HIV infected patients with *P. carinii* pneumonia are already receiving glucocorticoids as part of their immunosuppression/chemotherapy and the benefits of adjunctive dose increases have not clearly been demonstrated. Adjunctive glucocorticoid regimens include prednisolone 40 mg twice daily orally for 5 days, then 40 mg once daily on day 6 to 10, 20 mg once daily on days 11 to 21 (or methylprednisolone intravenously at 75 per cent of these doses). An alternative regimen is methylprednisolone 1 g intravenously for 3 days, then 0.5 g intravenously on days 4 and 5, followed by prednisolone reducing from 40 mg orally once daily to zero over 10 days.

Adverse reactions

Adverse reactions to co-trimoxazole, which usually occur between day 6 and day 14 of treatment, are commoner in HIV-infected patients than in patients with other causes of immunosuppression. Anaemia and neutropenia (up to 40 per cent of patients), rash and fever (up to 30 per cent), and biochemical hepatitis (up to 15 per cent) are the most frequent adverse reactions. Coadministration of folic or folinic acid does not prevent or attenuate haematological toxicity and may be associated with increased therapeutic failure.

Glucose-6-phosphate dehydrogenase deficiency

Patients with glucose-6-phosphate dehydrogenase deficiency should not receive co-trimoxazole, dapsone, or primaquine.

Prophylaxis

HIV-infected patients are at increased risk of *P. carinii* pneumonia as the CD4+ lymphocyte count decreases. Primary prophylaxis (to prevent a first episode of *P. carinii* pneumonia) is given when the CD4 count falls below 200/µl or the CD4:total lymphocyte ratio is less than 1:5, to patients with HIV- associated constitutional features such as unexplained fever of 3 weeks' or more duration, or oral candida, irrespective of CD4 count, and to patients with other AIDS-defining diagnoses, for example Kaposi's sarcoma. Secondary prophylaxis is given after an episode of *P. carinii* pneumonia.

The first choice agent for primary and secondary prophylaxis is co-trimoxazole 960 mg daily. Lower doses, that is 960 mg three times weekly or 480 mg daily, may be equally effective and have fewer side effects. Co-trimoxazole may also protect against bacterial infections and reactivation of cerebral toxoplasmosis.

Adverse reactions, including rash with or without fever, occur in up to 20 per cent of patients receiving co-trimoxazole as prophylaxis. Desensitization may be attempted in those unable to tolerate co-trimoxazole; alternative less effective options include nebulized pentamidine 300 mg once per month via jet nebulizer (once per fortnight if the CD4 count is 50/µl or less), dapsone 100 mg daily with pyrimethamine 25 mg once weekly (pyrimethamine may also protect against cerebral toxoplasmosis), or atovaquone 750 mg twice daily.

Non-HIV infected patients with high attack rates of *P. carinii* pneumonia should receive prophylaxis (drug choice and doses as above). At risk groups include those with acute lymphoblastic leukaemia, severe combined immunodeficiency syndrome, Hodgkin's disease, rhabdomyosarcoma, primary and secondary central nervous

system tumours, Wegener's granulomatosis, and organ transplantation including allogenic bone marrow, renal, heart, heart/lung, and liver.

Areas of uncertainty/future research

The mode of transmission of *P. carinii* infection is unclear, but recent molecular data suggest that transmission from infected patients to susceptible immunocompromised individuals may occur. The drug target for sulfamethoxazole and dapsone is dihydropteroate synthase. The possibility that *P. carinii* may develop resistance to sulpha drugs is suggested by the finding of non-synonymous single nucleotide polymorphisms (which are associated with resistance in other organisms) in the dihydropteroate synthase gene of human *P. carinii* which occur more frequently in those who have received prophylaxis with co-trimoxazole or dapsone. The limited availability of other equally effective drugs for prophylaxis restricts the use of 'drug switching' as a strategy for preventing emergence of resistance of *P. carinii* to sulpha drugs.

Of new anti *P. carinii* drugs under development, and most promising are sordarin derivatives which target translation elongation factor-2 and inhibit fungal protein synthesis.

7.12.6 Infection due to pencillium marneffei

Thira Sirisanthana

Introduction

Penicillium marneffei was first isolated from bamboo rats (*Rhizomys sinensis)* in Vietnam in 1956. The fungus is endemic in southeast Asia, northeast India, south China, Hong Kong, and Taiwan. Fewer than 40 cases of infection with *P. marneffei* were reported prior to the HIV epidemic. The incidence of disseminated *P. marneffei* infection has increased markedly over the past few years. This increase is mainly due to infection in patients already infected with HIV. The majority of patients have been reported from Thailand, Hong Kong, and Taiwan. Cases have also been reported in HIV-infected individuals from the United States, the United Kingdom, The Netherlands, Italy, France, Germany, Switzerland, Sweden, and Australia following visits to the ndemic region.

Aetiology

P. marneffei is the only dimorphic fungus of the genus *Penicillium*. The fungus grows in a mycelial phase at 25 °C on Sabouraud dextrose agar. Mould-to-yeast conversion is achieved by subculturing the fungus on to brain–heart-infusion agar and incubating at 37 °C. In its mycelial form, the colony is greyish white and downy. The colour of the colony may vary during differentiation. The reverse side becomes cerise to brownish red, as a soluble red pigment diffuses into the agar medium. Microscopic examination of the mycelial form shows structures typical of the genus *Penicillium*. Colonies of the yeast form of *P. marneffei* have a wrinkled or cerebriform surface. They are light tan to brown in colour. Microscopic examination of the yeast form reveals unicellular, pleomorphic, ellipsoidal-to-rectangular cells, about 2 µm by 6 µm in size, that divide by fission and not by budding.

Natural history

Many features of the natural reservoir, mode of transmission, and natural history of *P. marneffei* infection remain unknown. The fungus has been isolated from several species of bamboo rats in the endemic area. Since bamboo rats usually live near the forest and have limited contact with people, it is believed that both humans and bamboo rats become infected with *P. marneffei* from a common source, rather than the patients being infected by the rats. By analogy with other endemic systemic mycoses, such as histoplasmosis, it is likely that *P. marneffei* conidia are inhaled from a contaminated reservoir in the environment and subsequently disseminate from the lungs when the host experiences immunosuppression. The disease is more likely to occur in the rainy season, suggesting that there may be an expansion of the environmental reservoirs with favourable conditions for growth at this time.

In endemic areas it is likely that a certain proportion of the population is infected, but remains asymptomatic. Patients have been reported with long periods of asymptomatic infection before presentation with clinical *P. marneffei* infection. In other cases, clinical manifestation of *P. marneffei* infection occurred within weeks of exposure to the fungus.

Clinical features

Patients with *P. marneffei* infection commonly present with symptoms and signs of infection of the reticuloendothelial system. These include fever, chills, lymphadenopathy, hepatomegaly, and splenomegaly. Cough, dyspnoea, and lung crepitations may be present. Other manifestations are secondary to dissemination of the fungus via the bloodstream. Cutaneous and subcutaneous lesions are observed in up to two-thirds of patients. Arthritis and osteomyelitis are not uncommon. Cases with mesenteric lymphangitis, colitis, genital or oropharyngeal ulceration, retropharyngeal abscess, or pericarditis have been reported.

In HIV-infected patients, *P. marneffei* infection occurs late in the course of the disease. The patient's CD4+ cell count at presentation is usually below 50 cells per microlitre. HIV-infected patients with *P. marneffei* infection have a more acute onset and higher fever. They are more likely to have fungaemia and shock and their skin lesions are more numerous and tend to be papules with central necrotic umbilication. Patients who are not infected with HIVare more likely to have one or several subcutaneous nodules which may develop into abscesses and cause skin ulceration.

Biochemical and haematological laboratory findings are non-specific and include elevation of liver enzymes, anaemia, and leucocytosis. Chest radiographs may show diffuse interstitial, localized alveolar, or diffuse alveolar infiltrates. Cases with cavitary lesions or lung masses have been reported.

Diagnosis

Presumptive diagnosis can be made by microscopic examination of Wright's-stained samples of bone marrow aspirate, and/or touch smears of skin biopsy specimens, and/or lymph node biopsy specimens. Many intracellular and extracellular basophilic, spherical, oval, and elliptical yeast cells can be seen using this staining technique. Some of these cells had clear central septation, which is a characteristic feature of *P. marneffei*. The diagnosis is confirmed by histopathological section and/or by culturing the fungus from the blood, skin biopsy specimens, bone marrow, or lymph nodes. Cases of *P. marneffei* infection can clinically resemble tuberculosis, histoplasmosis, and cryptococcosis. Tests to detect antibodies or *P. marneffei* antigens have been developed. Clinical trials are needed to show their usefulness in the diagnosis of active *P. marneffei* infection and in predicting relapses. They may also be used to identify HIV-infected individuals who are infected with *P. marneffei* but who are still asymptomic. These persons may then benefit from pre-emptive treatment with an antifungal agent.

Treatment

P. marneffei infection is potentially fatal. The fungus is sensitive to ketoconazole, fluconazole, itraconazole, and amphotericin B. The recommended treatment is to give amphotericin B intravenously in a dose of 0.6 mg/kg/day for 2 weeks, followed by itraconazole 400 mg/day orally in two divided doses for the next 10 weeks. The majority of patients respond well, with resolution of fever and other signs of infection within the first 2 weeks. After initial treatment, HIV-infected patients should be given 200 mg/day of itraconazole orally as secondary prophylaxis for life.

7.13.1 Amoebic infections

R. Knight

The amoebic species infecting humans belong to two very different groups. First, the obligate parasitic species of the gut that include the major pathogen *Entamoeba histolytica*, several non-pathogenic species including *E. dispar*, and a minor pathogen *Dientamoeba fragilis*. The second group are free-living, water and soil amoebae, which can become facultative tissue parasites. All motile feeding amoebae are called trophozoites; they move with pseudopodia and divide by binary fission. The hyaline external cytoplasm, the ectoplasm, is a contractile gel that surrounds the sol endoplasm containing numerous phagocytic and pinocytic vacuoles. Most species can form environmentally resistant cysts by rounding up and secreting a chitinous cyst wall.

Entamoeba histolytica infection

Biology and pathogenicity

Following ingestion of infective cysts a population of trophozoites becomes established in the caecum and proximal colon. Some degree of tissue invasion occurs in all subjects with at least low-titre seroconversion. Tissue invasion is frequently mild, self-limiting, and with minimal symptoms, but at the other end of the clinical spectrum it can lead to extensive destruction of the colonic mucosa. Invasive trophozoites have a characteristic morphology; they may reach 30 to 40 µm in diameter and are very active with apparently purposeful, unidirectional movements during which they become considerably elongated. Their most important diagnostic characteristic is the presence of host erythrocytes within the endoplasm, which otherwise appears clear and contains no bacteria. Trophozoites containing red blood cells are described as erythrocytophagous. Progression through tissues is by active movement, facilitated by secreted collagenase; leucocytes are drawn chemotactically towards the amoebae but most are rapidly destroyed on contact.

The transmissive cystic form of the parasite is derived entirely from a commensal population within the colonic lumen. Live commensal amoebae measure 10 to 20 µm in diameter, the endoplasm is granular and contains bacteria; the pseudopodia are blunt and movement is sluggish. Intestinal hurry from any cause, including the use of laxatives, can lead to the appearance of commensal trophozoites in the faeces. Cysts are spherical and measure 11 to 14 µm in diameter; when mature they contain four nuclei, several chromatoid bodies that are a ribosome store, and a glycogen vacuole.

Host factors may increase susceptibility to overt disease. Steroid therapy given systemically or locally into the rectum carries great risk, as may cytotoxic therapy. Severe bowel disease is particularly common in late pregnancy and the puerperium. Before puberty both sexes are equally susceptible to hepatic amoebiasis, but in adults this condition is at least seven times more common in males. Local disease can also favour tissue invasion; thus amoebic ulceration may be superimposed upon colonic and rectal cancers, or those of the uterine cervix. Colonic disease is favoured by concurrent *Trichuris* infection and intestinal schistosomiasis. Infection with human immunodeficiency virus appears to have little effect on outcome.

The taxonomic separation of *E. dispar* as a discrete non-pathogenic species from *E. histolytica* was formally made in 1993. Characterization of cultures by zymodeme, using isoenzyme electrophoresis of a small set of glycolytic enzymes, was the first convincing biochemical distinction between these two species, but many genomic differences have now been identified. All strains of *E. histolytica* are now regarded as pathogenic.

Epidemiology

The incidence of disease is particularly high in Mexico, South America, Natal, the west coast of Africa, and South-East Asia. In most temperate countries *E. histolytica* is now rare and nearly all amoebic disease seen in such countries will have been acquired elsewhere. Symptomless or convalescent carriers are the main source of infection; patients with dysentery normally pass only trophozoites in their stool, and are therefore non-infectious. Cysts remain viable in the environment for up to 2 months. The infection is eventually self-limiting and rarely exceeds 4 years. Tissue invasion can occur at any time during an infection, but is much more common during the first 4 months; the incubation period may be as short as 7 days.

The incidence of amoebiasis in a population is best estimated from seropositivity surveys. Surveys for cysts are of no value as differentiation from *E. dispar* is impossible. All the modes of faeco-oral transmission occur in amoebiasis; of special importance are the food handler and contaminated vegetables; transmission by flies and drinking water is less common. Drinking water can be contaminated in the home or at surface-water sources. Direct spread can produce outbreaks; it occurs within institutions for children and the mentally handicapped, and with contaminated colonic irrigation equipment. Household clustering is common; hand-fed infants are frequently infected from the fingers of their mother. Contamination of piped water supplies can lead to serious disease outbreaks as happened in the Chicago hotels epidemic in 1933. Nearly all *Entamoeba* infections among male homosexuals are due to *E. dispar*, *E. coli*, or *E. hartmanni*.

Pathology

The basic lesion is the result of cell lysis and tissue necrosis, which, by creating locally anoxic and acidic conditions, favours further penetration of the parasite; most amoebae are seen at the advancing edge of the lesion with little inflammatory cell response. In tissue sections amoebae stain indistinctly with haematoxylin and eosin but appear bright red with periodic acid–Schiff stain; iron haematoxylin is necessary to show nuclear detail. Cysts of *E. histolytica* are never seen in tissue.

Amoebic lesions of the gut are most common in the rectosigmoid and caecum but can occur anywhere in the large bowel; involvement may be patchy or continuous, less commonly the appendix or terminal ileum are affected. The initial lesions are either small, discrete erosions of the mucosa, or minute crypt lesions. Unrestrained, the lesions extend through the mucosa, across the muscularis mucosa, and into the submucosa, where they expand laterally to produce lesions that are typically flask shaped in cross-section. Further lateral spread of the submucosal lesions leads to their coalescence, and later, to denudation of overlying mucosa. The bowel wall may become appreciably thickened. Blood vessels involved in the disease may thrombose, bleed into the gut lumen or, in the case of portal-vein radicles, provide a vehicle for the dissemination of amoebae to the liver. In very severe lesions, and usually in association with toxic megacolon, there is an irreversible coagulative necrosis of the bowel wall.

Amoebomas are tumour-like lesions of the colonic wall measuring up to several centimetres in length; they are most common in the caecum and may be multiple. Histologically there is tissue oedema, with a mixed picture of healing and new areas of epithelial loss and tissue destruction; round-cell infiltration is patchy. Lesions may be annular and rarely an amoeboma initiates an intussusception; narrow, stricture-like amoebomas may occur in the anorectal region.

Amoebae reach the liver in the portal vein. Once initiated the amoebic lesion extends progressively in all directions to produce the liver-cell necrosis and liquefaction that constitute an 'amoebic liver abscess'. The lesions are well demarcated from surrounding liver tissue; untreated, nearly all will eventually extend into adjacent structures. Secondary bacterial infection is rare and usually follows rupture or aspiration.

Clinical manifestations

Invasive intestinal amoebiasis (Plate 1, Plate 2)

The clinical features show a wide spectrum from minimal changes in bowel habit to severe dysentery. Lesions may be limited to a small part of the large bowel or extend throughout its length. A relapsing course is common.

Amoebic colitis with dysentery

Dysentery, the passage of loose or diarrhoeal stools containing fresh blood, occurs when there is generalized colonic ulceration, or when more localized lesions occur in the rectum or rectosigmoid. Onset may be gradual, intermittent, or much less commonly, acute. Typically, constitutional upset is initially mild and the patient remains ambulant; mild or moderate abdominal pain is common, often colicky and maximal over affected parts of the gut. Tenesmus can occur but is rarely severe. Stools vary in consistency from semiformed to watery. They are foul-smelling and always contain visible blood; even when watery, faecal matter is nearly always present. Symptoms frequently wax and wane over a period of weeks or even months and such patients can become debilitated and wasted. In a few patients the disease runs a fulminating course. The most frequent physical sign is abdominal tenderness in one or both iliac fossas; but tenderness may be generalized. Affected gut may be palpably thickened. A low fever is common, but dehydration is uncommon. Abdominal distension occurs in the more severely ill patients, who sometimes pass relatively small amounts of stool.

When stool microscopy reveals no erythrocytophagous trophozoites, a careful proctoscopy or sigmoidoscopy should be done. The endoscopic appearances may be non-specific in early, acute, or very severe colitis; the findings are hyperaemia, contact bleeding, or confluent ulceration. In more chronic cases the presence of normal-looking intervening mucosa is highly suggestive of amoebiasis; early lesions are often elevated, with a pouting opening only 1 to 2 mm in diameter; later, ulcers may reach 1 cm or more in diameter, with an irregular outline and often a loosely adherent, yellowish or grey exudate. Mucosal scrapings or superficial biopsies taken at endoscopy should be examined immediately by wet-preparation microscopy.

Special forms of amoebic colitis

Fulminant colitis

This may arise *de novo*, for example in pregnant women or during steroid therapy, or it may evolve during a dysenteric illness. Patients show progressive abdominal distension, vomiting, and watery diarrhoea. Bowel sounds are absent and there may be little or no abdominal tenderness, guarding, or rigidity. Plain radiographs may reveal free peritoneal gas, together with acute gaseous dilatation of the colon; affected segments of bowel may appear relatively narrow and show visible musosal pathology. Barium enema and full sigmoidoscopy are contraindicated. Stools contain erythrocytophagous trophozoites.

Amoebic colitis without dysentery

When ulceration is limited to the caecum or ascending colon, or when early, mild, or localized lesions occur elsewhere in the colon there may be no dysenteric symptoms. Patients complain of change in bowel habit, blood-staining of the stool, flatulence, and colicky pain. Often the only physical sign is tenderness in the right iliac fossa, or elsewhere along the course of the colon. Some patients eventually go into complete remission; others progress to a dysenteric illness.

The most important diagnostic measure is repeated stool examination for erythrocytophagous amoebae; the finding of cysts or commensal trophozoites is of little diagnostic value, especially in endemic areas. Sigmoidoscopy is often normal when the distal bowel is not involved but colonoscopy may reveal typical lesions.

Amoeboma

These present as an abdominal mass, most frequently in the right iliac fossa. The lesion may be painful, tender, and associated with fever. Bowel habit is altered and some patients have intermittent dysentery, especially if lesions are multiple or distal. Evidence of partial or intermittent bowel obstruction may be present, particularly when lesions are distal and annular.

Localized perforation and amoebic appendicitis

Sudden perforation with peritonitis can occur from any deep amoebic ulcer; alternatively, leakage may lead to a pericolic abscess or retroperitoneal cellulitis. Amoebic appendicitis is an uncommon but important condition that occurs when amoebic lesions are confined to the appendix and caecum. The clinical presentation can resemble that of simple appendicitis, often with some clinical evidence of dysentery. If unrecognized at appendicectomy, the outcome can be disastrous with gut perforation; fresh smears should be made from the resected appendix, and examined immediately.

Rectal bleeding

Some patients with amoebiasis present with rectal bleeding, with or without tenesmus; this occurs particularly in children. Massive bleeding into the gut lumen can occur in any form of amoebic colitis but is rare.

Differential diagnosis

Amoebic colitis must be differentiated from other causes of infective colitis. High-volume diarrhoea, copious mucus, and severe tenesmus are all uncommon in amoebiasis. In temperate countries, non-specific ulcerative colitis and colorectal carcinoma create the greatest diagnostic problems. Parasitic conditions to be considered are intestinal schistosomiasis, heavy *Trichuris* infection, and balantidiasis. More chronic amoebic pathology may clinically resemble Crohn's disease, ileocaecal tuberculosis, diverticulitis, or anorectal lymphogranuloma venereum.

Hepatic amoebiasis

Less than half of all patients give any convincing history of dysentery and few have concurrent dysentery. In those with no dysenteric history the interval between presumed infection and presentation may be as short as 3 weeks, or as long as 15 years; for most it is between 8 weeks and a year.

The dominant symptoms are fever and sweating, liver or diaphragmatic pain, and weight loss. Onset of constitutional symptoms is often insidious; but pain may begin abruptly. Most patients seek medical help within 1 to 4 weeks. Fever is typically remittent, with a prominent evening rise, brief rigors, and very profuse sweating. Liver pain may be poorly localized initially and later become pleuritic, referred to the right shoulder tip, or localized to the abdominal wall. Within a few weeks, patients lose much weight and often become anaemic; a painful dry cough is common.

The most important clinical finding is liver enlargement (Fig. 1) with localized tenderness, which should be searched for in the right hypochondrium, the epigastrium, and along all the intercostal spaces overlying the liver. Liver pain, on compression or heavy digital percussion, is a less useful sign. Left-lobe lesions can present as an epigastric mass. Hepatomegaly may be difficult to detect by abdominal palpation when enlargement is mainly upwards, but bulging of the right chest wall may be noted, together with a raised upper level of liver dullness on percussion. Reduced breath sounds or crepitations may be heard at the right lung base.

Fig. 1 Amoebic liver abscess. Hepatic enlargement with focal tenderness in a Thai woman. (By courtesy of Professor S. Looareesuwan.)

Important radiological findings are a raised, or locally upward-bulging, right diaphragm (Fig. 2) with immobility on screening, areas of lung collapse or consolidation, and sometimes a pleural effusion. A neutrophil leucocytosis is almost invariable, the erythrocyte sedimentation rate is raised, and normochromic normocytic anaemia is common. 'Liver function tests' are frequently completely normal, or there may be a raised alkaline phosphatase; less commonly the serum transaminase or bilirubin is elevated. Liver scanning to demonstrate a filling defect is of great value; about 70 per cent of lesions are solitary, but multiple lesions are common in children and those with concurrent dysentery. Ultrasonographic scans and computed tomography are the most useful. Lesions appear round or oval, and are usually 4 to 10 cm in diameter at the time of presentation. On ultrasonography most are hypoechoic with well-defined walls without enhanced echoes. Even when concurrent dysentery is absent the stools are frequently, but not always, positive for *E. histolytica*. Colonoscopy may reveal unsuspected lesions.

Fig. 2 Amoebic liver abscess, radiographic changes: (a) elevated right diaphragm; (b) enormous abscess in the right lobe of the liver outlined with air (fluid level) after the aspiration of more than 1 litre of pus; (c) lateral view, same patient as (b). (By courtesy of Professor S. Looareesuwan.)

Complications

Most complications involve extension of hepatic lesions into adjacent structures: usually the right chest, the peritoneum, and the pericardium. Upward extension usually produces adhesions between the liver, the diaphragm, and the lung; in consequence, subphrenic rupture and amoebic empyema are rare, although a right serous pleural effusion is not uncommon. Untreated, the disease process advances upwards through lung tissue leading to hepatobronchial fistula and expectoration of brownish, necrotic liver tissue, the so-called 'anchovy sauce' sputum. Rupture into the peritoneum can occur at any time; it is sometimes the mode of presentation of an amoebic liver abscess, the cause of peritonitis being discovered only at laparotomy. Amoebic pericarditis usually results from upward extension of a left-lobe liver lesion. Initially patients have retrosternal pain, a pericardial friction rub, or a serous effusion; later rupture produces cardiac tamponade. The diagnosis is most difficult when an underlying liver abscess was not suspected.

Less commonly the lesion extends through the skin producing a sinus and cutaneous lesion. The gut, stomach, vena cava, spleen, and kidney are occasionally involved by direct spread. Bloodborne spread to the lung produces a lesion resembling an isolated pyogenic lung abscess. Amoebic brain abscesses due to *E. histolytica* are rare; most are discovered after death (Fig. 3). Jaundice occurs when a large lesion compresses the common bile duct or when multiple lesions compress several intrahepatic bile ducts. Rupture into a major bile duct can cause haemobilia. Portal-vein compression occasionally produces portal hypertension and congestive splenomegaly.

Fig. 3 Metastatic brain abscess in a patient with an amoebic liver abscess. (By courtesy of Professor S. Looareesuwan.)

Differential diagnosis

Amoebic serology and scanning have now greatly simplified diagnosis. However, a few patients, generally less than 5 per cent, are initially seronegative; scanning patterns may be atypical before lesions have liquefied. Pyogenic abscess, especially when cryptogenic, may be clinically indistinguishable and this condition is quite common in some Asian countries. Other conditions to be distinguished are primary and secondary carcinoma of the liver, lesions of the right lung base and right pleura, subphrenic abscess, cholecystitis, septic cholangitis including that resulting from aberrant *Ascaris* worms, and liver hydatid cysts.

Needle aspiration of the liver (Fig. 4) may be necessary for diagnostic or therapeutic purposes (see below). Suspected pyogenic abscess is the main indication for the former; blood cultures should also be taken. Typically the aspirate in hepatic amoebiasis is pinkish-brown ('anchory sauce') (Plate 3), odourless, and bacteriologically sterile; a thinner, malodorous, or frothy aspirate suggests bacterial infection. A therapeutic amoebicide trial is generally preferable to diagnostic needling of the liver.

Fig. 4 Diagnostic/therapeutic aspiration of 'anchovy sauce pus' from a patient with amoebic liver abscess. (Copyright Professor D.A. Warrell.)

Cutaneous and genital amoebiasis

Skin ulceration due to *E. histolytica* produces deep, painful, and foul-smelling lesions that spread rapidly. Secondary bacterial infection is common and may mask the amoebic pathology. Lesions are most frequent in the perianal area, but also occur at colostomy stomas, laparotomy scars, and at the site of skin rupture by a hepatic lesion.

Female genital involvement results from faecal contamination, the extension of perianal lesions, or by the formation of internal fistulas from the gut, which can involve the bladder. Lesions of the vulva and uterine cervix may resemble carcinoma. Male genital lesions follow rectal coitus, the lesion beginning as a balanoposthitis and progressing rapidly.

Laboratory diagnosis

Microscopy and culture

The identification of live erythrocytophagous trophozoites in temporary wet mounts is of prime importance because it confirms the diagnosis of invasive amoebic disease. Amoebae should be sought in dysenteric bowel-wall scrapings, the last portion of aspirate from a liver abscess (Fig. 5), sputum, and tissue smears from skin lesions. In non-dysenteric stools, flecks of pus, blood, or mucus should be looked for and examined. The amoebae remain active for about 30 min at room temperature and so recently voided stool samples should be examined without delay ('hot stool'). Other microscopical features of faeces in amoebic colitis are scanty or absent leucocytes (methylene blue staining), clumped or degenerating red cells, and sometimes Charcot–Leyden crystals. If wet preparations are not made, or are negative, a portion of the specimen should be preserved in polyvinyl alcohol or SAF (sodium acetate–acetic acid–formalin) fixative for later smear preparation; alternatively, drying faecal smears should be fixed in Schaudinn's solution. In either case fixed smears should be stained with Gomori trichrome or Heidenhain's iron haematoxylin.

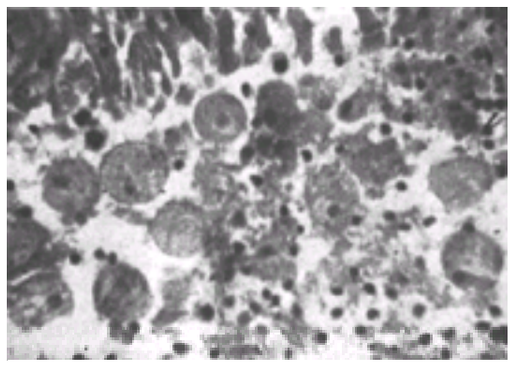

Fig. 5 Aspirate from amoebic liver abscess showing margin of hepatocytes and erythrocytophagous trophozoites of *E. histolytica*. (By courtesy of Professor S. Looareesuwan.)

Cysts and commensal trophozoites of *E. histolytica* found in wet faecal mounts are indistinguishable from those of *E. dispar*. The cysts of both species can be differentiated from the smaller *E. hartmanni* using an eyepiece micrometer. Direct mounts are made by emulsifying a small portions of stool in 1 per cent eosin, and in Lugol's iodine; however, the diagnostic sensitivity, per specimen, is only about 30 per cent. Concentration methods for cysts such as formol-ether sedimentation give a 70 per cent sensitivity per specimen. Cultivation of intestinal amoebae with bacterial associates in Robinson's medium is relatively easy; species identification requires immunofluorescent staining. Culture lysates provide material for zymodeme assay. Positive cultures from extraintestinal sites confirm invasive *E. histolytica*; amoebae are often difficult to find microscopically in liver aspirates.

Unless invasive trophozoites are found, differentiation of *E. histolytica* from *E. dispar* is only possible using zymodeme assay, or immunofluorescent staining of trophozoites in fixed faecal or amoebic culture smears.

Immunological tests

E. histolytica antigen can now be detected in faecal specimens and where this test is available it greatly simplifies diagnosis in both amoebic disease and in carriers; sensitivity and specificity of these tests is good. Assays for antigen in serum have also been used.

Many serodiagnostic methods have been applied to amoebiasis, most detectable antibody is IgG, with some IgM in active disease. However, seropositivity does not distinguish current and past tissue invasion. The more sensitive methods are indirect haemagglutination, enzyme immunoassay, and indirect immunofluorescence. Latex agglutination and gel-diffusion precipitation are also used, the former being commercially available as a slide test, taking only minutes to perform. Using sensitive tests, over 95 per cent of patients with liver abscess are seropositive, as are about 60 per cent of those with invasive bowel disease; patients with amoeboma are nearly all seropositive. All patients with tissue invasion eventually become seropositive. Titres decline after therapy but may remain positive for 2 years or more with the most sensitive tests.

Patient management

Chemotherapy

Nitroimidazoles are tissue amoebicides, and metronidazole for 5 days will be the first choice in most patients. The usual adult dose of metronidazole is 800 mg three times daily for 5 or 8 days; the paediatric dose is 35 to 50 mg/kg in three divided doses. An alternative is tinidazole, which has the advantage of a single daily dose of 2 g in adults and 50 to 60 mg/kg in children. A 5- or even a 3-day course may be sufficient for tissue amoebae but rates of parasitological cure may be low. When nitroimidazoles are contraindicated, or not available, erythromycin is useful in non-severe colitis.

The alkaloid emetine hydrochloride is a potent tissue amoebicide but has cumulative cardiotoxicity. Where appropriate nitroimidazoles are unavailable, as continues to be the case in many tropical contexts, this drug will continue to be life-saving, especially when a parenteral drug is needed. Emetine at 1 mg/kg daily (maximum 60

mg) by intramuscular injection for 5 days is usually sufficient; the synthetic derivative dehydoemetine hydrochloride is less toxic and more rapidly excreted in the urine, the daily intramuscular dose is 1.25 mg/kg (maximum 90 mg). Chloroquine is an effective alternative amoebicide in hepatic amoebiasis but is now little used; for adults a course of 150 mg of base twice daily is necessary.

Cutaneous and genital amoebiasis respond well to metronidazole, partly perhaps because these lesions often contain anaerobic bacteria. Amoebiasis at other sites is nearly always secondary to hepatic lesions and the chemotherapy will be the same. Metronidazole crosses the blood–brain barrier and should be used in the desperate situation of amoebic brain abscess due to *E. histolytica*.

Elimination of carrier state ('cyst'-passers)

All patients with *E. histolytica* infection treated with a tissue amoebicide should also be given diloxanide to eliminate all infection from the bowel and so prevent recurrence of tissue invasion or transmission to others. The dosage of diloxanide for adults is 500 mg three times daily for 10 days; the daily dose in children is 20 mg/kg in three divided doses.

Convalescent carriers should always be treated and also infected family contacts. Persons entering temperate countries from the tropics or new residents from such countries should be screened if there is a significant risk of infection; those with *E. histolytica* faecal antigen, or who are seropositive and have four-nucleated *Entamoeba* cysts in their stools, should be treated. In such cases, diloxanide is the drug of choice. Metronidazole is less effective, even using an 8-day course, and side-effects are troublesome. Unfortunately, cure rates with tinidazole are very low when followed up at 1 month.

Supportive and surgical management

Intestinal amoebiasis

Supportive management plays a major role in patients with complicated amoebic colitis, with emphasis on fluid and electrolyte replacement, gastric suction, and blood transfusion as necessary. Gut perforation in the context of extensive colitis carries a very poor prognosis; management may have to be medical. Parenteral metronidazole is invaluable in these contexts because of its activity against anaerobic bacteria in the peritoneum and bloodstream. Gentamicin plus a cephalosporin will normally be given as well.

Amoebomas respond well to metronidazole; a slow response should arouse suspicion that the amoebic lesion is superimposed upon other pathology, particularly a carcinoma. Surgical management is important in several situations. Acute colonic perforation in the absence of diffuse colitis, or ruptured amoebic appendicitis may be amenable to local repair. In the case of diffuse colitis, local repair, or end-to-end anastomosis, may not be possible because of the poor condition of the gut wall: temporary exteriorization with an ileostomy may be necessary. In fulminant colitis with multiple perforation the viability of the gut wall is uncertain and the only definitive option is total colectomy.

Hepatic amoebiasis

Parenteral metronidazole can be used in patients who undergo laparotomy. A favourable response to medical treatment alone can be expected in about 85 per cent of patients. Liver abscesses may rupture before, during, or after chemotherapy. Intra-abdominal rupture will always require laparotomy. Extension into the pleural or pericardial cavities necessitates drainage of these structures, together with aspiration of the liver lesion; pericardial drainage is most urgent when tamponade is present. Hepatopulmonary lesions generally require drainage of the liver lesion but medical treatment alone has been successful in some cases. Antimicrobials will always be needed when the abscess ruptures into the peritoneum or lung.

The most common management problem is slow response to the amoebicide. Patients whose pain and fever do not subside within 72 h are at significantly greater risk of rupture or therapeutic failure, and aspiration is generally to be recommended. A likely explanation of poor initial response is a tense lesion that restricts drug entry. Regular ultrasonographic monitoring is of great value as it will indicate the risk of rupture and guide the aspiration procedure. No change in lesion size on ultrasound can be expected during the first 2 weeks, although its outline may become clearer. Percutaneous aspiration with a wide-bore needle will be possible in most patients; if unsuccessful or anatomically contraindicated, then surgical help should be sought. Resolution time for small or moderate lesions is unaffected by aspiration. All patients with hepatic amoebiasis should be given a 10-day course of diloxanide to elimanate bowel infection.

Prognosis

Uncomplicated invasive intestinal disease and uncomplicated hepatic amoebiasis should normally have a mortality rate of less than 1 per cent. In complicated disease the mortality is much greater and may reach 40 per cent for amoebic peritonitis with multiple gut perforation. Prognosis is usually better n centres where the disease is common and more likely to be recognized early. Late diagnosis increases the probability of complicated disease and mortality rises accordingly.

Unless parasitological cure is achieved, and the gut completely freed of *E. histolytica*, clinical relapse is quite common, although probably limited by immunological responses. There is so far no evidence of naturally occurring strains of *E. histolytica* being resistant to normally used drugs. Hepatic scans show that nearly all liver abscesses completely disappear within 2 years; the median resolution time is 8 months. In secondarily infected lesions, bizarre hepatic calcification may be seen years afterwards. Healing of the bowel is remarkably rapid and complete; occasionally fibrous strictures persist after severe dysentery.

Prevention

Chlorination of water supplies does not destroy amoebic cysts, but adequate filtration will remove them. Regular stool screening of food handlers and domestic staff is of no value, but health education is important with encouragement to have a medical check if diarrhoea occurs.

Visitors to the tropics should not attempt chemoprophylaxis; in particular, long-term unsupervised use of hydroxyquinoline drugs must be strongly deprecated. Simple hygienic measures provide considerable protection. Boiling water for 5 min kills cysts. Routine examinations in temperate countries for returning visitors from the tropics or for new residents coming from such countries is of no value unless *E. histolytica* can be differentiated from *E. dispar*. Amoebic serology is particularly useful in those with gut symptoms or a history of dysentery.

Other parasitic gut amoebae including *Dientamoeba fragilis*

In addition to *E. histolytica* five species of *Entamoeba* infect humans, all have a nucleus with a small central endosome and abundant peripheral chromatin. *E. gingivalis* has no cystic stage and lives in the mouth within gingival pockets and tonsillar crypts. It is spread by kissing or more indirect oral contact. Its possible role in periodontal disease was formerly dismissed but there is now renewed interest following recognition of its high prevalence in individual lesions in people with this condition; it may act as a bacterial vector within the lesions. It has been found on intrauterine devices removed because of symptoms. Both in the uterus and in the mouth this amoeba occurs in association with the bacterium *Actinomyces israeli*.

The other *Entamoeba* species are non-pathogenic colonic commensals. *E. coli* has eight nuclei and is the commonest species in most surveys. *E. dispar* and *E. hartmanni* both have cysts with four nuclei; the former was previously known as 'non-pathogenic *E. histolytica*', and the latter as 'small race *E. histolytica*'; size is the only simple diagnostic criterion for *E. hartmanni*, its cysts are less than 10 µm in diameter. The global prevalence of *E. dispar* is about 10 per cent; even in the tropics the prevalence ratio of *E. dispar* to *E. histolytica* is often between 4:1 and 10:1. Lastly there is *E. polecki*, which is primarily a pig parasite; the cyst has one nucleus and an 'inclusion body'. Human infections are common in highland Papua New Guinea where humans and pigs may share a peridomestic environment; elsewhere it is rare.

Endolimax nana and *Iodamoeba buetchlii* both have nuclei with large endosomes and no visible peripheral chromatin. Cysts of the former are oval in shape with four nuclei; those of the latter are somewhat irregular in shape with a single nucleus and a large glycogen vacuole that stains prominently with iodine. Neither species is pathogenic.

Dientamoeba fragilis is overlooked in most parasitological laboratories and most reports are from developed countries. There is good evidence that it can cause

colonic inflammation; however, this is not severe and there is no ulceration or systemic spread. It has no cystic stage and unless this organism is specifically looked for it will be missed. In fixed stained smears, about 60 per cent of trophozoites have two nuclei; the endosome is large and lobulated without peripheral chromatin. Alternatively it may be identified in faeces or cultures using immunofluorescence with specific antibody. Transmission is believed to be nearly always within the eggs of the threadworm *Enterobius*. It causes a relatively mild diarrhoeal illness that may persist for several weeks, sometimes there is a superficial eosinophilic colitis. Blood eosinophilia is quite common and seropositivity is reported. This infection is common in some institutional contexts, but sudden outbreaks are not reported, presumably because of its mode of transmission. It is found within some resected appendices but a causal role is unlikely. Electron micrographs indicate that *D. fragilis* is an amoeboflagellate or a trichomonad rather than a true amoeba. The infection responds to metronidazole.

Free-living amoebae

Several species produce cytopathic changes in cultured cell monolayers and cerebral invasion after intranasal inoculation into mice and other animals. These amoebae are aerobic and their cytoplasm contains mitochondria, Golgi complexes, and a contractile vacuole; their natural food is bacteria. A shared feature is the very large central nuclear endosome, quite different from that of *E. histolytica*, from which differentiation may be necessary in tissue sections. Under dry conditions, trophozoites form resistant cysts that permit survival and also airborne dispersal; cysts can resist chlorination. Many species are thermophilic and they are one of the causes of 'humidifier fever', a form of extrinsic allergic alveolitis presenting with fever, cough, and sometimes progressive pulmonary fibrosis and dyspnoea. Some bacteria including *Legionella* and *Listeria* may live symbiotically within amoebae persisting within the phagosome, being resistant to lyzosomal enzymes. Surprisingly, *Legionella* can survive encystment: the amoebae provide a refuge for these bacteria when chlorination or other antibacterial measures are applied. The following three genera of free-living amoebae cause human infections.

Naegleria is an amoeboflagellate with two trophozoite forms. The amoeba moves rapidly with a single pseudopodium, it can transform into a non-feeding flagellate in hypotonic media and these free-swimming forms facilitate dispersal. Cysts are thin walled and spherical. It may be cultured aerobically on a confluent growth of *Escherichia coli*.

Acanthamoeba has no flagellate form. The small pseudopodia are multiple, thin, and spike-like (Fig. 6); they are called acanthopodia. Cysts are thick walled, angulated, and buoyant (Fig. 7); their dispersal may be wind-borne. It can be cultured on a confluent growth of *Escherichia coli.*

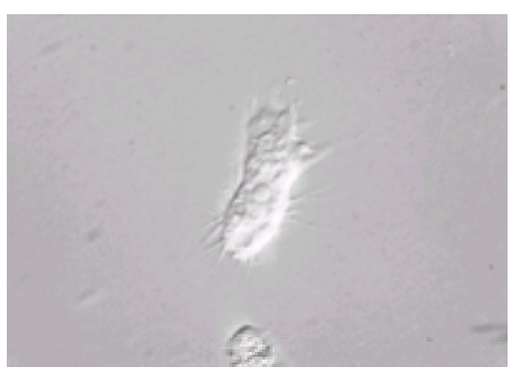

Fig. 6 Trophozoite of *Acanthamoeba* showing spike-like acanthopodia. (Copyright V. Zaman.)

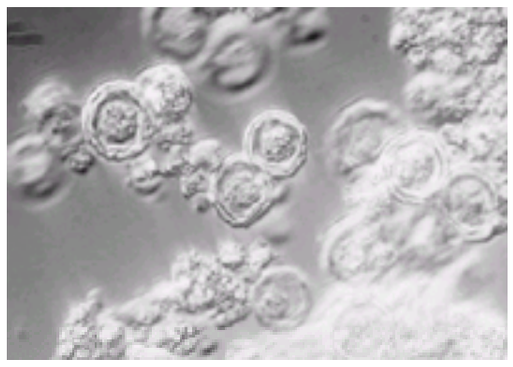

Fig. 7 Cysts of *Acanthamoeba.* (Copyright V. Zaman.)

Balamuthia is a leptomyxid amoeba; it shows little directional movement and has an irregular or branched shape. Cysts are thick walled and wrinkled. Human infections formerly attributed to *Hartmanella* are now all thought to be due to *B. mandrillaris*, a species described in 1993 from a mandrill baboon that died of meningoencephalitis in San Diego zoo. *Balamuthia* can only be cultured on tissue culture monolayers.

Primary amoebic meningoencephalitis due to *Naegleria fowleri*

Epidemiology and pathology

Nearly all patients give a history of swimming or diving in warm fresh water, or spa water, between 2 and 14 days before the illness began. Common-source outbreaks occur during warm summer months in temperate countries. Amoebic trophozoites cross the cribriform plate from the nasal mucosa to the olfactory bulbs and subarachnoid space. At autopsy the brain shows cerebral softening and damage to the olfactory bulbs; cysts are never formed in the tissues. So far only about 200 cases have been documented since the first human case was reported in 1965. However, some are missed clinically and discovered at autopsy, or in preserved pathological material. Specific antisera enable amoebae to be recognized by immunofluorescence staining.

Clinical features and diagnosis

Most patients are young adults and children. Initial nasal symptoms and headache are soon followed by fever, neck rigidity, coma, and later, convulsions; most die within a few days. Cerebrospinal fluid is often turbid, and bloodstained with high protein and low glucose levels and neutrophils. Amoebae must be urgently looked for in wet specimens using phase-contrast microscopy. Unless amoebae are seen, bacterial meningitis will be suspected; on Gram staining, amoebae appear as indistinct smudges. Fixed preparations stained with iron haematoxylin will show full details of nuclear structure. Confirmation is by culture at 37°C. Amphotericin B is the only effective drug. It should be given by daily intravenous infusion, and intrathecally, with the dosage regimens used for cryptococcal meningitis. So far, very few patients have survived, but this may partly be due to diagnostic delays.

Amoebic keratitis due to *Acanthamoeba*

Corneal lesions are painful and present as indolent and progressive ulcers leading eventually to perforation. Recognition may be in the context of lesions unresponsive to antibiotics or corticosteroids; differention must be made from herpes simplex. Inflammatory cells are mainly neutrophils. Infection may be by wind-borne cysts upon a damaged epithelium or from contact lenses. Solutions used to store, or wash, lenses can be contaminated by these amoebae, many of which are resistant to some antiseptics, especially as cysts.

Five species of *Acanthamoeba* are recognized to cause keratitis, the most common are *A. castellani* and *A. polyphaga.* Amoebae are found in corneal scrapings or histologically in corneal tissue but can be missed unless stained with iron haematoxylin or immunofluorescence using specific antisera. Cysts may be seen in tissue.

Cultures from fresh material should be at 30°C.

Lesions usually respond to local propamidine and neomycin, but the latter is not cysticidal; combinations of topical propamidine with chlorhexidine, or with polyhexamethylene, have recently been successful. Alternatives are topical miconazole and oral ketoconazole. Corneal grafting may be necessary. Wearers of contact lenses must take especial care to avoid contamination, especially when storage cases are used; raw tap water may contain *Acanthamoeba*. The most appropriate disinfectants are chlorhexidine and hydrogen peroxide.

Granulomatous amoebic encephalitis due to *Acanthamoeba*

Humans become infected by swallowing or inhaling cysts or amoebae; or these may contaminate wounds, or skin or mucosal ulcers. *Acanthamoeba* species are sometimes isolated from throat or nasal swabs, or from stool specimens.

Many patients have predisposing factors such as craniofacial trauma, vascular brain infarct, or a systemic disorder such as lymphoma, other malignancy, collagen disorder, alcoholism, or diabetes mellitus. Relatively acute cerebral lesions are described in a few patients with AIDS. Cerebral lesions arise haematogenously, by direct spread, or rarely from the nasal mucosa as with *Naegleria*. Pathologically, lesions resemble chronic bacterial brain abscesses or localized subacute haemorrhagic necrosis; involvement of the meninges is common. Some patients present with headache and meningism, others with evidence of a focal brain lesion. Primary lesions have been described from the lung, orbit and other cranial structures, and the gastric wall.

Unless these amoebae are found in wet-tissue preparations or cerebrospinal fluid, the diagnosis will be based upon histology. Cysts may be seen in tissue, but trophozoites may be missed unless stained with iron haematoxylin or immunofluorescence using specific antisera. Cultural diagnosis from fresh biopsies or cerebrospinal fluid is sometimes possible.

Survival of patients with this condition is very rarely reported. Total excision of cerebral lesions is occasionally possible. The drug sensitivities are poorly defined; a wide spectrum of resistance is common. Systemic amphotericin B or flucytosine will be the initial choice, but ketoconazole is an alternative.

Amoebic meningoencephalitis due to *Balamuthia mandrillaris* infection

Since 1990, when this condition was recognized in a non-human primate, more than 60 human cases have been reported, in the Americas, Europe, and Australia. Immunocompetent as well as immunocompromised patients may be infected. Exposure may be associated with contact with fresh water in pools. Cerebral lesions may be subacute and necrotizing, with prominent vasculitis, or chronic and granulomatous. Some patients have associated granulomatous facial lesions (Plate 4). Prolonged treatment with albendazole and itroconazole has proved effective in Peru. Diagnosis is made by finding amoebic trophozoites and cysts in infected tissue and by indirect immunofluorescence.

7.13.2 Malaria

*D. J. Bradley and D. A. Warrell**

Introduction

Malaria is the most important human parasitic disease globally, causing over 170 million clinical cases annually, of which over a million die, mostly in Africa. It has had large effects on the course of history and settlement in tropical regions. In recent years malaria has been subject to massive control efforts, with varying degrees of success but the disease has been resurgent for the last two decades. Resistance of falciparum malaria parasites to the main antimalarial drugs is now a serious problem in SE Asia. Malaria epidemics are an increasing problem. Malaria remains the dominant tropical vector-borne disease but, after decades of neglect, international interest in its control has recently revived.

Parasitology

There are over a hundred species of malarial parasite (*Plasmodium* spp.), but only four species have humans as their natural vertebrate host: *P. falciparum*, *P. malariae*, *P. vivax*, and *P. ovale* (Plate 1). Rare zoonotic infections have been recorded from non-human primate malarias such as *P. knowlesi, P. simium,* and *P. cynomolgi*.

Although each of the human malarias has distinguishing biological, morphological, and clinical characteristics (Table 1), their overall biology and lifecycles are similar (Fig. 1).

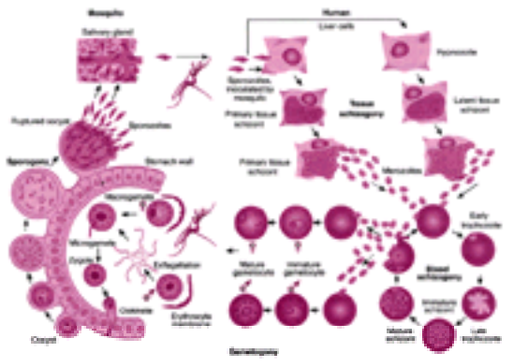

Fig. 1 Development cycle of *Plasmodium* spp. (redrawn by permission of F. Hoffman-la-Roche Ltd, Basel).

In both the mosquito and mammalian hosts the lifecycle of *Plasmodium* spp. has alternating stages of invasion and intracellular asexual division. The sexual stage, by facilitating the exchange of genetic information between different parasite strains or genotypes, assists in the generation of genetic diversity within the parasite population.

Infection is initiated when sporozoites from the salivary glands of a female *Anopheles* mosquito are inoculated during a blood meal into the human bloodstream. These organisms invade hepatic parenchymal cells within a few minutes, the process being largely complete within 30 min. Once inside the liver cell, two pathways of differentiation are possible.

In all species there is intracellular asexual multiplication. In addition, in *P. vivax* and *P. ovale* infections some parasites enter a cryptobiotic phase termed 'hypnozoites', which may lie dormant for months or even years before starting to divide and giving rise to late relapses. In *P. falciparum* and *P. malariae* infections there is no cryptobiotic phase and so relapses from the liver do not occur, although blood infections may persist for a few years in the case of *P. falciparum* or decades in the case of *P. malariae*.

The time required to complete the intrahepatic multiplication depends on the parasite species (Table 1). The products of the liver stage (extraerythrocytic merozoites) are liberated in their thousands into the bloodstream. Here they attach to and invade circulating erythrocytes. Inside the erythrocyte, asexual division begins and, over a period of 48 h (*P. falciparum, P. vivax, P. ovale*) or 72 (*P. malariae*), the parasites develop through a series of morphological changes from 'ring' forms to trophozoites and finally to schizonts containing daughter erythrocytic merozoites. These are liberated by red-cell lysis and immediately invade uninfected erythrocytes, producing a repetitive cycle of invasion and multiplication. Because the intraerythrocytic division cycle is usually fairly synchronous (particularly in *P. vivax* and *P. ovale* infections) and also tied to the diurnal cycle of the host, red-cell lysis and merozoite release occur at approximately the same time of day for a given individual. 'Malarial pyrogens' released at this time induce cytokine production (for example, tumour necrosis factor-a (**TNF-a**) and interleukin-1 (**IL-1**)) giving rise to the periodic 'agues' or paroxysms of fever that have long been a diagnostic feature of malaria infection. The asexual blood forms are the only forms of the parasite that give rise to clinical symptoms.

A small proportion of the merozoites within red cells develop into male and female gametocytes. Once mature, these gametocytes may return to the mosquito if ingested during a blood meal.

Inside the mosquito's midgut, male and female gametes are liberated from their host red cells and fuse to form a zygote which develops into an ookinete, able to penetrate the gut wall and form an oocyst. At this point a further series of asexual divisions takes place, giving rise to sporozoites that migrate to the insect's salivary glands to complete the lifecycle.

Genetics of the parasite

Variation has been found in isoenzyme types, antigenic markers, drug-resistance markers, and in the virulence of different isolates. Such genetic diversity has an important bearing on the disease, for an individual infection may consist of different parasite genotypes of varying drug resistance and exposure to a variety of antigenic types that may be needed before clinical immunity develops. During the intraerythrocytic cycle in the blood, the parasites are haploid. The diploid phase of the lifecycle occurs after gamete fusion in the mosquito where meiosis takes place .

Resistance to chloroquine and pyrimethamine results from mutations at unlinked loci. However, in the case of resistance to chloroquine alone, multiple mutations at independent loci may give rise to resistance. In some cases, resistance is stable in the absence of drug pressure. A locus on chromosome 7 segregates with the resistant phenotype.

Molecular biology

DNA from *P. falciparum* has proved to have an unusual base composition with an average A+T content of approximately 80 per cent. A very high proportion of genes, including 'housekeeping genes', contain large blocks of tandemly repeated amino acid sequences. It has been proposed that these sequences may act as immunological decoys by acting as T-independent antigens. The presence of multiple, low-affinity cross-reactivities between different repeats may serve to prevent the affinity maturation of specific B cells.

Comparison of rRNA sequences of different species of *Plasmodium* shows that *P. falciparum* is more closely related to avian malarias than to other mammalian species.

Proteins/antigens

The surface proteins of the sporozoite and sexual stages are dealt with in the section on vaccination below. Some of the molecules expressed on the surface of the merozoite, the invasive free-living form, are involved in the process of invasion of new erythrocytes. Other proteins bind specifically to the surface of normal red cells, but not to cells rendered refractory to invasion. Because red-cell invasion is an essential step in asexual parasite multiplication, understanding its molecular basis could lead to new forms of therapy.

Molecules on the surface of the infected red cell determine the adherence of infected cells to vascular endothelium and are a target of the protective immune response. Biochemical, immunochemical, and cell biological data reveal that a family of high molecular-weight molecules undergo a process of rapid, clonal, antigenic variation. The genes for this group of proteins (**PfEMP-1**, *Plasmodium falciparum* erythrocyte membrane protein-1), have recently been cloned.

Many other parasite-derived proteins are secreted into the host red cell, but do not find their way to the cell surface. Some interact specifically with the red-cell cytoskeleton modifying the host-cell environment in favour of the parasite.

In vitro culture

Since 1975 it has been possible to grow asexual forms of *P. falciparum* in long-term culture, using a suitable growth medium with uninfected red cells in an atmosphere of low oxygen and high carbon dioxide tension. The availability of large numbers of *P. falciparum* parasites, without recourse to patients or experimental non-human primates, has speeded up much of the basic research on malaria and has permitted the development of *in vitro* tests for sensitivity to certain antimalarial drugs. The complete development of the hepatic stage of *P. falciparum* has also been achieved *in vitro*. Gametocytes can also be produced from *in vitro* culture of asexual blood forms.

Biology of the mosquito vector

Human malarial parasites are transmitted only by Anopheles mosquitoes. There are many species with varying habits, breeding places, and effectiveness as malaria vectors. Anopheles can be distinguished from other adult mosquitoes by the way that the female, when taking a blood feed, inclines her whole body at an angle to her victim, while in the other, culicine mosquitoes, the body is parallel to the skin surface (Fig. 2). The culicine and anopheline larval stages are also distinguishable (Fig. 3).

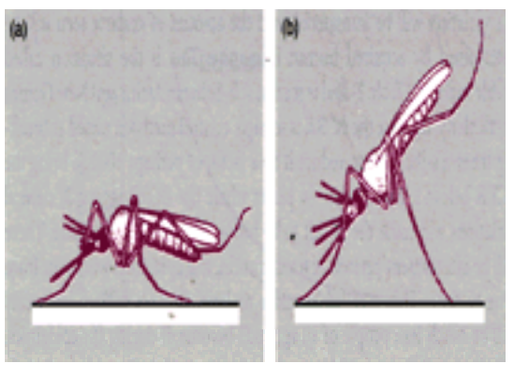

Fig. 2 Feeding posture of different types of adult mosquito. (a) Culicine, (b) anopheline.

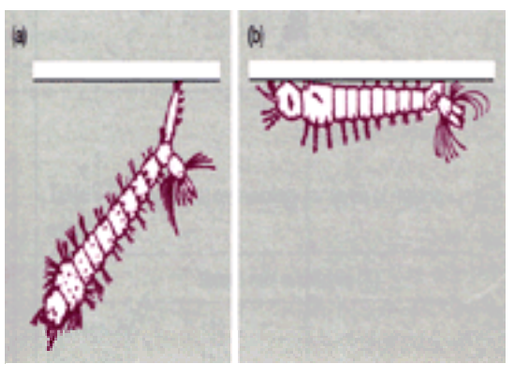

Fig. 3 Resting posture of different types of mosquito larva. (a) Culicine, (b) anopheline.

Since the female Anopheles needs a blood meal before egg laying, her adult life consists of finding a suitable blood meal, resting while it is digested, flying off to lay eggs at a suitable body of water, and then repeating this cycle every few days. The eggs, larvae, and pupae develop in water and the winged adults emerge. For ecological reasons, only a few species of Anopheles in a given locality are likely to be important malaria vectors, because to transmit malaria the mosquitoes need to be sufficiently abundant, to bite people rather than only some other vertebrate host, and to live long enough for ingested gametocytes to develop through to sporozoites. Identification of the main vector species in an area determines the design of specific control measures. Since most species are selective in their breeding sites, knowledge of the larval ecology permits engineering and other measures to be directed at the selective removal of the vector habitat, a process called 'species sanitation'.

The behaviour of the adult mosquito will dictate which insecticidal strategies are most likely to succeed. Anophelines vary in their preferred feeding and resting locations, though the majority bite in the evening and night. They may bite indoors (endophagic) or outside (exophagic). This determines whether the use of bednets and screened doors and windows will protect, or whether long sleeves and protective footwear when outside the house are more relevant. Of greater importance is where the female rests overnight to digest the blood meal. Endophilic mosquitoes, which rest on the inside walls of houses and in the roof, are thereby exposed to residual insecticides previously sprayed on the walls, whereas exophilic mosquitoes, resting outside houses, may escape the effects of insecticidal attack. The success of many antimalarial efforts has depended on the major vectors in several continents being endophilic, and failures of attempted eradication have sometimes resulted from exophilic vector species being present, as in many forested areas of SE Asia. Anopheline mosquitoes extend into temperate countries, and in the United Kingdom several indigenous species, notably *A. atroparvus*, were responsible for transmitting the historical English 'agues' (*P. vivax* and *P. malariae*).

Epidemiology

Malaria is widely distributed throughout the tropics (Fig. 4) except for the south-central Pacific islands from which anopheline mosquitoes are absent. *P. falciparum* is the predominant species in the highly endemic areas of Africa, New Guinea, and Haiti, while *P. vivax* is more common in Central America, North Africa, and southern and western Asia. Both species are prevalent in South America, the rest of Asia, and Oceania. *P. malariae* is widespread but often overlooked, and in West Africa *P. ovale* largely replaces *P. vivax,* to which the indigenous inhabitants are resistant.

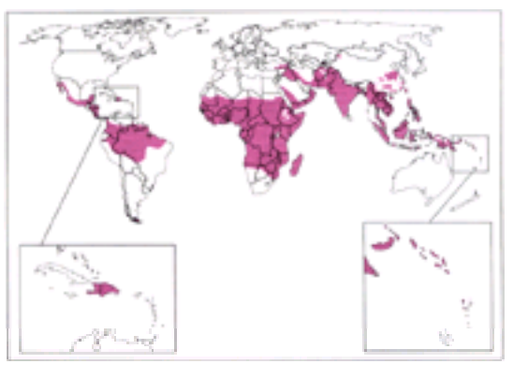

Fig. 4 Malarious areas of the world.

The epidemiological features of human malaria differ markedly even between endemic areas. At one extreme, as in tropical Africa, everyone is infected shortly after birth, parasitaemia is almost universal throughout childhood, and he brunt of mortality falls in early childhood; epidemics do not occur except at high altitude. By contrast, as in parts of India, malaria is an epidemic disease affecting all ages and causing temporary dislocation of community life due to the concurrent illness of the people. These differences result from differing levels of malaria transmission affecting the pattern of immunity in the human population, so that to understand even the clinical spectrum of malaria seen in patients from a given locality it is essential to understand the local epidemiological situation. The epidemiology of malaria is complex but relatively well understood. Attempts at control in recent years have changed the epidemiological pattern in many areas.

Climate and mosquito ecology are the primary determinants of malarial epidemiology. Once the biology of the relevant anopheline mosquito is understood, much of the complex epidemiology of malaria falls into place. There is some variation in susceptibility to malaria within the anophelines, so that *P. falciparum* from Africa may

fail to develop in some European anophelines even under optimal conditions, but usually in a given locality the indigenous anopheline mosquitoes will be capable of transmitting the local malaria strains, so that the importance of a vector species depends particularly on their behaviour and ecology.

The epidemiological pattern is determined by the density, human-biting habit, and longevity of the mosquito. Density is the number of vectors present in a locality relative to the human population. Malaria transmission will tend to be proportional to mosquito density, as might be expected. The human-biting habit combines two features: the frequency with which the female mosquito feeds and the choice of host. The human-biting frequency rises to as high as 0.5/day in *A. gambiae*, an African mosquito that feeds on alternate days and preferentially on people; while *A. culicifacies*, a vector in South Asia, may feed only every third day and as few as 10 per cent of its meals may be from people, giving a human-biting habit of 15-fold less. Because malaria transmission is proportional to the square of the human-biting habit, and as transmission involves both parasite uptake by bite and subsequent inoculation to human by a second bite, this factor has a large effect on malaria transmission.

Mosquito longevity has an even greater effect. The duration of the 'extrinsic cycle', the interval between when a mosquito ingests infective gametocytes and the first day on which sporozoites are present in the salivary glands ready for transmission, depends on the ambient temperature (Fig. 5), but it will rarely be less than 10 days. Only mosquitoes that become infected and then survive for longer than the duration of the extrinsic cycle (say 10 days) can pass on the infection. As mosquitoes of a given species have a relatively constant probability of dying during a day, regardless of their age, the longevity may be described by the probability of surviving through one day, and it varies greatly between mosquito species and environments. It will affect transmission very greatly indeed: if the chance of survival through one day is *p* and the duration of the extrinsic cycle *n* days, then transmission is proportional to *pn*, that is, something like the tenth power of *p*. Thus the most effective transmission of malaria will be by a long-lived mosquito that occurs at high density and frequently bites people. *A. gambiae* and *A. funestus* best fit this description well and are the predominant African malaria vectors.

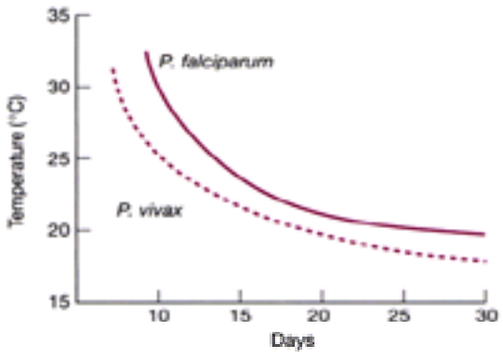

Fig. 5 The period of extrinsic development of *P. falciparum* and *P. vivax*.

Malaria transmission is most conveniently measured in terms of the basic case reproduction rate (**BCRR**). This is the average number of new cases of malaria that will result from one human case of malaria in a locality, assuming all the other people are non-immune and uninfected. The BCRR may vary from over 1000 in some areas of Africa to below 1. Where the BCRR is less than 1, the infection will not replace itself and the disease will die out. In the 'real world', the BCRR will vary considerably about a mean value. In areas with a very high BCRR everyone will become infected, the variation will be immaterial, and the amount of malaria seen will be determined by acquired human immunity. This is the situation called 'stable malaria' (Table 2) and is seen in sub-Saharan Africa and New Guinea particularly. Because the BCRR is so high, control methods aimed at breaking transmission have to reduce it by a factor of perhaps 1000 to bring the BCRR below 1. By contrast, in places where the BCRR is, say, 3, natural variations will cause the BCRR to be below 1 for much of the time. There will be intermittent periods of transmission, and epidemics will occur from time to time. This is called 'unstable malaria'. Because human immunity will be much less, people of all ages will become ill during the epidemics, but the transmission will be much easier to control. Unstable malaria is dramatically evident but kills fewer people than stable malaria, in which the brunt of the mortality falls on young children.

Even in stable malaria, seasonal variation may occur. In the African savannah, no mosquitoes may bite during the hot dry season and in more temperate zones it may be too cold for transmission for part of the year, but the annual peaks will be comparable, with all children infected each year. While the division between stable and unstable malaria is the most useful (Table 2), an earlier classification of areas by the parasite prevalence in children or by the proportion of children aged 2 to 9 years with enlarged spleens is often still used (Table 3). The prevalence of splenic enlargement gives a better cumulative picture of the amount of malaria than does the parasite prevalence, which is influenced by casual chemotherapy.

Under endemic conditions there is still a great deal of variation in risk to a non-immune visitor. At one extreme, in some parts of rural Africa an unprotected person is likely to be bitten on average by more than one infective mosquito nightly, whilst in a highly malarious part of India the corresponding rate is perhaps five times yearly or less. Yet both will be rightly perceived as highly malarious places by the local inhabitants.

The epidemiological background to clinical malaria is likely to change over time in most places due to environmental changes (often man-made, whether local or global), changing resistance of parasites to drugs, and the consequences of attempts at malaria control.

The widespread availability of chloroquine and other effective chemotherapeutic agents in endemic areas has resulted in the early treatment of a proportion of infections. This often leads to disparities between a high spleen rate in children and an artificially low parasite rate. With the increasing use of chemotherapy and of bed nets for personal protection, the acquisition of immunity is somewhat deferred. Under the most intense transmission, severe and often fatal anaemia in infants predominates. With rather less transmission, cerebral malaria in early childhood may be more apparent. Cerebral malaria will also be the main hazard in falciparum malaria epidemics and in non-immune individuals who contract it. Human migration is commonly associated with malaria epidemics, because population pressure in hilly areas drives the inhabitants down into malarious regions, or the aggregation of workers at new sites mixes infected people with those who are susceptible, or refugees may have impaired resistance to infection and public health measures may have collapsed. Migrants are commonly blamed for introducing malaria, but more usually they are non-immune individuals suffering from the disease acquired from the indigenous inhabitants.

Susceptibility to infection and innate resistance

People of West African origin are strikingly resistant to *P. vivax* infection. This correlates with the extreme rarity of the Duffy blood-group antigen alleles *Fya* and *Fyb*, which are receptors for penetration of the red cell by the merozoites.

Other genetic determinants affect the course and outcome of infection. Although *P. falciparum* is responsible for around 1 million deaths of African children annually, the mortality would be much greater but for a number of inherited resistance factors, and for the processes of acquired resistance discussed in the next section.

The high mortality associated with malaria is perhaps best illustrated by the way in which a number of otherwise disadvantageous genes have been selected in chronically exposed populations because of the resistance to malaria that they confer. In 1948, J.B.S. Haldane first suggested that heterozygotes of thalassaemia might be 'fitter than the normal [and] more resistant to attacks by the sporozoa that cause malaria'.

It has since become clear for several mutations affecting haemoglobin production or structure that these have reached their present frequencies by this selective mechanism. The best-known example is sickle-cell disease, due to a point mutation in position six of the b-globin chain. Here the mutant-gene frequency is stabilized because the enhanced survival of heterozygotes is counterbalanced by the lethal consequences of homozygosity in developing countries. Protection afforded to heterozygotes is seen most dramatically in case-control studies, which show that the relative risk of contracting severe malaria by heterozygotes and controls is about 1 to 10, respectively. Perhaps surprisingly, parasite rates and densities at the population level are very similar in normal and AS individuals, except in very young children, indicating that heterozygotes are resistant to disease rather than to infection.

Table 4 lists the genotypes for which there is either epidemiological or clinical evidence of selection by malaria. Despite this often clear evidence of protection, the

mechanisms involved are still controversial.

Acquired resistance

Those exposed to repeated malarial infection in endemic areas gradually acquire immunity in several stages, but it is rarely complete. Immunity is species-specific and largely strain-specific. The first change observed is a reduction in clinical symptoms and signs for a given level of parasitaemia. This is sometimes known as 'tolerance' but the mechanism is not understood.

Acquired resistance to the parasites takes months to develop and first affects the density of gametocytes in the peripheral blood. Subsequently, the density of asexual erythrocytic parasites, trophozoites, and schizonts falls and gradually reaches very low levels, so that under conditions of holoendemic transmission the prevalence of infection falls by half in those aged 15 years compared with children. Infected older children and adults from highly endemic areas often have very low-level, persistent, asymptomatic parasitaemias combined with relative resistance to superinfection.

It is clear that in a highly endemic area for *P. falciparum* there are several parasite strains circulating, and concepts of why resistance is so slowly acquired may either emphasize a balance in immune responses or the successive infection with various strains combined with a largely strain-specific response. The latter is favoured at present. Severe malaria in very young children is ascribed to multiple infections over a short time, and the cerebral malaria that predominates in slightly older children is possibly due to some more virulent strains.

Infants born to immune mothers are partially protected against severe malaria attacks by transplacental antibodies and those acquired from breast milk, for a few months, after which the infant suffers from severe malaria attacks with only gradual acquisition of resistance. Adult non-immune people, including visitors to the tropics from non-malarious areas, are equally susceptible to high mortality in their first few attacks, while women from an endemic area become more susceptible during pregnancy (second trimester), especially the first pregnancy. Splenectomy, for any reason, also increases susceptibility to malaria, which may have a fatal outcome.

Immunity is stage-specific, in that immunity to either sporozoite challenge or to gametocyte transmission does not protect against asexual parasites. It also has components that are specific for the parasite species, strain (genome), and antigenic variant within a strain. Thus protection against infection by sporozoites appears to be mediated largely by cytotoxic T cells, which can kill infected hepatocytes, although antibody to the repeat regions of the circumsporozoite protein may also have a role. Specific T and B cells, in addition to non-antigen-specific mechanisms, are involved in the control of asexual parasitaemia. The central role of antibody has been demonstrated by a variety of passive transfer experiments in people and experimental animals. Pooled immunoglobulin from highly immune donors is extremely effective in rapidly reducing parasitaemia, but not in the long-term control of infection. Maintaining parasite numbers below subclinical levels requires the involvement of T cells, as shown by adoptive transfer experiments in animals. Work in rodents suggests that early in infection, TH1 cells are critical but that later during the course of infection cells of a TH2 phenotype are more important. High levels of cytokines, such as TNF-a, during acute infection are a feature of severe malaria and are associated with a poor outcome. The acute response in non- or semi-immune individuals, while vital to the control of parasitaemia, may also contribute to the pathogenesis of disease by triggering a variety of non-specific effector mechanisms.

Clinical immunity takes many years and several infections to be effectively induced. It is also a non-sterilizing response, as immune adults are constantly and demonstrably reinfected. Several explanations have been put forward for these observations. Generalized, parasite-induced immunosuppression certainly does occur and may be clinically relevant in the response to certain non-malarial antigens such as meningococcal vaccine. It is not clear, however, whether overall it is any more severe than in other acute viral or bacterial infections. One area where it does seem to play a definite part is in the development of Burkitt's lymphoma, in which case it has been shown that individuals with acute *P. falciparum* infection have impaired T-cell control of endogenous, Epstein–Barr virus-infected, B-cell proliferation. Other explanations for the difficulty in inducing effective immunity have involved interference by the parasite in the development of specific responses. This could either be by the presence of important T-independent antigens, which induce a relatively poor response with no memory, or by the effect of crossreactive, tandem-repeat elements in inhibiting affinity maturation of specific B cells. Perhaps the most likely explanation is the extreme polymorphism or clonal variation of immunologically relevant antigens, such that the host requires exposure to a variety of 'strains' before a broadly effective response can develop. If the latter is true, then it presents formidable problems to vaccine development.

Malaria and HIV-immunosuppression

For at least 20 years, falciparum malaria and HIV-immunosuppression have coexisted in Africa, but the effects of their interaction on the clinical course of both diseases is still uncertain. Early studies that suggested an association between HIV and falciparum malaria in African children were vitiated by the greater risk of HIV-contaminated blood transfusions in children with severe malaria-related anaemia in this region. However, *P. falciparum* parasitaemia has been found to be more frequent among HIV-1-infected multigravidae than controls in malaria holoendemic areas of Central/Southern Africa, associated with increased perinatal mortality. Both HIV and malaria contribute to maternal anaemia and low birth-weight babies and, in Lusaka, Zambia, a dramatic increase in maternal morbidity over the last 20 years has been attributed to malaria, HIV-immunosuppression, AIDS-associated tuberculosis, and chronic respiratory illnesses. Recently, in a study of 613 adults with microscopically confirmed falciparum malaria in an area of unstable transmission in KwaZulu Natal, South Africa, the results suggested that underlying HIV infection might double the risk of severe malaria and increase the risk of fatal malaria by five- to sevenfold.

Molecular pathology

All the pathology associated with malaria infection is attributable to asexual parasite multiplication in the bloodstream. No adverse effects are caused by the quantitatively small degree of parasite invasion and multiplication within hepatocytes, nor by the presence of relatively small numbers of circulating gametocytes. The consequences to the host of the intraerythrocytic multiplication of parasites range from a variety of severe, but not life-threatening, symptoms common to all the species that infect humans, to the potentially lethal complications associated with acute *P. falciparum* infection and the chronic renal damage caused by some infections with *P. malariae*. The relative severity of *P. falciparum* infections, as well as the ability to culture this parasite *in vitro*, has meant that it has been the focus of most experimental effort.

It had been noted for centuries that malaria was characterized by periodic fevers. Once the causative organism was identified, it was clear that the bouts of fever generally followed the synchronous release of new merozoites into the bloodstream as each cycle of erythrocytic multiplication was completed. While it was assumed that the release of infected cell contents that occurs at this time was responsible for fever induction, it was not until very recently that it was proven that components of the infected cell such as the lipid, glycosyl phosphatidyl inositol anchor of a parasite membrane protein (perhaps **MSP-1**, merozoite surface protein-1) could directly induce the release of cytokines such as TNF-a and IL-1 from macrophages. Moreover, it was demonstrated that the older stages of parasites within erythrocytes were differentially sensitive to physiological increases in temperature, so that the effect of fever was both to limit parasite multiplication and to maintain synchronous development. Measurements of TNF-a in children suffering from severe malaria also demonstrated that very high levels of this cytokine were associated with a lethal outcome, although the correlation was not sufficient to be a useful prognostic indicator.

The principal life-threatening complications of *P. falciparum* in African children are cerebral malaria and severe anaemia often associated with metabolic acidosis and respiratory distress. The clinical picture in non-immune adults is more complex and can include single or multiple organ failure. Mechanisms responsible for severe malarial anaemia are poorly understood, but include parasite-induced dyserythropoiesis and accelerated red-cell clearance of both normal and infected cells by both immune and non-immune mechanisms (see below). However, the central event underlying the pathology of most other manifestations of severe falciparum malaria is the cytoadherence and resulting sequestration of infected cells, which is unique to this organism (Fig. 6 and Fig. 7 and Plate 2). Only the younger developmental stages of the parasite circulate, as the more mature forms adhere to specific receptors on venular endothelium. The distribution of infected cells found in tissue sections suggests that the chief sites of infected cell sequestration correlate with specific organ dysfunction. It is assumed, but not formally proven, that the reduction in, or obstruction of, local blood flow associated with the partial occlusion of small vessels with infected cells results in reduced perfusion and tissue damage. Some have suggested that the sequestered cells may induce the local release of a number of potentially toxic or pharmacologically active compounds (such as reactive oxygen species or nitric oxide) from macrophages, neutrophils, or endothelium, and that these may affect tissues locally.

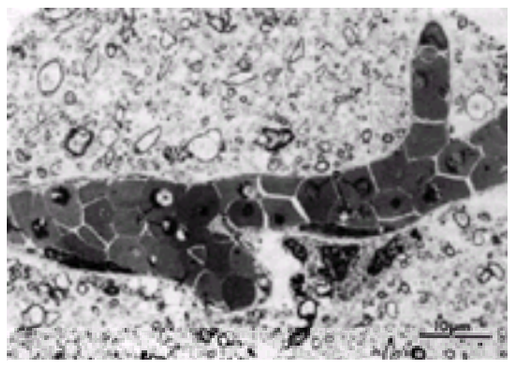

Fig. 6 Brain section of a patient who died of cerebral malaria, showing a blood vessel packed with red blood corpuscles, the majority of which were identifed as being infected by the presence of parasites (P), or at a higher magnification, the presence of knobs (by courtesy of Dr D. Ferguson, Oxford).

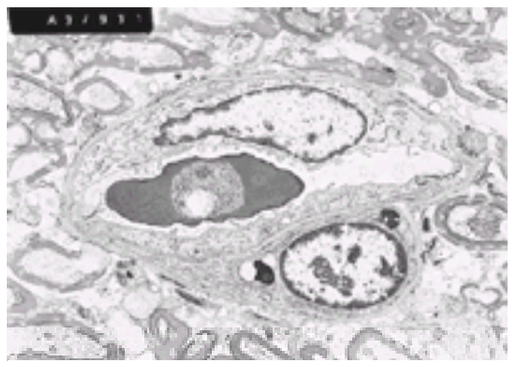

Fig. 7 Human cerebral malaria. Electron micrograph showing endothelial cell microvilli making contact with a parasitized erythrocyte via electron-dense strands (upper right). (Copyright N. Francis.)

While the detailed mechanisms by which sequestered cells result in the specific symptoms seen in cases of severe falciparum malaria remain largely unresolved, much more progress has been made in understanding the molecular interactions that lead to sequestration. Several endothelial receptors have been identified, including CD36 (formerly platelet glycoprotein IV), thrombospondin, intercellular adhesion molecule-1 (**ICAM-1**), and more recently, vascular cell-adhesion molecule (**VCAM**) and E-selectin (Table 5). Most field isolates bind to CD36 and thrombospondin and the majority bind to ICAM-1; to date there are insufficient data on VCAM and E-selectin. *In vitro* assays of purified proteins reveal great variability in the absolute levels of adhesion between isolates. No good correlation has yet emerged between the ability of parasites to bind to individual receptors and disease pattern. These studies are, however, fraught with difficulty and many more data are needed to resolve this point. The parasite molecules involved in adhesion are well characterized biochemically but have not yet been cloned, so that primary-sequence data are not available. They form a family of red-cell surface proteins that undergo clonal antigenic variation during a single infection and that also appear to be targets of a host-protective antibody response.

Some parasite isolates show two other properties: the rosetting of uninfected erythrocytes around red cells containing mature developmental forms of the parasite (Fig. 8) and autoagglutination of infected erythrocytes in the absence of immune serum. Rosetting has been linked to cerebral malaria in some, but not all, studies. It is presumed that the multicellular aggregates, if they occur *in vivo,* may exacerbate vascular obstruction caused by sequestration.

Fig. 8 Rosetting *in vitro*. The central parasitized erythrocyte shows many electron-dense protruberances (knobs) beneath its membrane (bar = 1 µm). (Copyright D. Ferguson.)

Despite the life-threatening nature of severe falciparum malaria, and the enormous number of childhood deaths that it causes in sub-Saharan Africa, the mortality rate of all malaria infections is extremely low. In holoendemic areas, infections in children are universal and constant, yet only a small proportion of those infected show clinical symptoms at any one time and only a fraction of these go on to develop severe illness. This is probably only partially explained by the known innate resistance factors and acquired immunity, and so it is likely that unidentified factors are also important in determining how far individual infections progress from parasitaemia to clinical illness and finally to severe disease.

Pathology

Brain

Only falciparum malaria causes cerebral pathology. At autopsy, the brain is sometimes oedematous but evidence of cerebral, cerebellar, or medullary herniation is rarely seen. The small blood vessels, including those of the leptomeninges, are congested with parasitized red blood cells containing malaria pigment (Fig. 6 and Fig. 7). This gives the surface of the brain its characteristic leaden or plum-coloured appearance and the cut surface a slatey-grey hue. Many of the parasites are schizonts and other mature forms. In larger vessels, parasitized red cells form a layer along the endothelium ('margination'). Up to 70 per cent of erythrocytes in the cerebral vessels are parasitized and these are more tightly packed than in other organs. The cerebrovascular endothelium shows pseudopodial projections, which may be in close apposition to electron-dense, knob-like protruberances on the surface of parasitized red cells (Fig. 7). Numerous petechial haemorrhages are seen in the white matter, resulting from haemorrhages from end arterioles, proximal to occlusive plugs of parasitized red cells and fibrin. Focal ring haemorrhages can be found centred on small subcortical vessels. Dürck's granulomas, small collections of microglial cells surrounding an area of demyelination, may develop at the site of these haemorrhages, but an inflammatory cell response is generally lacking.

Bone marrow

There is evidence of iron sequestration, erythrophagocytosis, dyserythropoiesis, and cytoadherence with plugging of sinusoids in the acute phase of falciparum malaria. Maturation defects are present in the marrow for at least 3 weeks after clearance of parasitaemia. Increased numbers of large, abnormal-looking megakaryocytes have been found in the marrow and the circulating platelets may also be enlarged, suggesting dyspoietic thrombopoiesis. Malaria pigment and

parasites can be found in monocytes and phagocytes in the marrow, even when they are not detectable in peripheral blood.

Liver

The liver is affected by all four species of human malaria parasites, but changes are most severe in falciparum malaria. The liver is enlarged and oedematous, and coloured brown, grey, or even black as a result of malaria pigment deposition. Hepatic sinusoids are dilatated, containing hypertrophied Kupffer cells and parasitized red cells that appear to obstruct the circulation. Parasitized and uninfected red cells are phagocytosed by Kupffer cells, endothelial cells, and sinusoidal macrophages. Small areas of centrilobular necrosis, which are occasionally seen in severe cases, may be attributable to shock or disseminated intravascular coagulation. Hepatocytes usually show only mild abnormalities but may be depleted of glycogen in some patients who are hypoglycaemic. Lymphocytic infiltration of portal tracts has been described (see also Tropical splenomegaly syndrome, below).

Gastrointestinal tract

Cytoadherent, sequestered, parasitized red cells may be found in the small and large bowel, especially in capillaries of the lamina propria and larger submucosal vessels. The bowel may appear congested, with mucosal ulceration and haemorrhage.

Kidney

Glomerular lesions range from the acute transient glomerular nephritis of falciparum malaria to the chronic lesions of quartan malarial nephrosis. In severe falciparum malaria, with or without 'blackwater fever', acute renal failure is associated with the histopathological changes of acute tubular necrosis. Parasitized red cells may be found in glomerular and peritubular capillaries, with fibrin thrombi and pigment-laden macrophages. Tubular pigment casts are prominent in cases of blackwater fever.

Lung

The lungs are oedematous in almost all patients dying of malaria. Pulmonary capillaries and venules are packed with inflammatory cells including neutrophils, plasma cells, and pigment-laden macrophages, and with parasitized red cells. The vascular endothelium is oedematous, causing narrowing of the capillary lumen, and there is interstitial oedema and hyaline-membrane formation. Secondary bronchopneumonia is a common finding.

Spleen

The spleen is large, engorged, and dark-red or greyish-black in colour. The red and white pulp is congested and hyperplastic, and the splenic cords and sinuses are filled with phagocytic cells containing pigment, parasitized red cells, and non-infected red cells. Tropical splenomegaly syndrome is described below.

Heart

There is no evidence of myocarditis. Subendocardial and epicardial petechial haemorrhages are unusual. The myocardial capillaries are congested with parasitized red cells, pigment-laden macrophages, lymphocytes, and plasma cells. However, the parasitized cells are not tightly packed and there is no evidence of cytoadherence.

Pathophysiology

Anaemia

This is attributable mainly to the destruction or phagocytosis of parasitized red cells, but other mechanisms contribute. The bone marrow shows dyserythropoietic changes. Initial iron sequestration and hypoferraemia may be explained by the very marked hyperferritinaemia, an acute-phase reaction. There is evidence of immune-mediated haemolysis in some populations. Erythrocyte survival is reduced even after the disappearance of parasitaemia. Increased splenic clearance of non-parasitized as well as parasitized red cells has been demonstrated.

Intravascular haemolysis occurs in patients whose erythrocytes are congenitally deficient in enzymes such as glucose 6-phosphate dehydrogenase (**G6PD**) in response to oxidant drugs such as primaquine. However, in classical blackwater fever, G6PD levels are, by definition, normal and the mechanism of haemolysis is unknown, although quinine-mediated haemolysis has been suspected.

Thrombocytopenia

This is attributable to sequestration in the spleen, failure of production by the marrow, and immune-mediated lysis.

Cerebral malaria

Mechanical obstruction to the microcirculation of the brain by cytoadherent, parasitized red cells, and perhaps 'rosettes' of uninfected red cells stuck around a parasitized red cells, is thought to be the principal mechanism leading to coma. Red blood cells infected with some strains of *P. falciparum* develop adhesive properties as they mature. Parasite-derived protein such as PfEMP-1 expressed on the surface of the parasitized red cell may act as a ligand that binds to receptors such as ICAM-1 on cerebral venular endothelium (Table 5). The expression of ICAM-1, and some other receptors involved in the cytoadherence of parasitized red cells, may be increased by TNF-a and other cytokines. Obstruction to cerebral blood flow could result in 'stagnant anoxaemia', leading to coma. In Thai adults with cerebral malaria, it was found that global cerebral blood flow was inappropriately low and there was evidence of cerebral anaerobic glycolysis with increased lactate concentrations in the cerebrospinal fluid. In African children with cerebral malaria, plasma concentrations of TNF-a, IL-1a, and other cytokines correlate closely with disease severity, as judged by parasitaemia, hypoglycaemia, case fatality, and the incidence of neurological sequelae. As well as enhancing cytoadherence, cytokines may have other effects on cerebral function, perhaps by releasing nitric oxide, which interferes with neurotransmission, or by leading to the generation of free oxygen radicals. Cytokines may also be responsible for fever, hypoglycaemia, coagulopathy, dyserythropoiesis, and leucocytosis in falciparum malaria.

In SE Asian adults, the opening pressure of cerebrospinal fluid at lumbar puncture was usually normal and cerebral oedema was demonstrable (by computed tomography (**CT**) scanning) during life in only a small minority, and usually as an agonal phenomenon. In these patients there was little evidence that brain swelling contributed to coma. However, in African children with cerebral malaria, intracranial pressure is usually elevated and there is evidence of brain swelling in the majority of those examined by CT scan. Ischaemic damage resulting from a critical reduction in cerebral perfusion pressure and other factors such as hypoglycaemia and status epilepticus are thought to be important in the mechanism of brain damage in these children.

Pulmonary oedema

This may develop in patients who have been overloaded with fluid in hospital and have elevated central venous and pulmonary-artery wedge pressures. More commonly, the clinical picture is of adult respiratory distress syndrome, with normal or low hydrostatic pressures in the pulmonary vascular bed. In these cases, the mechanism is likely to be increased pulmonary capillary permeability resulting from leucocyte products and cytokines. The histological appearances of neutrophil sequestration in the pulmonary capillaries, increased permeability, and hyaline membrane formation are consistent with this hypothesis.

Hypoglycaemia

This can be caused by cinchona alkaloids (quinine or quinidine), which are potent stimulators of insulin secretion by the pancreatic b-cells. The resulting reduction in hepatic gluconeogenesis and increased peripheral glucose uptake by tissues results in hypoglycaemia. In malaria, glucose consumption is increased by fever, infection, anaerobic glycolysis, and the metabolic demands of the malaria parasites. Glycogen reserves may be depleted, especially in children and pregnant women, as a result of fasting and 'accelerated starvation'. In African children with severe malaria, adult patients with severe disease, and pregnant women, hypoglycaemia develops spontaneously (without treatment with cinchona alkaloids) and is associated with appropriately low plasma insulin concentrations. Plasma lactate and alanine concentrations are elevated and ketone bodies are moderately increased. Counter-regulatory hormone levels are usually very high. The mechanism of

hypoglycaemia in these cases may be inhibition of hepatic gluconeogenesis by TNF-a and other cytokines.

Acute renal failure

Hypovolaemia, from dehydration, is responsible for acute renal failure in the majority of patients whose acute oliguria and renal dysfunction is reversible by fluid replacement. Hyperparasitaemia, jaundice, and haemoglobinuria are associated with a high risk of acute tubular necrosis. Renal cortical perfusion is reduced during the acute stage of the disease. Renal cortical necrosis must be rare, as survivors rarely show evidence of chronic renal impairment. Cytoadherence of parasitized red blood cells in the renal microvasculature, deposition of fibrin microthrombi, and prolonged hypotension ('algid malaria') may contribute to acute renal failure. Quartan malarial nephrosis is discussed below.

Hyponatraemia

In patients with relatively normal plasma osmolalities, hyponatraemia has been attributed to the inappropriate secretion of ADH triggered by fever or reduced effective plasma volume. However, the levels of ADH were appropriately high in Thai patients who were proved to be grossly hypovolaemic by carefully monitored fluid-repletion studies. Mild hyponatraemia is often attributable to intravenous therapy with 5 per cent dextrose alone in patients who are salt-depleted and dehydrated.

Hypovolaemia and 'shock' ('algid malaria')

This may result from hypovolaemia (dehydration and, rarely, haemorrhagic shock following splenic rupture or gastrointestinal haemorrhage) but is most often associated with a secondary Gram-negative bacteraemia. The source may be an intravenous cannula, urethral catheter, or aspiration pneumonia. Transient immunosuppression, impaired macrophage function, or 'blockade' of the reticuloendothelial system may increase the susceptibility of patients to severe secondary bacterial infections.

Clinical features

The pathogenic species of *Plasmodium* cause acute febrile illnesses characterized by periodic febrile paroxysms occurring every 48 or 72 h, with afebrile asymptomatic intervals and a tendency to recrudesce or relapse over periods of months or even years. The severity of the attack is determined by the species and strain, and hence the geographical origin, of the infecting parasite; on the age, genetic constitution, state of immunity, general health, and nutritional state of the patients, and on their use of antimalarial drugs.

Falciparum malaria ('malignant' tertian or subtertian malaria)

The shortest interval between an infecting mosquito bite and parasitaemia is 5 days, but this prepatent period is usually 9 to 10 days. The incubation period (the interval between infection and the first symptom) usually ranges from 7 to 14 days (mean 12 days) but may be prolonged further by immunity, chemoprophylaxis, or partial chemotherapy. In Europe and North America, 98 per cent of patients with imported falciparum malaria present within 3 months of arriving back from the malarious area. A few present up to 1 year later, but none after more than 4 years.

Several days of prodromal symptoms such as malaise, headache, myalgia, anorexia, and mild fever are interrupted by the first paroxysm. Suddenly the patient feels inexplicably cold (in a hot climate) and apprehensive. Mild shivering quickly turns into violent shaking with teeth-chattering. There is intense peripheral vasoconstriction and gooseflesh. Some patients vomit. The rapid increase in core temperature may trigger febrile convulsions in young children. The rigor lasts up to 1 h and is followed by a hot flush with throbbing headache, palpitations, tachypnoea, prostration, postural syncope, and further vomiting while the temperature reaches its peak. Finally, a drenching sweat breaks out and the fever defervesces over the next few hours. The exhausted patient sleeps. The whole paroxysm is over in 8 to 12 h, after which the patient may feel remarkably well. These symptoms are typical of a classical 'endotoxin reaction' produced by typhoid vaccine, infection with Gram-negative bacteria, or the release of TNF-a and other cytokines by other agents. Classical tertian or subtertian periodicity (48 and 36 h between fever spikes) is rarely seen with falciparum malaria. A high irregularly spiking, continuous or remittent fever, or daily (quotidian) paroxysm, is more usual. Other common symptoms are headache, backache, myalgias, dizziness, postural hypotension, nausea, dry cough, abdominal discomfort, diarrhoea, and vomiting. The non-immune patient with falciparum malaria usually looks severely ill, with 'typhoid' facies and, in dark-skinned races, a curious greenish complexion. Commonly, there is anaemia and a tinge of jaundice, with moderate tender enlargement of the spleen and liver. Useful negative findings are the lack of lymphadenopathy and rash (apart from herpes simplex 'cold sores') and focal signs.

Cerebral malaria and other severe manifestations and complications

The global case fatality of falciparum malaria is probably around 1 per cent or 1 to 3 million deaths per year. Cerebral malaria is the most important of the severe manifestations of *P. falciparum* infection, accounting for 80 per cent of these deaths. Patients who have been feverish and ill for a few days may have a generalized convulsion from which they do not recover consciousness, or their level of consciousness may decline gradually over several hours. High fever alone can impair cerebral function causing drowsiness, delirium, obtundation, confusion, irritability, psychosis, and, in children, febrile convulsions. The term 'cerebral malaria', implying encephalopathy specifically related to *P. falciparum* infection, should be restricted to patients in an unrousable coma (no appropriate verbal response and no purposive motor response to noxious stimuli—Glasgow Coma Scale £9/14) and evidence of acute *P. falciparum* infection, in whom other encephalopathies, including hypoglycaemia and transient postictal coma, have been excluded. Patients with cerebral malaria may have mild meningism but neck rigidity and photophobia are rare. Retinal haemorrhages (Plate 3) are present in about 15 per cent of African and SE Asian cases, but exudates are rare. (In Papua New Guinea these changes are not confined to patients with severe falciparum malaria.) Papilloedema is very rare (0.5 per cent of cases). Dysconjugate gaze is common. In adult patients the pupillary, corneal, oculocephalic, and oculovestibular reflexes are normal. Muscle tone and tendon reflexes are usually increased and there is ankle clonus. The plantar responses are extensor and abdominal reflexes are absent. In African children, brainstem reflexes may be abnormal and there may be neurological evidence of severe intracranial hypertension with rostrocaudal progression suggesting cerebral, cerebellar, and medullary herniation. Hypotonia is more common than in adults. In patients of all ages, abnormal flexor or extensor posturing (decerebrate or decorticate rigidity), associated with sustained upward deviation of the eyes (not the transient upward gaze of oculogyric crisis), pouting and stertorous breathing, is sometimes, but not always, associated with hypoglycaemia (Fig. 9(a) and Fig. 9(b)). About half of adult patients and more children have generalized convulsions. In children, seizures may be subtle and detectable only as twitching of the facial muscles, deviation with nystagmus of the eyes, irregularities of breathing, and sometimes posturing of one arm. Less than 5 per cent of adult survivors have persisting neurological sequelae; these include cranial-nerve lesions, extrapyramidal tremor, and transient paranoid psychosis. However, more than 10 per cent of African children who survive an attack of cerebral malaria suffer from sequelae such as hemiplegia, cortical blindness, epilepsy, ataxia, and mental retardation.

Fig. 9 (a) and (b) Extensor posturing (decerebrate rigidity) in a Thai woman with cerebral malaria and profound hypoglycaemia (Copyright D. A. Warrell).

Anaemia (see above) is an inevitable consequence of all but the mildest infections. It is most common and severe in pregnant women, children (Plate 4), and in

patients with high parasitaemia, schizontaemia, secondary bacterial infections, and renal failure.

Spontaneous bleeding, from the gums (Plate 5) and gastrointestinal tract, is seen in less than 5 per cent of adult patients with severe malaria. It is rare in children.

Jaundice (Plate 6) is common in adults but rare in children. Biochemical evidence of severe hepatic dysfunction is unusual. Hepatic failure suggests concomitant viral hepatitis or another diagnosis.

Hypoglycaemia is being increasingly recognized in patients with malaria. Pregnant women with severe or uncomplicated falciparum malaria and other patients with severe disease may become hypoglycaemic a few hours to 6 days after starting treatment with quinine or quinidine, even after the parasitaemia has cleared. Pregnant women and children with malaria, and other patients with hyperparasitaemia and complicating bacteraemias, may all become hypoglycaemic early in their illness and without quinine therapy. The symptoms and signs of hypoglycaemia—anxiety, tachycardia, breathlessness, feeling cold, confusion, sweating, light-headedness, restlessness, fetal bradycardia, other signs of fetal distress, coma, convulsions, and extensor posturing—may be misinterpreted as merely manifestations of malaria.

Hypotension and shock ('algid malaria') is seen in patients who develop pulmonary oedema, metabolic acidosis, complicating bacteraemias, and massive gastrointestinal haemorrhage. Mild supine hypotension with a marked postural drop in blood pressure is usually attributable to vasodilatation and relative hypovolaemia. Cardiac arrhythmias are rare but may be precipitated by rapid infusion or excessive doses of antimalarial drugs such as chloroquine, quinine, or quinidine. Patients with coronary insufficiency may develop angina during febrile crises of malaria. Patients with severe malaria sometimes develop complicating bacterial infections such as aspiration pneumonia, urinary-tract infections, infected bedsores, and phlebitis at intravenous drip sites.

Oliguria, with increased blood urea and serum creatinine concentrations, is seen in about one-third of patients with severe malaria. Although most of these patients respond to cautious rehydration, 10 per cent develop renal failure requiring dialysis.

In patients whose red blood cells are deficient in G6PD (and other enzymes), intravascular haemolysis and haemoglobinuria (Plate 7) may be precipitated by oxidant antimalarial drugs, especially primaquine, whether or not they have malaria. Classical blackwater fever is the association of haemoglobinuria with severe manifestations of falciparum malaria—including renal failure, hypotension and coma—in a non-immune patient who is not G6PD deficient.

Metabolic acidosis is seen in association with hyperparasitaemia, hypoglycaemia, and renal failure. Usually it results from lactic acidosis, even in patients with renal failure. In African children, respiratory distress manifested as deep (Kussmaul) breathing, associated with severe anaemia and metabolic acidosis, is emerging as a syndrome, and which carries a higher mortality than cerebral malaria.

Pulmonary oedema (Fig. 10) appears to be the terminal event in most fatal cases of falciparum malaria in adults. It may develop late in the clinical course as a result of fluid overload or in patients with severe disease in the absence of fluid overload. It may also appear suddenly after delivery in pregnant women who are in positive fluid balance. The earliest sign is an increase in respiratory rate. Pulmonary oedema may be difficult to differentiate from aspiration pneumonia, a common complication in comatose patients, and metabolic acidosis. Radiography may be needed to make this distinction with confidence. The patients who are not fluid-overloaded resemble those with adult respiratory distress syndrome with a normal jugular venous, central venous, or pulmonary-artery wedge pressure.

Fig. 10 Pulmonary oedema in a Vietnamese woman with cerebral malaria (copyright D. A. Warrell).

Cerebellar dysfunction

A rare presentation of falciparum malaria is cerebellar ataxia with unimpaired consciousness. Similar signs may be seen in patients recovering from cerebral malaria and, in Sri Lanka, delayed cerebellar ataxia has been described 3 to 4 weeks after an attack of fever attributable to falciparum malaria. Complete recovery is the rule.

Malarial psychosis

Acute psychiatric symptoms in patients with malaria may be attributable to their drug treatment, including antimalarial drugs such as chloroquine, mefloquine, and the obsolete mepacrine, and to exacerbation of pre-existing functional psychoses. However, in some patients, organic mental disturbances associated with malaria infection have been the presenting feature or, more often, have developed during convalescence after attacks of otherwise uncomplicated malaria or cerebral malaria. Depression, paranoia, delusions, and personality changes should probably be classified as brief reactive psychoses. These symptoms rarely last for more than a few days.

Vivax, ovale, and malariae malarias

The prepatent and incubation periods are given in Table 1. Some strains of *P. vivax*, especially those from temperate regions (*P. v. hibernans* from Russia, *P. v. multinucleatum* from China) may have very long incubation periods (250–637 days). Only about one-third of imported cases of vivax malaria present within a month of returning from the malarious area; 5 to 10 per cent will present more than a year later.

The 'benign' malarias cause paroxysmal, feverish symptoms no less hectic and distressing than those of falciparum malaria. Prodromal symptoms are said to be more severe with *P. malariae* infection. In untreated cases, the characteristic tertian (48–50 h) interval between fever spikes may be seen with *P. vivax* and *P. ovale* and the quartan (72 h) pattern in *P. malariae* infections.

This periodicity is established after several days of irregular fever. Vivax and ovale malarias have a persistent hepatic cycle, which may give rise to relapses every 2 to 3 months for 5 to 8 years in untreated cases. *P. malariae* does not relapse but a persisting, undetectable parasitaemia may cause recrudescences for more than 50 years.

Although symptoms may be severe and temporarily incapacitating, especially in non-immune individuals, the acute mortality is very low. For example, during the 1967 to 1969 Sri Lankan epidemic of predominantly vivax malaria, there were more than half a million cases with a case fatality of only 0.1 per cent. Only in immunocompromised, splenectomized or debilitated patients are the 'benign' malarias likely to prove life-threatening. However, acute pulmonary oedema has been documented in several cases of vivax malaria in non-immune travellers (Fig. 11).

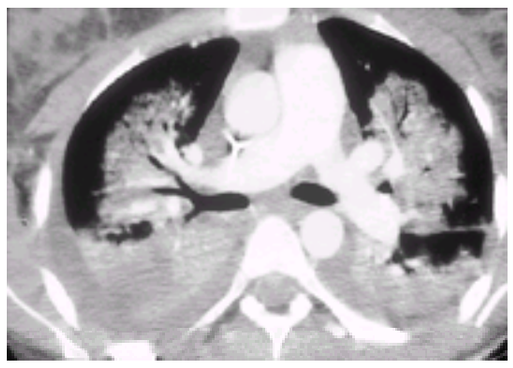

Fig. 11 Pulmonary oedema in a 20-year-old woman with vivax malaria and bilateral pleural effusions (copyright D. A. Warrell).

An important practical point is that indigenous West Africans are very rarely infected with *P. vivax*. Patients suffering from vivax malaria may become anaemic, thrombocytopenic, and mildly jaundiced with tender hepatosplenomegaly. Splenomegaly may be particularly gross in areas of *P. malariae* infection (see also Tropical splenomegaly syndrome, below). In debilitated patients with vivax malaria, anaemia rarely may be severe enough to be life-threatening. Splenic rupture, which carries a mortality of 80 per cent, is said to be more common with vivax than falciparum malaria. It results from acute, rapid enlargement of the spleen, with or without trauma; chronically enlarged spleens are less vulnerable. A ruptured spleen presents with abdominal pain and guarding, haemorrhagic shock (tachycardia, postural hypotension, and prostration), fever, and a rapidly falling haematocrit. These features may be misattributed to malaria itself.

Cerebral vivax malaria has occasionally been reported especially with the long incubation period strain in China. Mixed falciparum infection or another encephalopathy must be adequately excluded in such cases. The same strictures apply to cerebral *P. malariae* malaria, especially as this parasite coexists with *P. falciparum* throughout most of its range. The acute symptoms of ovale and malariae malarias may be as severe as those of vivax infection, but anaemia is less severe and the risk of splenic rupture is lower. *P. ovale* causes negligible mortality, but *P. malariae* causes many deaths from nephrotic syndrome (see below).

Malaria in pregnancy and the puerperium

Malaria is a major cause of maternal anaemia, death, abortion, stillbirth, premature delivery, low birth weight, and neonatal death in those areas of the tropics where malaria transmission is unstable and women of childbearing age have little acquired immunity. Even in some hyperendemic areas, clinical symptoms and parasitaemia are worse in primiparous than in multiparous women and other patients. In non-immune individuals, cerebral and other forms of severe falciparum malaria are more common in pregnancy. In the great epidemic of falciparum malaria in Sri Lanka during 1934 to 1935 the mortality among pregnant women was 13 per cent, twice that in non-pregnant women, and in Thailand, where malaria has been the most important cause of maternal mortality, cerebral malaria in late pregnancy had a mortality of 50 per cent. In some parts of Africa, one-quarter to one-half of all placentas are parasitized. The incidence is highest in primiparae. Changes in humoral and cell-mediated immunity in pregnancy do not explain this vulnerability, but it is clear that the placenta is a privileged site for parasite multiplication. An adhesion receptor for some strains (genotypes) of *P. falciparum*, chondroitin sulphate A, is expressed on the surface of the syncytiotrophoblast. This may explain sequestration in the placenta.

In most endemic regions, birth weights of neonates born to women with malaria are significantly less than those of controls. Fetal distress was observed in 6 out of 12 Thai women with malaria who were beyond the twenty-ninth week of pregnancy. Painless uterine contractions were detected in seven out of eight who were not in labour. This uterine activity subsided as the patients' temperatures were reduced by simple cooling.

Special risks to the mother of malaria during pregnancy are hyperpyrexia, hypoglycaemia, anaemia, cerebral malaria, and pulmonary oedema.

Severe anaemia, exacerbated by malaria, is an important complication of pregnancy in many tropical countries. Especially in communities where chronic hookworm anaemia is prevalent, high output anaemic cardiac failure may develop in late pregnancy.

Asymptomatic hypoglycaemia may occur in pregnant women with malaria before antimalarial treatment, and pregnant women with severe uncomplicated malaria are particularly vulnerable to quinine-induced hypoglycaemia (see above).

There is an increased risk of pulmonary oedema precipitated by fluid overload or by the sudden increase in peripheral resistance, or autotransfusion of hyperparasitaemic blood from the placenta, which occurs just after delivery (Fig. 10).

Prevention

Malaria is so dangerous in pregnancy that pregnant women who cannot leave the area of transmission must be given intermittent preventive treatment with sulfadoxine–pyrimethamine or antimalarial prophylaxis extending into the early puerperium. This is a most important part of antenatal care.

Congenital and neonatal malaria

Vertical transmission of malaria can be diagnosed by detecting parasitaemia in the neonate within 7 days of birth, or later if there is no possibility of postpartum, mosquito-borne infection. Save for a few discordant reports, most evidence from malarious parts of the world indicates that congenital malaria is rarely symptomatic, despite the high prevalence of placental infection. This confirms the adequacy of protection provided by IgG from the immune mother, which crosses the placenta to active immunization from exposure to soluble malarial antigens *in utero* and to the high proportion of fetal haemoglobin in the neonate, which retards parasite development. Congenital malaria is, however, much more common in infants born to non-immune mothers, and there is an increased incidence during malaria epidemics. It can cause stillbirth or perinatal death. All four species can produce congenital infection, but because of its very long persistence *P. malariae* causes a disproportionate number of cases in non-endemic countries. Fetal plasma quinine and chloroquine concentrations are about one-third of the simultaneous maternal levels. Thus, antimalarial concentrations that are adequate to cure the mother might result in subtherapeutic concentrations in the fetus. Quinine and chloroquine are excreted in breast milk, but the suckling neonate would receive only a few mg/day. Maternal hypoglycaemia, a common complication of malaria or its treatment with quinine, may produce marked fetal bradycardia and other signs of fetal distress.

Differential diagnosis

The clinical features of congenital malaria include fever, irritability, feeding problems, hepatosplenomegaly, anaemia, and jaundice. Unless parasites are found in a smear from a heel prick or cord blood, the patient may be misdiagnosed as having rhesus incompatibility or another congenital infection such as cytomegalovirus, herpes simplex, rubella, toxoplasmosis, or syphilis.

Transfusion malaria, 'needlestick', and nosocomial malaria

Malaria—like trypanosomiasis, Colorado tick fever, HIV, hepatitis viruses, and some other pathogens—can be transmitted in blood from apparently healthy donors. Exceptionally, donors may remain infective for up to 5 years with *P. falciparum* and *P. vivax,* 7 years with *P. ovale,* and 46 years with *P. malariae.* Because the infecting forms are erythrocytic (not sporozoites), no exoerythrocytic (hepatic) cycle will be established and so vivax and ovale malarias will not relapse. Theoretically, parasitaemia might be detectable immediately and hence the incubation period should be shorter than with mosquito-transmitted malaria. However, the incubation period tends to be longer because of the time needed to build up parasitaemias sufficient to cause symptoms. Mean incubation periods are 12 (range 7–29) days for *P. falciparum*, 12 (range 8–30) days for *P. vivax*, and 35 (range 6–106) days for *P. malariae*. Whole blood, packed cells (blood products), leucocyte or platelet concentrates, fresh plasma, marrow transplants, and haemodialysis have been responsible for transfusion malaria. As patients requiring transfusion are likely to be debilitated and may be immunosuppressed, and there may be a long delay before making the diagnosis because malaria is not suspected, unusually high parasitaemias may develop with *P. falciparum* and *P. malariae.* With *P. ovale* and *P. vivax* infections, the parasitaemia is usually limited to 2 per cent because only reticulocytes are invaded. Severe manifestations are common, mortality may be high, for example 8 out of 11 in a group of heroin addicts, and even acute *P. malariae*

infections may prove fatal.

Nosocomial malaria has resulted from contamination of saline used for flushing intravenous catheters, contrast medium, and intravenous drugs. Malaria has complicated parenteral drug abuse.

Prevention

Outside the malaria endemic area, donors who have been in the tropics during the previous 5 years should be screened for malarial antibodies (indirect fluorescent antibody) (see below). In the endemic area, recipients of blood transfusions can be given antimalarial chemotherapy, or at least should be watched carefully for evidence of infection.

Monkey malarias

Human erythrocytes can be infected with at least six species of simian plasmodia. There have been rare cases of natural infections or accidental laboratory infections by *P. brazilianum, P. cynomolgi, P. inui, P. knowlesi, P. schwetzi* and *P. simium*. Severe feverish and systemic symptoms have been described, but no cerebral or other severe complications. No patient has died. Parasitaemia may remain undetectable for 2 to 6 days after the start of symptoms. Periodicity is quotidian (*P. knowlesi*) or tertian (*P. simium* and *P. cynomolgi*). Infectivity and virulence may be enhanced by repeated passage in humans. Chloroquine is the treatment of choice.

Diagnosis

Malaria can present with a wide range of symptoms and signs, none of them diagnostic. **It must be excluded by repeated thick and thin blood smears in any patient with acute fever and an appropriate history of exposure.** Until malaria is confirmed or an alternative diagnosis emerges, smears should be repeated every 8 to 12 h. **However, if the patient is severely ill, or the symptoms persist or deteriorate, a therapeutic trial of antimalarial chemotherapy must not be delayed.** Antimalarial chemoprophylaxis should be stopped while the patient is under investigation for malaria, as this may make microscopical diagnosis more difficult. Patients should be asked about travel to malaria endemic countries during the previous year. The possibility of malaria must not be dismissed because the patient took prophylactic drugs, for none is completely protective. Short airport stopovers, even on the runway, or working in or living near an international airport, may allow exposure to an imported, infected mosquito. Transmission by blood transfusion, 'needlestick', or nosocomial infection should be borne in mind. Those who grew up in an endemic area will probably lose their immunity to disease after living for a few years in the temperate zone and become vulnerable when they return to their homeland on holiday. In malaria endemic regions, a large proportion of the immune population may have asymptomatic parasitaemia and it cannot be assumed that malaria is the cause of the patient's symptoms even if parasitaemia is detected. The diagnosis of malaria may be missed, even in the endemic zone, during an epidemic of some other infection (for example, meningitis, pneumonia, cholera).

Differential diagnosis (Table 6)

Malaria should be considered in the differential diagnosis of any acute febrile illness until it can be excluded by a definite lack of exposure, by repeated examination of blood smears, or by a therapeutic trial of antimalarial chemotherapy. In Europe and North America, imported malaria has been misdiagnosed as influenza, viral hepatitis, viral encephalitis, or travellers' diarrhoea, sometimes with fatal consequences. Cerebral malaria must be distinguished from other infective meningoencephalitides. Cerebrospinal fluid (**CSF**) examination will identify most of these infective causes (see Chapter 24.14.1). Abdominal reflexes are brisk in patients with psychotic stupor and hysteria but absent in cerebral malaria. Recognition of poisoning will depend largely on the history or the clinical circumstances. Overdose of antimalarial drugs (chloroquine and quinine) can be confused with cerebral malaria. Intravenous drug abusers are at risk both from severe malaria and drug overdose. Alcoholism may be confused with cerebral malaria, whether the patient presents simply as 'drunk', with delirium tremens, or encephalopathy.

Misdiagnosis of a viral haemorrhagic fever in a case of imported malaria is potentially dangerous, for patients may be placed in a high-containment unit where they may be denied basic investigations such as examination of a blood smear because of a fear of infection. Jaundice is a common feature of yellow fever, but not other viral haemorrhagic fevers.

Malaria in pregnancy may be confused with viral hepatitis, acute fatty liver with liver failure or eclampsia, and in the puerperium with puerperal sepsis or psychosis.

Laboratory diagnosis

Microscopy

It is most important to confirm the diagnosis by examining thick and thin blood films on several occasions (Plate 1). Parasites may be found in blood taken by venepuncture, finger-pulp or ear-lobe stabs, and from the umbilical cord and impression smears of the placenta. In fatal cases, cerebral malaria can be confirmed rapidly as the cause of death by making a smear from cerebral grey matter obtained by needle necropsy through the foramen magnum, superior orbital fissure, ethmoid sinus via the nose, or through a fontanelle in young children. Sometimes no parasites can be found in peripheral blood smears from patients with malaria, even in severe infections. This may be explained by partial antimalarial treatment or by sequestration of parasitized cells in deep vascular beds. In these cases, parasites or malarial pigment may be found in a bone marrow aspirate. Pigment may be seen in circulating neutrophils. A number of Romanowski stains, including Field's, Giemsa, Wright's, and Leishman's, are suitable for malaria diagnosis. The rapid Field's technique, which can yield a result in minutes, and Giemsa are recommended. Smears may be unsatisfactory because the slides are not clean; stains are unfiltered, old, or infected; the buffer pH is incorrect (it should be 7.0–7.4); drying is too slow, especially in a humid climate (producing heavily crenated erythrocytes); or the blood has been stored in anticoagulant causing lysis of parasitized erythrocytes. It is difficult to make a good smear if the patient is very anaemic. Common artefacts resembling malaria parasites are superimposed platelets, particles of stain and other debris, and pits in the slide. Other erythrocyte infections such as bartonellosis and babesiosis may be misdiagnosed as malaria. Parasites should be counted in relation to the total white-cell count (on thick films when the parasitaemia is relatively low) or erythrocytes (on thin films). An experienced microscopist can detect as few as 5 parasites/µl (0.0001 per cent parasitaemia) in a thick film and 200/µl (0.004 per cent parasitaemia) in a thin film.

Fluorescent microscopy

Becton-Dickinson's QBC (quantitative buffy coat) method involves spinning blood in special capillary tubes in which parasite DNA is stained with Acridine Orange and a small float presses the parasitized red blood cells against the wall of the tube where they can be viewed by ultraviolet microscopy. In expert hands, the sensitivity of this method can be as good as with conventional microscopy of thick blood films but species diagnosis is difficult, and the method is much more expensive.

Malarial antigen detection

Becton-Dickinson's 'Para Sight F' and ICT Diagnostics' 'ICT Malaria Pf' dipstick antigen-capture assays employ monoclonal antibody detecting *P. falciparum* histidine-rich protein-2 (**PfHRP-2**) antigen. These tests are rapid (taking about 20 min), sensitive, and specific for *P. falciparum*. A number of other, species-specific, antigen-detection methods are now marketed, such as OptiMAL (Flow Laboratories) which detects parasite lactate dehydrogenase.

Other methods

Enzyme and radioimmunoassays, DNA probes (using chemoluminescence for detection), and polymerase chain reaction (**PCR**) methods now approach the sensitivity of classical microscopy. They take much longer (up to 72 h), are much more expensive, and are unlikely to replace microscopy for routine diagnosis. However, some of these newer methods could be automated for screening blood donors or for use in epidemiological surveys and, in the case of PCR, identification of parasite strains as well as species is possible.

Serological techniques

Malarial antibodies can be detected by immunofluorescence, enzyme immunoassay, or haemagglutination for epidemiological surveys, for screening potential blood donors, and occasionally for providing evidence of recent infection in non-immune individuals. These tests are not useful in making an acute diagnosis of malaria. In

future, detection of protective antibodies will be important in assessing the response to malaria vaccines (see below).

Other laboratory investigations

Anaemia is usual, with evidence of haemolysis. Serum haptoglobins may be undetectable. The direct antiglobulin (Coombs') test is usually negative. Neutrophil leucocytosis is common in severe infections whether or not there is a complicating bacterial infection, but the white-cell count can also be normal or low. The presence of visible malarial pigment in more than 5 per cent of circulating neutrophils is associated with a bad prognosis. Thrombocytopenia is common in patients with *P. falciparum* and *P. vivax* infections; it does not correlate with severity. Prothrombin and partial thromboplastin times are prolonged in up to one-fifth of patients with cerebral malaria. Concentrations of plasma fibrinogen and other clotting factors are normal or increased, and serum levels of fibrin(ogen) degradation products are normal in most cases. Fewer than 10 per cent of patients with cerebral malaria have evidence of disseminated intravascular coagulation. However, antithrombin III concentrations are often moderately reduced and have prognostic significance. Total and direct (unconjugated) plasma bilirubin concentrations are usually increased, consistent with haemolysis, but in some patients with very high total bilirubin concentrations there is a predominance of conjugated bilirubin, indicating hepatocyte dysfunction. Some patients have cholestasis. Serum albumin concentrations are usually reduced, often grossly. Serum aminotransferases, 5'-nucleotidase, and especially lactic dehydrogenase are moderately elevated, but not into the range seen in viral hepatitis. Hyponatraemia is the most common electrolyte disturbance. Mild hypocalcaemia (after correction for hypoalbuminaemia) and hypophosphataemia have been described, especially when the patient has been given blood or a glucose infusion. Biochemical evidence of generalized rhabdomyolysis (elevated serum creatine kinase concentration, myoglobinaemia, and myoglobinuria) has been found in some patients. In about one-third of patients with cerebral malaria, the blood urea concentration is increased above 80 mg/dl (13 mmol/l) and serum creatinine above 2 mg/dl (176 µmol/l). Lactic acidosis occurs in severely ill patients, especially those with hypoglycaemia and renal failure. It may be suspected if there is a wide 'anion gap'. Blood glucose must be checked frequently, especially in children, pregnant women, and severely ill patients, even if the patient is not receiving quinine treatment and is fully conscious. A 'stix' method, with or without photometric quantification, is rapid and convenient. Microscopy and culture of cerebrospinal fluid is important in patients with cerebral malaria to exclude other treatable encephalopathies. In cerebral malaria the cerebrospinal fluid may contain up to 15 lymphocytes/µl and an increased protein concentration. Pleocytosis of up to 80 cells/µl, mainly leucocytes, may be found in patients who have had repeated generalized convulsions. The CSF glucose level will be low in hypoglycaemic patients and this result may be the first hint of hypoglycaemia. In view of the finding of cerebral compression and high opening pressures in many African children with cerebral malaria, some paediatricians prefer to delay lumbar puncture, while covering the possibility of bacterial meningoencephalitis with empirical antimicrobial treatment. Blood cultures should be performed in patients with a high white-cell count, shock, persistent fever, or an obvious focus of secondary bacterial infection. Gram-negative rod bacteria (*E. coli, Pseudomonas aeruginosa*, etc.) have been cultured from the blood of adult patients with 'algid' malaria. In Gambian children an association was found between malaria and non-typhoid salmonella septicaemia.

Urine should be examined by microscope and dipstix. Common abnormalities are proteinuria, microscopic haematuria, haemoglobinuria, and red-cell casts. The urine is literally black in patients with severe intravascular haemolysis. Urine specific gravity should be measured: the optical method is most convenient when urine output is small. Rapid measurement of plasma quinine or quinidine concentrations is possible in some hospitals. This is a valuable way of monitoring chemotherapy.

Treatment

Antimalarial drugs

Antimalarial drugs can be grouped as follows:

1. arylaminoalcohols, comprising quinoline methanols such as the cinchona alkaloids, quinine and quinidine (extracted from the bark of the cinchona tree), mefloquine, halofantrine, and lumefantrine;
2. 4-aminoquinolines, such as chloroquine and amodiaquine;
3. folate-synthesis inhibitors, including type 1 antifolate drugs, which compete for dihydropteroate synthase (e.g. sulphones and sulphonamides), and type 2 antifolate drugs, which inhibit malarial dihydrofolate reductase (e.g. the biguanides, proguanil and chlorproguanil, and the diaminopyrimidine, pyrimethamine);
4. 8-aminoquinolines, such as primaquine and tafenoquine (Etaquine, WR238,605);
5. antibiotics, such as tetracycline, doxycycline, clindamycin, azithromycin, and fluoroquinolones;
6. peroxides (sesquiterpene lactones)—artemisinin (qinghaosu) derivatives from the Chinese medicinal plant, *Artemisia annua,* and its semisynthetic analogues (artemether, arteether, artesunate, and artelinic acid); and
7. naphthoquinones, such as atovaquone (BW566C80).

The stages of the lifecycle sensitive to some of the principal antimalarial drugs are shown in Fig. 12. Among blood schizonticides, artemisinin derivatives can prevent the development of rings or trophozoites, but quinine and mefloquine cannot stop development before the stage of mature trophozoites, and pyrimethamine–sulphadoxine combinations do not prevent the development of schizonts.

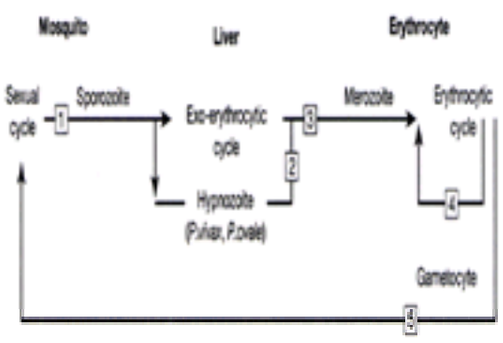

Fig. 12 Stage specificity of antimalarial drugs. 1. Sporontocidal (e.g. proguanil, pyrimethamine, atovaquone); 2. hypnozoitocidal (e.g. primaquine WR238,605); 3. tissue schizontocidal (e.g. proguanil, pyrimethamine); 4. blood schizontocidal (e.g. chloroquine, quinine, artemisinin); 5. gametocytocidal (e.g. primaquine, tafenoquine; chloroquine for *P. vivax, P. malariae,* and *P. ovale*).

Mechanism of action of antimalarial drugs

The mode of action of the antifolate drugs is well understood and described above. Chloroquine is concentrated in the parasite's lysosomes, where haemoglobin is digested, and may act by inhibiting the haempolymerase that converts toxic haemin into insoluble haemozoin (malarial pigment). Alternatively, the drug may interfere with parasite feeding by disrupting its food vacuole. Antimalarial antibiotics are all inhibitors of ribosomal protein synthesis and probably act on the parasite's mitochondria. In the case of artemisinin derivatives, iron within the parasite probably catalyses the cleavage of the endoperoxide bridge leading to the generation of free radicals, which then form covalent bonds with parasite proteins (alkylation). Naphthoquinones, such as atovaquone, act on the electron-transport chain in malarial mitochondria through their structural similarity to coenzyme Q. No satisfactory explanation of the mode of action of the other antimalarial drugs is yet available.

The alarming spread of drug resistance has prompted great experimental effort to reveal the mechanism of resistance. The observation that chloroquine resistance could be reversed *in vitro* by high concentrations of drugs such as the calcium-channel blocker verapamil, which in other situations could reverse the multidrug resistance (**mdr**) phenotype acquired by some tumour cells, focused attention on a malarial homologue of the human *mdr* gene. Recent work suggests involvement of the *P. falciparum mdr1* gene early in the development of resistance, but segregation of resistance in the cloned progeny of a cross showed that the product of a second, uncharacterized gene product from chromosome 7 was also required.

Chloroquine

Despite the widespread resistance of *P. falciparum* to this drug, and the recent emergence of chloroquine-resistant *P. vivax* in New Guinea and adjacent areas of Indonesia, chloroquine is still the most widely used antimalarial drug. It remains the treatment of choice for vivax, ovale, and malariae infections, and for

uncomplicated falciparum malaria acquired in the few areas where the parasite remains sensitive to this drug (Central America north-west of the Panama Canal, Haiti and the Dominican Republic, and parts of the Middle East). In the rest of the malaria-endemic region, the emergence of chloroquine resistance is having a devastating effect on malarial morbidity and mortality. For example, in Senegal, mortality form malaria in children under 5 years old, increased up to 11-fold between 1984 and 1995. After oral administration, chloroquine is rapidly and almost completely absorbed, peak plasma concentrations being reached in about 2 h. Absorption after intramuscular or subcutaneous injection is very rapid, which can produce dangerously high plasma concentrations unless small doses are given frequently. This probably explains the deaths of some children soon after they had received intramuscular injections of chloroquine. About half the absorbed dose is excreted unchanged by the kidney, the remainder being converted to active metabolites in the liver. Therapeutic blood concentrations persist for 6 to 10 days after a single dose and the terminal elimination half-time is 1 to 2 months. Plasma concentrations above about 250 ng/ml produce unpleasant symptoms such as dizziness, headache, diplopia, disturbed visual accommodation, dysphagia, nausea, and malaise. Chloroquine, even in small doses, may cause pruritus in dark-skinned races. Chloroquine may exacerbate epilepsy and photosensitive psoriasis. Cumulative, irreversible retinal toxicity from chloroquine has been reported after lifetime prophylactic doses of 50 to 100 g base (i.e. after 3–6 years of taking 300 mg of base per week), although this is most unusual. Chloroquine overdose is described in Chapter 8.1. Chloroquine is safe during pregnancy and lactation.

Amodiaquine, a 4-aminoquinoline that is structurally similar to chloroquine, retains activity against chloroquine-resistant strains of *P. falciparum* in some geographical areas. Unlike chloroquine, it is metabolized to a toxic quinoneimine that can produce a toxic hepatitis and potentially lethal agranulocytosis (which occurred in up to 1 in 2000 people taking amodiaquine prophylactically). Amodiaquine is still quite widely used, but, because of its risks and the limited therapeutic advantage over chloroquine, its use for prophylaxis and repeated treatment is now discouraged by the World Health Organization.

Quinine

The advent of chloroquine-resistant *P. falciparum* restored quinine to being the treatment of choice for falciparum malaria. Its antimalarial properties were discovered in Peru around 1600. Given by mouth it is rapidly and almost completely absorbed, producing peak plasma concentrations within 1 to 3 h. Some 20 per cent is excreted in the urine and the rest is metabolized in the liver. The elimination half-time in healthy people is approximately 11 h, and in patients with malaria approximately 16 h. Intravenous injection of quinine is dangerous as high plasma concentrations may result during the distribution phase, causing fatal hypotension or arrhythmias. However, quinine can be given safely if it is diluted and infused intravenously over 2 to 4 h. When intravenous infusion is not possible, but parenteral treatment is needed, quinine may be given by intramuscular injection divided between the anterior part of the thighs. For intramuscular injection, the stock solution of quinine dihydrochloride (300 mg/ml) should be diluted to 60 mg/ml. It is well absorbed from this site and complications are rare provided that strict sterile precautions are observed. Because most deaths from severe falciparum malaria occur within the first 96 h of starting treatment, it is important to achieve parasiticidal plasma concentrations of quinine as quickly as possible. This can be accomplished safely by giving a loading dose of twice the maintenance dose. A loading dose of 20 mg of the salt per kg of body weight and an 8- to 12-hourly maintenance dose of 10 mg/kg have proved safe and effective in children and adults in many tropical countries. The initial dose of quinine should not be reduced in patients who are severely ill with renal or hepatic impairment, but in these cases the maintenance dose should be reduced to between 3 and 5 mg/kg if parenteral treatment is required for longer than 48 h. Little is known about the optimal and safe quinine dosage in elderly and obese patients outside malaria endemic areas.

The minimum inhibitory concentration of quinine for *P. falciparum* in SE Asia and other areas of the tropics has risen steadily. Longer courses of quinine and in combination with other drugs, such as Fansidar, tetracycline, or clindamycin, have been required for complete cure. Recently, cases of RII and RIII resistance (failure to clear or failure to reduce parasitaemia in the first 7 days of treatment) to quinine have been documented in Thailand and Vietnam. Quinine should not be withheld or stopped in patients who are pregnant or haemolysing. In the doses used to treat malaria it does not stimulate uterine contraction or cause fetal distress. Hypoglycaemia is the most important complication of quinine treatment (see above). Plasma quinine concentrations above 5 mg/l produce a characteristic group of symptoms—'cinchonism'—transient high-tone deafness, giddiness, tinnitus, nausea, vomiting, tremors, blurred vision, and malaise. Rarely, quinine may give rise to haemolysis, thrombocytopenia, disseminated intravascular coagulation, hypersensitivity reactions, vasculitis, and granulomatous hepatitis. Blindness, deafness, and central nervous depression are commonly observed in patients who have attempted suicide by taking overdoses of quinine. These features are rarely seen in patients being treated for malaria, even though their plasma quinine concentrations may exceed 20 mg/l. This discrepancy may be explained by the increased binding of quinine to a-1 acid glycoprotein (orosomucoid) and to other acute-phase reactive serum proteins in patients with malaria.

Quinidine, the dextrorotatory stereoisomer of quinine, is more effective against resistant strains of *P. falciparum* but is more cardiotoxic than quinine. Because of its use for treating cardiac arrhythmias, it is more generally available (as quinidine gluconate injection) than parenteral quinine in continental Europe and North America, and in the United States has replaced quinine for the parenteral treatment of malaria. It must be infused slowly while the electrocardiogram and blood pressure are monitored. Infusion should be slowed if the blood pressure falls, the plasma concentration exceeds 22 µmol/1 (7 mg/ml), or if the Q–Tc interval increases by more than 25 per cent.

Mefloquine ('Lariam')

This synthetic drug is effective against some *P. falciparum* strains resistant to chloroquine, pyrimethamine–sulphonamide combinations, and quinine. It is too irritant to be given parenterally, but is well absorbed when given by mouth, reaching peak plasma concentrations in 6 to 24 h. The elimination half-time is 14 to 28 days. The drug can be given as a single dose but, to reduce the risk of vomiting and other gastrointestinal side-effects, the dose is best divided into two halves given 6 to 8 h apart. Gastrointestinal symptoms occur in 10 to 15 per cent of patients but are usually mild. Less frequent side-effects include nightmares and sleeping disturbances, dizziness, ataxia, sinus bradycardia, sinus arrhythmia, postural hypotension, and an 'acute brain syndrome' consisting of fatigue, asthenia, seizures, and psychosis. Mefloquine treatment should be avoided in pregnant women, especially during the first trimester, and pregnancy should be avoided within 3 months of stopping mefloquine. People taking b-blockers and those with a past history of epilepsy or psychiatric disease should also avoid the drug. Unfortunately, *in vitro* resistance to mefloquine and treatment failures have now been reported in SE Asia, Africa, and South America.

Halofantrine

This synthetic antimalarial compound is active against multiresistant, including mefloquine-resistant, *P. falciparum*, but is no longer recommended because of its cardiotoxicity.

Artemisinin

Artemisinin or qinghaosu (pronounced 'ching-how-soo') is the active principle of the Chinese medicinal herb *Artemisia annua*—family Compositae (sweet wormwood), which has been used as a treatment for fevers in China for more than 1000 years. The active principle was isolated in China during 1971 to 1972. It is a sesquiterpene lactone with an endoperoxide (trioxane) active group. It destroys young trophozoites as well as other blood stages of *P. falciparum,* including chloroquine-resistant strains, and clears parasitaemia more rapidly than any other antimalarial drug. Dihydroartemisinin, the active metabolite, is cleared rapidly. In severe falciparum malaria, most experience has been gained with intramuscular artemether, given in a loading dose of 3.2 mg/kg on the first day (as a single dose or divided, 12 h apart) followed by 1.6 mg/kg per day until the patient is able to take an oral drug such as mefloquine. The efficacy and safety of artemether was compared with quinine in a series of large randomized trials in children and adults with severe falciparum malaria in Africa, Asia, and Papua New Guinea. A meta-analysis of trials involving nearly 2000 patients confirmed it to be as effective as quinine, judged by case fatality and incidence of neurological sequelae, but it cleared parasitaemia more rapidly and was significantly superior in preventing 'adverse outcome' (either death or neurological sequelae). Artesunate, although inherently unstable in aqueous solution, can be made up with 5 per cent bicarbonate just before injection and given by intravenous or intramuscular injection (2 mg/kg on the first day followed by 1 mg/kg until the patient can take oral treatment). An extra dose of 1 mg/kg can be given 4 to 6 h after the initial loading dose in hyperparasitaemic patients. Suppository formulations of artemisinin have proved effective in severe falciparum malaria and should prove particularly valuable in treating children at peripheral levels of the health service. A combination of artemether and lumefantrine (Riamet, Co-artemether) is being marketed for the oral treatment of multiresistant falciparum malaria.

The severe neurotoxicity reported in animals given large doses of artemisinin has not been detected in any of the tens of thousands of human patients treated with these compounds.

Primaquine

This is the only readily available drug effective against exoerythrocytic (hepatic) forms of *P. vivax* and *P. ovale*, and is essential for the radical cure of these infections. It is also gametocytocidal for all species of malaria. Mass treatment of patients with *P. falciparum* infection could eliminate the sexual cycle in mosquitoes by sterilizing

gametocytes. Its elimination half-time is 7 h. The principal drawback of primaquine is that it causes haemolysis in patients with congenital deficiencies of erythrocyte enzymes, notably G6PD. However, severe intravascular haemolysis is unusual even in G6PD-deficient patients, except in certain areas of the world such as the Mediterranean (for example, Sardinia) and Sri Lanka. Primaquine can cross the placenta and cause severe haemolysis in a G6PD-deficient fetus, most commonly a boy. It is also excreted in breast milk. It should not be used during pregnancy or lactation in areas where G6PD deficiency is prevalent. Primaquine, like sulphonamides and sulphones (for instance, dapsone) can produce severe haemolysis and methaemoglobinaemia in patients with congenital deficiency of **NADH** (the reduced form of nicotinamide adenine dinucleotide) methaemoglobin reductase. The patient quickly develops dusky cyanosis, noticed first in the nail beds. In patients with G6PD deficiency, weekly dosage with 45 mg of primaquine is better tolerated than the usual daily dose of 15 mg. In the Solomon Islands, Indonesia, Thailand, and Papua New Guinea a total dose of 6.0 mg/kg (twice the usual dose) or even more may be needed to eliminate the primaquine-resistant Chesson-type strain of *P. vivax*. This is usually given as 15 mg base/day for 28 days. Tafenoquine (Etaquine), a new 8-aminoquinoline, is now in clinical trials. As a hypnozoiticide, it is over 10 times more active than primaquine, and is also a potent schizontocide.

Pyrimethamine–sulphonamide combinations (Fansidar, Metakelfin, etc.)

These synergistic combinations were once valuable in the treatment of chloroquine-resistant falciparum infections worldwide. A single adult dose of three Fansidar tablets (75 mg pyrimethamine, 1500 mg sulfadoxine) proved safe and effective, and is useful as an emergency standby for travellers out of the reach of medical facilities and as an adjunct to quinine in the treatment of *P. falciparum* infections in areas of increasing quinine resistance. However, in most of SE Asia, China, Oceanea, Latin America, and Africa already troubled by chloroquine resistance, resistance to pyrimethamine–sulphonamide combinations is also spreading. It results from mutations at residues 108, 51, 59, 16, and 164 of the parasite's dihydrofolate reductase gene. An intramuscular formulation has proved effective against *P. falciparum* in southern Africa. Pyrimethamine is a folate inhibitor and so may cause folic acid deficiency in pregnant women and others unless folinic acid supplements are given. The sulphonamide components of these combinations are potentially dangerous. In patients who are hypersensitive to sulphonamide they may cause systemic vasculitis, the Stevens–Johnson syndrome, or toxic epidermal necrolysis. In the United States the risk of fatal reactions has been calculated as 1 in 18 000–26 000 prophylactic courses. Aplastic anaemia and agranulocytosis can also occur. Both pyrimethamine and sulphonamide cross the placenta and are excreted in milk. In the fetus and neonate, sulphonamides can displace bilirubin from plasma protein-binding sites, thus causing kernicterus. For these reasons, pyrimethamine–sulphonamide combinations are not recommended for treatment during pregnancy or lactation unless no alternative drug is available, nor for prophylaxis at all.

P. vivax and *P. malariae* parasitaemias are generally cleared by all the drugs effective against *P. falciparum.* However, in some scattered areas, pyrimethamine–sulphonamide combinations may not be effective because of pyrimethamine resistance.

Chlorproguanil–dapsone ('lapdap')

This combination has been developed as an alternative to pyrimethamine–sulphonamide combinations (**PSD**) to replace chloroquine for the treatment of uncomplicated falciparum malaria in Africa. It has proved more effective than PSD in treating parasites with 108, 51, and 59 mutations, but should probably be further combined with an artemisinin to extend its useful therapeutic life.

Hydroxynaphthoquinones

Atovaquone (BW566C80) is marketed in combination with proguanil as 'Malarone' for the treatment and prevention of multiresistant *P. falciparum*. It inhibits the parasite's mitochondrial respiration by binding to the cytochrome bc, complex. The drug is poorly and variably absorbed, but bioavailability is greatly enhanced by a fatty meal. Its elimination half-life is between 50 and 70 h.

Antibiotics

Tetracycline, clindamycin, azithromycin, quinolones, and sulphonamides such as co-trimoxazole, have some antimalarial activity. Generally, they kill parasites too slowly to be used alone. In an emergency, in the absence of quinoline antimalarials, they could be used to treat malaria.

Practical antimalarial chemotherapy

Prescribing quinoline antimalarial drugs

The various salts of quinoline compounds contain greatly differing amounts of base. If the prescription fails to specify salt or base, or which particular salt is intended, serious problems can arise. Where possible, the dose of base should be prescribed. This is generally accepted for chloroquine, amodiaquine, mefloquine, and primaquine, but, in the case of quinine and quinidine, weights of salts are usually quoted. Conversions are given in Table 7.

Treatment of uncomplicated malaria (Table 8)

Chloroquine is the treatment of choice for *P. vivax, P. ovale, P. malariae*, and uncomplicated *P. falciparum* malarias in those geographical areas where this drug can still achieve a satisfactory clinical response. Chloroquine-resistant *P. vivax* has so far been reported only from New Guinea and adjacent islands of Indonesia. It should be treated by increasing the dose of oral chloroquine. Chloroquine resistant *P. falciparum* is very widespread.

Chloroquine is cheap, safe, and in the usual 3-day course well tolerated. However, despite the clinical improvement following chloroquine treatment, attributable to its anti-inflammatory action, its failure to eliminate parasitaemia and the subsequent recrudescences may eventually lead to the development of profound anaemia. Patients with *P. vivax* or *P. ovale* malarias who will not subsequently reside in malarious areas should be given a course of primaquine (or the new 8-aminoquinoline drug, tafenoquine) to destroy persistent exoerythrocytic stages (see Table 8) unless they are G6PD-deficient.

For the treatment of *P. falciparum* malaria in most parts of the malaria endemic area, chloroquine has been replaced by pyrimethamine–sulphonamide combinations such as 'Fansidar' and 'Metakelfin'. These have the great advantage of being single-dose treatments that are usually well tolerated. In Africa, chlorproguanil–lapudrine ('lapdap') is more effective than PSD against parasites with dihydrofolate reductase gene mutations. Quinine is an effective replacement for chloroquine in most areas where multidrug-resistant strains of *P. falciparum* are prevalent. However, it has the disadvantage of producing unpleasant symptoms. In some countries a short course (3–5 days) of quinine followed by a single dose of pyrimethamine–sulphonamide is still effective. Quinine has also been combined with antibiotics such as tetracycline and clindamycin to improve its efficacy. Mefloquine, given as a single dose, or in divided doses 6 to 8 h apart to reduce the risk of vomiting, was initially highly effective against multiresistant strains of falciparum malaria throughout the world. However, in some areas, notably in the border regions of Thailand, mefloquine resistance has developed rapidly and this drug is now used in combination with artemisinin derivatives such as artesunate. The newer combination drugs 'Malarone' and 'Co-artemether' are effective against multiresistant *P. falciparum*

Patients with uncomplicated malaria can usually be given antimalarial drugs by mouth. However, feverish patients may vomit the tablets. The risk of vomiting can be reduced if the patient lies down quietly for a while after taking an antipyretic such as paracetamol. The initial dose of antimalarial drug may have to be given by injection for those who vomit persistently.

Treatment of severe falciparum malaria (Table 9)

Appropriate chemotherapy should be started as soon as possible as there is a highly significant relationship between delay in chemotherapy and mortality. **In sick and deteriorating patients, a therapeutic trial is indicated even if initial smears have proved negative.** Whenever possible, the dosage should be calculated according to the patient's body weight. The parenteral administration of drugs is the rule for patients with severe and complicated falciparum malaria and in any patient who vomits and is unable to retain swallowed tablets. In the case of cinchona alkaloids, this is most safely and effectively achieved by infusing the drug, diluted in isotonic fluid, intravenously over a period of 2 to 4 h.

The therapeutic response must be carefully monitored by frequent clinical assessments, measurement of temperature, pulse, and blood pressure, and examination of blood films. Patients should be switched to oral treatment as soon as they are able to swallow and retain tablets. They must be watched carefully for signs of drug toxicity. In the case of cinchona alkaloids, the most common toxicity during antimalarial treatment is the development of hypoglycaemia. The blood sugar should,

therefore, be checked frequently.

General management

Patients with severe malaria should be transferred to the highest level of care available, preferably the intensive care unit. They must be nursed in bed because of their postural hypotension and because of the risk of splenic rupture were they to fall. Body temperatures above 38.5 °C are associated with febrile convulsions, especially in children, and between 39.5 and 42 °C with coma and permanent neurological sequelae. In pregnant women, hyperpyrexia contributes to fetal distress. Temperature should therefore be controlled by fanning, tepid sponging, a cooling blanket, or antipyretic drugs such as paracetamol (15 mg/kg in tablets by mouth, or powder washed down a nasogastric tube, or as suppositories). As the slight prolongation of parasitaemia associated with the use of paracetamol (and possibly other methods for controlling fever) is clinically insignificant, this possible disadvantage and theoretical arguments against lowering the temperature are outweighed by the symptomatic benefits. Pyrazolones such as metamizole sodium (Dipyrone) are widely used in tropical countries but carry an unacceptable risk of inducing agranulocytosis.

Cerebral malaria

Convulsions, vomiting, and aspiration pneumonia are common, so patients should be nursed in the lateral position with a rigid oral airway or endotracheal tube in place. They should be turned at least once every 2 h to avoid bed sores. Vital signs, Glasgow coma score, and occurrence of convulsions should be recorded frequently. Convulsions can be controlled with diazepam given by slow intravenous injection (adults 10 mg, children 0.15 mg/kg) or intrarectally (0.5–1.0 mg/kg), or with paraldehyde drawn in a glass syringe and given by intramuscular injection (0.1 ml/kg). Anaphylactic use of phenobarbital was associated with increased case fatality in a placebo-controlled study in African children and is not recommended. Stomach contents should be aspirated through a nasogastric tube to reduce the risk of aspiration pneumonia. Elective endotracheal intubation is indicated if coma deepens and the airway is jeopardized. Deepening coma with signs of cerebral herniation is an indication for CT or magnetic resonance imaging, or a trial of treatment to lower intracranial pressure, such as an intravenous infusion of mannitol (1.0–1.5 g/kg of a 10–20 per cent solution over 30 min) or mechanical hyperventilation to reduce the arterial P_{CO2} to below 4.0 kPa (30 mmHg).

A number of potentially harmful remedies of unproven value have been recommended for the treatment of cerebral malaria. Two double-blind trials of dexamethasone (2 mg/kg and 11 mg/kg intravenously over 48 h) in adults and children in Thailand and Indonesia showed no reduction in mortality but prolongation of coma and an increased incidence of infection and gastrointestinal bleeding. Low molecular-weight dextrans, osmotic agents, heparin, adrenaline (epinephrine), ciclosporin A, prostacyclin, and pentoxifylline (oxpentifylline), malarial hyperimmune globulin, and anti-TNF-a monoclonal antibodies have proved ineffective in the treatment of cerebral malaria. Most of these interventions were associated with serious side-effects.

Anaemia

Indications for transfusion—preferably with fresh, compatible whole blood or packed cells—include a low (less than 20 per cent or rapidly falling) haematocrit, severe bleeding or predicted blood loss (for example, imminent parturition or surgery), hyperparasitaemia, and failure to respond to conservative treatment with oxygen and plasma expanders. When the screening of transfused blood is inadequate and infections such as human immunodeficiency virus (**HIV**), human T-cell leukaemia virus-1 (**HTLV-1**), and hepatitis viruses are prevalent in the community, the criteria for blood transfusion must be even more rigorous. Exchange transfusion is a safe way of correcting the anaemia without precipitating pulmonary oedema in those who are fluid-overloaded or chronically and severely anaemic. The volume of transfused blood must be included in the fluid-balance chart. Diuretics such as furosamide (frusemide) can be given intravenously in a dose of 1 to 2 mg/kg body weight to promote diuresis during the transfusion, and in all cases transfusion must be cautious with frequent observations of the jugular or central venous pressure and auscultation for pulmonary crepitations. Survival of compatible donor red cells is greatly reduced during the acute and convalescent phases of falciparum malaria.

Disturbances of fluid and electrolyte balance

Fluid and electrolyte requirements must be assessed individually in patients with malaria. Circulatory overload with intravenous fluids or blood transfusion may precipitate fatal pulmonary oedema, but untreated hypovolaemia may lead to fatal shock, lactic acidosis, and renal failure. Hypovolaemia may result from salt and water depletion through fever, diarrhoea, vomiting, insensible losses, and poor intake. The state of hydration is assessed clinically from the skin turgor, peripheral circulation, postural change in blood pressure, peripheral venous filling, and jugular or central venous pressure. The history of recent urine output and measurement of urine volume and specific gravity may be useful. Adult patients with severe falciparum malaria usually require between 1000 and 3000 ml of intravenous fluid during the first 24 h of hospital admission. Fluid replacement should be controlled by observations of jugular, central venous, or pulmonary artery wedge pressures. Hyponatraemia (plasma sodium concentration 120–130 mmol/l) usually requires no treatment, but these patients should be cautiously rehydrated with isotonic saline if they are clinically dehydrated, have low central venous pressures, a high urinary specific gravity, and a low urine sodium concentration (below 25 mmol/l).

Renal failure

Patients with falling urine output and elevated blood urea nitrogen and serum creatinine concentrations can be treated conservatively at first, but established acute renal failure must be treated with haemofiltration or dialysis. Hypovolaemia is corrected by the cautious infusion of isotonic saline until the central venous pressure is in the range +5 to +15 cmH_2O. If urine output remains low after rehydration, increasing doses of slowly infused intravenous furosemide (frusemide) (up to a total dose of 1 g) and finally an intravenous infusion of dopamine (2.5–5 µg/kg per min) can be tried. If these measures fail to achieve a sustained increase in urine output, a strict fluid balance should be enforced with particular emphasis on fluid restriction. Indications for haemoperfusion/dialysis include a rapid increase in serum creatinine level, hyperkalaemia, fluid overload, metabolic acidosis, and clinical manifestations of uraemia (diarrhoea and vomiting, encephalopathy, gastrointestinal bleeding, and pericarditis). Haemofiltration is the most effective technique in malaria but haemodialysis or peritoneal dialysis are also effective. The initial doses of antimalarial drug should not be reduced in patients with renal failure but, after 48 h of parenteral treatment, the maintenance dose should be reduced by one-third to one-half.

Metabolic acidosis

This is usually attributable to lactic acidosis and is an important life-threatening complication, especially in anaemic children. It should be treated by improving perfusion and oxygenation by blood transfusion and correcting hypovolaemia, clearing the airway, increasing the inspired oxygen concentration, and by treating septicaemia, a frequently associated complication.

Pulmonary oedema

This must be prevented by propping the patient up at an angle of 45 degrees and controlling fluid intake so that the jugular or central venous pressure is kept below +5 cmH_2O. Those who develop pulmonary oedema should be propped upright and given oxygen to breathe. In a well-equipped intensive care unit, the judicious use of vasodilator drugs can be controlled by monitoring haemodynamic variables, fluid overload can be corrected by haemoperfusion, and oxygenation can be improved by mechanical ventilation with positive end-expiratory pressure.

Hypotension and 'shock' ('algid malaria')

This should be treated as for bacteraemic shock. The circulatory problems should be corrected with blood transfusion (for example, in anaemic children with respiratory distress and acidosis), plasma expanders, dopamine, and broad-spectrum antimicrobial treatment (such as gentamicin with ceftazidime or cefuroxime plus metronidazole) should be started immediately, bearing in mind that likely routes of infection include the urinary tract, lungs, and the gut. Other causes of shock in patients with malaria include dehydration, blood loss (for instance, following splenic rupture), and pulmonary oedema.

Hypoglycaemia

This may be asymptomatic, especially in pregnancy, and its clinical manifestations may be confused with those of malaria. Blood sugar must be checked every few hours, especially in patients being treated with cinchona alkaloids. Hypoglycaemia may arise despite continuous intravenous infusions of 5 or even 10 per cent dextrose. A therapeutic trial of dextrose (1 ml/kg by intravenous bolus injection) should be given if hypoglycaemia is proved or suspected. This should be followed by a continuous infusion of 10 per cent dextrose. Glucose may be given by nasogastric tube to unconscious patients or by peritoneal dialysis in those undergoing this

treatment for renal failure. Among agents that block insulin release, diazoxide was ineffective, but octreotide (Sandostatin), a synthetic somatostatin analogue, proved effective in some severe cases of quinine-induced hypoglycaemia.

Hyperparasitaemia and exchange blood transfusion

In non-immune patients, mortality increases with parasitaemia, exceeding 50 per cent with parasitaemias above 500 000/µl. Exchange transfusion reduces parasitaemia more rapidly than optimal chemotherapy alone, although this advantage will be less when artemisinins are used, and could have the additional benefit of removing harmful metabolites, toxins, cytokines and other mediators, and restoring normal red-cell mass, platelets, clotting, factors, albumin, etc. Potential dangers of the procedure include electrolyte disturbances (for example, hypocalcaemia), cardiovascular complications, and the introduction of infectious agents into the blood and through infection of intravascular lines. The use of exchange transfusion, haemopheresis, and plasmapheresis has been reported in more than 100 patients, the vast majority of whom survived. There was undoubtedly some reporting bias. Some patients showed clinical improvement, such as recovery of consciousness, and restoration of urine flow, soon after the procedure. A meta-analysis discovered no higher survival rate compared to chemotherapy alone and there have been a few recent reports of adult respiratory distress syndrome developing during the procedure. The efficacy of exchange transfusion is never likely to be put to the test of a randomized comparative study, but, where facilities allow and screening of donor blood is adequate, the procedure should be considered in non-immune patients who are severely ill, who have deteriorated on conventional treatment, and who have parasitaemias in excess of 10 per cent. The introduction of antimalarial agents, such as artemisinins, which clear parasitaemia very rapidly, may obviate the need for exchange transfusion.

Splenic rupture

Acute abdominal pain and tenderness with left shoulder-tip pain and shock in patients with vivax and falciparum malaria should suggest the possibility of splenic rupture, especially if there is a history of abdominal trauma. Free blood in the peritoneal cavity and a torn splenic capsule can be detected by ultrasound or CT and confirmed by needle aspiration of the peritoneal cavity, laparoscopy, or laparotomy. Conservative management with blood transfusion and close observation in an intensive care unit is sometimes successful but access to surgical help is essential in case there is a sudden deterioration.

Disseminated intravascular coagulation

Patients with evidence of a coagulopathy should be given vitamin K (adult dose 10 mg by slow intravenous injection). Prothrombin complex concentrates, cryoprecipitates, platelet transfusions, and fresh-frozen plasma should be considered.

Management of the pregnant woman with malaria

Malaria must be diagnosed and treated rapidly in pregnant women. Unwarranted fears of abortifacient and fetus-damaging effects of antimalarial drugs have led to the delay or even withdrawal of treatment, but experience since the nineteenth century has confirmed the safety of quinine in pregnancy. Chloroquine has been used extensively without ill effect to mother or fetus. However, pyrimethamine–sulphonamides, tetracycline, primaquine, and aspirin (but not paracetamol) are contraindicated in late pregnancy and mefloquine should be avoided if possible. In pregnant women, the total apparent volume of distribution of quinine is reduced and the drug is eliminated more rapidly. Initial dosage is the same as in non-pregnant patients, but in severe cases requiring prolonged parenteral treatment, the dose, but not the frequency of administration, should be reduced. The main danger of quinine in pregnancy is its stimulation of insulin secretion with resulting hypoglycaemia (see above). Blood glucose must be checked at least once a day in pregnant women with malaria, whether or not they are receiving quinine. Maternal fever should be reduced as soon as possible. Induction of labour, caesarean section, or speeding up of the second stage of labour with forceps or vacuum extractor should be considered in patients with severe falciparum malaria. Fluid balance is particularly critical in these patients. If possible, the central venous pressure should be monitored. Exchange transfusion of 1000 to 1500 ml of blood in late pregnancy proved an effective way of managing severe anaemia with high-output cardiac failure in Nigeria. Circulating volume could be reduced and the risk of postpartum pulmonary oedema lessened by replacing exfused blood with a smaller volume of packed cells.

Prognosis

The mortality of acute vivax, ovale, and malariae malarias is negligible. Strictly defined cerebral malaria has a mortality of about 10 to 15 per cent when medical facilities are good, and may be less than 5 per cent in Western intensive care units. Antecedent factors that predispose to severe falciparum malaria include the lack of acquired immunity or lapsed immunity, splenectomy, pregnancy, and immunosuppression. There is a strong correlation between the density of parasitaemia and disease severity. Severe clinical manifestations, such as impaired consciousness, retinal haemorrhages, renal failure, hypoglycaemia, haemoglobinuria, metabolic acidosis, and pulmonary oedema, carry a bad prognosis. The case fatality of pregnant women with cerebral malaria, especially primiparae in the third trimester, is approximately 10 times greater than in non-pregnant patients. The following laboratory findings carry a poor prognosis: peripheral schizontaemia, peripheral leucocytosis exceeding 12 000/µl, malarial pigment in >5 per cent of circulating neutrophils, high CSF lactate or low glucose, low plasma antithrombin III, serum creatinine exceeding 265 µmol/l, or a blood urea nitrogen of more than 21.4 mmol/l, haematocrit less than 20 per cent, blood glucose less than 2.2 mmol/l, and elevated serum enzyme concentrations (for example, aspartate and alanine aminotransferases, lactate dehydrogenase).

Chronic immunological complications of malaria

Quartan malarial nephrosis

In parts of East and West Africa, South America, India, South-East Asia, and Papua New Guinea, there is epidemiological evidence linking *P. malariae* infection to immune-complex glomerulonephritis, leading to nephrotic syndrome. Few of those exposed to repeated *P. malariae* infections develop nephrosis, suggesting that additional factors are involved. The histological changes, which are not entirely specific, are of a progressive focal and segmental glomerulosclerosis with fibrillary splitting or flaking of the capillary basement membrane, producing characteristic lacunae. Electron-dense deposits beneath the endothelium can be seen by electron microscopy. Immunofluorescence reveals glomerular deposits of immunoglobulins and C3, and *P. malariae* antigen, in about 25 per cent of cases. More than half the patients present by the age of 15 years with typical features of nephrotic syndrome. *P. malariae* is frequently found in blood smears and *P. malariae* antigen in renal biopsies in children but not in adults. The renal lesions may be perpetuated by autoimmune mechanisms. The pattern of immunofluorescent staining has some prognostic significance. Few patients respond to corticosteroids, but some are helped by azathioprine and cyclophosphamide, especially those whose renal biopsies show the coarse or mixed patterns of immunofluorescence. Antimalarial treatment is not effective. This condition could be prevented by antimalarial prophylaxis and has disappeared in countries such as Guyana during a period of malaria eradication.

Tropical splenomegaly syndrome (hyper-reactive malarial splenomegaly)

Transient splenomegaly is a feature of acute attacks of malaria in non-immune or partially immune patients, while progressive splenomegaly is seen in children resident in malarious areas during the process of their acquiring immunity to the infection. However, a separate entity has been described in Africa (especially Nigeria, Uganda, and Zambia), the Indian subcontinent (Bengal, Sri Lanka), South-East Asia (Vietnam, Thailand, and Indonesia), South America (Amazon region), Papua New Guinea, and the Middle East (Aden). The defining features are residence in a malarious area, chronic splenomegaly, elevated serum IgM and malarial antibody levels, hepatic sinusoidal lymphocytosis, and a clinical and immunological response to antimalarial prophylaxis. This condition is thought to result from an aberrant immunological response to repeated infection by any of the species of malaria parasite.

Pathophysiology

In Flores, Indonesia, *P. vivax* infection leads to the production of IgM lymphocytotoxic antibodies specific for the suppressor T lymphocytes, which normally regulate IgM production. The resulting disinhibition of B lymphocytes leads to their overproduction of IgM, forming macromolecular aggregates of IgM (cryoglobulins). The need to clear these aggregates stimulates the reticuloendothelial system and causes the progressive and eventually massive splenomegaly and hepatomegaly. The decrease in suppressor/cytotoxic (CD8) lymphocytes increases the helper:suppressor (CD4:CD8) ratio. Antimalarial chemoprophylaxis, by removing the antigenic stimulus provided by repeated malarial infections, allows the patient's immune system to return to normal. There are some differences between tropical splenomegaly syndrome in Africa, Flores, and Papua New Guinea. In Africa, but not in Flores or Papua New Guinea, there is a peripheral lymphocytosis resulting from an increase in B lymphocytes, and distinction from chronic lymphatic leukaemia may be difficult. In Ghana, clonal rearrangements of the JH region of the immunoglobulin gene were found in patients with tropical splenomegaly who failed to respond to proguanil chemoprophylaxis, suggesting that the syndrome may evolve into a malignant lymphoproliferative disorder. Some of these patients had features of splenic lymphoma with villous (hairy) lymphocytes. In Africa and Papua New Guinea, IgG levels

were significantly increased, but not in Flores. In Flores only the titres of *P. vivax* IgM antibodies were higher in patients with the splenomegaly syndrome, but in Papua New Guinea titres of *P. falciparum, P. vivax,* and *P. malariae* were increased, and in Africa *P. falciparum* and *P. malariae* are the species involved. The familial tendency of the tropical splenomegaly syndrome in Africa and Papua New Guinea suggests a genetic factor.

Clinical features

In malaria endemic areas, patients with tropical splenomegaly syndrome are distinguishable by their progressive splenic enlargement persisting beyond childhood. The spleen may be enormous, filling the left iliac fossa, extending across the midline and anteriorly, producing a visible mass with an obvious notch. The liver is usually enlarged, especially its left lobe. Symptoms attributable to the spleen include a vague dragging sensation and occasional episodes of severe pain with peritonism, suggesting perisplenitis or splenic infarction. Anaemia may become severe enough to cause the features of high-output cardiac failure. Acute haemolytic episodes are described. These patients are vulnerable to infections, especially of the skin and respiratory system, and most deaths are attributable to overwhelming infection. Chronic hypersplenic neutropenia or failure to mobilize neutrophils in response to acute bacterial infections may be the cause. In Papua New Guinea, 57 per cent of those with massive splenomegaly were dead within 7 years.

Patients with splenic lymphoma with villous lymphocytes (Ghana) had splenic discomfort, anorexia, and hepatosplenomegaly, with infiltration of the bone marrow with villous lymphocytes.

Laboratory findings

Severe chronic anaemia is the result of destruction and pooling in the spleen and dilution in an increased plasma volume. Thrombocytopenia may also be caused by splenic sequestration; it rarely causes bleeding. There is neutropenia and, in African patients, peripheral lymphocytosis and lymphocytic infiltration of the bone marrow. Serum IgM is greatly elevated.

The essential histopathological feature is lymphocytosis of the hepatic sinusoids with Kupffer-cell hyperplasia. In some cases, round-cell infiltration of the portal tracts is associated with fibrosis, leading to portal hypertension. In the spleen there is dilatation of the sinusoids, hyperplasia of the phagocytic cells with evident erythrophagocytosis, and infiltration with lymphocytes and plasma cells. No histopathological explanation has been found for the episodes of acute splenic pain.

In patients with splenic lymphoma and villous lymphocytes, more than 30 per cent of circulating lymphocytes are villous. These cells can be distinguished from hairy-cell leukaemia by their lack of CD25, CD11c, and tartrate-resistant acid phosphatase markers.

Differential diagnosis

Tropical splenomegaly syndrome must be distinguished from other causes of chronic, painless, massive splenomegaly, including leukaemias, lymphomas, myelofibrosis, thalassaemias, haemoglobinopathies, visceral leishmaniasis (by examination of bone marrow or splenic aspirates), and schistosomiasis (by liver biopsy, rectal snip, and stool examination). Lymphomas (especially chronic lymphatic leukaemia and follicular lymphoma—see above) and even leukaemias may develop in patients with tropical splenomegaly syndrome. Non-tropical idiopathic splenomegaly (normal serum IgM) and Felty's syndrome produce a similar histological picture in the liver. Many cases of splenomegaly in the tropics remain undiagnosed.

Treatment

Prolonged antimalarial chemoprophylaxis is the most important element of treatment. In Papua New Guinea, 70 per cent of the patients showed marked improvement after 12 months of chemotherapy. The choice of drug will depend on the local sensitivity of whichever species or group of species of malaria parasite are thought to be responsible for this syndrome (see Chemoprophylaxis below). The short- and long-term dangers of splenectomy rule out this procedure in the rural tropics. Similarly, splenic irradiation and antimitotic agents are dangerous and unnecessary. Folic acid may be needed. Diagnosis of patients with splenic lymphoma with villous lymphocytes (Ghana) is important as, in this condition, the risks of splenectomy are outweighed by the benefits.

Endemic Burkitt's lymphoma (see Chapter 7.10.3)

Endemic Burkitt's lymphoma, a tumour of the jaw, abdomen, and other areas that spreads to the bone marrow or meninges, is the most common type of childhood malignant disease in many parts of East and West Africa and Papua New Guinea. It has also been reported from Brazil, Malaysia, and the Middle East. Burkitt noticed that its distribution (by altitude, temperature, and rainfall) and even its seasonal incidence followed that of holoendemic falciparum malaria. Outside the malaria endemic area, Burkitt's lymphoma occurs sporadically. There is a suggestion that the B-cell line in Caucasian cases comes from lymphoid tissue, whereas in African cases it comes from the bone marrow. Epstein–Barr virus (**EBV**) produces a lifelong infection of B lymphocytes. In normal individuals this is controlled by specific, HLA-restricted, cytotoxic T cells, which recognize a virus-induced, lymphocyte-detected membrane antigen (**LYDMA**) on B cells. Immunosuppression, as in recipients of renal allografts, allows uncontrolled proliferation of the EBV-infected B-cell line, which may give rise to one of the three chromosomal translocations [t(8;14), t(2;8), t(8;22)] that activate the c-*myc* oncogene on chromosome 8 responsible for malignant transformation. Acute *P. falciparum* infection leads to a reduction in the numbers of suppressor T (CD8) lymphocytes and a decrease in the helper:suppressor (CD4:CD8) ratio, allowing proliferation and increased immunoglobulin secretion by EBV-infected B cells. No lymphocytotoxic antibody is found in acute plasma samples to explain the decrease in suppressor T cells. These tumours may grow so rapidly that massive local tissue destruction results in urate nephropathy and acute renal failure. Cyclophosphamide, vincristine, methotrexate, and prednisolone are used in chemotherapy, producing remissions in 80 to 90 per cent of patients and a long-term survival of 20 to 70 per cent. Breakdown of large tumours during the first week of chemotherapy may be so dramatic that the acute tumour lysis syndrome may be precipitated. This consists of metabolic acidosis, hyperuricaemia, hyperphosphaturia, hyperphosphataemia, hyperproteinaemia, and hyperkalaemia, which may result in fatal cardiac arrhythmia and acute uric-acid nephropathy with renal failure.

Malaria control

Malaria control relies on breaking the chain of transmission, often by attacks on the vector. As the insecticide resistance of mosquitoes and drug resistance of parasites increase, the environmental methods previously used to control anopheline breeding are being revived. The use at night of insecticide-treated bed nets (**ITNs**) has been a major innovation, combining personal protection with population protection (the mass effect) in some situations. No vaccine is yet available for operational use. There is currently a more balanced approach to malaria control than in the past, with emphasis on the early diagnosis and prompt treatment of infected people, selective and sustainable use of antivector measures, and epidemic control. The importance of malaria control has been acknowledged at the political level and available methods are being more energetically applied than for some decades, for example, in the WHO's 'Roll back malaria' programme.

Transmission control

Mosquitoes may be controlled in two ways: by removing, poisoning, or otherwise changing their larval habitats and so reducing their numbers; or by killing the adult mosquitoes by means of insecticides. These may be sprayed into the air for a transient effect or put on to the surfaces where mosquitoes rest to obtain a persistent or residual effect. Other methods may simply deter mosquitoes from biting people. Combination methods whereby insecticide is put on a mechanical barrier such as a bednet are currently much favoured and are discussed separately. For the future, there is also much interest in finding ways to transfect mosquitoes with genes to render them unable to transmit malaria, incorporating them into an infective agent that will spread through mosquito populations. Although killing the adult mosquitoes or their larvae will reduce mosquito numbers, and malaria transmission proportionately, residual insecticides have a greater effect on the survival of infected mosquitoes to the age at which they can pass on the infection, thereby reducing malaria transmission much more than might otherwise be expected.

Mosquito species are highly selective in their choice of larval habitat, and there are usually few major vector species in a given locality. The selective destruction of vector breeding sites (species sanitation), is a long-term method of mosquito control. Sites can be made unsuitable for vector breeding by drainage, changing the rate of water flow, and adding or removing shade, cutting emergent vegetation, and altering the margins of bodies of water. Near the sea, salinity changes may be relevant. For small reservoirs and irrigation canals, cyclical changes in water level by means of a large siphon may control larvae by alternately stranding and flushing. Intermittent drying out of irrigation channels may be of value. No generalizations are possible as, for example, water fluctuations that control vectors in the southern United States would increase breeding in sub-Saharan Africa. Enough local information is available to guide public-health engineering interventions in most endemic areas. As these and other measures against breeding reduce mosquito density, to which transmission is proportional, environmental control is most effective in areas of unstable malaria. Because costs of environmental measures are related to the area involved, and the resources and benefits are related to the human

population, environmental control is most likely to be feasible in areas of high population density. In cities it needs to extend beyond the periurban fringe where the poor are concentrated. Control of mosquitoes such as *A. gambiae,* which utilize temporary pools as small as hoof prints, is very difficult by environmental means without ruthless discipline.

Where habitats cannot be drained or rendered structurally unsuitable, chemical larvicides may be used. Diesel oil, at 40 1/hectare of water surface with or without the addition of insecticides, will prevent the larvae breathing when it is spread on the water surface with the addition of a spreading agent. In the correct formulation, 1 kg/hectare of Paris Green is effective, but 2 to 20 kg/hectare of temephos (Abate) granules is a safer alternative, usually needing to be repeated weekly or fortnightly.

The use of residual insecticides applied to walls and other indoor surfaces gives a far more persistent effect, so that **DDT** (dichlorodiphenyltrichloethane) at 2 g/m ^{2} will remain toxic to endophilic anophelines for 6 months or more on a non-absorbent wall material, as may l-cyhalothrin at a much lower dosage, while organophosphorus insecticides such as malathion, propoxur, and fenitrothion at the same dosage last about 3 months. This approach is a community one, requiring coverage of all houses and shelters, as it relies on killing the mosquito after it has fed. Where the aim is individual or family protection, a knock-down insecticide used before evening in a screened house is more relevant.

Prudent behaviour can greatly reduce the risk of an infective mosquito bite, especially for the visitor to an endemic area. As anophelines bite mostly in the evening, remaining in a screened area from dusk, wearing long sleeves and leg coverings, and sleeping beneath a mosquito net are of real, if underestimated, benefit. Recently, the use of bednets impregnated with synthetic pyrethroids such as permethrin or l-cyhalothrin has been found to give substantial malaria protection in endemic areas, reducing the number of clinical attacks even in areas of high transmission by 50 per cent, and where high coverage is achieved reducing the all-cause infant mortality rate by up to 27 per cent. The effect is due to a combination of reduced access of mosquitoes to people because of the net, a repellent and lethal effect of the insecticide on the mosquitoes trying to bite, and sometimes an effect on mosquito density so that even those outside the nets may get some protection. Nets are most effective when mosquito biting is concentrated late at night, and they can give good protection to babies in cots. The large-scale operational use of impregnated bednets in endemic areas is currently expanding, but as the net is a commodity rather than a health service, the best economic basis for sustainable high coverage by ITNs, and for their regular retreatments, are still being explored. ITNs appear to be one of the most hopeful means of control pending development of an operational vaccine.

As engineering methods are costly, though long lasting, and insecticides can be viewed as polluting the environment, other methods of mosquito control have been sought, with variable success. Genetic control of anophelines is not feasible at present; biological control is often a useful accessory method and usually relies on small fish, especially of such genera as *Gambusia* and *Lebistes* that preferentially feed on mosquito larvae. Species of fish that survive drying out of the habitat as eggs are now of interest. The micro-organism *Bacillus thuringiensis* is used in control, but it effectively functions as a biological insecticide because it produces a toxin.

Prevention of malaria in travellers

Advice to travellers

The prevention of malaria in travellers, particularly those usually resident in non-malarious areas but visiting endemic regions, is becoming increasingly difficult, owing to the spread of resistance to the commonly available antimalarial agents, which means that prevention cannot be completely successful. The four components of advice to travellers must therefore be: (1) to be aware of the risk; (2) to reduce exposure to being bitten by anopheline mosquitoes; (3) to take chemoprophylaxis where appropriate; (4) to seek immediate medical advice in the event of any fever or 'flu-like illness developing while in the area, or within 3 or more months of leaving it, and to consider malaria as a possibility regardless of the precautions taken. The first two of these are at least as important as the third in preventing mortality from malaria.

Preventive advice is subject to uncertainty. This is because unequivocal data on efficacy are often unavailable, published studies are conflicting, and the distribution of resistance to many prophylactics is not well mapped. The balance between the risk of malaria and the risk of side-effects involves value judgements on which experts differ. Moreover, prospective travellers consult several sources of advice, obtain different opinions, and compliance with any regimen thus falls. Published advice is usually by country (the World Health Organization annually produces the most useful list of risk areas) and is inevitably directed towards prophylaxis for the areas of greatest transmission. Consultation with someone who knows the country and the traveller's itinerary may well lead to good advice that differs and is more specific. Intelligent travellers need to be made aware of these issues but they also require clear advice that must include the general points discussed in the following paragraph.

For any traveller to an endemic area there is a risk of malaria. No prophylactic regimen will give total protection, but many will reduce the risk of a malaria attack substantially. In the event of a fever while travelling, or afterwards, malaria must be considered as a diagnosis. Strict compliance, even with a suboptimal prophylactic regimen, is more important than vacillation over finding the optimal one.

Prevention of mosquito bites

There are many additional ways to reduce the risk of malaria. Bednets impregnated with a pyrethroid insecticide (permethrin, deltamethrin, or l-cyhalothrin) should be used, properly tucked in, and without tears or other holes through which mosquitoes might enter. A well-screened bedroom and other accommodation, combined with use of a knock-down insecticide when the doors are closed, will give substantial protection. Clothes that deter mosquito bites, repellent sprays and soaps (containing *N*, *N*-diethyl-*m*-toluamide (**DEET**) or permethrin), and avoiding exposure to bites in the evenings will also help.

Chemoprophylaxis

Chloroquine and/or proguanil

In malarious areas from which chloroquine-resistant *P. falciparum* is absent, mainly in Western Asia, North Africa, and Central America, chloroquine 300 mg (base), usually two tablets taken once a week, will give good protection. However, since it acts as a suppressive of the blood forms of *Plasmodium* it will not prevent late attacks of *P. vivax* or *P. ovale.* Proguanil, 100 mg daily, or 200 mg daily in areas of intense transmission, will act as a true causal prophylactic but is poorly protective against *P. vivax* in these doses. The extremely low incidence of adverse side-effects from proguanil makes it acceptable to long-term residents in endemic areas. Chloroquine is suitable for up to 6 years of use, but beyond this proguanil may be substituted. Recommendations are summarized in Table 9 and Table 10.

By 1993, chloroquine-resistant *P. falciparum* had been reported from most malarious countries, and it constitutes a massive and increasing problem in sub-Saharan Africa and in SE Asia (where multiple drug resistance is common). Newer drugs and the more effective drug combinations for prophylaxis against chloroquine-resistant *P. falciparum* carry a significant risk of severe toxic side-effects that has to be balanced against the malaria risk, which varies greatly within countries, especially in Asia. Where the proportion of malaria resistant to chloroquine is low or the degree of resistance limited, the combination of chloroquine and proguanil ((b)1, Table 10) has the advantage of low toxicity and appears to be effective in many areas, including India and the rest of South Asia. These two drugs also have a good safety record in pregnant women and in young children. Long-term use of prophylactic chloroquine only carries a risk of retinopathy (probably very small) once the total cumulative dose exceeds 100 g of base (over 6 years at the standard prophylactic dose). Pruritis can be a problem in those with dark skins.

However, the combination of chloroquine and proguanil no longer provides adequate protection in sub-Saharan Africa where the malaria challenge in rural areas may exceed one infective bite per night and resistance is common, nor in SE Asia where there is a much lower transmission rate but a greater range of drugs to which *P. falciparum* is resistant.

Other prophylactic drugs

Other prophylactic regimens involve the use of mefloquine, doxycycline, and the combination of atovaquone and proguanil. Mefloquine was the most widely used of these three regimens and there are far more data on its use in malaria prevention than for the other two. Doxycycline was only recently licensed in the United Kingdom for the chemoprophylaxis of malaria, although it has been in use for the prevention of acne for many years; it has also been used as an antimalarial agent outside the license. There is much less experience with the combination of atovaquone and proguanil, though each of its component medicines has been used without high resistance and without high levels of side-effects. Trials of the efficacy of all three regimens demonstrate good protection against chloroquine-resistant falciparum malaria and the choice between them depends on the traveller, destination, and duration of travel. In the absence of specific resistance, mefloquine has a

prophylactic efficacy of around 90 per cent against falciparum malaria, and doxycycline is almost as effective in trials in Asia. However, the data on the combination of atovaquone and proguanil come mainly from studies of semi-immune people and are less extensive. Although the atovaquone/proguanil regimen gives a similar level of efficacy to the other two prophylactics, more information is needed: its particular advantage lies in the low level of serious adverse effects observed in studies to date.

Mefloquine ('Lariam')

Mefloquine has a long half-life and on a weekly dosage schedule the blood level rises to a plateau from about 7 weeks. The majority of the side-effects, which are the main problem with its use, are associated with the initial three doses of mefloquine. The drug should therefore be started 2½ weeks prior to departure for a malarious place, so that if side-effects are troublesome an alternative may be used. Although it is usual to avoid taking mefloquine for longer than a year, American experience suggests that no additional problems arise after 2 to 3 years. The main serious early side-effects of mefloquine are neuropsychiatric, and include anxiety, depression, delusions, fits, and psychotic attacks. The frequency of these is disputed. Airline passenger surveys have shown a frequency of 1:10 000, but experienced doctors in the United Kingdom assert a much higher frequency and further data are needed. As its safety during early pregnancy is uncertain, it is not recommended for those in the first trimester of pregnancy or those at risk of pregnancy during the 3 months after the end of chemoprophylaxis There is some evidence from SE Asia of an increased stillbirth rate in those taking it in later pregnancy, but the risk from malaria is also great in pregnancy. It is contraindicated in people with a history of epilepsy or psychiatric disease. Sporadic cases of mefloquine resistance are already reported from Africa, and on the border between Thailand and Cambodia up to 40 per cent of cases of falciparum malaria are mefloquine-resistant.

Doxycycline

Doxycycline has been shown to give good protection against drug-resistant falciparum malaria in trials in Oceania, and it is being increasingly used, especially for those with adverse reactions to, or who are unwilling to take, mefloquine. It should not be used in children or pregnant women. The main side-effects are photosensitization, which occurs in up to 3 per cent of users making it less than ideal for beach holidays in the tropics, a tendency to precipitate attacks of candidiasis in women (hence it is helpful for women to take doxycycline with a one-dose therapy for candidal infections), and the rare risk of *Corynebacterium difficile* diarrhoea. However, doxycycline is likely to reduce the risk of the commoner travellers' diarrhoeas; but gastrointestinal discomfort from the doxycycline itself is not uncommon. The drug is taken daily with food, taking care not to miss any days, but avoiding lying down too soon after taking it to avert a real risk of acute pain from ulceration of the lower oesophagus. It is best to start a few days before travel: this is to get accustomed to taking the daily medication rather than for pharmacological reasons.

Atovaquone–proguanil ('Malarone')

This combination, which has been successfully used for malaria treatment for several years, has now been licensed in the United Kingdom (and previously in the United States) and Europe for malaria prophylaxis. It appears to have two great advantages: the level and severity of adverse effects has so far been lower than for the mefloquine and doxycycline; and, in part, it acts as a causal prophylactic, attacking the pre-erythrocytic stages of the malarial parasites. As a consequence, it is continued for 7 days after leaving the malarious area, so that the chance of compliance with this shorter period is improved. There are two concerns over it at present: although it appears to afford comparable protection as the alternative drugs against falciparum malaria, the evidence in non-immune individuals is scanty, and it is uncertain how soon resistance to this drug combination will emerge. Although resistance to atovaquone alone readily occurs, resistance to the combination is a much rarer event. Malarone is extremely expensive. However, since it is taken daily the different overall regimen means that the cost for short visits is more comparable to the alternatives, but the cost rises greatly for longer visits (and it is currently licensed for up to 4 weeks abroad). There is no experience of its use in pregnancy and the licence for its use in Europe currently excludes pregnancy and childhood, though it is used for children in the United States where paediatric tablets are available.

Continuation of chemoprophylaxis after leaving the malarious area

All antimalarial agents except Malarone must be continued for 4 weeks after leaving the malarious area.

Choice of chemoprophylaxis (Table 10)

Where there is a substantial risk of chloroquine-resistant falciparum malaria, either mefloquine, doxycycline, or Malarone are appropriate, so providing a better range of protective options than a few years ago for healthy adults. However, of these only mefloquine is licensed for children, and none is ideal for pregnant women who are best advised to avoid such areas. Doses of prophylactic antimalarial drugs for children are given in Table 11.

Chemoprophylaxis in people with epilepsy

In patients with epilepsy, proguanil or atovaquone/proguanil or doxycycline do not increase the risk of fits and can be used for prophylaxis, depending on the particular geographical area and level of risk.

The fixed drug combination Maloprim (12.5 mg pyrimethamine and 100 mg dapsone per tablet), marketed as Deltaprim in parts of Africa, has been of value in patients with epilepsy and for others unable to take the first-line drugs. It is now hard to obtain, and it is important not to confuse Malarone and Maloprim. Maloprim alone gives poor protection against *P. vivax* and chloroquine may be given concurrently. The dose of Maloprim must not exceed one tablet a week or the incidence of the otherwise uncommon side-effect, agranulocytosis, rises. Methaemoglobinaemia occasionally occurs with Maloprim chemoprophylaxis.

Rejected chemoprophylactic drugs

The following drugs are unsuitable for chemoprophylaxis (but Fansidar has a role in treatment): amodiaquine because of the high risk of agranulocytosis; Fansidar (25 mg pyrimethamine and 100 mg sulfadoxine per tablet) because of the frequency of severe skin reactions; and pyrimethamine on its own, because it is ineffective in most malarial areas.

Risk of malaria and need to take chemoprophylaxis

The risk of malaria is much higher in sub-Saharan Africa than elsewhere and it would be folly not to take prophylactics, except where the altitude is too great for transmission to occur or in the non-endemic southern parts of the continent (see Fig. 4). In Asia, the risk is usually much lower. Visitors to the air-conditioned hotels of the larger cities of SE Asia do not need prophylaxis but elsewhere in Asia there may be urban malaria. Mefloquine does not protect adequately against malaria in SE Asia, and travellers to the areas of higher transmission will need regimens (c)2 or (c)3 (Table 10). Those residing for long periods in such areas may prefer to adopt vigilance and the early treatment of fevers, but awareness of the risk is essential. Freedom from malaria in Asia by travellers does not mean that they will escape infection in Africa!

Because no prophylactic is completely effective in chloroquine-resistant *P. falciparum* areas, travellers who may be in remote areas and away from prompt medical assistance should carry a therapeutic dose of Fansidar, Malarone, mefloquine, or Riamet/Co-artem ether. Resistance to Fansidar has been reported from many countries with highly chloroquine-resistant malaria. The prophylactic regimen used should be continued for the appropriate time, usually 4 weeks, after returning to a non-endemic area. Compliance is hard to achieve, but this will prevent most cases of imported malaria. However, no regimen is 100 per cent protective and whatever precautions are taken, the possibility of malaria must, however, be borne in mind by the traveller and pointed out to any medical adviser, whom he or she must seek in case of a fever.

Malarial vaccines

Difficulties facing the development of a malaria vaccine

No satisfactory vaccine has emerged from the many attempts, over the last 70 years, to immunize animals and humans against malaria. A major problem is the impracticability of producing large quantities of attenuated micro-organisms, the basis for most effective viral and bacterial vaccines. The alternative, a subunit vaccine, has proved much more difficult to produce. Other problems are attributable to biological features of the malaria parasite, selected by evolutionary pressure to enable it to persist long enough in the human host to be taken up by a mosquito and propagated. During the different stages of its lifecycle—in the bloodstream,

hepatocytes, and erythrocytes of the human host and in mosquitoes—*P. falciparum* expresses a variety of antigens. Antibodies elicited against sporozoites, the infective stage inoculated by the mosquito, will not recognize blood-stage antigens. A different set of immunizing antigens is therefore needed to target each stage of the lifecycle. The large and complex genome of *P. falciparum* (25–30 megabases with 5–6000 genes, many of them polymorphic, on 14 chromosomes) shows great diversity, and an attack of malaria may involve simultaneous infection with as many as eight different *P. falciparum* genomes. Antigenic variation of some parasite proteins, such as the high molecular weight PfEMP-1 on the surface of infected erythrocytes, enables *P. falciparum* to evade the host's immune response. Another problem facing the widespread use of a malaria vaccine is the variation in the innate genetic resistance of humans to the pathological effects of malaria infection, related, for example, to their MHC class I polymorphism (Table 4). The immune response to vaccines may also be determined genetically.

Pre-erythrocytic stage vaccines

Irradiation-attenuated sporozoites

The first successful attempt to immunize a human against malaria was reported by DF Clyde and his colleagues in 1973. Their technique was based on studies in mice infected with *P. berghei*, in which protective immunity had been achieved by repeated intravenous injections of live, irradiation-attenuated sporozoites or by exposure to bites by irradiated infected mosquitoes. In mice, protection was associated with the development of precipitating antibodies to circumsporozoite antigens. Over a period of 84 days, three healthy adult volunteers were exposed, on six occasions, to bites by *Anopheles stephensi* mosquitoes which had been irradiated after becoming heavily infected with sporozoites of the Burma (Thau.) strain of *P. falciparum*. After being challenged through bites by non-irradiated mosquitoes bearing the same strain of *P. falciparum*, 98 days after the start of immunization, two of them developed malaria but one remained uninfected. This uninfected man was exposed to bites by irradiated mosquitoes on five further occasions, after which he was challenged again on day 327. Again, he failed to develop parasitaemia but was not protected against an intravenous injection of blood-stage parasites of the same strain, illustrating the stage-specific nature of malarial immunity. Work over the next 20 years confirmed the principle that protective immunity could be induced in humans by bites of irradiated infected mosquitoes. Between 1989 and 1999 further studies were carried out of immunization by the bites of irradiated *P. falciparum*-infected mosquitoes. A group of 11 volunteers, immunized by receiving more than a thousand bites from irradiated mosquitoes harbouring infectious sporozoites of *P. falciparum* strain NF54 and the 3D7 clone of NF54, were protected against 33 out of 35 challenges through bites by non-irradiated infected mosquitoes. Protection lasted for at least 36–42 weeks and extended to parasitic strains from geographical areas different from the immunizing strains.

These studies of artificial infections by mosquito-borne attenuated sporozoites provided the first evidence that vaccination against malaria was possible. However, such a prolonged, intensive, and laborious process could never become a practicable way of immunizing even small groups of non-immune travellers, let alone endemic populations. The immunological mechanism of protection conferred by irradiated sporozoite immunization has been studied in the mouse model and in human volunteers. In mice, CD8+ T-cell recognition of infected hepatocytes, by targeting sporozoite proteins expressed within the cell, is the most important mechanism. Humoral antibodies to proteins on the sporozoite's surface and CD4+ T-cells may also play a role.

Effector T-cell vaccines

An encouraging recent development, based on these findings, has been the preparation and testing of effector T-cell vaccines targeting pre-erythrocytic stages of the lifecycle, in infected hepatocytes. Theoretically, these vaccines could prevent both blood-stage infection and transmission in malaria endemic areas. The two most productive strategies have been the use of protein-adjuvants (for example, in RTS,S/(SB)AS02 vaccine) and heterologous prime–boost immunization.

RTS,S/(SB)AS02 malaria vaccine

RTS,S is a fusion protein combining most of the circumsporozoite protein of *P. falciparum* with Hb_sAg with a complex adjuvant (AS02) capable of inducing strong antibody and CD4+ T-cell responses. This vaccine protected 50 per cent of volunteers challenged within 2 to 3 weeks of their last immunization, but after 6 months, only one in five was protected. Field trials in The Gambia showed an overall efficacy against infection during the whole surveillance period of 34 per cent (95 per cent confidence interval (CI), 8.0–53 per cent; $p = 0.014$). Efficacy was 71 per cent (46–85 per cent) during the first 9 weeks but there was no protection after that. A single booster vaccination led to similar protection during the next malaria season (efficacy, 47 per cent (3.8–71 per cent); $p = 0.037$). Protection correlated with a short-lived vaccine peptide-specific CD4+ T-cell response. It is hoped to improve this vaccine by modifying the adjuvant, by boosting with a vaccinia recombinant circumsporozoite protein, and by the addition of a blood-stage (MSP-1) antigen. Trials in Gambian children are underway.

Heterologous prime–boost immunization

AVS Hill and his colleagues have pioneered the strategy of priming with a DNA-based vaccine and boosting with a recombinant poxvirus. This is particularly effective in inducing CD8+ cytotoxic T lymphocytes and in enhancing TH1-type CD4+ T-cell responses, both of which are associated with protection. The DNA vaccine encodes a number of sporozoite epitopes together with the entire thrombospondin-related adhesion protein (**TRAP**), while the poxvirus recombinant consists of a highly attenuated vaccinia virus strain (Modified Vaccinia [Virus] Ankara, **MVA**)—which does not replicate in mammalian cells—containing the same malaria insert. Phase I and II studies in Oxford and The Gambia have confirmed the safety and immunogenicity of the regime and challenge studies are in progress. An even more promising regimen, based on mouse studies, consists of priming with a Fowlpox (Avipox FP9) recombinant, and boosting with the MVA recombinant.

7.13.3 Babesia

P. Brasseur

Babesia are intraerythrocytic, tick-transmitted, protozoan parasites that infect a broad variety of wild and domestic animals including cattle, horses, dogs, and rodents. Human babesial infection may occur occasionally.

Epidemiology

Two species of *Babesia*, *B. microti* and *B. divergens*, are responsible for most human cases. More than 200 cases of *B. microti* infections have been reported since 1966 along the north-east coast of the United States, especially in Massachusetts including Nantucket Island, Martha's Vineyard, and Cape Cod. *B. microti* is transmitted by *Ixodes dammini* and the reservoir host of parasites is the common white-footed mouse, *Peromyscus leucopus*. The zoonotic *Borrelia burgdorferi* causing Lyme disease is also transmitted by *I. dammini*; coinfections are documented among residents of coastal New England, where the risk of both babesiosis and Lyme disease is highest in June when nymphal *I. dammini* are most abundant. *B. microti* babesiosis may occur in people with intact spleens as well as in asplenic subjects.

After the first description of a case in 1957, 28 additional cases have been documented in Europe. Seventy six per cent of cases were due to *B. divergens*, a common cattle pathogen transmitted by *Ixodes ricinus* and responsible for economic losses, by reducing weight gains and milk production. France, the British Isles, and Ireland account for more than 50 per cent of European cases. They usually occur between May and October, the season of activity of tick vectors such as *I. ricinus*, which often seems to be responsible for human transmission. Most patients were residents of rural areas such as farmers and foresters, or visitors such as campers and hikers. Splenectomized people are at highest risk, comprising 24 out of 29 patients with babesiosis including all 22 *B. divergens* cases. Although no transfusion-associated case has been reported in Europe, this route of transmission is possible because *B. divergens* survives in packed red blood cells for several weeks at 4°C. No case has been recorded among HIV-infected patients.

Pathogenesis

Ticks infected with *Babesia* inoculate parasites while feeding on a vertebrate, the parasites enter red blood cells directly and multiply by budding to form two or four parasites, rarely more, in about 8 to 10 h. These are released and will invade other erythrocytes. The spleen plays a major role in resistance to babesial infections, especially for *B. divergens* babesiosis.

Clinical features

Human *B. microti* babesiosis is characterized by a gradual onset of malaise, anorexia, and fatigue with subsequent development of fever, drenching sweats, and generalized myalgia appearing 1 to 4 weeks after a tick bite. Other clinical manifestations such as headache, shaking chills, nausea, depression, and hyperaesthesia have been observed less frequently. The only finding on clinical examination is occasional mild hepatosplenomegaly. Anaemia, thrombocytopenia, and generally a low or normal white blood cell count is observed. A mild to severe haemolytic anaemia is frequent. Lactate dehydrogenase, liver enzymes, and bilirubin levels may be increased. Parasites are found in the peripheral blood of 1 to 20 per cent of patients with intact spleens, but in up to 80 per cent of asplenic patients. Most patients infected with *B. microti* have no history of splenectomy, but splenectomized patients generally have a more severe illness. Babesiosis is more severe in people over 40 years old and in HIV-infected patients. The acute illness lasts from 1 to 4 weeks, but weakness and malaise often persist for several months. A low and asymptomatic parasitaemia may persist several weeks after recovery.

In Europe, babesial infections are usually more severe (in 76 per cent of cases, with 38 per cent mortality) than in North America. After an incubation period of 1 to 3 weeks, severe intravascular haemolysis begins suddenly, causing haemoglobinuria, severe anaemia, and jaundice, associated with non-periodic high fever (40 to 41°C), hypotension, shaking chills, intense sweats, headache, myalgia, lumbar pain, abdominal pain, vomiting, and diarrhoea (Plate 1). Peripheral blood *B. divergens* parasitaemia may vary from 5 to 80 per cent. Patients rapidly develop renal failure which may be associated with pulmonary oedema, coma, and death. In severe cases, haemoglobin falls to 7 to 8 g/dl, sometimes to 4 g/dl, in spite of blood transfusions. Plasma haemoglobin levels may exceed 4 g/dl, haptoglobin decreases dramatically, and bilirubin and liver enzymes are markedly elevated.

Diagnosis

Babesiosis should be suspected in any patient with fever and a history of tick bite from any area. Initially, *Plasmodium falciparum* infection may be suspected, but splenectomy, lack of recent travel to a malaria-endemic area, or blood transfusion should lead to suspicion of babesiosis. Diagnosis is based on discovery of parasites in Giemsa-stained thin blood smears. Although the variable morphology of the parasites may be confusing, *Babesia* species can be distinguished from malaria parasites by the absence of gametocytes and pigment in erythrocytes containing mature stages.

B. microti is characterized by multiple basket-shaped parasites. In some cases, parasitaemia is sparse and inoculation of patient's blood into hamsters may facilitate diagnosis. This method may detect parasitaemias as low as 300 parasites/ml. Amplification by polymerase chain reaction using species-specific primers may establish the diagnosis in 24 h with high specificity and sensitivity.

B. divergens infection is suspected if there are symptoms of intravascular haemolysis and renal failure. The presence of double piriform intraerythrocytic parasites or tetrads is typical of *B. divergens*, but annular, punctiform, and filamentous forms may also be encountered. Inoculation of infected blood in gerbils (*Meriones unguiculatus*) may confirm the diagnosis. Serological tests may be useful especially in *B. microti* infections, but correlation between antibody titres and severity is poor. Using an indirect immunofluorescent test, antibody titres rise during the first weeks and fall after 6 months. Serology is not used for rapid diagnosis of *B. divergens* infection.

Treatment and prevention

Chloroquine, sulphadiazine, pyrimethamine, co-trimoxazole, pentamidine, and berenil (diminazene aceturate) appear ineffective in completely eliminating *B. microti*. A combination of quinine and clindamycin is effective except in immunocompromised individuals, especially those with HIV. Quinine should be given orally in doses of 650 mg every 6 to 8 h daily and clindamycin intravenously at 1200 to 2400 mg in three or four divided doses daily for at least 7 to 10 days. In fulminating infection, exchange transfusion is recommended.

In Europe, babesiosis should be treated as a medical emergency. Immediate chemotherapy should reduce parasitaemia and prevent extensive haemolysis. Exchange transfusion should be considered at the first sign of *B. divergens* infection. Massive exchange transfusion (2 to 3 total blood volumes) followed by administration of intravenous clindamycin at a dose of 600 mg four times daily for at least 10 days has proved successful. Imidocarb, which is used to treat babesiosis in cattle, has been used successfully in two patients in Ireland, although this drug has not been approved for human use. Atovaquone is active *in vitro* and in gerbils, but has not yet been used in human *B. divergens* infections.

7.13.4 Toxoplasmosis

J. Couvreur and Ph. Thulliez

Parasitology, epidemiology, transmission

Toxoplasma gondii is a ubiquitous coccidian parasite. Its definitive host is the cat. It exists in three forms: (i) the oocyst, which is excreted with the cat faeces, can remain viable for months in the soil under certain conditions of temperature and humidity; (ii) the tachyzoite, which multiplies intracellularly (Fig. 1); and (iii) cysts, the result of this intracellular multiplication, which can persist as viable parasites in the brain and striated muscles throughout the life of the host.

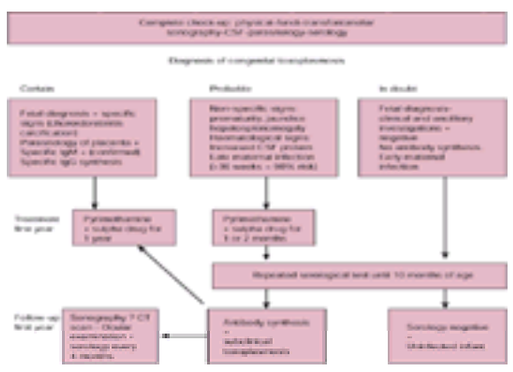

Fig. 1 Algorithm for neonates at risk of toxoplasmic fetopathy (mother infected during pregnancy).

The prevalence of toxoplasma antibodies is high in most populations. It depends mostly upon eating habits. Prevalence is well defined in fertile women—for instance 72 per cent seropositivity in Paris, 36 per cent in Stuttgart, 54 per cent in Padua, and 21 per cent in London.

Toxoplasmosis is usually acquired by ingestion of cysts. There are four stages: acute, subacute, chronic, and relapses. Organisms spread from the gut by lymphatics and the bloodstream, reaching every organ, where they multiply intracellularly (acute stage). Termination of this stage depends upon the development of both cellular and humoral immunity. In immunocompetent hosts, the parasite encysts and will persist without any inflammatory process as long as the cysts are not disrupted (chronic stage). If the host is or becomes immunocompromised, there is a tendency for the cysts to release bradyzoites and toxoplasma becomes an opportunistic agent. Congenital infection occurs through transplacental transmission of tachyzoites when a previously uninfected woman is infected during pregnancy.

Acute acquired toxoplasmosis

Acquired toxoplasmosis is usually subclinical. The typical presentation is lymphadenopathy affecting posterior cervical, suboccipital, retroauricular, or submental nodes. Supraclavicular, axillary, pectoral, epitrochlear, and inguinal localizations are less frequent. Lymphadenopathy is usually localized but it can be generalized. Nodes can be painful and tender for 1 or 2 weeks. They are rarely larger than walnuts, smooth, well defined, and mobile. They never suppurate; they can persist for months and even a year. Mesenteric lymphadenopathy has been observed. Other clinical signs and symptoms are fatigue for several weeks, headache, myalgias, low-grade fever for one or several weeks, and rarely, a transient rash. Ocular involvement can be observed. Hepatomegaly and splenomegaly are rare. Neurological signs and myocarditis are exceptional in immunocompetent patients.

The blood count shows a relative neutropenia with lymphocytosis. Atypical lymphocytes indistinguishable from those of infectious mononucleosis may be seen. Inversion of the CD4/CD8 ratio has been noted more often in clinical than in subclinical toxoplasmosis. Features suggesting toxoplasmosis rather than infectious mononucleosis are absence of pharyngitis, oral petechias, and splenomegaly and a less marked but more persistent lymphadenopathy. The histological pattern is characteristic when there are groups of epithelioid cells scattered throughout the node, or immature sinus histiocytosis and follicular hyperplasia with phagocytosis and nuclear debris. Inflammatory infiltrates sometimes extend into perinodal tissues and may be misinterpreted as lymphangioma, lymphoma, or sarcoidosis.

Toxoplasmosis of the central nervous system

In acquired toxoplasmosis, central nervous system involvement is observed most commonly in the immunodeficient patient. The selectivity of toxoplasma for brain tissue has been ascribed to low local immunity. In animal experiments, tachyzoites are demonstrable in brain 5 days after intraperitoneal inoculation, with ensuing perivascular inflammation with mononuclear cells. Tachyzoite-infected cells provoke multiple foci of micronecrosis. Mononuclear cells gather into microglial nodules associated with toxoplasma antigen. Cysts appear away from the inflammatory process. Intermediate appearances are observed between disseminated foci of microglial nodules, more or less numerous large necrotic areas, and large space-occupying masses.

Clinical features of central nervous damage are protean and may develop insidiously: generalized encephalitis with meningeal involvement and localizing signs with fever, headache, drowsiness progressing into coma, and death within a few days or weeks; encephalitis with low-grade meningeal involvement; 'pseudotumour cerebri' syndrome with transient intracranial hypertension; space-occupying mass mimicking a tumour or a brain abscess; multiple mass lesions; miscellaneous patterns—confusion, psychiatric features, seizures, and signs of brainstem or spinal cord injury. The above patterns can progress to death fulminantly within 2 weeks or persist for months or even years with or without therapy (chronic relapsing encephalitis).

The diagnosis of toxoplasmosis of the nervous system is often difficult. Clinical signs and results of imaging are not specific and can be misleading. Serological data are often perplexing. Biopsy is advocated whenever the diagnosis is uncertain. It is mandatory to look for an underlying disease or an immunodeficiency.

Ocular toxoplasmosis

Toxoplasma infection is the most common cause of retinochoroiditis and posterior uveitis. The focal necrotizing retinitis in its acute or subacute stage appears as cottonwool-like patchy areas of the fundus with vitreous exudate. The lesion heals within 3 to 6 weeks leaving a punched-out scar with central atrophy and a peripheral black pigmentation. The lesion can be peripheral or central, single or multiple. It may reach the size of the optic disc. Atypical presentations include retinal

detachment, haemorrhage, and optic nerve injury.

The natural history of ocular toxoplasmosis suggests that the first retinal lesion occurs more commonly during the subacute stage, weeks or months after the begining of the infection, than later during the chronic stage of the infection. It results from a previous colonization of the retina. The immediate cause is the rupture of a cyst. Its mechanism involves delayed sensitivity to toxoplasma antigens, and secondary proliferation of parasites.

Congenital toxoplasmosis is currently considered the major cause of ocular toxoplasmosis. Ninety per cent of retinochoroiditis discovered in infants and young children, and at least 20 per cent in adults, is attributable to congenital toxoplasmosis. It can be seen at birth or may occur much later, even in a previously normal retina, as is the case for 35 to 85 per cent of children with untreated congenital toxoplasmosis. There is a peak frequency of new lesions during puberty and adolescence. The common presenting signs are amblyopia or strabismus. There is some evidence that early treatment of even subclinical congenital toxoplasmosis decreases this risk. Ocular disease can complicate acquired toxoplasmosis more often than was previously considered. It can occur early following the acute stage of the infection, or after 2 years or more in one-third of cases. It is unilateral, with relapses in one-third of cases. It is generally isolated, being associated with neurological signs in no more than 10 per cent of cases, and most often without underlying immunodeficiency.

The diagnosis of ocular toxoplasmosis cannot be based on fundoscopic examination alone. The fact that it occurs mainly during the chronic stage of the infection while the antibody titre is low is a major problem. This can be solved by the demonstration of a local synthesis of antibodies in the aqueous humour.

Toxoplasmosis and immunodeficiency

Any patient with severe toxoplasmosis should be investigated for an immune defect, even subtle, and for an underlying disease, particularly AIDS. Conversely an immunodeficiency, either spontaneous or iatrogenic, can be complicated by severe toxoplasmosis. The last is generally related to chronic infection. The long persistence of cysts, particularly in brain, striated muscles, and myocardium is a well documented fact. In animals with chronic infection, corticoids, irradiation, or immunodeficiency can induce cyst rupture and proliferation of toxoplasma in the nervous tissue.

Among malignancies, the most common condition associated with cerebral toxoplasmosis is Hodgkin's disesase and less often lymphoproliferative disorders such as lymphosarcoma, non-Hodgkin's lymphoma, and angioimmunoblastic lymphadenopathy. All types of leukaemia are involved.

Severe toxoplasmosis can occur in organ transplant recipients. It is rare in renal, liver, and bone marrow transplantations but is more frequent in heart and heart–lung transplantations in which the risk can reach 57 per cent in mismatched transplantations of a serologically positive donor and negative recipient. This risk is mainly related to the infected heart-tissue transplant. It is increased by the use of steroids for graft rejection. Conversely, cyclosporin has an antiparasitic activity. The risk is reduced by antiparasitic treatment in all recipients.

Severe toxoplasmosis of the central nervous system, lungs, and heart appeared as a major problem in patients with AIDS. Toxoplasma encephalitis was observed in 25 to 80 per cent of patients with signs of cerebral injury. The risk of such an encephalitis was 6 to 12 per cent in toxoplasma seropositive patients and it was definitely increased by several factors: late stage of the disease; the presence of antibodies, particularly if the IgG titre was more than 150 IU; and a CD4 lymphocyte count of less than 200 per m. The risk of cerebral toxoplasmosis has been markedly reduced by the administration of co-trimoxazole for prevention of pneumocystis in these patients.

It is often difficult to prove that clinical manifestations encountered in immunocompromised patients are attributable to toxoplasmosis. Antibody titres may not be significantly elevated. Attempts to isolate toxoplasma from cerebrospinal fluid, from myocardial or cerebral biopsies, or from bronchoalveolar lavage may be necessary.

Congenital toxoplasmosis

Maternofetal transmission

Following seroconversion during pregnancy, 31 per cent of infants are infected, 2 per cent suffer intrauterine death, but 67 per cent are uninfected. These overall data vary according to the date of maternal infection: before pregnancy, 0 per cent; during the first month, 1 per cent; during the second and third month, 17 per cent; from the fourth to the sixth month, 45 per cent as an average; and later an increased risk up to 80 per cent during the ninth month. The date of the maternal infection is also important for the clinical pattern of the fetopathy: 83 per cent of the fetuses infected during the first trimester have clinical involvement, often severe, while clinical signs, mostly mild and ocular, are seen in only 12 per cent of the infants whose mothers were infected during the ninth month. The risk of fetopathy is reduced by more than 50 per cent if spiramycin is given to the mother. Very rare cases of transmission following chronic infection even years before pregnancy have been observed in immunocompromised mothers.

The placenta is the transmitting organ and placental infection is synonymous with fetopathy. If maternofetal transmission occurs early after maternal infection, fetopathy will be severe. If it is delayed, the fetus will be protected by passively transmitted maternal antibodies and toxoplasma will have a tendency to encyst in fetal tissues without causing serious early injury. Serological and clinical progression may thus be delayed for months after birth.

Clinical patterns

Five patterns can be identified in the protean presentation of congenital toxoplasmosis.

1. Systemic disease of the newborn baby with rash, jaundice, thrombocytopenic purpura, hepatosplenomegaly, pneumonia, progressive uveitis, high protein content of cerebrospinal fluid, cerebral ventricular dilation, and encephalomyelitis.
2. Neurological disease: hydrocephalus or microcephaly, microphthalmia, retinochoroiditis, and cerebral calcification. Hydrocephaly, always related to a stenosis of the duct of Sylvius, can be discovered *in utero* or several months after birth as well as in an infant initially considered as normal. Shunting is required.
3. Mild disease with isolated retinochoroiditis or mild cerebral calcification without any clinical signs of cerebral injury.
4. Subclinical infection. Prospective studies of women with acquired infection during pregnancy revealed that this is the most common pattern encountered in more than 70 per cent of the infected babies. The differentiation between subclinical toxoplasmosis and absence of infection is a common challenge for the paediatrician.
5. Relapses: flare-ups of retinochoroiditis can occur in infants, children, adolescents, or adults even in a previously intact retina in up to 85 per cent of cases (see Ocular toxoplasmosis). The possibility of late relapses in cerebral tissue is confirmed by the frequency of increased local synthesis of antibodies in the cerebrospinal fluid (see Laboratory diagnosis). Complete work-up, particularly examination of the cerebrospinal fluid is mandatory in any form of congenital toxoplasmosis even when subclinical.

Laboratory diagnosis

Serological methods are the main tools for diagnosis, but in the fetus and the immunocompromised patient the demonstration of parasites in body fluids and tissues is the preferred method of diagnosis.

Serology

In a non-immune pregnant woman who is tested repeatedly throughout pregnancy, seroconversion definitely proves the acquisition of infection. In the absence of seroconversion, the diagnosis of recent infection requires the demonstration of a significant rise of IgG antibody titre and the presence of IgM in serial samples obtained at 3-week intervals and tested in parallel. A stable IgG titre is consistent with an infection acquired at least 2 months before the first specimen was obtained. Since IgM antibodies may be detected for over a year after the infection, the use of complementary methods, based on acute-phase IgG antibodies, is necessary to rule out a recent infection, particularly in women who are evaluated late in pregnancy. The differential AC/HS agglutination test and the measurement of IgG avidity in enzyme immunoassay are suitable for this purpose.

In the newborn baby, the detection of specific IgM after 2 days of life or of specific IgA after 10 days is diagnostic of congenital infection. Synthesis of anti-toxoplasma

IgG antibodies can be demonstrated by comparing the ratio: specific IgG titre/total IgG on monthly serial samples. In the absence of infection, this ratio decreases as the infant produces IgG that does not contain toxoplasma-specific antibodies. If the ratio remains the same or increases, the diagnosis is proved. Synthesis of specific IgG, IgM, or IgA can also be demonstrated by immunoblotting or by using enzymze-linked immunofiltration assay. In some cases, the only marker of congenital infection is production of specific IgG which may be delayed for several months. Consequently, in infants born to women infected during pregnancy, serological tests must be repeated until specific IgG disappears within the first 12 months of life, before ruling out a congenital infection.

In HIV-infected patients, tests for determination of specific antibodies must be sensitive enough to avoid underdiagnosing a latent infection which should be considered for specific prophylaxis.

Intrathecal or intraocular production of specific antibodies can be determined by comparing the ratio of specific to total IgG in cerebrospinal fluid or aqueous humour with that of serum. A coefficient higher than 3 is considered positive.

Detection of *Toxoplasma gondii*

Parasites can be isolated from tissues or biological fluids by inoculation into mice or into cell cultures. Isolation from blood or cerebrospinal fluid indicates the presence of an acute infection. Conversely, positive isolation from muscle after enzymatic digestion, from brain, or from heart tissues is possible in old, chronic infections and does not prove a recent or progressing infection. Positive isolation from the placenta is indicative of congenital infection.

Polymerase chain reaction can be used to detect toxoplasma DNA in various clinical samples. It has proved reliable for diagnosis in immunocompromised patients. It is the method of choice for prenatal diagnosis of congenital infection on a single sample of amniotic fluid. The method is rapid and specific provided that carry-over contamination of the samples and contamination risks associated with handling steps are avoided. This is the most sensitive diagnostic method although all congenital infections cannot be identified prenatally because a delayed transmission of toxoplasma from the placenta to the fetus may occur after the date of the amniocentesis.

Treatment

Drugs

The combination of pyrimethamine and sulpha drugs is the mainstay of treatment. Pyrimethamine is given orally in a daily dose of 1 mg/kg or 50 mg in adults. The dosage of sulphadiazine, the sulpha drug currently used, is 50 to 100 mg/kg per day in infants, up to 2 to 6 g in adults in two to four divided doses. It is necessary to monitor weekly the antiparasitic treatment with blood counts because of the risk of bone marrow depression resulting in leucopenia with pyrimethamine or leucopenia and granulopenia with sulphadiazine. Folinic acid at a dose of 50 mg by oral or intramuscular route every 3 to 6 days can prevent the pyrimethamine side-effects.

The combination of 25 mg of pyrimethamine and 500 mg of sulphadoxine (Fansidar) may be given orally in a dose of one tablet per 20 kg every 7 to 10 days for months. Other drugs of interest are atovaquone, co-trimoxazole, or macrolides—spiramycin given in a daily oral dose of 3 g to infected pregnant women to prevent maternofetal transmission of the parasite or clarithromycin, clindamycin, and azithromycin in various combinations.

Indications

Acquired toxoplasmosis

Indications for treatment are marked systemic symptoms, and evidence of organ involvement. The pyrimethamine–sulphadiazine combination can be given for one or several weeks according to the clinical pattern.

Immunocompetent pregnant women

Seroconverters are given spiramycin throughout pregnancy. A positive *in utero* diagnosis of fetopathy warrants pyrimethamine–sulphadiazine treatment with written consent. Serial ultrasound examination of the fetus is mandatory to detect cerebral involvement as a guide to elective termination.

Congenital toxoplasmosis

Any case, even if subclinical, must be treated to control active disease and/or to prevent the risk of secondary retinochoroiditis. The combination pyrimethamine–sulphadiazine is given daily for 3 to 6 months according to the clinical data, followed by treatment three times a week until 1 year of age.

Cerebral toxoplasmosis in AIDS

In the acute stage of infection, the regimen of choice is 50 mg of pyrimethamine, 6 to 8 g sulphadiazine, and 20 mg folinic acid per day for 3 to 6 weeks. Maintenance therapy is necessary throughout life. The risk of toxoplasma encephalitis is markedly reduced by routine administration of co-trimoxazole.

Ocular toxoplasmosis

A flare-up requires emergency treatment with pyrimethamine–sulphadiazine together with steroids. The pyrimethamine–sulphadoxine combination can then be given for 6, 12, or more months if there is a tendency for repeated relapses.

Prevention

Any patient at risk should avoid contact with cats, as their faeces is potentially infectious (litter, soil, garden sand pits, vegetables), and eat meat that is well cooked or preserved by deep freeze.

7.13.5 Cryptosporidium and cryptosporidiosis

D. P. Casemore and D. A. Warrell

Introduction

The cryptosporidia are obligate intracellular parasites of which primarily one species, *Cryptosporidium parvum*, is associated with infection in man, young livestock, and other mammalian species. First described in laboratory mice, by Tyzzer in 1912, *C. parvum* was first recognized as a cause of human infection in 1976. In the 1980s it emerged worldwide as a common cause of severe or life-threatening infection in severely immunocompromised patients, especially those with AIDS, and of acute, self-limiting gastroenteritis in otherwise healthy subjects, especially children.

Biology

Cryptosporidium spp. are members of the coccidia (phylum Apicomplexa) with oocysts that contain four sporozoites. The oocysts, an environmentally robust transmissible stage, are fully sporulated and infective when excreted. Cryptosporidia are monoxenous, that is, they complete their lifecycle in a single individual (Fig. 1). *C. parvum* is not tissue specific but shows a predilection for the lower ileum during the primary stages of infection.

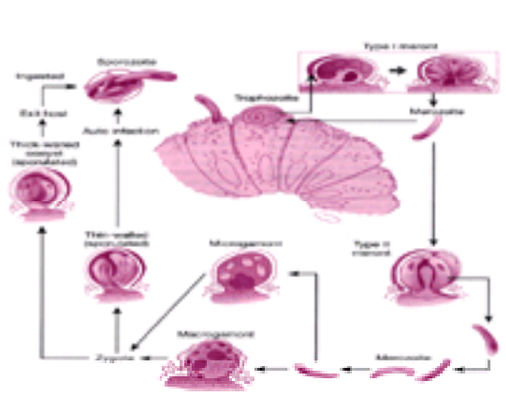

Fig. 1 Diagrammatic representation of the lifecycle of *C. parvum*. Following ingestion, the motile sporozoites are released, attach to cells, and develop into fixed trophozoites (uninucleate meronts) in an intracellular but extracytoplasmic location. These undergo schizogony (asexual multiple budding), the first-stage meronts producing eight merozoites, some of which recycle to form further type I meronts. Type II meronts produce four merozoites, which form gamonts (sexual stages) that mature as either macrogametes, or as microgamonts containing 16 motile microgametes. Most of the zygotes formed after fertilization develop into thick-walled, environmentally resistant, transmissible oocysts, which then sporulate, usually by the time they are excreted. Some have only a thin unit membrane, which ruptures to release the sporozoites *in situ* to produce an autoinfective cycle. (Adapted from a drawing by Kip Carter, University of Georgia, and shown by courtesy of Dr W.I. Current and CRC Press, Inc., Boca Raton.)

Following ingestion of oocysts, the motile sporozoites are released, through a suture in the oocyst wall, in the lumen of the small bowel. They quickly attach superficially to cells, rounding up to form fixed trophozoites (meronts). The initial site of infection is the brush border of enterocytes in the small bowel, but the parasite is able to infect other epithelial and parenchymal cells. The complex lifecycle includes both asexual and sexual stages of replication (Fig. 1 and Fig. 2). The endogenous (tissue) stages develop within a parasitophorous vacuole, the outer layer of which is derived from the host cell's outer membranes, in a unique intracellular but extracytoplasmic location.

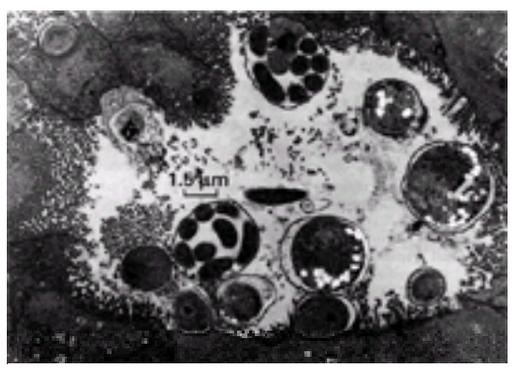

Fig. 2 Electron micrograph of a transverse section of small bowel of a mouse infected with *C. parvum*. The section shows numerous developmental stages: uninucleate meronts (trophozoites); type I meronts (schizonts) containing merozoites in which may be seen the darker granules of the apical complex organelles; the degenerate remains of a schizont and a free-swimming merozoite within the lumen; macrogamonts showing dark wall-forming granules and electron-lucent amylopectin (polysaccharide) food-storage granules. The parasitophorous vacuole can be clearly seen surrounding the parasite stages. Some of the intracellular

stages appear to be free within the lumen because of the plane of sectioning.

Molecular biology

Various genes and sequences have been studied and some have been cloned; chromosomes have been identified. Sequences coding for structural proteins such as actin and tubulin involved in parasite motility and attachment have been identified and may prove useful targets for the development of anticryptosporidial compounds. Nucleic acid sequences have differentiated recognized species and isolates within species, while some of the genotypes found may represent cryptic species. Differences between isolates of *C. parvum* from various sources show that those derived from animal hosts (genotype 2 or C) may, as expected, also be found in humans, but some isolates from humans appear to be relatively specific for humans (genotype 1 or H). Several other less common genotypes have been described, including from cats and dogs, the latter also having been found in a few immunocompromised humans. These findings have considerable public health significance and may also account for some of the variable responses seen in trials of specific anticryptosporidial therapy. Sensitive, genetically based probes are being applied to the detection of the parasite in clinical and environmental samples.

Epidemiology

C. parvum occurs worldwide and is common in humans and in livestock animals, especially lambs and calves, and has been reported from goats, horses, pigs, and farmed deer, as well as in mammalian wildlife. Prevalence in humans varies both geographically and temporally. Because of the diversity of host species, the epidemiology of the human infection is complex and involves both direct and indirect routes of transmission from animals to man (zoonotic transmission) and from person to person ('urban' cycle).

Direct zoonotic infection

Transmission from livestock is common, particularly in children, including those from urban homes and schools visiting educational farms and rural activity centres. Household pets are an infrequent source of infection in otherwise healthy subjects. Cryptosporidiosis is rarely seen in adults in rural areas, presumably as a result of frequent exposure and the development of immunity.

Urban transmission

Infection is common in children attending playgroups and day-care centres and outbreaks have been reported in the United Kingdom and the United States. This results mainly from direct (person-to-person) faecal–oral transmission, although the infection may be introduced in the first instance through zoonotic contact. Affected adults may acquire infection from young children in the home or occupationally. Infection may be transmitted sexually where this involves faecal exposure. Cryptosporidium is a cause of travellers' diarrhoea although apparently not as frequently as is the case with giardia.

Waterborne infection

In the United Kingdom, the United States, and elsewhere, there have been numerous well-documented outbreaks resulting from contamination of public drinking-water supplies. Some have been associated with human-specific isolates and thus are likely to have been the result of contamination of the supply by human sewage. Other outbreaks have been associated with the zoonotic type, while isolates from endemic (sporadic) cases, some of which will be waterborne, fall into both categories. Oocysts have been demonstrated widely in both raw and treated water and legislation has been introduced in the United Kingdom in an attempt to limit the latter.

Cryptosporidiosis associated with swimming pools has been reported from several countries, including the United Kingdom, America, and Australia, resulting from accidental faecal contamination from bathers, and may also be acquired from recreational use of natural waters.

Foodborne infection

Foods associated with infection include unpasteurized milk, sausage meat, and salad. Isolation of oocysts from such foods is generally extremely difficult. In the United States infection has resulted from the consumption of fresh-pressed apple juice.

Nosocomial infection

Transmission has been reported between health-care staff and patients and between patients, particularly the immunocompromised. Large numbers of oocysts may be present in patients' stools and in vomit; transmission via fomites occurs although this route of transmission is limited by the susceptibility of oocysts to desiccation. Poor hand-washing practice has been identified as an important factor. In an outbreak with high mortality in a ward of immunocompromised patients in Denmark, transmission was probably by patients' hands via a ward ice-making machine.

Demography

Age and sex distribution

In the United Kingdom approximately two-thirds of *Cryptosporidium*-positive samples are from children 1 to 10 years of age, with a secondary peak in adults under 45 years; the infection is uncommon in infants less than 1 year old and in the elderly. Distribution appears to be the same in both sexes. A relative increase in adult cases is often seen in waterborne outbreaks. In developing countries, infection is common in infants less than 1 year old and asymptomatic infection is common in older subjects.

Temporal distribution

In the United Kingdom there are peaks in the spring and in the autumn, which do not necessarily both occur in any one locality, nor recur year by year, which coincide generally with lambing and calving. The zoonotic genotype is more prevalent in humans in the spring, some of which may result from secondary spread. Similar seasonal peaks are seen in patients with AIDS. The human-specific type shows some increase in frequency later in the year and this may be associated with foreign travel.

Frequency of occurrence

Laboratory rates of detection in non-immunocompromised subjects average about 2 per cent (range: less than 1 to 5 per cent) in developed countries and about 8 per cent in developing countries (range: 2 to 30 per cent), about fourth in the list of pathogens detected in stools submitted to the laboratory. In the United Kingdom about 5000 to 6000 confirmed cases are reported annually, somewhat less frequent generally than giardiasis. Among young children in the United Kingdom, cryptosporidiosis is more common than salmonella infection and during peak periods detection rates may exceed 20 per cent.

Cryptosporidiosis is one of the most common causes of diarrhoea in patients with AIDS and in some studies prevalence has exceeded 50 per cent. The infection rate in patients with AIDS in the United Kingdom has been falling in recent years, which has been attributed to infection control advice and the use of multiple antiretroviral therapy. Infection rates are not generally increased for most other immunocompromised groups.

Clinical aspects

Pathology

Histopathology

There is mucosal involvement of the small bowel, other parts of the gastrointestinal tract, and sometimes beyond. Moderate to severe abnormalities of villous architecture occur, with stunting and fusion of villi and lengthening of crypts. There may be evidence of mild inflammation, with some cellular infiltration into the lamina propria.

The endogenous stages of the parasite in the luminal surface are generally inconspicuous and appear as small (2 to 8 µm) bodies, apparently superficially attached to the brush border, unevenly distributed over the apical cells and within the crypts of the villi (Fig. 1 and Fig. 2). Peaking and apoptosis of infected cells have been reported. There is usually little intracellular change at the ultrastructural level beyond the attachment zone of the parasite. Rectal biopsy may reveal mild, non-specific proctitis. Extensive and chronic involvement of the bile duct and gallbladder is seen in some patients with AIDS.

Immunological response

The particular immunodeficient conditions in which cryptosporidiosis has been reported to show increased severity or persistence suggest that both humoral and cellular factors have a role in limiting infection. An immune response has been demonstrated in the main immunoglobulin classes, although the initial IgG response may be poor. Serological diagnostic tests are, however, of little clinical value. Seroprevalence studies indicate that the infection is common, even in developed countries, and this may reflect water supply quality or other exposures.

Reports differ on the effect of breast feeding on incidence in infancy; some studies suggest a protective effect although protection from the environment by breast feeding may also be important.

Although functioning humoral and cellular immunity seem to be important in limiting or controlling infection, it currently appears that, in animal models, CD4+ and CD8+ T lymphocytes and interferon-g are especially important in this respect. In humans, CD4 cell counts of fewer than 200 cells/mm ^{3} probably indicate the need to take special care to avoid exposure to *Cryptosporidium*, and fewer than 100 cells/mm^{3} indicates a poor prognosis if infection occurs.

Possible pathogenic mechanisms

The watery diarrhoea is characteristic of non-inflammatory infection of the small bowel, especially that associated with toxin-producing organisms and enteric viruses. Several mechanisms have been suggested to explain the symptoms: reduction in absorptive capacity, particularly for water and electrolytes; increase in secretory capacity from crypt hypertrophy; osmotic effects from loss of brush-border enzymes (e.g. disaccharidases) resulting in malabsorption of sugars, increased osmolality of chyme, and subsequent microbial fermentation of sugars in the colon (which may account for the characteristic offensive smell); toxic activity has been described.

Clinical presentation in otherwise healthy (immunocompetent) people

Cryptosporidiosis in the immunocompetent person is a self-limiting, acute gastroenteritis with a variety of presenting symptoms. In cases where the time of exposure has been known the incubation period was about 5 to 7 days (range probably 2 to 14 days; wider limits have been suggested but are unlikely). There may be a prodrome of one to a few days, with malaise, abdominal pain, nausea, and loss of appetite. Gastrointestinal symptoms start suddenly, the stools being described as watery, greenish with mucus in some cases, without blood or pus, and very offensive. Patients may open their bowels more than 20 times a day but more usually 3 to 6 times. Other symptoms include colicky, abdominal pain, especially after meals, anorexia, nausea and vomiting, abdominal distension, and marked weight loss. 'Flu-like' systemic effects, including malaise, headache, myalgias, and fever, commonly occur. Gastrointestinal symptoms usually last about 7 to 14 days, but weakness, lethargy, mild abdominal pain, and intermittent loose bowels sometimes persist for up to a further month.

There is no evidence of transplacental transmission but infection during late pregnancy may cause metabolic disturbances in the mother, leading to the infant's failure to thrive. Failure to thrive has also been observed in older infants and children, and may be associated with persistent infection and enteropathy, especially in underdeveloped countries.

Reported sequelae include pancreatitis (associated with severe abdominal pain), toxic megacolon, and reactive arthritis. In immunocompetent patients, deaths are rarely attributable to cryptosporidiosis.

Clinical presentation in immunocompromised patients

Susceptibility to cryptosporidiosis and the severity of the disease is increased in patients who are immunocompromised as a result of AIDS, hypo- or agammaglobulinaemia, severe combined immunodeficiency, leukaemia, malignant disease, and bullous pemphigoid. Disease susceptibility and severity are also increased during immunosuppressive treatment with cyclophosphamide and corticosteroids as in patients undergoing bone marrow transplantation, and in children immunosuppressed by measles and chickenpox, especially where there is associated malnutrition. Infection in patients with leukaemia may be unusually severe and has sometimes proved fatal, particularly when associated with aplastic crisis, and may then require modification of chemotherapy to control the infection.

Symptoms of cryptosporidiosis are generally similar but often develop insidiously in immunocompromised patients. In those with late-stage AIDS with very low CD4 cell counts, or in some other profound deficiency states, diarrhoea may be frequent, profuse, and watery, like cholera. Patients may open their bowels frequently, passing up to 20 litres of infected fluid stool per day; persistent nausea and vomiting is usually associated with severe diarrhoea and suggests a poor prognosis. Associated symptoms include colicky, abdominal pain often associated with meals, severe weight loss, weakness, malaise, anorexia, and low-grade fever. Cryptosporidial infection in immunocompromised patients may involve the pharynx, oesophagus, stomach, duodenum, jejunum, ileum, appendix, colon, rectum, gallbladder, bile duct, pancreatic duct, and the bronchial tree. Cryptosporidial cholecystitis (presenting with severe right upper-quadrant abdominal pain), sclerosing cholangitis, pancreatitis, hepatitis, and respiratory-tract symptoms may occur, with or without diarrhoea. The clinical picture may include other features of HIV infection and there is often coinfection with other pathogens such as cytomegalovirus, *Pneumocystis carinii*, and *Toxoplasma*.

Patients with less severe impairment of immunity may experience resolution or a more chronic course, with less profuse diarrhoea, sometimes with remission and then recurrence, possibly associated with biliary tract involvement. Except in those patients whose immune suppression can be relieved by stopping immunosuppressant drugs, or, in the case of HIV, intensifying antiretroviral therapy, severe symptoms may persist until the patient dies. This is either as a result of dehydration, acid–base or electrolyte disturbances, and cachexia, from some other opportunistic infection or malignant disease, or a combination of these.

Laboratory investigations

In early acute cases the stools are usually watery, greenish with mucus in some cases, without blood or pus.

Peripheral leucocytosis and eosinophilia are found rarely. Serum electrolyte abnormalities will develop in patients who become severely dehydrated. In immunocompromised patients with cryptosporidial cholecystitis, serum alkaline phosphatase and g-glutamyl transpeptidase levels are raised, while aminotransferases and bilirubin levels may remain normal.

In patients with AIDS, common associated infections are with cytomegalovirus and *Isospora belli*. Mixed infection with *Campylobacter* and *Giardia* species may be found in immunocompetent patients.

In the bowel mucosa there is histological evidence of enterocyte damage, villous blunting, and inflammatory-cell infiltration of the lamina propria; cell peaking and apoptosis have been reported. Histopathological appearances of the affected biliary tract resembles primary sclerosing cholangitis. Radiographic abnormalities include dilatation of the small bowel, mucosal thickening, prominent mucosal folds, and abnormal motility, and in the biliary system, dilated distal biliary ducts, stenosis with an irregular lumen, and other changes reminiscent of primary sclerosing cholangitis.

Differential diagnosis

The absence of blood, pus, cells, or Charcot–Leyden crystals may distinguish cryptosporidiosis from some acute bacterial diarrhoeas and that associated with amoebiasis and isosporiasis. In immunocompetent patients, the symptoms of cryptosporidiosis resemble those of giardiasis or cyclosporiasis. Intense abdominal pain and cramps are generally more common in cryptosporidiosis, but bloating and weakness less common. In immunocompromised patients, especially in those with AIDS, isosporiasis is clinically indistinguishable, but can be diagnosed by finding the organisms in the stool, when Charcot–Leyden crystals may also be found. This infection responds to treatment with trimethoprim and sulphamethoxazole, as does cyclosporiasis.

Treatment of cryptosporidiosis

In immunocompetent patients, the illness is self-limiting, but they may become dehydrated and require intravenous fluids, electrolytes, and symptomatic treatment for their vomiting and diarrhoea.

Immunocompromised patients with persistent severe diarrhoea, malabsorption, and other complications may require prolonged palliative treatment. They should avoid excess milk, as lactose intolerance may develop. Parenteral feeding and fluid, electrolyte, and nutrient replacement may be needed. Antiperistaltic agents such as loperamide, diphenoxylate, or opiates may increase abdominal pain and bloating. Antiemetics may be needed for symptomatic relief. Temporary relief of biliary obstruction has been achieved by endoscopic papillotomy and of cholecystitis by cholecystectomy. Diarrhoea and vomiting may, however, prove intractable.

Some reports suggest possible activity with letrazuril/diclazuril, somatostatin, azidothymidine, diloxanide furoate, furazolidone, amprolium, the macrolides, roxithromycin, and nitazoxanide. Paromomomycin has also been suggested as an active agent although a very recent report indicates that it is no more effective than placebo for cryptosporidiosis in patients with advanced HIV infection. Zydovudine (Retrovir™) therapy may result in remission or amelioration of symptoms, as may treatment of coinfecting agents. Separating the effect of the drugs on copathogens or of fluctuations in immune competence, both spontaneous and drug-induced, may be difficult. Immunotherapy (e.g. with bovine colostrum, hyperimmune immunoglobulin, transfer factor, and interleukin 2) has been attempted, with variable results.

Laboratory detection and diagnosis

The characteristic endogenous stages (Fig. 1 and Fig. 2) may be found in histological sections, using light and electron microscopy, but diagnosis is usually by detection of oocysts in stools. (Plate 1, Plate 2, Plate 3, Plate 4, Plate 5, Plate 6, Plate 7, Plate 8, Plate 9 and Plate 10) Oocysts have also been found in vomit and sputum in some cases, especially those associated with AIDS. The oocysts of *C. parvum* are spherical or slightly ovoid, about 4 to 6 µm, and appear refractile in wet faecal preparations with a highly refractile inner body, the cytoplasmic residuum; the four sporozoites within may be distinguished with difficulty using special optical systems. Several conventional stains have been adapted for diagnostic purposes, such as the modified Ziehl–Neelsen method and phenol–auramine fluorescent stain. Immunofluorescent antibody and enzyme immunoassay methods, using monoclonal antibodies, are commercially available but are expensive. Standardization of approach to screening and of reporting is essential for epidemiological purposes. Ideally, all stool samples from cases of diarrhoea should be screened; restriction, where unavoidable, should be based on age group (see demography) and not on factors such as stool consistency. Concentration of stool specimens is not usually required for diagnosis in acute cases.

Fungal spores, yeasts, cysts of *Balantidium*, sporocysts of *Isospora*, and oocysts of *Clyclspora* may readily be mistaken for cryptosporidial oocysts.

Infectivity, resistance, and control

Infectivity

In studies using monkeys and lambs, the infective dose for *C. parvum* was fewer than 10 oocysts. Human volunteer studies in the United States, initially with the zoonotic genotype, suggest the minimum infective dose varies from fewer than 10 oocysts to more than 1000, varying with the isolate. Symptomatic reinfection was achieved in some subjects despite the presence of antibody. Studies with the human-specific genotype are now in progress.

Resistance and disinfection

Oocysts can survive for many months in a cool, moist environment but are highly susceptible to desiccation, prolonged freezing, and moderate heat (pasteurization temperatures). They are remarkably resistant to most disinfectants and antiseptics, including chlorine at concentrations far greater than those used in water treatment and even to glutaraldehyde under normal use conditions. Some disinfectants may be more effective if used at elevated temperature (37°C or higher). Oocysts are sensitive to 10 volume (3 per cent) hydrogen peroxide, and to appropriate levels of ozone and medium or high-pressure ultraviolet. The adequate disinfection of instruments such as endoscopes is difficult and prolonged immersion in disinfectant, preferably at elevated temperature and after thorough cleaning, is recommended. Recent studies suggest that a high concentration (200 p.p.m.) of chlorine dioxide is effective.

Control of transmission

Primary control is by limiting the opportunity for faecal–oral transmission, both direct and indirect. Symptom-free subjects not in contact with immunocompromised patients can normally be permitted to work if their hygiene is scrupulous. Spread via fomites is possible but this route is limited by the susceptibility of oocysts to desiccation. Patients with AIDS may be more susceptible to infection with uncommon species or genotypes including those normally associated with cats, dogs, and birds and advice may be needed to limit exposure.

Contamination of water supplies is inevitable from time to time, even in developed countries, and may be the source of some sporadic cases as well as outbreaks. When a public advisory notice is issued to boil water, raising the water just to boiling point is sufficient. In general, bottled water and water from point-of-use filters are unlikely to contain parasites but may carry an increased bacterial load, the health significance of which is uncertain for the immunocompromised. Patients with AIDS and others who are profoundly compromised should be advised never to drink water that has not been boiled or filtered through a suitable device. Users of filters should remember that these devices may concentrate potential pathogens and care is needed in replacing and disposing of filter elements.

Hospitals involved in the care of profoundly immunocompromised patients should be particularly vigilant in the management of patients with cryptosporidiosis. Long-term arrangements should be made for the provision of safe water for the immunocompromised to avoid difficulties when a notice to boil water is issued.

7.13.6 Cyclospora

D. P. Casemore

Introduction

Cyclospora are coccidian or coccidian-like enteric parasites producing large, acid-fast oocysts (spore-like forms) initially recognized in faecal specimens examined by modified Ziehl–Neelsen stain for the detection of cryptosporidium. Isolates were first described variously as cryptosporidium-like bodies, fungal spores, and cyanobacteria (blue–green algae-like) associated with diarrhoeal illness. They have since been definitively identified as oocysts of a newly recognized protozoan parasite. They have been detected worldwide, most often in residents of, or travellers returning from, developing countries, and there is some evidence for foodborne and waterborne transmission.

Natural history

Cyclospora are apicomplexan protozoans which are widespread in nature but not previously described in man. Morphologically they resemble coccidia, but recent molecular evidence suggests that they may be more closely related to the *Eimeria*. They have a monoxenous life cycle similar to the cryptosporidia, with both sexual and asexual stages developing in the same host animal, resulting in the production of oocysts, the environmentally hardy transmissible stage. The species found in man, tentatively named *Cyclospora cayetanensis* new species, has an oocyst stage of about 8 to 10 µm in size which, when first excreted, unlike cryptosporidium, is unsporulated, with a characteristic morular inner structure (see below). During the extrinsic sporulation period, about 7 to 15 days depending on temperature, the oocysts develop two inner membrane-bound sporocysts, each containing two large sporozoites (1.2 × 9.0 µm). This species has not been found in other hosts, and experimental transmission to a variety of potential host species has been unsuccessful. It may thus, like many other species of coccidia, be restricted to a single host species. Oocysts of a morphologically similar cyclospora have been found in some primates but their precise identity is uncertain. Undefined cyclospora-like like bodies have been reported from dogs and some birds, although human isolates cannot be transmitted to these host species.

Epidemiology

Infection occurs in people of all ages; reported most commonly in young children from developing countries and among travellers to Nepal, Indonesia, Southern and Central America, and other underdeveloped areas, most of whom are adult. Sporadic cases have been identified in patients in the United States and the United Kingdom without a history of foreign travel. In recent years outbreaks have been identified in the United States associated with food consumption, particularly with raspberries imported from Guatemala, but also with some other fresh produce including mesclun (mixed lettuce leaves) and the herb basil. The precise mechanism of contamination is unclear, although contaminated water seems the most likely vehicle. The requirement for an extrinsic period of sporulation implies that transmission is likely to be indirect.

Clinical presentation

Enteric symptoms include watery diarrhoea, flatulence, bloating, dyspepsia, abdominal cramps, nausea, and vomiting: generalized symptoms include marked weight loss, malaise, and influenza-like symptoms. The infection tends to be protracted, lasting 14 days or more (range 1 to more than 60 days). Asymptomatic infection occurs in indigenous people in developing countries, probably reflecting endemicity and recurrent infection in the immune.

Diagnosis (Plate 1, Plate 2 and Plate 3)

Moderate numbers of oocysts are excreted in stools during the acute stage and variably thereafter; they can be detected by modified Ziehl–Neelsen staining, although the acid-fast staining is variable. The oocysts are 8 to 10 µm in size and have visible surface and internal structure. Phase contrast microscopy reveals the internal morula, a collection of refractile, membrane-bound spherical bodies, 1 to 2 µm in size, within an outer wall; fluorescence microscopy shows characteristic blue autofluorescence of oocysts. Stools stored at room temperature in 2.5 per cent potassium dichromate sporulate in about 7 to 15 days to show the two sporocysts; the sporozoites within cannot readily be seen.

The site of infection is primarily the small intestine. Endogenous stages may be detected intracellularly beneath the brush border of enterocytes in jejunal biopsy specimens, and possibly other tissues, by light and electron microscopy (Fig. 1). Histology shows altered mucosal architecture with shortening and widening of intestinal villi, diffuse oedema, mixed inflammatory cellular infiltrate, reactive hyperaemia with vascular dilatation, and capillary congestion. The parasite is found within a parasitophorous vacuole, midway between the nucleus and the cell membrane at the luminal side. Transmission electron microscopy reveals typical apicomplexan structures.

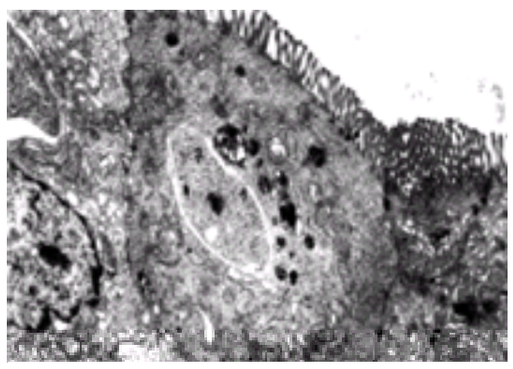

Fig. 1 Longitudinal section through jejunal biopsy specimen showing a single intracellular parasite by transmission electron microscopy. (© The Lancet Ltd and reproduced with permission from Bendall RP *et al. Lancet*, 1993; **341**: 590–2.)

Treatment

Cotrimoxazole (one tablet twice a day for 7 days) has proved to be effective in eradicating the infection.

Control

As the source of the parasite is currently unknown, specific recommendations to limit the reservoir cannot be made. Transmission is almost certainly primarily by an indirect faecal–oral route and hence can be limited by the usual hygienic precautions including avoidance of unboiled water, water-washed unpeeled fruit, salads,

uncooked vegetables, etc., in endemic areas. The parasite is difficult to remove from the surface interstices of fruit such as raspberries.

7.13.7 Sarcocystosis

V. Zaman

Humans can act as both the final and intermediate host of parasites belonging to the genus *Sarcocystis*. In their lifecycle there is an alternation of a sexual generation of the parasite in the intestinal tissues of a predator host (carnivores including snakes, omnivores, and scavenger animals) and an asexual generation in the tissues of a prey animal (herbivores and omnivores including rodents). The predator animals act as the final hosts and excrete oocysts or sporocysts in the faeces. The animal eaten by a predator acts as an intermediate host because cysts are present in the muscles and other tissues (Fig. 1).

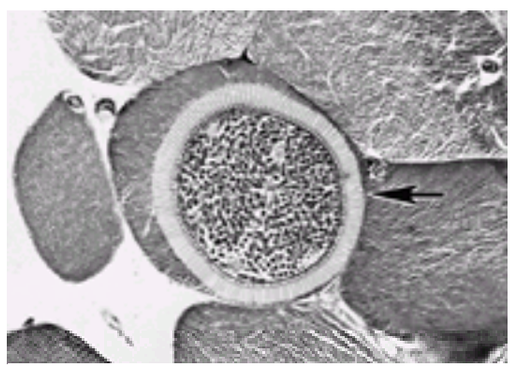

Fig. 1 Sarcocyst in muscle: the thickness of the cyst wall varies in different species; in this species a thick, striated wall is visible and the elongated structures inside the cyst are cystozoites (× 400).

Sarcocystis hominis (syn. *Isospora hominis*)

The intermediate host is cattle. Human infection results from eating uncooked beef. Prevalence in human populations is not known but the lifecycle has been studied in human volunteers.

Clinical aspects

Most patients who pass oocysts are asymptomatic and the development of the sporogonic stage in the human intestine is either non-pathogenic or only slightly pathogenic, resulting in mild gastrointestinal upset. However, the symptoms may vary, depending on the number of parasites ingested. Severe symptoms may occur after ingestion of heavily infected beef. This probably happened in six patients from Bangkok who developed symptoms suggestive of segmental necrotizing enteritis.

Diagnosis

This is based on the detection of oocysts or sporocysts in the faeces of infected individuals (Fig. 2). Sporocysts range in size from 13.6 to 16.4 µm by 8.3 to 10.6 µm. Occasionally, sporocysts may be seen attached in pairs and covered by a thin, transparent cyst wall (Fig. 3).

Fig. 2 *Sarcocystis hominis*: sporocyst with sporozoites; the residium (food store) can be seen at one end (× 1000).

Fig. 3 *Sarcocystis hominis*: sporocysts attached in a pair (× 1000).

Treatment

No chemotherapeutic agents are available. Prevention consists of not eating uncooked beef.

Sarcocystis suihominis

The lifecycle is similar to that of *S. hominis*, except that the intermediate host is the pig.

Clinical aspects

Human volunteers given infected tissues have experienced diarrhoea and mild fever.

As in the case of *S. hominis*, the intensity of symptoms probably varies with the size of the infective dose. If large amounts of heavily infected pork are ingested, symptoms could be quite severe. As this rarely happens, symptoms in most patients are mild or absent.

Diagnosis

This is based on the detection of oocysts or sporocysts in faeces; these are almost identical to those of *S. hominis*.

Treatment

No chemotherapeutic agents are available. Prevention consists of not eating raw pork.

Sarcocystis spp.

These produce sarcocystis in human muscles. There is probably more than one species involved. Infection is acquired by the ingestion of oocysts or sporocysts passed in the final hosts. The final hosts are unknown but could be carnivores, such as dogs or cats.

Clinical aspects

Most cases are asymptomatic. The infection is an incidental finding in muscle biopsies for other diseases or at autopsy. It appears that the cysts of some species are found only in skeletal muscles while others occur in cardiac and skeletal muscles. On the basis of morphology it is possible to differentiate the cysts into four types.

Diagnosis

In tissue sections, *Sarcocystis* can be diagnosed easily and it is generally not difficult to differentiate it from *Toxoplasma* tissue cysts. *Sarcocystis* has a distinct cyst wall and the cystozoites are larger. *Toxoplasma* cystozoites are positive to periodic acid-Schiff reagent, while *Sarcocystis* cystozoites are negative.

Treatment

None is available.

7.13.8 Giardiasis, balantidiasis, isosporiasis, and microsporidiosis

Martin F. Heyworth

Giardiasis

Aetiology

Giardia intestinalis (synonyms *Giardia lamblia* and *G. duodenalis*) colonizes the lumen of the small intestine. The parasite's lifecycle comprises two stages: motile trophozoites (Fig. 1) and thick-walled ellipsoidal cysts that are excreted in the faeces. *G. intestinalis* trophozoites are dorsoventrally flattened organisms with eight flagella, two nuclei, and a ventral adhesive disc that enables them to become attached to the luminal surface of intestinal epithelial cells. Trophozoites absorb nutrients in the small intestinal lumen and multiply in this anaerobic environment. New hosts become infected by ingesting *G. intestinalis* cysts; exposure of cysts to gastric acid leads to emergence of trophozoites from the cysts. Trophozoites encyst in the intestinal lumen, and the resulting cysts are excreted from the host.

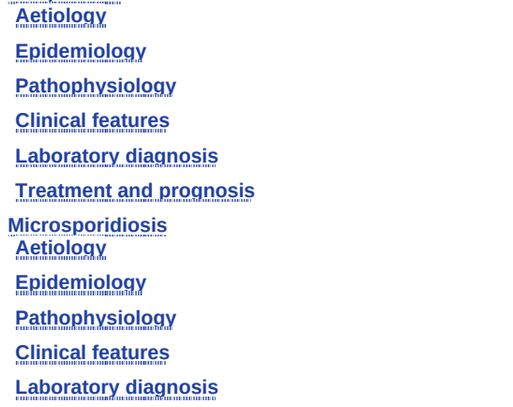

Fig. 1 Scanning electron micrograph of three *Giardia intestinalis* trophozoites on a jejunal biopsy specimen from a patient with giardiasis. The dorsal surfaces of two trophozoites are visible (D), and the ventral adhesive disc of the other trophozoite is shown (V). (Illustration by courtesy of Dr Robert L. Owen; modified from Carlson JR, Heyworth MF, Owen RL (1984). Giardiasis: Immunology, diagnosis and treatment. *Survey of Digestive Diseases* **2,** 210–23, S. Karger AG, Basel. Used by permission.)

Epidemiology

G. intestinalis infection is usually acquired by drinking water that contains cysts. Other modes of spread include direct faecal–oral transmission of cysts, as in day-care centres for small children, and occasional foodborne transmission of cysts. Waterborne giardiasis occurs as a result of drinking unfiltered, unboiled water from streams and lakes containing *G. intestinalis* cysts. Swimming in (and inadvertently drinking) such water is also a risk factor for giardiasis. Outbreaks of this infection have resulted from the unintended presence of *G. intestinalis* cysts in public water supplies.

Worldwide, many species of domestic, farm, and wild animal are hosts for *G. intestinalis*. Giardia cysts have been found in faecal specimens from cattle, sheep, horses, pigs, dogs, and cats. To what extent non-human mammals are sources of human giardiasis is, however, an unanswered question, which may be resolved by genotyping of giardia organisms isolated from various hosts.

Giardiasis occurs in temperate and tropical countries. Several genetically distinct, genetically stable, strains of *G. intestinalis* are known. Accordingly, some authors regard this species as a 'species complex', rather than a single species.

Immunodeficiency predisposes to the occurrence of severe and persistent giardiasis. Human immunodeficiency states that are associated with giardiasis include conditions that impair host antibody responses (notably, 'common variable' hypogammaglobulinaemia and X-linked immunoglobulin deficiency). Impairment of intestinal IgA production is a feature of these particular immunodeficiency diseases and may explain how they predispose to chronic giardiasis (via impaired production of antitrophozoite IgA). Some patients with common variable hypogammaglobulinaemia and chronic giardiasis have abnormally enlarged lymphoid follicles in the small intestine (nodular lymphoid hyperplasia), which contain numerous immature B lymphocytes that express IgM. These B lymphocytes appear to be developmentally arrested, such that they do not mature (as would normally be the case) into IgA-expressing B lymphocytes and IgA-secreting intestinal plasma cells.

Pathogenesis and pathophysiology

The mechanism(s) responsible for diarrhoea and malabsorption in giardiasis are not understood. In one study, the histological appearance of duodenal biopsies was reportedly normal (apart from the presence of trophozoites) in 96.3 per cent of patients with giardiasis (462/480 total patients); the other 3.7 per cent (18/480) had 'duodenitis' with 'mild villus shortening'. Shortening of microvilli on the luminal surface of intestinal epithelial cells has been observed in small intestinal biopsies from patients with giardiasis. Reduced activity of intestinal disaccharidases has been reported in giardia-infected human subjects and rodents. This functional enzyme deficiency could, conceivably, lead to osmotic diarrhoea (via the presence of undigested disaccharides in the intestinal lumen).

G. intestinalis trophozoites cultured in the presence of sodium glycocholate take up this bile salt from the culture medium. Uptake of bile salts by trophozoites in the intestinal lumen might, therefore, contribute to the fat malabsorption that occurs in some patients with giardiasis (by reducing the availability of bile salts for fat emulsification). In a study of neonatal rats infected with *G. intestinalis*, different strains of the parasite induced different degrees of small intestinal damage (as judged by alteration in villus length and in electrolyte absorption). This work raises the theoretical possibility that differences in severity of symptoms, among different patients with giardiasis, might reflect infection by distinct strains of *G. intestinalis* with different pathogenicities.

Study of immunity against giardia species has been more feasible in rodents than in human subjects. In mice, clearance of *Giardia muris* infection appears to be dependent on CD4+ (helper) T lymphocytes, and to follow the generation of an intestinal IgA response against the parasite. In human volunteers who were deliberately infected with *G. intestinalis*, a corresponding intestinal IgA response occurred. IgA directed against trophozoites binds to these organisms and may, conceivably, inhibit their attachment to the intestinal epithelium, such that they are susceptible to peristaltic expulsion from the host.

Clinical features

G. intestinalis infection can be asymptomatic (as shown by cyst excretion in the absence of symptoms), and can also cause various clinical problems. These include abdominal discomfort, tenderness, and distension, a sensation of 'fullness', nausea, anorexia, and watery diarrhoea. Other clinical features include 'heartburn', flatulence, steatorrhoea, and weight loss. In immunologically normal persons, untreated giardiasis typically lasts for several weeks, with symptoms that fluctuate in severity. Clinical sequelae that have occasionally been reported include megaloblastic anaemia resulting from impaired absorption of vitamin B_{12} or folic acid.

Laboratory diagnosis

In a patient suspected of having parasitic infection of the gastrointestinal tract (with one or more species of parasite that might include *G. intestinalis*), faecal light microscopy may be informative. If the patient has giardiasis, *G. intestinalis* cysts may be seen during this examination. Diagnostic sensitivity can be increased by immunofluorescence microscopy of faecal specimens incubated with a fluorescent monoclonal antibody directed against *G. intestinalis* cysts. If there is a strong suspicion of infection with *G. intestinalis*, in the absence of other species of gastrointestinal parasite (or if the aim is to check the effectiveness of treatment in clearing known giardiasis), immunoassay for *G. intestinalis* antigen(s) is the test of choice. This approach, which involves enzyme-linked immunoassay (**EIA**) of faecal specimen(s) with one of several commercially-available kits, is more objective and less labour intensive than immunofluorescence microscopy (which detects whole cysts). Various EIA kits for diagnosis of giardiasis have sensitivities in the range 88 to 100 per cent and specificities in the range 99 to 100 per cent. Commercially available EIA kits detect *G. intestinalis* cyst wall protein(s) in faecal specimens.

Immunocompetent persons with giardiasis develop serum antibodies against *G. intestinalis* trophozoites. Testing of human sera for such antibody is not useful for diagnosing current giardiasis in individual subjects, but can be informative in population studies examining the prevalence of this infection.

Treatment

Table 1 summarizes various drug regimens for treating giardiasis. Metronidazole resistance of *G. intestinalis* is an increasingly recognized problem.

Prevention

G. intestinalis cysts can be removed from water by filtration, for example using membrane filters with a pore diameter of less than 5 mm. Cysts in water are killed by boiling. Water intended for human consumption can be screened for *G. intestinalis* cysts by filtration, followed by immunofluorescence microscopy of particulate material retrieved on the filter(s), using a fluorescent anticyst monoclonal antibody. Experimental protocols for detecting giardia cysts in water, by amplification of giardia DNA using polymerase chain reaction (**PCR**), have also been described.

Controversies and future research

Efforts to confirm, or refute, the idea that intestinal antibody protects against giardia infections are justified. Studies with mice, kittens, and puppies have suggested that vaccination against giardia infections is feasible. Whether a vaccine against human giardiasis would have much practical utility, however, is an open question, even if it is biologically feasible to develop one. Interest has been expressed in sequencing the entire *G. intestinalis* genome.

Balantidiasis

Aetiology

This infection is caused by *Balantidium coli*, a ciliate protozoan that is the largest protozoan parasite of man. *B. coli* has a two-stage lifecycle comprising motile trophozoites that invade the colonic mucosa (Fig. 2) and non-motile cysts. Spread of the infection to new hosts occurs by ingestion of the parasite.

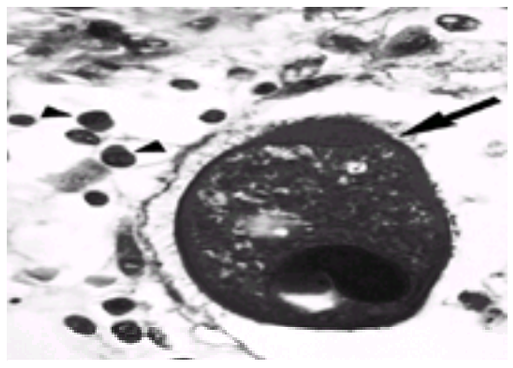

Fig. 2 Light micrograph of *Balantidium coli* trophozoite (arrow) in colonic tissue. Cilia are visible on the surface of the organism. Arrowheads indicate tissue plasma cells (× 705). (Modified from Neafie RC (1976). Balantidiasis. In: Binford CH, Connor DH, eds. *Pathology of tropical and extraordinary diseases*, Vol 1, pp 325–7. Armed Forces Institute of Pathology, Washington DC. Used by permission.)

Epidemiology

Balantidiasis occurs in temperate and tropical countries. There is circumstantial evidence that man can acquire the infection from animals. *B. coli* infection has been described in pigs and in many species of non-human primate. A high prevalence of the infection has been seen in human communities that live in close proximity to *B. coli*-infected pigs (for example, in New Guinea). Consequently, there has been speculation that pigs are a reservoir for spread of *B. coli* to man. However, balantidiasis has also occurred in human subjects who had no known contact with pigs or other animals. Clusters of cases of balantidiasis have been seen in

long-stay psychiatric hospitals. In India, *B. coli* cysts have been found in water available for either drinking or use in cooking.

Pathophysiology

B. coli trophozoites are invasive organisms that cause ulceration of the colonic mucosa. The mechanism(s) responsible for tissue invasion by these organisms are not known.

Clinical features

Human subjects with *B. coli* infection can be asymptomatic, or can develop diarrhoea with stools that are either watery or that consist of blood and mucus. In severe *B. coli* infection, patients can develop colonic perforation, peritonitis, gangrene of the appendix (resulting from the presence of *B. coli* in the appendiceal wall), and spread of the parasite to the liver or lungs. Balantidiasis is a rare cause of liver abscess. As is evident from the clinical features outlined above, balantidiasis may be clinically indistinguishable from amoebiasis, bacillary dysentery, and ulcerative colitis, and can be fatal.

Laboratory diagnosis

Balantidiasis can be diagnosed by microscopic examination of diarrhoeal stools, or of colonic mucus obtained at sigmoidoscopy. Examination may show motile trophozoites or, less frequently, cysts of *B. coli*. Histological examination of rectal biopsies may reveal *B. coli* trophozoites.

Treatment and prevention

Patients with balantidiasis have been treated empirically with various antimicrobial drugs. There is, however, little interpretable information about the effectiveness of such treatment, although eradication of *B. coli* has been reported in some individuals treated with metronidazole or tetracycline. Surgical intervention may be necessary in patients with liver abscess or clinical evidence of appendicitis or colonic perforation.

Prevention of balantidiasis involves avoidance of *B. coli* cyst ingestion (via filtration or boiling of drinking water, hand washing before handling food, and careful cleaning and cooking of food).

Isosporiasis

Aetiology

Isospora belli, the cause of isosporiasis, is a coccidian parasite of the human small intestine. Coccidia of the genus *Isospora* infect many species of vertebrate, and are relatively or absolutely host-specific. There is no evidence that, under natural conditions, *I. belli* infects any vertebrate species other than man, although this coccidian has been transmitted experimentally to gibbons.

I. belli oocysts are ellipsoidal structures that are excreted in the faeces of infected individuals (Fig. 3). Studies of isospora species that parasitize non-human hosts indicate that infection occurs via ingestion of oocysts, and that sporozoites (which emerge from oocysts) penetrate epithelial cells of the small intestine. Subsequent development of isospora species comprises: (i) an asexual pathway, with production of merozoites, which can infect additional epithelial cells; and (ii) a sexual pathway, in which fusion of gametes produces oocysts that are excreted from the host.

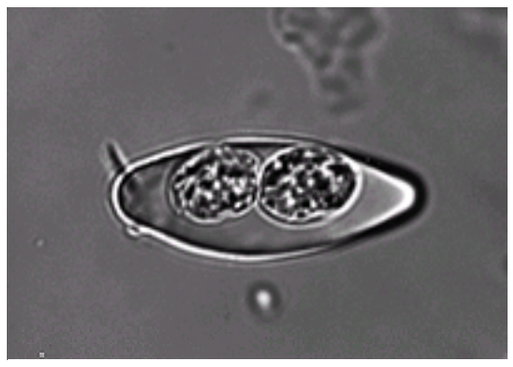

Fig. 3 Light micrograph of an *Isospora belli* oocyst (× 2500). (Illustration by courtesy of Dr William L. Current. From Garcia LS (2001). *Diagnostic medical parasitology*, 4th edn. ASM Press, Washington DC. Used by permission.)

Epidemiology

I. belli infection has been documented in immunosuppressed and, rarely, in immunocompetent individuals. Reported prevalence rates of this infection in patients with acquired immunodeficiency syndrome (**AIDS**) have been 1 per cent in Los Angeles, 8 per cent in Zambia, and 15 per cent in Haiti. Vehicle(s) for transmission of *I. belli* oocysts to human subjects have not been identified, but presumably include water and/or food.

Pathophysiology

Mechanism(s) responsible for the watery diarrhoea that occurs in isosporiasis are unknown. Presumably, the parasitization of epithelial cells in the small intestine contributes to the diarrhoea.

Clinical features

In patients infected with human immunodeficiency virus (**HIV**), *I. belli* infection is associated with chronic watery diarrhoea, abdominal cramps, nausea, fever, and weight loss. Severe dehydration can result from diarrhoea attributable to *I. belli* infection in HIV-infected patients. Reports of *I. belli* infection in immunocompetent persons are uncommon. In such individuals, however, symptoms ascribed to isosporiasis are similar to those that occur in AIDS-associated *I. belli* infection.

Rarely, extraintestinal *I. belli* infection has been described in patients with AIDS; in the relevant patients, tissues parasitized by *I. belli* have included gallbladder epithelium, liver, spleen, and mesenteric lymph nodes.

Laboratory diagnosis

Isosporiasis can be diagnosed by microscopic examination of faecal samples for *I. belli* oocysts. Although these structures are relatively large (approximately 20 to 30 mm in length), they are translucent and may be difficult to see in unstained samples. Their visibility is increased by incubation with carbol fuchsin, which stains oocyst internal structures red. An alternative approach is to examine faecal smears under ultraviolet light; with this type of illumination, *I. belli* oocysts show blue autofluorescence.

Treatment and prognosis

Because isosporiasis is diagnosed infrequently, most of the literature dealing with its treatment consists of anecdotal case reports. In the 1980s, oral

trimethoprim–sulphamethoxazole was found to be an effective drug combination for treating *I. belli*-induced diarrhoea, in a study of patients with AIDS and isosporiasis in Haiti. Recognition of adverse drug reactions to trimethoprim–sulphamethoxazole, and less than 100 per cent efficacy of this drug combination in treating isosporiasis, have prompted alternative therapeutic approaches. Diclazuril, albendazole–ornidazole, and pyrimethamine–sulphadiazine are three such alternatives that have shown anecdotal promise in treating isosporiasis associated with HIV infection.

In immunocompetent patients without HIV infection, isosporiasis can persist for weeks or months if untreated. The overall prognosis in patients with isosporiasis and HIV infection is determined by the HIV infection.

Microsporidiosis

Aetiology

Microsporidia are protozoa with features that are sufficiently distinctive for the organisms to be classified as a separate phylum (Microspora). They are obligate intracellular parasites of hosts that include insects, fish, and mammals. The lifecycle of microsporidia comprises an extracellular stage (spore) and stages that occur in the cytoplasm of host cells. Spores (Fig. 4) are shed into the environment by infected hosts, and infect other members of the host species. The spores induce infection by extruding a hollow tube, which penetrates a host cell and forms a channel for delivering sporoplasm (spore contents) into this cell. Replication of the parasite and subsequent production of spores occur in host cells.

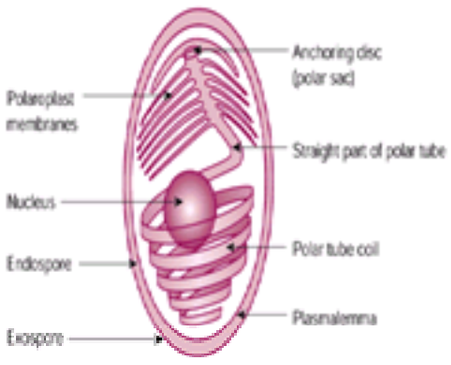

Fig. 4 Diagram of a microsporidian spore, showing internal structure. (Illustration by courtesy of Professor Elizabeth U. Canning. Modified from Canning EU and Hollister WS (1992). Human infections with microsporidia. *Reviews in Medical Microbiology* **3**, 35–42. Used by permission.)

Microsporidia that infect man are listed in Table 2. Several species listed in this table were unknown in any context before the 1990s. When it has been sought, *Enterocytozoon bieneusi* has been found in up to 30 per cent of patients with both diarrhoea and HIV infection. Authenticated human infections with microsporidia other than *E. bieneusi*, *Encephalitozoon intestinalis*, and *E. hellem*, are rare. Some of the microsporidian species listed in Table 2 have been found in one or two patients only. 'Microsporidium' (Table 2) is a non-taxonomic genus created for microsporidia of unclear identity.

Epidemiology

Before 1985, when *E. bieneusi* infection was first described, very few cases of human microsporidiosis had been reported. From the mid-1980s onwards, most of the documented clinical experience with microsporidiosis has occurred in patients with HIV infection. After its initial description, as an intestinal parasite in the HIV-infected population, *E. bieneusi* was reported in several HIV-negative, purportedly immunocompetent persons with diarrhoea. Similarly, human encephalitozoon infections have been reported most frequently in HIV-infected patients, but also occur in immunocompetent individuals. A serological survey revealed anti-encephalitozoon antibodies in sera from 8 per cent of 300 presumably healthy Dutch blood donors, and from 5 per cent of 276 pregnant French women.

Experimental work with animals suggests that human infection with some species of microsporidia occurs via ingestion of spores. Environmental sources of microsporidian spores that can infect human subjects appear to include water and, possibly, non-human hosts. In France, *E. bieneusi* DNA has been found in river water (by filtration and PCR amplification). Using a similar approach, DNA of *E. bieneusi* and of *Encephalitozoon intestinalis* has been detected in water in Arizona. Risk factors for *E. bieneusi* infection, in a population of HIV-infected patients surveyed in France, included swimming in a pool in the 12 months before the survey. In rural Mexican households, faecal excretion of encephalitozoon spores was associated with the use of unboiled water for drinking and for preparing food. Collectively, these observations suggest that *E. bieneusi* and encephalitozoon infections can be waterborne. Heavy parasitization of respiratory tract epithelial cells with *Encephalitozoon hellem*, in at least one HIV-infected patient examined at autopsy, raises the possibility that some microsporidian infections can be acquired by inhaling spores.

Some species of microsporidia listed in Table 2 are known to infect non-human hosts. For example, *E. hellem* infection has been described in budgerigars and parrots. Spores of *E. intestinalis* have been identified in faecal specimens from non-human mammals (dog, pig, goat, cow, and donkey), by immunofluorescence microscopy and PCR. *Enterocytozoon bieneusi* can infect pigs, and *Encephalitozoon cuniculi* (a rarely documented cause of microsporidiosis in HIV-infected patients) infects various hosts, including rabbits, dogs, and pigs. Genetically distinct strains of *E. bieneusi* and of *E. cuniculi* have been described; there is some evidence that the different strains show host selectivity.

Pathophysiology

In HIV-infected patients, diarrhoea is the clinical feature that has been most frequently associated with microsporidiosis. In particular, this symptom has been linked to infection with *Enterocytozoon bieneusi* and with *Encephalitozoon intestinalis*. The diarrhoea in these microsporidian infections presumably results from the presence of microsporidia in the small intestinal mucosa.

In mice at least, interferon-g contributes to protective immunity against *E. intestinalis* and *E. cuniculi* infections.

Clinical features

Clinical features of microsporidian infections reflect the anatomical site colonized by the microsporidia (Table 2). Besides watery diarrhoea, weight loss and fat malabsorption have been reported in HIV-infected patients with intestinal microsporidiosis. Microsporidian infection of the gallbladder has been described in occasional HIV-infected patients, who had acalculous cholecystitis (characterized by right upper abdominal pain, nausea, and vomiting), and who were treated by cholecystectomy. Symptoms of sinusitis, and cough and dyspnoea, have been reported in patients with microsporidian infection of the paranasal sinuses and respiratory tract. Symptomatic urethritis has been ascribed to microsporidian infection in occasional HIV-infected patients.

Microsporidian infection of the conjunctiva and corneal epithelium causes symptoms of keratoconjunctivitis (foreign body sensation in the eye, ocular discomfort and redness, photophobia, blurred vision, and sometimes reduced visual acuity). Microsporidian infections of the corneal stroma lead to reduced visual acuity, with or without corneal ulceration. Clinical features in patients with actual or presumed cerebral microsporidiosis have included headache, cognitive impairment, nausea, vomiting, and epileptic seizures. Symptoms of myositis (muscle pain, tenderness, weakness, and wasting) have been described in patients with microsporidian infection of skeletal muscles.

Laboratory diagnosis

Human microsporidian infections were originally documented by microscopic examination of tissue sections obtained by biopsy or at autopsy. The small size of microsporidia favoured the use of electron microscopy (rather than light microscopy) for diagnosing microsporidiosis in early studies. Because this is a

labour-intensive approach requiring equipment that may not be readily accessible, simpler diagnostic methods than electron microscopy were sought.

One such approach (which is non-invasive) involves examining faecal samples for microsporidian spores, which are ovoid in shape. The spores can be detected by using a number of stains, including crystal violet plus iodine and chromotrope 2R (leading to violet staining of the spores), optical brighteners such as Uvitex 2B and Calcofluor White M2R (which bind to chitin in the spores), and fluorescent antibodies directed against the spores. Spores can be seen by light microscopy (after staining with crystal violet/iodine/chromotrope 2R), or by fluorescence microscopy after incubation with optical brighteners (which lead to fluorescence of the spores) or fluorescent antibodies. Intestinal infection with *E. bieneusi* or *E. intestinalis* can be diagnosed by finding microsporidian spores in faecal samples. Spores of *E. bieneusi* are smaller (about 1.5 µm × 0.9 µm) than those of *E. intestinalis* (about 2.5 µm × 1.5 µm). In addition, microsporidian infection of the nasal mucosa and paranasal sinuses can be diagnosed by microscopic examination of nasal secretions for spores (after staining, as outlined above). Similarly, microsporidian spores can be found in urine and bile from patients with urinary tract and biliary tract microsporidiosis, respectively.

Approaches to diagnosis of microsporidian keratoconjunctivitis include examining conjunctival/corneal scrapings or biopsies for spores and (non-invasively) *in vivo* examination of the cornea with a scanning confocal microscope to look for spore-filled epithelial cells.

The commonest clinical situation that calls for efforts to diagnose microsporidiosis is the HIV-infected patient with diarrhoea. To supplement (or, perhaps, eventually replace) diagnostic methods that require microscopy, many authors have developed molecular methods for diagnosing microsporidiosis. Such approaches usually involve DNA extraction (for example, from faecal samples) and PCR amplification using primers specific for regions of gene(s) that encode(s) RNA in the small subunit of microsporidian ribosomes (SSU-rRNA). The DNA obtained by PCR amplification is detected by agarose gel electrophoresis.

Treatment and prognosis

HIV-infected patients with *E. bieneusi* infection and chronic diarrhoea have been treated with various drug regimens in an attempt to clear the *E. bieneusi* infection. To date, the most effective regimen for this purpose has been 'highly-active anti-retroviral therapy' (**HAART**), which involves simultaneous treatment with several drugs directed against HIV, including HIV protease inhibitor(s). When effective in HIV-positive, *E. bieneusi*-infected patients, HAART leads to reduction of HIV load, elevation of the circulating CD4+ T-lymphocyte count, clearance of *E. bieneusi* infection, and cessation of diarrhoea. Uncontrolled trials and anecdotal reports suggest that thalidomide, furazolidone, fumagillin, and atovaquone are potentially useful drugs for treating *E. bieneusi* infection.

Encephalitozoon infections can be treated effectively with albendazole. In a small controlled trial, HIV-infected patients with *E. intestinalis* infection were treated with either albendazole, 400 mg twice daily by mouth, or placebo. Albendazole treatment led to clearance of gastrointestinal *E. intestinalis* infection in this study. Uncontrolled trials and anecdotal case reports describe partial or complete resolution of symptoms (diarrhoea, sinusitis, and keratoconjunctivitis) in patients with *E. intestinalis*, *E. hellem*, or *E. cuniculi* infection following albendazole treatment. Pregnancy is a contraindication to albendazole treatment.

Microsporidial keratoconjunctivitis has been treated successfully with fumagillin eye drops in HIV-infected patients. HIV-negative patients with microsporidian infection of the corneal stroma have been treated by corneal transplantation, with results that have ranged from failure (opacification of the transplant) to apparent success, as judged by transparency of the graft 6 months after transplantation.

Individual patients infected with *Trachipleistophora hominis* or *Brachiola vesicularum* reportedly showed some clinical improvement after treatment with albendazole–sulphadiazine–pyrimethamine, or albendazole–itraconazole, respectively.

In HIV-infected patients with microsporidiosis, the overall prognosis is determined by the HIV infection.

Future research

Further efforts are warranted to identify environmental sources of microsporidia that infect human subjects. One unanswered question is the extent to which domestic water supplies contain viable spores of pathogenic microsporidia. Further work is also warranted on the prevalence of microsporidian infections in immunocompetent persons (including the extent to which these infections cause symptoms in the immunocompetent human population).

7.13.9*Blastocystis hominis* infection

R. Knight

This is an anaerobic protist of the caecum and colon, its taxonomic affinity has long been uncertain. Sequencing of ribosomal RNA genes indicates that it is a stramenopile, a group that includes certain unicellular, mostly flagellated, algae. The form commonly described in faeces, and also in cultures, is spherical, 5 to 8 µm in diameter, with a prominent central body surrounded by peripheral cytoplasm containing granules; electron microscopy reveals a nucleus, with a crescentic cap of heterochromatin, and mitochondria with tubular cristae (Fig. 1, Fig. 2, and Fig. 3). The organism grows readily in cultures with mixed bacteria but axenic cultures can be established; division is by binary fission and also probably by schizogony within the central body. Electron microscopy of faeces reveals a multivacuolar form with multiple small vesicles that can either form cysts or transform into the familiar form. Colonoscopy specimens have shown an amoeboid form that ingests bacteria with pseudopodia. Bizarre environmentally induced forms with huge vacuoles may develop in cultures. The common 'univacuolar form' was named *Blastocystis* by Brumpt in 1912, who considered it to be a yeast, although it was first described by Alexieff in 1911 as a protozoan cyst.

Fig. 1 *B. hominis* from culture showing binary fission; the cytoplasm is lying at the periphery. v, vacuole. Phase contrast, × 400.

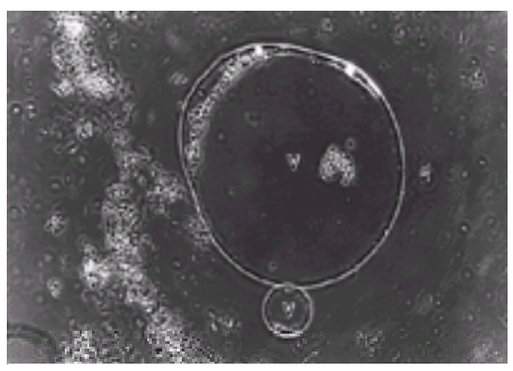

Fig. 2 *B. hominis* from culture showing the great variation in size. v, vacuole. Dark field, × 400.

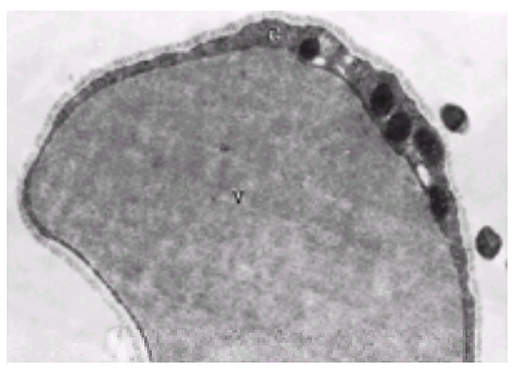

Fig. 3 *B. hominis.* Electron micrograph showing the peripheral cytoplasm (c) and the central vacuole (v); the inclusions in the cytoplasm are mitochondria. × 5000.

Epidemiology

Prevalence is high in many human populations in contexts of high faeco-oral transmission. This infection is associated with travel and institutions and may occur in outbreaks. Similar *Blastocystis* organisms of uncertain pathogenicity occur in birds, pigs, and monkeys. The recently recognized cysts are the transmissive stage.

Diagnosis

It is usually recognized in direct wet faecal smears or formol ether concentrates; wet mounts can be stained with iodine giving a brownish central body; or with toluidine blue. The organism is often numerous in symptomatic subjects. Permanent mounts stain well with trichrome. *Blastocystis* can resemble amoebic cysts but lacks their characteristic nuclei. In fixed smears stained specifically for *Cryptosporidium* there is no oocyst wall.

Clinical features and treatment

A diarrhoeal illness lasting 3 to 10 days is attributed to this organism. Sometimes symptoms continue for weeks or months. Associated features are abdominal bloating, flatulence, and anorexia. Symptoms are more prolonged in immunocompromised subjects. There is no association with irritable bowel syndrome. Illnesses are self-limiting in most people but infection can be eliminated with metronidazole or tinidazole; the organism is also sensitive to furazolidine and co-trimoxazole.

Evidence for pathogenicity

Serum antibody is detectable in symptomatic subjects; preliminary studies suggest *in vitro* cytotoxicity to tumour cell monolayers, and local lesions have been

produced in mice after intramuscular injection.

The situation with *Blastocystis* in humans may be similar to that of several anaerobic lumen-dwelling protozoa infecting vertebrates in which a self-limited non-invasive pathogenicity is followed by a longer carrier state. Such a relationship remains very difficult to prove or disprove, especially as there is genetic heterogeneity between *Blastocystis* isolates. Clinical response to metronidazole is hardly compelling evidence for pathogenicity since concurrent infection with other enteropathogens is common and this drug has a wide spectrum of activity, including an effect upon small bowel bacterial overgrowth. More well-documented outbreaks and cytopathic evidence are needed.

7.13.10 Human african trypanosomiasis

August Stich

Introduction

Sleeping sickness or human African trypanosomiasis (HAT) is caused by subspecies of the protozoan haemoflagellate *Trypanosoma brucei* transmitted to man and animals by tsetse flies (*Glossina* spp.). The distribution of the vector restricts sleeping sickness to the African continent between 14° north and 29° south (Fig. 1). Human disease occurs in two clinically and epidemiologically distinct forms, *gambiense* or West African and *rhodesiense* or East African sleeping sickness (Table 1). A third subspecies of the parasite, *T.b. brucei*, causes disease in cattle but is non-pathogenic in humans.

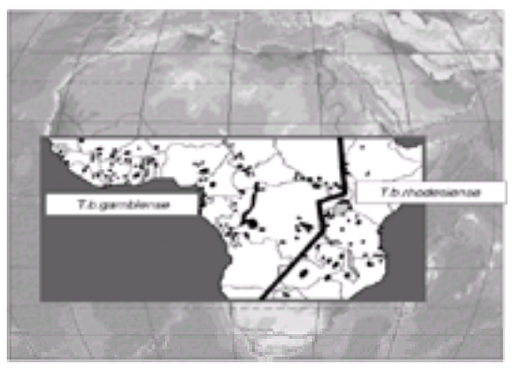

Fig. 1 The geographical distribution of human African trypanosomiasis.

First reports of the disease go back to the fourteenth century. In the past, the impact on health in Africa has been enormous. Many areas had long been rendered uninhabitable for people and livestock. During the first decades of the twentieth century, millions may have died in Central Africa around Lake Victoria and in the Congo basin (Fig. 2). The success of control programmes in the 1960s promised the disappearance of sleeping sickness as a public health problem. However, recent epidemics in the Democratic Republic of Congo, Northern Angola, Sudan, Uganda, and other countries confirm a major resurgence of HAT. According to current estimates by WHO, the achievements in sleeping sickness control during colonial times will be completely reversed in the near future.

Fig. 2 Sleeping sickness patients on an island in Lake Victoria; historical photograph taken during Robert Koch's research expedition to East Africa.

Today, 60 million people in some 40 African countries are exposed to the risk of HAT. Half a million are believed to be infected (almost all with *T.b. gambiense*). They are doomed if left untreated. For tourists and expatriates, sleeping sickness has always been a rare disease, but a recent cluster of cases in tourists to Tanzania re-emphasizes that it is also important in travel medicine.

Aetiology

In 1895, Sir David Bruce (1855–1931) suggested an association between trypanosomes and 'cattle fly fever', a major problem for livestock in southern Africa. In 1902, Robert M. Forde and Everett Dutton identified trypanosomes in the blood of a patient during a research expedition in The Gambia, and in 1903, Aldo Castellani isolated trypanosomes from the cerebrospinal fluid. In the same year, tsetse flies were identified as the vector.

Trypanosoma brucei (phylum Sacromastigophora, order Kinetoplastida) is an extracellular protozoal parasite. Like *Leishmania*, it possesses a centrally placed nucleus and a kinetoplast, a distinct organelle with extranuclear DNA. The kinetoplast is the insertion site of an undulating membrane, which extends over nearly the whole cell length and ends as a free flagellum.

The three subspecies of *Trypanosoma brucei* are indistinguishable morphologically. However, they differ considerably in their interaction with their mammalian host and the epidemiological pattern of the diseases they cause. Formerly, *T.b. gambiense* and *T.b. rhodesiense* isolates were characterized either by isoenzyme analysis or by animal inoculation. The advent of molecular techniques created expectations of more reliable tools for their differentiation. However, genomic characterization has revealed several more subdivisions rather than the three expected. Whereas West African isolates proved relatively homogeneous, East African isolates from humans and animals did not simply conform to what is still called *T.b. rhodesiense* and *T.b. brucei* but showed a complex relationship with evidence of sexual genetic exchange in the vector. Further molecular research may soon lead to a comprehensive phylogenetic tree and a deeper insight into trypanosomal evolution and biology.

Transmission

Although congenital, blood-borne, and mechanical transmission have been reported and may play an occasional role, the main mode of transmission is through the bite of infected tsetse flies (*Glossina* spp., order Diptera; Fig. 3 and Plate 1). These are biologically unique insects, which occur only in Africa in 31 distinct species and subspecies. Less than half are potential vectors of HAT. Their distinctive behaviour, ecology, and chosen habitat explain many epidemiological features of sleeping sickness. Tsetse flies can live for many months in the wild, but give birth to only about eight to 10 larvae per lifetime. Both sexes feed on blood. They are fastidious in requiring warm temperatures, shade, and humidity for resting and larviposition and so their distribution is highly localized. Recently, the mapping and monitoring of possible HAT transmission foci has become possible with the use of satellite imaging techniques.

Fig. 3 Adult tsetse fly (*Glossina morsitans*). (See also Plate 1.)

During the blood meal on an infected mammalian host, the tsetse fly takes up trypanosomes ('short-stumpy form') into its mid-gut, where they develop into procyclic forms and multiply. After about 2 weeks, they migrate to the salivary glands as epimastigotes where they finally develop into infective metacyclic forms. With the next blood meal, they are then injected into the new vertebrate host where they appear and multiply as 'long-slender' trypomastigotes.

Molecular and immunological aspects

The cyclic changes of the trypanosome into different developmental stages are accompanied by variations in morphology, metabolism, and antigenicity. Several unique metabolic pathways have been described in trypanosomes, distinct from their host and thus qualifying as potential drug targets.

The blood stream forms of *T. brucei* are covered with a dense coat of identical glycoproteins, numbering up to about 500 aminoacids per molecule. Being highly immunogenic, they stimulate the production of specific antibodies, mainly of the IgM subclass. Once the surface glycoproteins have been recognized by host antibodies, the parasitic cell will be attacked and destroyed through complement activation and cytokine release.

However, about 2 per cent of *T. brucei* in each new generation change the expression of their specific surface glycoprotein. The 'coat' will then be different in the new clone ('variant' surface glycoprotein: VSG). This phenotypic switch is done mainly by programmed DNA-rearrangements, moving a transcriptionally silent VSG gene into an active, telomerically located expression site. Within a trypanosome population, the potential repertoire of such different VSG copies seems to be virtually infinite.

Every new VSG copy is antigenically different, thus stimulating the production of a new IgM population. This antigenic variation is the major immune evasion strategy of the parasite, enabling the trypanosome to persist in its vertebrate host. It also reduces parasite load and prolongs the infection. But the inevitable outcome is immune exhaustion of the host, penetration of trypanosomes into immune-privileged sites such as the central nervous system, and finally death.

Clinical features

Sleeping sickness is a dreadful disease, causing great suffering to patients, their families, and the affected community. The infection often has an insidious onset, but *T. brucei*, whether the East or West African subspecies, will invariably kill if the patient is not treated in time. The natural course of HAT can be divided into different and distinct stages. Their recognition and differentiation is important for the management of the patient.

The trypanosomal chancre

Tsetse bites can be quite painful, usually leaving a small and self-healing mark. In the case of a trypanosomal infection, the local reaction can be quite pronounced and longer lasting. A small raised papule will develop after about 5 days. It increases rapidly in size, surrounded by an intense erythematous tissue reaction (Fig. 4 and Plate 2) with local oedema and regional lymphadenopathy. Although some chancres have a very angry appearance, they are not usually very painful unless they become ulcerated and superinfected. They heal without treatment after 2 to 4 weeks, leaving a permanent, hyperpigmented spot.

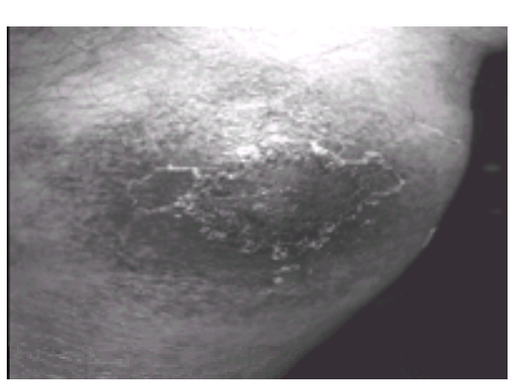

Fig. 4 Trypanosomal chancre on the shank of a missionary returning from the Congo. (See also Plate 2.)

Trypanosomal chancres occur in about half the cases of *T.b. rhodesiense*. In *T.b. gambiense*, they are much less common. They often go undetected in endemic populations.

Haemolymphatic stage (HAT stage I)

After local multiplication at the site of inoculation, the trypanosomes invade the haemolymphatic system, where they can be detected after 7 to 10 days. During this period of spread, they are exposed to vigorous defence mechanisms of the host, which they evade by antigenic variation. This continuous battle between antigenic switches and humoral defence results in a fluctuating parasitaemia with parasites frequently becoming undetectable, especially in *gambiense* HAT. The cyclic release of cytokines during periods of increased cell lysis results in intermittent, non-specific symptoms: fever, chills, rigors, headache, and joint pains. These can easily be misdiagnosed as malaria, viral infection, typhoid fever, or many other conditions. Hepatosplenomegaly and generalized lymphadenopathy are common, indicating activation and hyperplasia of the reticuloendothelial system.

A reliable sign, particularly in *T.b. gambiense* infection, is the enlargement of lymph nodes in the posterior triangle of the neck (Winterbottom's sign). Other typical signs are a fugitive patchy rash, a myxoedematous infiltration of connective tissue ('puffy face syndrome'), and an inconspicuous periostitis of the tibia with delayed hyperaesthesia (Kérandel's sign).

In *T.b. rhodesiense* infection, this haemolymphatic stage is very pronounced with severe symptoms, sometimes even resulting in early death through cardiac involvement (myocarditis). In the early stage of *T.b. gambiense* infection, symptoms are usually infrequent and mild. Febrile episodes become less severe as the disease progresses.

Meningoencephalitic stage (HAT stage II)

Within weeks in *T.b. rhodesiense* and months in *T.b. gambiense* infection, cerebral involvement will invariably follow; trypanosomes cross the blood–brain barrier. In children, HAT progresses even more rapidly towards this meningoencephalitic stage.

The onset of stage II is insidious. The exact time of central nervous system involvement cannot be determined clinically. Histologically, perivascular infiltration of inflammatory cells ('cuffing') and glial proliferation can be detected, resembling endarteritis. As the disease progresses, patients complain of increasing headache, and their families may detect a marked change in behaviour and personality. Neurological symptoms, which follow gradually, can be focal or generalized, depending on the site of cellular damage in the central nervous system. Convulsions are common, usually indicating a poor prognosis. Periods of confusion and agitation slowly evolve towards a stage of distinct perplexity when patients lose interest in their surroundings and their own situation. Sleep abnormalities result finally in a somnolent and comatose state. Progressive wasting and dehydration follows the inability to eat and drink.

There is no unique, clinical sign of late HAT, opening up a wide range of possible neurological and psychiatric differential diagnoses. However, the appearance of the patient, with apathy and the typical expressionless face, is a very characteristic sight in endemic areas (Fig. 5 and Plate 3).

Fig. 5 Patient with late-stage trypanosomiasis. (See also Plate 3.)

Diagnosis

HAT can never be diagnosed with certainty on clinical grounds alone. Definitive diagnosis requires the detection of the parasite in chancre aspirate, blood, lymph juice, or cerebrospinal fluid using various parasitological techniques. The methods for diagnosis are essentially the same for *gambiense* and *rhodesiense* HAT (Table 2).

Lymph node aspirate

Lymph node aspiration is widely used, especially for the diagnosis of *gambiense* HAT. Fluid of enlarged lymph nodes, preferably of the posterior triangle of the neck (Winterbottom's sign), is aspirated and examined immediately at 400 × magnification. Mobile trypanosomes can be detected for a few minutes between the numerous lymphocytes.

Wet preparation, thin, and thick blood film

During all stages of the disease, trypanosomes may appear in the blood where they can be detected in unstained wet or in stained preparations. The yield of detection is highest in the thick blood film, a technique widely used for the diagnosis of blood parasites such as *Plasmodia* or microfilaria. Giemsa or Field staining techniques are appropriate (Fig. 6 and Plate 4).

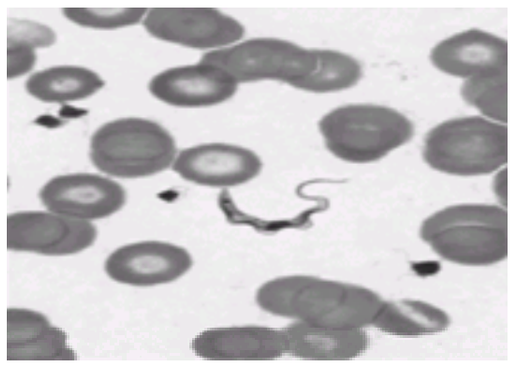

Fig. 6 Trypanosomes in thin human blood film (Giemsa stain, ×1000 magnification). (See also Plate 4.)

Especially in *gambiense* HAT, parasitaemia is usually scanty and fluctuating, often being undetectable. Repeated examinations on successive days are sometimes necessary until trypanosomes can be documented.

Concentration methods

To increase the sensitivity of blood examinations, various concentration assays have been developed. Trypanosomes tend to accumulate in the buffy coat layer after centrifugation of a blood sample. The best results in the field have been obtained with the m-AECT (mini anion exchange column technique), where trypanosomes are concentrated after passage through a cellulose column, and the QBC method (quantitative buffy coat), which was originally developed for the diagnosis of malaria.

Serological assays

Serology is a useful tool to detect antibodies against trypanosomiasis. Various test methods have been described and are now commercially available. They are mainly based on ELISA technique or immunofluorescence, but provide reliable results only in *gambiense* HAT.

For rapid screening under field conditions, the CATT (card agglutination test for trypanosomiasis) is an excellent tool in areas of *T.b. gambiense* infestation. It is easy to perform and delivers results within 5 min. A visible agglutination in the CATT suggests the existence of antibodies, but does not necessarily imply overt disease.

Non-specific laboratory findings

Anaemia and thrombocytopenia are caused by systemic effects of cytokine release, especially of TNF-a. Hypergammaglobinaemia can reach extreme levels as a result of polyclonal activation of immunoglobulins. IgM levels detected in HAT are among the highest observed in any infectious disease.

Diagnosis of stage II

Stage determination is crucial for the correct management of a patient. This cannot be done on clinical grounds alone. Therefore, a lumbar puncture for the examination of the cerebrospinal fluid has to be performed in every patient found positive for trypanosomes in blood or lymph aspirate. In addition, a lumbar puncture should be performed in all patients with the clinical suspicion of HAT even if peripheral examinations had proved negative. A minimum of 5 ml of cerebrospinal fluid is required to examine for:

- Leucocytes—cerebral involvement in HAT stage II is accompanied by pleocytosis, mostly lymphocytes, in the cerebrospinal fluid. By convention a number of more than five cells per mm^3 cerebrospinal fluid defines central nervous system involvement even if the patient does not (yet) have neurological symptoms. Pathognomonic for HAT is the appearance of activated plasma cells with eosinophilic inclusions in the cerebrospinal fluid, the morular cells of Mott (Fig. 7 and Plate 5).
- Trypanosomes—the chances of detecting trypanosomes in the cerebrospinal fluid increase with the level of pleocytosis and the technique used. The highest yield is obtained by cerebrospinal fluid double centrifugation.
- Protein—in patients with HAT, a level of 37 mg of protein per 100 ml cerebrospinal fluid (dye-binding protein assay) is highly suggestive of the advanced stage. Stage II HAT is characterized by an autochthonous production of IgM antibodies in the cerebrospinal fluid, which can be selectively detected if suitable laboratory facilities exist (e.g. latex IgM test).

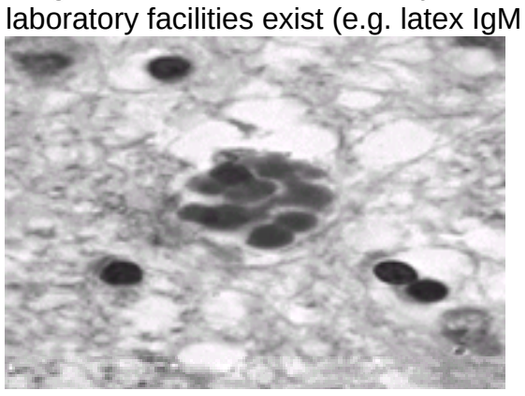

Fig. 7 Morular cell of Mott in a histological brain section of a stage II HAT patient (haematoxylin and eosin stain, ×1000 magnification). (See also Plate 5.)

Treatment

General considerations

HAT is curable, especially if the diagnosis is made in an early stage of the disease and treatment is administered correctly. In the stark reality of the African situation, however, there are many major obstacles to successful patient management:

1. Sleeping sickness is a disease of rural, remote places. The active foci of sleeping sickness are usually in far-away and insecure places, which are difficult to reach. Numerous treatment centres work under emergency conditions with extremely restricted resources. Many affected patients, without proper access to health care, are left unattended.
2. The diagnosis is difficult. Initial diagnosis and exact staging of trypanosomiasis requires sophisticated and dangerous methods, justified only in the hands of experienced personnel. Repetitive training programmes, constant supervision, and continuous quality control are necessary but in reality are rarely available.
3. The treatment of trypanosomiasis is extremely costly. Invariably it exceeds the locally available resources. However, external funding and a sustainable donor commitment for Africa is generally diminishing.
4. The treatment is complicated. Treatment of HAT is dangerous, prolonged, and usually requires hospitalization. Most patients with late-stage trypanosomiasis are severely ill and malnourished. Adverse drug reactions during treatment are difficult to assess due to concomitant pathologies. Their management requires considerable medical skill and good nursing care. Hospitals in rural Africa are often not sufficiently equipped to accomplish good patient care.
5. Many drugs are unavailable. Treatment of HAT is hampered by the limited availability of essential drugs on the international market. Many trypanosomicidal agents are on the verge of disappearance despite increasing demand. Many are no longer produced, as the affected patient populations cannot pay. The range of drugs is diminishing, and hardly any new treatments are in sight. This is especially worrying in view of the reported spread of drug resistance.
6. HAT treatment is not standardized. Trypanosomiasis treatment regimens vary considerably between countries and treatment centres. Results from different centres are comparable to only a very limited extent. Few properly conducted and sufficiently powerful clinical trials are available to evaluate duration, dosage, and possible combinations of drugs. There are few suitable research sites at major trypanosomiasis foci.

Stage I drugs

The treatment of HAT varies according to the trypanosome subspecies and the stage of the disease (Table 3).

Pentamidine

Since its introduction in 1937, pentamidine has become the drug of first choice for *gambiense* HAT stage I, achieving cure rates as high as 98 per cent. However, there are frequent failures in *rhodesiense* HAT. Lower rates of cellular pentamidine uptake in *T.b. rhodesiense* may explain these differences. Some cures of stage II infections have also been reported, but cerebrospinal fluid drug levels are usually not sufficiently high to guarantee a reliable trypanosomicidal effect in the central nervous system.

Pentamidine is usually given by deep intramuscular injection, manageable even in outpatients. If hospital care and reasonable monitoring conditions are available, an intravenous infusion, given in normal saline over 2 h, might be used instead. The main advantage of pentamidine over other drugs is the short treatment course and ease of administration. Adverse effects are related to the route of administration or its dose and are usually reversible (Table 4).

Pentamidine is also used as second-line therapy for visceral leishmaniasis and especially in the prophylaxis and treatment of opportunistic *Pneumocystis carinii*

pneumonia in AIDS. Since the advent of the HIV pandemic, the cost of pentamidine was increased more than tenfold by producers, making it unaffordable by health institutions in low-income countries. After an intervention by WHO, a limited amount of pentamidine is now made available for use in HAT at a subsidised rate.

Suramin

In the early twentieth century, the development of suramin, resulting from German research on the trypanosomicidal activity of various dyes ('Bayer 205'), was a major break-through in the field of tropical medicine. For the first time, African trypanosomiasis, at least in its early stages, became treatable.

Suramin is still used to treat stage I HAT, especially *rhodesiense*. Like pentamidine it does not reach therapeutic levels in cerebrospinal fluid. Suramin is injected intravenously after dilution in distilled water.

Adverse effects depend on nutritional status, concomitant illnesses (especially onchocerciasis) and the patient's clinical condition. Although life-threatening reactions have been described, serious adverse effects are rare and the drug remains one of the safest in trypanosomiasis treatment (Table 4).

Stage II drugs

Melarsoprol

Until the introduction of the arsenical compound melarsoprol in 1949, late stage trypanosomiasis was untreatable. Since then, it has remained the most widely used stage II antitrypanosomal drug both for *T.b. gambiense* and *rhodesiense* infections. It has saved many lives, but has a high rate of dangerous adverse effects. Increasing frequency of relapses and resistance has been reported in some parts of Uganda, Congo, and Angola.

Melarsoprol clears trypanosomes rapidly from the blood, lymph, and cerebrospinal fluid. Its toxicity usually restricts its use to late-stage disease. It is given by slow intravenous injection; extravascular leakage must be avoided.

A new, simpler regimen is based on recently acquired knowledge of the drug's pharmacokinetics (Table 4). The most important adverse effect is an acute encephalopathy, provoked around day 8 of the treatment course in 5 to 14 per cent of all patients. There is severe headache, convulsions, rapid neurological deterioration, or deepening of coma. Characteristically, the comatose patient's eyes remain open. Most probably, this is an immune-mediated reaction precipitated by release of parasite antigens in the first days of treatment. The overall case fatality ranges between 2 and 12 per cent, depending on the stage of disease and the quality of medical and nursing care. Simultaneous administration of glucocorticosteroids (prednisolone 1 mg/kg body weight; maximum 40 mg daily) reduces mortality, especially in cases with high cerebrospinal fluid pleocytosis. However, in areas where tuberculosis, amoebiasis, or strongyloidiasis are highly prevalent, corticosteroids have dangers of their own!

Eflornithine (DFMO)

Initially developed as antitumour agent, eflornithine was introduced in 1980 as an antitrypanosomal drug, in the hope that it might replace melarsoprol for treatment of stage II trypanosomiasis. However, exorbitant costs and limited availability have restricted its use to melarsoprol-refractory cases of *gambiense* sleeping sickness. *T.b. rhodesiense* isolates are normally much less sensitive.

It can be taken orally, but intravenous administration is preferred as it achieves a much higher bioavailability and success rate. Eflornithine should be administered slowly over a period of at least 30 min. Continuous 24-h administration is preferable if facilities allow.

The range of adverse reactions to eflornithine is wide, as with other cytotoxic drugs in cancer treatment. Their occurrence and intensity increase with the duration of treatment and the severity of the patient's general condition. Generally, all adverse effects of eflornithine are reversible (Table 4).

No pharmaceutical company has produced eflornithine for use against HAT since 1999, despite pressure by WHO. The discovery of its therapeutic effect in cosmetic creams against facial hair might help to restimulate production and thus have a beneficial 'spin-off effect' for HAT. In 2001 agreements were signed between WHO and two major drug producing companies which might help to assure a sufficient supply of eflornithine and other drugs essential for the treatment of HAT for the next few years.

Nifurtimox

Ten years after its introduction for the treatment of American trypanosomiasis in 1967, nifurtimox was found to be effective in the treatment of *gambiense* sleeping sickness. It has a place as second line treatment in melarsoprol-refractory cases or in a combination chemotherapy. Experience is limited to few cases treated on compassionate grounds. Prospective clinical trials in HAT are currently in progress.

Nifurtimox is generally not well tolerated, but adverse effects are usually not severe. They are dose-related and rapidly reversible after discontinuation of the drug (Table 4).

Combination treatments in HAT

Melarsoprol, eflornithine, and nifurtimox interfere with trypanothione synthesis and activity at different stages. There is also experimental evidence that combinations of suramin and stage II drugs might be beneficial. Therefore, by reducing the overall dosage of each individual component, drug combinations could perhaps reduce the frequency of serious side-effects, and the development of resistance, which are such common problems in the treatment of sleeping sickness.

Drug combination treatment of HAT is virtually confined to single-case reports. Properly conducted clinical trials are overdue.

Individual protection

HAT among tourists and occasional visitors of endemic areas is a rare event. Pentamidine or suramin chemoprophylaxis is historical, and can no longer be recommended. Long-sleeved, bright clothing and insecticide repellents are the best defence against attacking tsetse flies.

Prevention and control

In the past, tremendous efforts have been undertaken to control sleeping sickness as a threat to human lives and rural development. Control programmes are based on the five complementary pillars given in Table 5.

The most important strategy is active case finding. This requires mobile teams, which regularly visit villages in endemic areas. Mostly based on the results of CATT screening, patients, preferably in the early stage of the disease, are identified and treated. Gradually, the parasite reservoir is depleted. As *Glossina* is a relatively incompetent vector and susceptible to control measures such as insecticide application or trapping, the combination of various approaches can lead to a complete break of the transmission cycle. This was achieved in the past in many places. However, the recent resurgence of sleeping sickness in areas ridden by war and civil unrest, in combination with the decreasing availability of drugs on the international market and the general loss of interest in health in Africa, gives rise to the fear that HAT will soon be again uncontrollable and untreatable (Fig. 8).

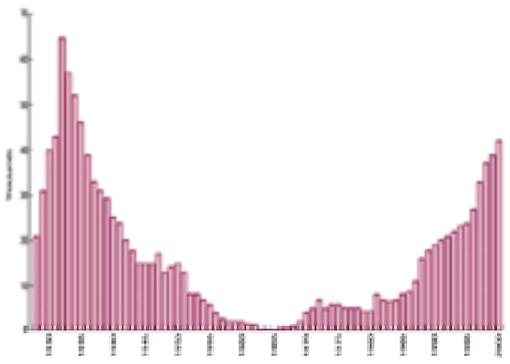

Fig. 8 Number of annually reported cases of HAT (source: WHO Report on Global Surveillance and Epidemic-prone Infectious Diseases); according to WHO, the actual patient numbers are about 10-fold higher.

Trypanosomiasis in the twenty-first century

There is hardly any other tropical disease which demonstrates more clearly the dichotomy characterizing our modern age. On one side, trypanosomes are kept in culture and studied extensively in numerous research laboratories. Their genome is sequenced, and many molecular, biochemical, and immunological phenomena have been discovered as a result of basic science research. General interest in this disease is usually restricted to research aspects only. On the other hand, diagnostic and especially therapeutic tools are increasingly unavailable, because the hundreds of thousands of infected people in Africa are not commercially viable consumers. The prospects for fighting trypanosomiasis look grim. African countries are less and less able to implement effective control programmes, because of political instability or financial incapacity. Global concern about the crisis of human trypanosomiasis in Africa is a question of scientific ethics and international solidarity.

7.13.11 Chagas' disease

M. A. Miles

A poeira de Curvelo
Não faz mal para ninguém não
Do pulmão lá ninguém morre
O que mata é o coração

The dust of Curvelo does not harm anybody
No-one dies there of lung disease
What kills is the heart

[From the poem 'O galo cantou na serra' by Luiz Claudio and Guimarães Rosa]

Introduction and aetiology

The Brazilian scientist, Carlos Chagas, discovered the disease that bears his name, and the entire lifecycle of the causative organism during a few months in 1907. Chagas first found the protozoan agent, *Trypanosoma cruzi*, in the gut of the large blood-sucking insect vector—the triatomine bug (Hemiptera: Reduviidae, subfamily Triatominae) (Fig. 1 and Plate 1). Later he returned to bug-infested houses and detected *T. cruzi* in the blood of sick children.

Fig. 1 Adult female triatomine bug (*Panstrongylus megistus*), with a single egg shown adjacent to the tip of the abdomen. (By courtesy of Dr T.V. Barrett.) (See also Plate 1.)

T. cruzi is a kinetoplastid protozoan. In addition to the nucleus, it has a second, microscopically visible, DNA-containing organelle—the kinetoplast. The main lifecycle stages (trypomastigote, amastigote, epimastigote) are distinguished by the position of the kinetoplast relative to the nucleus, and by the presence or absence of a free flagellum.

Vector-borne transmission of *T. cruzi* is by contamination of the mammal host with infected faeces of triatomine bugs, not by their bite. During or shortly after feeding, bugs release liquid faeces and urine on to the skin of the host. Infective forms (metacyclic trypomastigotes) penetrate mucous membranes or abraded skin. Inside the mammal, *T. cruzi* is primarily an intracellular parasite. Trypomastigotes enter non-phagocytic or phagocytic cells, in which they transform to ovoid or round amastigotes (no flagellum). Amastigotes multiply inside the cell by binary fission to produce a pseudocyst (Fig. 2 and Plate 2). After 5 days or more, the pseudocyst ruptures to release numerous new trypomastigotes, which reinvade cells or circulate in the blood. Multiplication may occur at the site of infection, but pseudocysts subsequently predominate in muscle, especially heart and smooth muscle. In the blood, trypomastigotes are small, often C-shaped, with a large terminal kinetoplast (Fig. 3 and Plate 3). Trypomastigotes do not multiply in the blood. Triatomine bugs become infected by taking a blood meal from an infected mammal; birds and reptiles are not susceptible to infection. Infection in the bug is confined to the alimentary tract, where *T. cruzi* multiplies by binary fission as epimastigotes (kinetoplast adjacent to the nucleus). Metacyclic trypomastigotes are produced in the hindgut and rectum of the bug. All stages of the *T. cruzi* ifecycle can be cultured *in vitro*. *T. cruzi* can also be transmitted by blood transfusion, organ transplantation, transplacentally, to the infant via breast milk (rarely), and orally through food contaminated by triatomine faeces and the raw meat of infected mammals. Sexual transmission has not been documented.

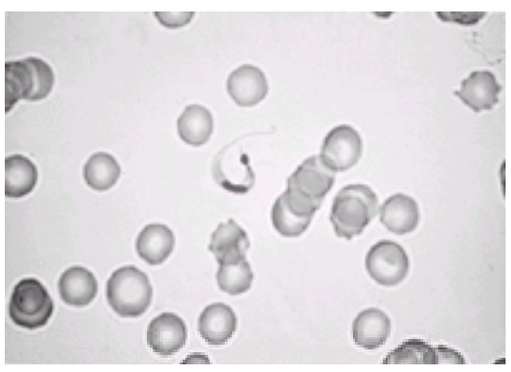

Fig. 3 *Trypanosoma cruzi* C-shaped trypomastigote in blood, note large posterior kinetoplast. (See also Plate 3.)

Epidemiology

T. cruzi is confined to the Americas, although closely related organisms of the same subgenus (*Schizotrypanum*) are cosmopolitan in bats. The vast majority of the 133 triatomine bug species are also restricted to the Americas. Their natural habitats are the refuges of mammals, birds, and reptiles, in trees, in burrows, and among rocks. All mammals are thought to be susceptible to *T. cruzi*, which has been reported from at least 150 mammal species. The opossum (*Didelphis* spp.) is the most common sylvatic host. A few triatomine species thrive as domestic colonies. More than 10 000 bugs have been found in a single house. *Triatoma infestans* is widespread in Southern Cone countries of South America (Argentina, Bolivia, Brazil, Chile, Paraguay, Uruguay, and in southern Peru). *Rhodnius prolixus* is the common vector in northern South America and Central America, with *Triatoma dimidiata* as secondary vector in that region. *Panstrongylus megistus* infests central and eastern Brazil, and *Triatoma brasiliensis* north-eastern Brazil. Animals that share human dwellings, such as guinea-pigs, dogs, cats, rats, and mice are domestic reservoirs of *T. cruzi* infection. Chickens, although not susceptible to *T. cruzi*, encourage bug infestation and can sustain large colonies.

Serological surveys suggest that up to 20 million people are infected with *T. cruzi* in South and Central America. In some communities seropositivity rates exceed 70 per cent. As expected from the precarious contaminative route of transmission, prevalence rises with age. Based on prevalence, it is estimated that up to 300 000 new infections might occur in Latin America each year. Less than 200 cases are known from the Amazon Basin, but that is because the local forest vectors do not colonize houses. For the same reason, autochthonous infection is very rare in the United States.

Initial acute infections are frequently asymptomatic or overlooked. It is thought that less than 10 per cent of acute infections in children are fatal. Morbidity due to Chagas' disease arises primarily from the chronic infection. Once acquired, infection is usually carried for life. Around 30 per cent of those infected will subsequently display electrocardiograph (**ECG**) abnormalities and chagasic cardiomyopathy, and a proportion of those have associated megaoesophagus or megacolon.

There are marked regional differences in the epidemiology of Chagas' disease. Mega syndromes are common in central and eastern Brazil but virtually unknown in northern South America and Central America. Molecular genetics' research has shown that *T. cruzi* is not a single entity, but a species with a vast subspecific heterogeneity. There are at least two radically distinct strain groups, TC1 and TC2. TC1 predominates in sylvatic and domestic transmission cycles, north of the Amazon. TC2 predominates in domestic transmission cycles in Southern Cone countries.

Pathogenesis and pathology

At the portal of entry, local multiplication of *T. cruzi* may lead to unilateral conjunctivitis or to a skin lesion (Fig. 4 and Plate 4). Unruptured pseudocysts in muscle apparently generate no inflammatory response. Pseudocyst rupture is followed by infiltration of lymphocytes, monocytes, and/or polymorphonuclear cells. Antigens released from pseudocysts may spread and be adsorbed on to adjacent uninfected cells. Such uninfected cells may be attacked by the immune response of the host, and destroyed. In this way expanded focal lesions may be produced. Postmortem histology on human hearts and experimental studies in dogs have demonstrated a clear association between ECG abnormalities and focal lesions in the conducting system of the heart. Much damage may occur in the acute phase of infection, particularly if pseudocysts are numerous. Postmortem histology has demonstrated that neurone loss is a feature of chagasic cardiopathy and of mega syndromes. Neurone loss may be exacerbated by further disease or age-related loss. Thus a threshold may be reached, often many years after the acute infection, at which organ function is perturbed. Further ECG abnormalities, aperistalsis, and organ enlargement may ensue. This 'neurogenic' pathogenesis has been linked to sudden death.

Fig. 4 Romaña's sign in acute Chagas' disease. (See also Plate 4.)

Pathological exposure of normal host sequestered antigens, or sharing of antigens between *T. cruzi* and its host, may precipitate autoimmune pathogenesis. Some chronic chagasic cardiomyopathy is said to display a renewed intense inflammatory response and a progressive diffuse myocarditis, and a slow decline in cardiac function.

The contribution of the lifelong infection to the pathogenesis of chronic Chagas' disease is controversial. After the initial acute phase, trypomastigotes are only detectable in the blood by sensitive indirect methods. Similarly, pseudocysts in the tissues are infrequent, but are detectable immunologically and by amplification of *T. cruzi* DNA.

T. cruzi infection is controlled primarily by a cell-mediated immune response, especially the TH1 arm of the immune response. Patients immunocompromised by **AIDS** (acquired immunodeficiency syndrome) have impaired TH1 responses. Thus **HIV** (human immunodeficiency virus)-positive patients chronically infected with *T. cruzi* may suffer reactivated acute Chagas' disease, with microscopically patent parasitaemia, and poor prognosis.

At the level of gross pathology, substantial megacardia may be seen. Thinning of the myocardium may be present, with focal aneurysms visible upon transillumination, especially at the apex of the left ventricle (Fig. 5) and thrombus in the right atrial appendage (Fig. 6). Apical aneurysm is considered to be a pathognomonic sign of chronic chagasic cardiomyopathy. Megaoesophagus (Fig. 7) and megacolon (see Fig. 9) may show enormous dilatation and thinning of the wall. Chagasic megaoesophagus is more frequent than chagasic megacolon, but both are known from single individuals and each is often accompanied by chagasic heart disease. Chagasic megaoesophagus may be a prelude to carcinoma.

Fig. 5 Apical aneurysm of the left ventricle in chronic Chagas' disease. (By courtesy of Dr J.S. de Oliveira.) (See also Plate 5.)

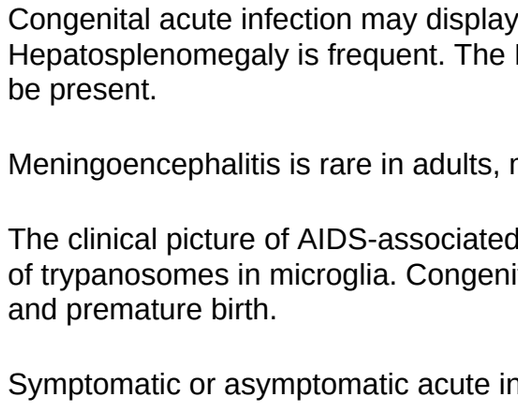

Fig. 7 Megaoesophagus seen by radiography in chronic Chagas' disease. (By courtesy of Dr J.S. de Oliveira.) (See also Plate 7.)

Clinical features

There are classically three clinical phases of Chagas' disease. Clinical signs in the acute phase may be fever, myalgia, headache, hepatosplenomegaly, generalized lymphadenopathy, facial or generalized oedema, rash, vomiting, diarrhoea, and anorexia. If *T. cruzi* has infected the eye, Romaña's sign may be present, with unilateral conjunctivitis and periophthalmic oedema (Fig. 4). If the portal of entry is the skin, an indurated oedematous cutaneous lesion (chagoma) may be seen. Regional lymphadenopathy may be present. Multiple chagomas may occasionally occur in acute-phase infections in infants. ECG abnormalities may include sinus tachycardia, increased P–R interval, T-wave changes, and low QRS voltage. The incubation period may be as short as 2 weeks, or as long as several months if infection is due to transfusion of contaminated blood. General lymphadenopathy and splenomegaly are frequent in blood transfusion-acquired infections.

Congenital acute infection may display fever, oedema, metastatic chagomas, neurological signs such as convulsions, tremors, and weak reflexes, and apnoea. Hepatosplenomegaly is frequent. The ECG is usually normal but low-voltage complexes, reduced T-wave height, and longer atrioventricular (**AV**) conduction time may be present.

Meningoencephalitis is rare in adults, more frequent in infants, common in immunocompromised patients, and carries a poor prognosis.

The clinical picture of AIDS-associated chagasic meningoencephalitis may be similar to toxoplasmosis. Haemorrhagic necrotic encephalitis is described in the nests of trypanosomes in microglia. Congenital infection may resemble toxoplasmosis, cytomegalic inclusion disease, or syphilis, with an increased likelihood of abortion and premature birth.

Symptomatic or asymptomatic acute infection may be followed by a symptom-free indeterminate phase of unpredictable length, which may be lifelong.

Chronic-phase symptoms may emerge in up to 30 per cent of patients recovering from the acute phase. Cardiac symptoms include arrhythmias, palpitations, chest pain, oedema, dizziness, syncope, and dyspnoea. The cardiac enlargement may be massive with chronic congestive cardiac failure, apical aneurysm (Fig. 5 and Plate 5), and thrombus in the right atrial appendage (Fig. 6 and Plate 6). The cardiac conducting system is involved, especially the sinus node, bundle of His and AV node, in which there is mononuclear and mast-cell infiltration, inflammation, and fibrosis. Characteristic ECG abnormalities are right bundle-branch block (**RBBB**) and left anterior hemiblock (**LAH**). AV conduction abnormalities, including AV block, may be present. Arrhythmias may include sinus bradycardia, sinoatrial block, ventricular tachycardia, primary T-wave changes, and abnormal Q-waves. The severity of heart disease is graded by the degree of disturbance. Sudden death is attributable, not to ruptured aneurysm but to arrhythmias often precipitated by exercise (e.g. on the football field). Radiography may reveal megacardia (Fig. 8). Signs of oesophageal involvement include loss of peristalsis, regurgitation, and dysphagia (Fig. 7 and Plate 7). Parotid enlargement may be associated. In megacolon there may be failure of defaecation, constipation, and faecaloma (Fig. 9 and Plate 8). Progressive dilatation of either organ can be graded clinically according to severity and may be detectable by radiography. Megaduodenum and megaureter are also described. The lymph nodes between the pulmonary trunk and the aorta are frequently enlarged.

Fig. 8 Chest radiograph showing gross cardiac enlargement in a Brazilian woman with chronic Chagas' disease. (Copyright D.A. Warrell.)

Fig. 9 Megacolon postmortem in chronic Chagas' disease. (By courtesy of Dr J.S. de Oliveira.) (See also Plate 8.)

A differential diagnosis requires distinction from other types of heart disease and ECG abnormality. RBBB and LAH are indicative, but a history of exposure to *T. cruzi* infection and laboratory diagnostic evidence must be considered (see below).

Laboratory diagnosis

A history of exposure to triatomine bugs, to potentially contaminated transfused blood, or a prolonged stay in endemic regions must be considered.

Motile trypomastigotes might be seen in unstained, wet blood preparations examined by microscopy. Nevertheless, parasitaemia is often scanty or undetectable by this method. The sensitivity of parasitological diagnosis may be enhanced by concentration methods, such as: microscopy of the centrifugation pellet from separated serum (Strout's method), microscopy of the haematocrit buffy coat layer, microscopy of Giemsa-stained thick films, or microscopy of the centrifugation sediment after lysis of red blood cells with 0.87 per cent ammonium chloride. All these tests may be negative if parasitaemia is low. Potentially infected blood must be handled with care, especially during haematocrit centrifugation, as a single trypomastigote can give rise to infection. Multiple blood cultures may also be performed, with a sensitive blood agar-based medium and physiological saline overlay. Even more sensitive than blood culture is xenodiagnosis, in which hungry fourth or fifth instar bugs from a triatomine colony, raised from bug eggs and fed only on birds, are allowed to feed on the patient. Bugs are applied in a plastic pot contained in a discrete black bag, which is tied beneath the patient's forearm. The bugs are dissected 20 to 25 days later. The hindgut and rectum are drawn out into a drop of sterile physiological saline, mixed with a blunt instrument (microspatula), and observed microscopically for motile epimastigotes and trypomastigotes. Dissection should be performed behind a small, Perspex safety screen or in a microbiological safety cabinet. *R. prolixus* is the most avid feeder for xenodiagnosis but may cause delayed hypersensitivity reactions in sensitized patients. The local vector should be used as the susceptibility of triatomine species varies with the strain of *T. cruzi*.

After the acute-phase infection, all the above methods of parasitological diagnosis will fail except xenodiagnosis, and possibly multiple blood cultures. Up to 50 per cent of patients in chronic phase may yield a positive xenodiagnosis, providing at least 10 triatomine bugs are used. Although polymerase chain reaction (**PCR**) amplification of *T. cruzi* DNA is sensitive and specific, it not available as a routine diagnostic test. Serum antibody is produced within a few days of *T. cruzi* infection and persists for life in untreated patients. There is an early IgM response, but it is not sustained at the high levels seen in African trypanosomiasis. Persistent IgG may be detected by the enzyme-linked immunosorbent assay (**ELISA**), by the indirect fluorescent-antibody test (**IFAT**), or by the indirect haemagglutination test (**IHAT**). Complement fixation, developed in 1913, is effective but now seldom used. Recombinant antigens are under trial but have not yet been adopted. Cross-reactions may occur, with visceral and mucocutaneous leishmaniasis, treponematoses, and possibly with other hyperimmune responses or autoimmune diseases. Serological assays must be standardized with negative and positive control sera, and by reference to experienced external reference centres to check reproducibility. Transplacentally acquired IgG may persist for up to 9 months in infants born of seropositive mothers. However, IgM specific seropositivity in such infants is an indicator of congenital infection.

Treatment

Proven acute cases must be treated promptly in an effort to minimize tissue damage and neurone loss. The synthetic oral nitrofuran, nifurtimox (LAMPIT ®) from Bayer was the first successful drug for the treatment of Chagas' disease but it is no longer readily available. Benznidazole (Rochagan ®) from Roche is now the sole first-line chemotherapy. An oral nitroimidazole, the adult dosage is 5 to 7 mg/kg for adults, in two divided doses, for 60 days; for children, 10 mg/kg also in two divided doses for 60 days. Adverse effects may demand interruption of treatment. These include rashes, fever, nausea, peripheral polyneuritis, leucopenia, and (rarely) agranulocytosis. Children tolerate treatment better than adults. Double or even higher doses have been used for immunocompromised patients, especially if meningoencephalitis is present. There is no guarantee that a full course of treatment will eliminate the infection. Although the value of drug treatment for chronic infections is still debated, it is favoured for children.

Chemotherapy is an important part of supportive treatment. In acute-phase heart failure, sodium intake is restricted and diuretics and digitalis may be indicated. Meningoencephalitis may require anticonvulsants, sedatives, and intravenous mannitol. Heart failure due to Chagas' disease may require vasodilatation (angiotensin-converting enzyme inhibitors) and maintenance of normal serum potassium levels; digitalis is a last resort because it may aggravate arrhythmias. A pacemaker may be fitted to improve bradycardia not responding to atropine, or for atrial fibrillation with a slow ventricular response that is not responsive to vagolytic drugs, or for complete AV block. Amiodarone has been suggested as the most useful drug to treat arrhythmias but it may still be aggravating. For ventricular extrasystoles lidocaine (lignocaine), mexiletine, propafenone, flecainide, and b-adrenoreceptor antagonists may be effective. Lidocaine may be used intravenously in emergencies. It is essential to consult detailed WHO expert reports and physicians with substantial experience in the management of chagasic heart disease.

Surgery is a vital part of case management for Chagas' disease. Resection of ventricular aneurysms has been suggested. Specialized surgery has been developed in Brazil for the treatment of megaoesophagus and megacolon. Early megaoesophagus may respond to balloon dilatation. The Heller–Vasconcelos operation, in which a portion of muscle at the junction of the oesophagus and stomach is removed, may alleviate megaoesophagus. Severe megaoesophagus requires replacement of the distal oesophagus, for example with a portion of jejenum. The modified Duhamel–Haddad operation has been considered the most successful surgery for correction of a megacolon: after resection, the colon is lowered through the retrorectal stump as a perineal colostomy. Subsequent suturing, under peridural anaesthesia, gives a wide junction between the colon and the rectal stump.

Prognosis, even in treated patients who show serological reversion, is unpredictable as the sequelae of damage due to the acute phase of Chagas' disease cannot be foreseen.

Prevention and control

There is no vaccine against Chagas' disease and no immunotherapy.

Chagas' disease flourishes on the back of poverty and in poor housing conditions. There are proven methods of controlling domestic triatomine bugs. These depend on insecticide spraying, health education, community support, and house improvement. Synthetic pyrethroids are the insecticides of choice, and several commercial sources are available. Vector control programmes consist of preparatory, attack, and vigilance phases. In the preparatory phase, the distribution of all dwellings must be mapped, the presence of infested houses assessed, and the attack and vigilance phases costed and planned. The attack phase involves spraying all houses and peridomestic buildings, irrespective of whether bugs have been found. During the vigilance phase, the community plays an essential role in reporting residual bug infestations, which elicit a rapid respraying response for the affected sites. Serology is vital for monitoring the success of control programmes. Children born after control programmes begin should be serologically negative beyond 9 months of age (to exclude transplacental transfer of IgG) except for infrequent cases of congenital transmission.

Blood donors in, or from, endemic areas should be screened serologically. If conditions demand the use of seropositive blood it can be decontaminated with crystal violet (250 mg per litre) and storage at 4 °C for at least 24 h. Potentially infected organ donors or recipients should be screened serologically. Seropositive

immunosuppressed recipients are likely to suffer reactivated acute-phase infection. Prophylactic chemotherapy with benznidazole may be effective.

The Southern Cone Programme launched a massive effort to eliminate *T. infestans* from Argentina, Bolivia, Brazil, Chile, Paraguay, Uruguay, and from southern Peru. Domestic infestation in Brazil has been reduced by 85 per cent. Uruguay and Chile are essentially free of vector-borne and blood-transfusion transmission. Substantial progress has also been made in the other participating countries. Similar international collaborations are planned for the Andean Pact countries and for Central America. Reinvasion of sylvatic bugs into domestic habitats may complicate vector control in some regions. A surveillance programme and rapid responses to new domestic triatomine populations are planned to protect the Amazon against domiciliation of vectors.

T. cruzi is of immense research interest. It is not entirely clear how the organism evades the host immune response. Furthermore, the pathogenesis of Chagas' disease is not fully understood. Molecular methods have radically changed our understanding of the epidemiology of *T. cruzi* infection. Molecular features unique to trypanosomatids (trypanosomes and leishmanias) make *T. cruzi* an attractive model for molecular biologists. Further research is required to produce a non-toxic, low-cost oral drug, which would eliminate the reservoir of infection in humans, and to clarify further the population genetics and epidemiological significance of diverse strains. The origins and evolution of the organism and its vectors are also of considerable academic interest.

Trypanosoma rangeli

The second human trypanosomiasis in the New World is due to *T. rangeli* infection. *T. rangeli* is also transmitted by triatomine bugs, in particular the genus *Rhodnius*. In *Rhodnius* spp., however, *T. rangeli* traverses the wall of the alimentary tract, infects the haemocoel, and reaches the salivary glands, in which the metacyclic infective trypomastigotes are produced. *T. rangeli* is thus transmitted by the bite of the triatomine bug and not by contamination with bug faeces. Although enzootic *T. rangeli* infection is widespread in Latin America, transmission to humans is virtually confined to areas in which *R. prolixus* is the domestic vector of *T. cruzi*. Co-infections of *T. cruzi* and *T. rangeli* may occur. The organism appears to be non-pathogenic in humans. *T. rangeli* can be pathogenic to *Rhodnius* spp. The importance of *T. rangeli* lies in the fact that it may confuse xenodiagnosis to detect *T. cruzi*. With care and experience, *T. rangeli* can be distinguished from *T. cruzi* either by its long slender epimastigotes (up to 80 µm in length), or by its smaller kinetoplast, or by its presence in the haemolymph or salivary glands of some xenodiagnosis bugs. The lifecycle in the mammalian host is uncertain, but *T. rangeli* is thought to divide in the peripheral blood. Trypomastigotes are rarely seen in human blood: they are much larger than *T. cruzi*, with a small subterminal kinetoplast. Antibodies to *T. cruzi* certainly crossreact strongly with *T. rangeli*. Based on experimental work in mice, *T. rangeli* infections are thought to induce very low crossreactive antibody titres to *T. cruzi*.

7.13.12 Leishmaniasis

A. D. M. Bryceson

Leishmaniasis is caused by parasites of the genus *Leishmania*, which are transmitted by phlebotomine sandflies. The infection may be anthroponotic or zoonotic. In humans, the disease is usually either cutaneous or visceral. The most important variant is mucosal leishmaniasis of South and Central America. In certain places the disease is common and important, but there are few accurate statistics. The World Health Organization estimates 500 000 cases of visceral leishmaniasis and 1.5 to 2 million cases of cutaneous leishmaniasis annually, with 200 million people at risk of each disease.

Aetiological agent and lifecycle

In its vertebrate host the oval amastigote form of the parasite, which is 2 to 3 µm in diameter, is found in cells of the reticuloendothelial system (Fig. 1). In the sandfly or in culture medium it is in the elongated, motile, promastigote form with an anterior flagellum.

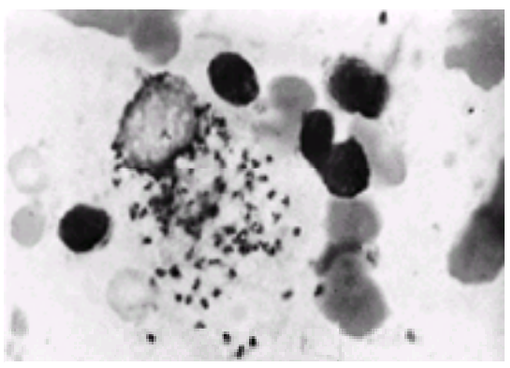

Fig. 1 Amastigotes of *Leishmania donovani* in a reticuloendothelial cell from the splenic aspirate of a patient with visceral leishmaniasis.

The most important species of *Leishmania* that cause disease in humans and their own reservoir hosts are shown in Table 1; isoenzyme patterns and DNA hybridization are used to distinguish species.

Sandflies require a precise microclimate that is provided in certain places in each endemic focus at particular seasons of the year. Transmission is often seasonal. Amastigotes are ingested from blood or tissues of the mammalian host by the female fly, and transform into promastigotes in the gut, rendering the fly infective after about 10 days.

Cutaneous leishmaniasis

Epidemiology (see Table 1)

The vectors of *Leishmania major* live in rodent burrows. Hunters, travellers, tourists, and dwellers at oases or in new settlements are affected. The disease may be sporadic or epidemic. The vectors of *L. tropica* live in crevices in buildings and walls. The disease may be endemic or epidemic. The vector of *L. aethiopica* bites people sleeping in their huts. The disease is endemic and most people are affected by early adulthood. *L. infantum* causes simple, self-healing skin lesions in some parts of southern Europe and North Africa. *L. donovani* causes post-kala-azar dermal leishmaniasis in India.

In the New World, transmission is usually in the forest. *L. brasiliensis*, the major cause of American cutaneous and mucosal leishmaniasis, is the most widely distributed of the New World species. Its vectors are highly anthropophilic and human infection is common. Periurban and urban foci of infection are increasing. Infection with *L. peruviana* occurs in high Andean valleys, where it may be locally common.

Pathogenesis and pathology

Leishmania inoculated by the sandfly invade and multiply in macrophages in the skin. The parasitized macrophage granuloma is infiltrated by lymphocytes and plasma cells. Piecemeal or focal necrosis destroys parasitized cells. The overlying epidermis shows hyperkeratosis, and ulcerates. In chronic lesions epithelioid cells and Langhans giant cells produce a picture similar to that of non-caseous tuberculosis. Rarely, the cellular immune response is suppressed and histology shows heavily parasitized macrophages with little or no lymphocytic infiltrate, characteristic of diffuse cutaneous leishmaniasis.

L. aethiopica, *L. mexicana*, and *L. brasiliensis* may invade cartilage. Cartilaginous lesions are extremely chronic. *L. brasiliensis*, and occasionally *L. panamensis* or *L. guyanensis*, may metastasize through the bloodstream to sites deep in the mucosa of the upper respiratory tract, where they may lie dormant. After months or years a lesion develops characterized by necrosis, vasculitis, and tissue destruction.

Immunity to a given species of *Leishmania* is usually lifelong. Second infections occur occasionally, especially in the elderly or immunosuppressed.

Clinical features

After an incubation period of a few days to several months an erythematous nodule develops at the site of the infected sandfly bite. A golden crust forms. The sore reaches its final size, usually 1 to 5 cm in diameter, over weeks or months. The crust may fall away leaving an ulcer with a raised edge (Fig. 2 and Plate 1). Satellite papules are common. After months or years the lesion starts to heal leaving a depressed, mottled scar. Secondary infection is unimportant. The lesion is not normally painful, but may disfigure or disable if scarring is severe or over a joint. Draining lymphatic vessels may be thickened or nodular.

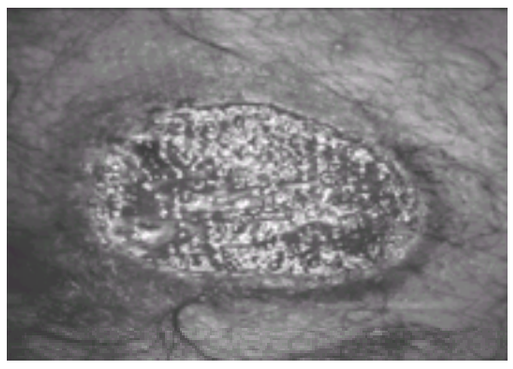

Fig. 2 Shallow ulcer with raised edge due to *L. brasiliensis* (copyright A.D.M. Bryceson). (See also Plate 1.)

There are many variations on this classical pattern. Sores due to *L. major* form and heal rapidly (mean 3–5 months) and may be inflamed and exudative: the so-called wet or rural sore. Sores due to *L. tropica* tend to be less inflamed and to heal more slowly (mean 10–14 months): the so-called dry or urban sore. Lesions due to *L. infantum* have an incubation period of many months, and may persist over several years. In *L. aethiopica* infections lesions are usually central on the face. Satellite papules accumulate to produce a slowly growing, shiny tumour or plaque that may not crust or ulcerate, taking 2 to 5 years to heal (Fig. 3); mucocutaneous leishmaniasis may develop, producing swelling of the lips and expansion and elongation of the nose.

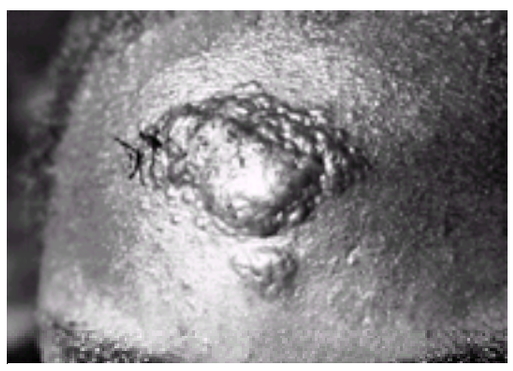

Fig. 3 Spreading nodular lesion, typical of *L. aethiopica*, Kenya.

L. brasiliensis often causes deep, spreading ulcers, which heal over 6 to 24 months. Up to 15 per cent of patients will relapse after spontaneous or therapeutic cure. *L. mexicana* lesions are commonly on the limbs or side of the face, and heal in 6 to 8 months. Sores on the pinna of the ear may invade the cartilage, persist for many years, and destroy the pinna.

Three forms of cutaneous leishmaniasis do not heal spontaneously: diffuse cutaneous leishmaniasis, leishmaniasis recidivans, and American mucosal leishmaniasis.

Diffuse cutaneous leishmaniasis

This occurs with *L. aethiopica* and *L. amazonensis* infections, but is rare. The primary nodule spreads locally without ulceration, and secondary blood-borne lesions appear on other sites in the skin, affecting especially the face and the cooler extensor surfaces of the limbs (Fig. 4). The eye, mucosae, viscera, and peripheral nerves are spared, in contrast with lepromatous leprosy with which it may be confused. The infection proceeds gradually over many years.

Fig. 4 Diffuse cutaneous leishmaniasis, caused by *L. aethiopica*, Ethiopia.

Leishmaniasis recidivans or lupoid leishmaniasis

This is a rare complication of *L. tropica* infection. The initial sore heals, but papules recrudesce in the edge of the scar and the lesion spreads slowly over many years (Fig. 5 and Plate 2).

Fig. 5 Lupoid or recidivans leishmaniasis in a citizen of Baghdad. (By courtesy of Dr Ahmed.) (See also Plate 2.)

American mucosal leishmaniasis, espundia

Up to 40 per cent of patients with untreated cutaneous ulcers due to *L. brasiliensis* may develop mucosal lesions, half of them within 2 years of the appearance of the original lesion, and 90 per cent within 10 years. About one in six patients gives no history of a previous skin lesion. In most cases the nasal mucosa is affected, and in one-third another site is also involved: the pharynx, palate, larynx, and upper lip, in order of frequency. The initial lesion is a nodule and the initial symptom is of nasal obstruction. It commonly presents as protuberant new growth of the nose or lips (Fig. 6 and Fig. 7 and Plate 3, Plate 4), or cicatrization which causes an elongated 'tapir' nose. Mucosal leishmaniasis is slowly destructive, the septum perforates, and eventually the whole nose and mouth may be destroyed. Death may result from secondary sepsis, starvation, or laryngeal obstruction.

Fig. 6 Swollen upper lip and nose due to mucosal leishmaniasis in Peru (copyright A.D.M. Bryceson). (See also Plate 3.)

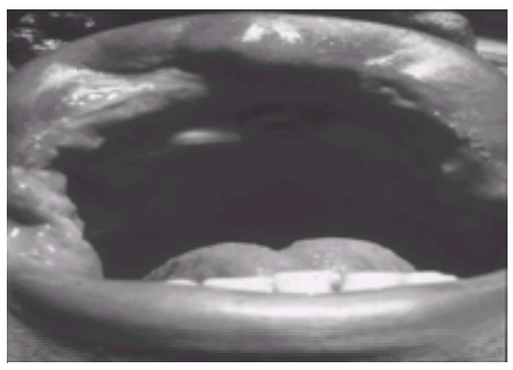

Fig. 7 Infiltration of lip and palate due to mucosal leishmaniasis in Peru (copyright A.D.M. Bryceson). (See also Plate 4.)

Laboratory findings

Parasitological diagnosis

Leishmania may normally be isolated from 80 per cent of sores during the first half of their natural course. The nodular part of the lesion is grasped firmly between the finger and thumb until it blanches. An incision a few millimetres long is made into the dermis with the point of a scalpel, which is used to scrape dermal tissue and juice. Material obtained may be used to inoculate special diphasic culture medium and to prepare smears for staining with Giemsa, Wright's, or Leishman's stain (Fig. 1). Biopsy material may be used to make impression smears, for culture and for histology. Diagnosis of mucosal leishmaniasis requires deep punch biopsy. Species diagnosis is desirable for American parasites, to assess the risk of mucosal leishmaniasis.

Immunological diagnosis

The leishmanin test is an intradermal test of delayed hypersensitivity which becomes positive in over 90 per cent of cases of self-healing forms of cutaneous leishmaniasis and mucosal leishmaniasis and is 95 per cent specific. Evaluation of a positive test must take into account naturally acquired positivity in the population at risk. Serology is unhelpful.

Treatment

Old World sores or those due to *L. mexicana*, *L. amazonensis*, and *L. peruviana* that are not troublesome may be left to heal naturally. But those that are disfiguring, potentially disabling, inconvenient, or around the ankle, where they heal slowly, should be treated either locally or systemically. Systemic treatment is required when there is risk that the sore may be due to *L. brasiliensis*, *L. panamensis*, or *L. guyanensis*, when the sore is too large or badly sited for local treatment, and for mucosal leishmaniasis, diffuse cutaneous leishmaniasis, and recidivans leishmaniasis.

Local treatment

Surgery, curettage, and cryotherapy are methods of removing small sores. Infiltration into the lesion with a pentavalent antimonial, twice weekly for 2 or 3 weeks, may be successful. Leishmanicidal ointments are under evaluation.

Systemic treatment (see Table 2 and Table 3 for dosage regimens)

All cutaneous species of *Leishmania* are sensitive to pentavalent antimonials in conventional dosage except *L. aethiopica*, when pentamidine or paromomycin may be used. Ketoconazole may be useful for *L. major* and *L. mexicana* infections. Patients with diffuse cutaneous leishmaniasis should be treated for at least 2 months longer than it takes to clear parasites from the skin, and relapses should be treated again promptly. Relapsed cases of mucosal leishmaniasis have usually become unresponsive to antimonials and should be treated with amphotericin B desoxycholate for at least 4 to 6 weeks or liposomal amphotericin B for 3 weeks. In addition they may require antibiotics for secondary sepsis, attention to nutrition, and later plastic surgery.

Visceral leishmaniasis

Epidemiology

Visceral leishmaniasis is found in four main zoogeographical zones (Table 1). Around the Mediterranean littoral, across the Middle East and central Asia, and in northern and eastern China human disease is endemic in many places. Children under 5 years of age are especially affected. In other places the disease is sporadic. Non-immune adults such as tourists, hunters, and soldiers are susceptible. The Ganges and Brahmaputra river valleys of India and Bangladesh are the home of epidemic visceral leishmaniasis, or kala-azar, which returns approximately every 15 to 20 years. The majority of cases are in young people under 15 years of age. In the interepidemic period the parasite survives in patients with post-kala-azar dermal leishmaniasis. Visceral leishmaniasis is endemic in parts of Sudan and Kenya. Older children and teenagers are most commonly affected. Sporadic cases also occur in nomads and visitors. An epidemic that began in southern Sudan in the late

1980s is still raging, and has caused over 100 000 deaths. It has been especially severe among refugees from the civil war.

In South America the disease is most common in northeastern Brazil, where older children are affected. Previously a rural disease, it is becoming increasingly important in towns.

Visceral leishmaniasis may be transmitted by blood transfusion from subclinical cases and appears unexpectedly in immunosuppressed patients, for example after renal transplantation, or as an opportunistic infection with HIV.

Pathogenesis and pathology

For every case of classical visceral leishmaniasis, there are about 30 subclinical infections that cause leishmanin positivity and lifelong immunity to *L. donovani.* Malnutrition predisposes to clinical disease. Established visceral infections are characterized by the failure of specific cell-mediated immunity. The leishmanin test is negative. The parasite multiplies freely in macrophages in the spleen, bone marrow, lymphoid tissues, and jejunal submucosa and Kupffer cells of the liver. Histology shows a variable degree of granuloma formation, and of interstitial inflammation in the liver that may lead to fibrosis. In the spleen especially there is massive reticuloendothelial hyperplasia and infiltration with plasma cells. Small splenic infarcts may develop.

Antibodies, polyclonal IgG, and immune complexes circulate at high concentration but rarely cause complications. About half of patients have mild malabsorption but seldom diarrhoea. Jaundice when present is usually due to intercurrent viral hepatitis. Spontaneous bleeding is unusual and is associated with hypoprothrombinaemia. Visceral leishmaniasis is characterized by anaemia, leucopenia, thrombocytopenia, and hypoalbuminaemia. The anaemia results mainly from shortened red-cell survival with destruction of cells in the spleen, together with splenic pooling and sequestration (hypersplenism). In young children, profound anaemia may develop rapidly as a result of severe haemolysis. Death is usually due to secondary infection.

Clinical features

The male/female ratio is between 3:1 and 4:1. The incubation period is usually 2 to 8 months. In endemic areas the onset is usually ill defined. The patient develops fever, discomfort from an enlarged spleen, abdominal swelling, weight loss, cough, or diarrhoea. Classically the fever spikes twice daily, usually without rigors, but daily, irregular, or undulant fevers are common. During an epidemic or in visitors to an epidemic area, the onset may be abrupt with high fever and rapid progression of illness with toxaemia, weakness, dyspnoea, and acute anaemia.

Physical examination of early cases may show only symptomless splenomegaly. Late cases are wasted with hair changes and pedal oedema typical of hypoalbuminaemia. Hyperpigmentation is characteristic of visceral leishmaniasis in India (kala-azar means black sickness). The spleen is huge, smooth, and non-tender unless there has been a recent infarct. The liver is moderately enlarged in one-third of cases. In Africa generalized lymphadenopathy is common.

Over months or years the patient becomes emaciated, with a distended abdomen (Fig. 8). Intercurrent infections are common, especially pneumococcal otitis, pneumonia, septicaemia, tuberculosis, measles, dysentery, other locally important infections, and rarely, cancrum oris. Untreated, 80 to 90 per cent of patients die.

Fig. 8 Visceral leishmaniasis in a Kenyan child. Note the wasting and massive enlargement of spleen and liver.

Post-kala-azar dermal leishmaniasis

Twenty per cent of Indian patients and 5 per cent of African patients develop a rash on the face and extensor surfaces of the arms and legs after recovery from visceral leishmaniasis. In India the rash begins after an interval of 1 or 2 years and progresses over many years: pale macules become erythematous plaques or nodules resembling lepromatous leprosy, and almost all the body surface may be involved (Fig. 9). In Africa the rash appears while the patient is still recovering, as discrete nodules which show a tuberculoid histology. It heals spontaneously within 6 months.

Fig. 9 Post-kala-azar dermal leishmaniasis in an Indian child, showing the typical hypopigmented macular rash. Note also the nodules on the lower lip.

Visceral leishmaniasis and AIDS

Visceral leishmaniasis may be associated with HIV infection and is an AIDS-defining illness in adults in southern Europe, where it is commonest among intravenous drug users. It may be due to reactivation of latent infection with *Leishmania* or to a recent infection. In Spain, over 50 per cent of adults with visceral leishmaniasis are HIV positive, and it is estimated that 9 per cent of HIV-infected individuals will acquire visceral leishmaniasis. The presentation may not be typical. Often the parasite is found by chance, for example in a rectal or skin biopsy taken for other purposes, or in bronchoscopic lavage. The bone marrow is teeming with parasites, but two-thirds of cases have no detectable antileishmanial antibodies. In 90 per cent of cases the CD4 count is less than 0.2×10^{6}/litre.

Laboratory diagnosis

Parasitological diagnosis

Leishmania may be isolated from reticuloendothelial tissue. Yields are of the order: spleen over 95 per cent, bone marrow or liver 85 per cent, African lymph node 65

per cent, and buffy coat 70 per cent. Bone marrow aspiration is most commonly used, but splenic aspiration is simple, painless, and safe if the prothrombin time is normal and the platelet count above 40 × 10^9/litre. Occasionally, the diagnosis is made accidentally on biopsy of bone marrow, liver, lymph node, or bowel mucosa. Antibodies are present in high titre. Indirect immunofluorescence is suitable for individual cases. Enzyme-linked immunosorbent assay or direct agglutination are the techniques of choice for field diagnosis. The leishmanin test is negative.

Other findings

There is normochromic, normocytic anaemia without reticulocytosis, and neutropenia, eosinopenia, and thrombocytopenia. Serum albumin is low (~20 g/litre) and globulin high (~70 g/litre), IgG and IgM being approximately thrice and twice the normal population values. Hepatic enzymes and prothrombin and partial thromboplastin times are usually normal.

Treatment

Chemotherapy (see Table 2 and Table 3 for dosage regimens)

Liposomal amphotericin B (AmBisome) by intravenous infusion is the best drug for visceral leishmaniasis. It is concentrated and retained in reticuloendothelial cells and is not toxic. All patients respond promptly, but HIV-coinfected patients relapse. At the moment it is far too costly for most countries where visceral leishmaniasis is endemic. Therefore, a pentavalent antimonial remains the drug of choice in most situations.

Sodium stibogluconate containing 100 mg antimony (Sb) per millilitre and meglumine antimoniate containing 85 mg Sb/ml, are of equal efficacy and toxicity. The drug is administered by intramuscular injection, which may be painful, or by intravenous injection through a fine-gauge needle, slowly or by infusion in 50 to 100 ml of 5 per cent dextrose over 20 min to reduce the risk of venous thrombosis. Treatment is given daily for 21 days. Usually the drug is well tolerated, but towards the end of treatment there may be malaise, anorexia, nausea, vomiting, and muscle pains. Should toxic effects develop, rest for 1 day and reduce each dose by 2 mg Sb/kg. Hepatic and pancreatic enzyme levels may rise and haemoglobin levels fall, but they return to normal when treatment is stopped. The electrocardiogram develops unimportant T-wave changes. At higher doses the corrected QT interval may be prolonged, heralding the development of a serious arrhythmia. If it is essential, for example during an epidemic, to give a shorter course of treatment, 10 mg Sb/kg may safely be given every 8 h for 10 days.

The aminoglycoside antibiotic paromomycin or aminosidine (IDA Pharmamed) is equally effective and well tolerated. It is given by intramuscular injection or intravenous infusion over 90 min.

In India, conventional amphotericin B desoxycholate is particularly effective. A new oral drug miltefosine is undergoing trials

Patients who are immunosuppressed as a result of HIV coinfection or immunosuppressive drugs respond slowly, require longer treatment, and are more liable to relapse than immunocompetent patients. Ideally, treatment of such patients should be monitored by splenic aspirate counts of parasites, and continued for 2 to 3 weeks beyond parasitological cure. Aminosidine is the drug of choice, as it is well tolerated and not prohibitively expensive. Renal function and hearing should be monitored. Clinical pancreatitis has been reported with the antimonials. Liposomal amphotericin B, although well tolerated, does not prevent relapse.

Supportive treatment

Intercurrent infection must be sought and treated, and nutritional deficiencies corrected. Blood transfusion is rarely needed.

Response to treatment

Fever, splenic size, haemoglobin, serum albumin, and body weight are useful monitors of progress. Proof of parasitological cure is not usually necessary. Reassessment at 6 weeks and 6 months will detect over 90 per cent of relapses. Relapse rates should be almost zero in Mediterranean and Indian disease and about 2 per cent in African disease. Relapsed patients are slower to respond, and run a 40 per cent chance of further relapse(s) and of becoming unresponsive to antimony. Primary resistance to antimonials is increasing in India where the first choice lies between aminosidine and amphotericin B desoxycholate.

Prevention and control of cutaneous and visceral leishmaniasis

Prevention is a matter of controlling reservoir hosts and sandfly vectors, or of avoiding bites by vectors. Successful control requires an accurate knowledge of transmission in each ecological focus.

In the Old World, urban cutaneous leishmaniasis is controlled by case-finding and treatment, better housing, and domestic spraying with residual insecticides, while rural leishmaniasis is controlled in the Middle East and North Africa by the destruction of gerbil colonies. Mediterranean and urban visceral leishmaniasis in South America may be controlled by the destruction or treatment of dogs. In India, mass campaigns to spray houses and cattle sheds are needed. In the interepidemic period, cases of post-kala-azar dermal leishmaniasis should be sought and treated.

Individuals may take precautions to prevent infection during the season of transmission by the use of insect repellent creams and fine mesh bed nets or chadors impregnated with permethrin.

7.13.13 Trichomoniasis

J. P. Ackers

Urogenital trichomoniasis is caused by infection with the protozoan *Trichomonas vaginalis*. About 170 million new cases each year may well make it the world's commonest non-viral sexually transmitted infection.

In clinical specimens or culture *T. vaginalis* is a motile, round or oval flagellate 10 to 13 µm long and 8 to 10 µm wide; fixed and stained it is about 25 per cent smaller (Fig. 1 and Plate 1). Diagnostic features include the jerky motility, undulating membrane, and microtubular rod (axostyle), which runs through the body and projects as a thin spine from the posterior end. In contact with vaginal epithelial cells *in vitro* the organism becomes extremely flattened and adherent. The lifecycle is simple; no resistant cysts are formed and there are no intermediate or reservoir hosts.

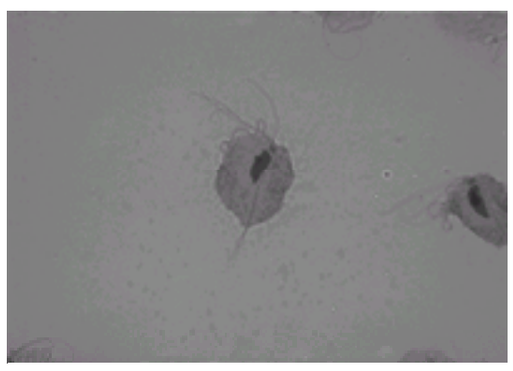

Fig. 1 Trichomonads, Giemsa stain, in vaginal secretions. (Copyright J.P. Ackers.) (See also Plate 1.)

Two other trichomonads—*T. tenax* and *Pentatrichomonas hominis*—are uncommon and probably harmless human parasites of the mouth and large bowel, respectively. All three species are site specific. Urogenital trichomoniasis is not due to contamination from other sites.

Epidemiology

Although it is often difficult to isolate the organism from male contacts of infected women, all epidemiological evidence suggests that the vast majority of infections are sexually acquired. *T. vaginalis* has been shown to survive for many hours at room temperature if kept damp so the theoretical possibility of non-venereal transmission exists. It is also known that a very small proportion of female babies of infected mothers will become infected during birth, but the infection is transient and trichomoniasis discovered in a child should immediately raise the suspicion of sexual abuse.

Very few studies have been made of genuinely unselected populations; the majority have examined either pregnant women or those attending sexually transmitted disease clinics. There are wide variations but most report that 10 to 25 per cent of patients are infected, although the full range is 0 to 63 per cent. Usually female cases outnumber males by 5 or 10 to 1. In several developed countries there has been a steady decline in the incidence of trichomoniasis in the past two decades, but this has not occurred in less-developed countries nor in deprived inner-city areas in industrialized nations. Human trichomoniasis is becoming a disease of the underprivileged.

Pathogenesis

In vitro, *T. vaginalis* has a well defined, contact-mediated, cytotoxic effect, but the relationship of this to pathogenesis *in vivo* is not known. The organism activates complement and attracts neutrophils; several together can kill the parasite, but their presence in large numbers may be responsible for much of the pathology observed. It seems likely that differences in clinical severity are due to both host and parasite factors.

Symptoms

In women trichomoniasis may present as anything from an asymptomatic infection (10 to 50 per cent of cases) to an acute inflammatory diseases with a copious and malodorous discharge; vulvovaginal soreness and irritation, dysuria, and dyspareunia are also frequently mentioned. The discharge may vary over time and, untreated, the infection may be spontaneously lost or persist for months or years. A recent study showed trichomoniasis significantly associated with symptoms of yellow vaginal discharge and vulvar itching and signs of colpitis macularis (strawberry cervix), purulent vaginal discharge, and vulval and vaginal erythema. Colpitis was seen frequently if colposcopy was undertaken, but hardly ever by naked-eye examination. Vaginal pH is usually elevated.

The majority of men with trichomoniasis are asymptomatic, but the parasite is responsible for a small but increasing proportion of cases of non-gonococcal urethritis.

Pathology

In women, *T. vaginalis* may be found in the vagina and the exterior cervix in over 95 per cent of infections, but is recovered from the endocervix in only 13 per cent. The urethra and Skene's glands are also commonly infected. In men the urethra is the most common site of infection, but the organism has also been recovered from epididymal aspirates. Dissemination beyond the lower urogenital tract is extremely rare even in severely immunocompromised patients.

Previously regarded as unpleasant but harmless, epidemiological studies have recently linked trichomoniasis in women with a modest increase in the risk of heterosexual HIV transmission and with adverse pregnancy outcome and have suggested that it might cause a few per cent of cervical neoplasias.

Laboratory diagnosis

The symptoms and signs are not sufficient to establish the diagnosis, which must be made by detecting the parasite. This is most frequently achieved by wet-film microscopic examination of vaginal (not endocervical) secretions, urethral scrapings, centrifuged urine sediment, or prostatic fluid. The specimen should be examined as soon as possible—a motile trichomonad is unmistakable. Sensitivity is moderate, 50 to 70 per cent in women but only 10 to 20 per cent in men.

Culture provides significantly greater sensitivity; media vary in efficiency but Diamond's TYM and the very convenient if rather expensive InPouch ® system are amongst the best.

Antigen detection, DNA probe, and polymerase chain reaction (**PCR**)-based tests have been developed; none has yet found widespread acceptance but the sensitivity

of the PCR-based methods offers new possibilities or making an accurate diagnosis on specimens obtained in less invasive ways including self-administered tampons.

Treatment

The 5-nitroimidazole drugs provided the first and so far only group of effective chemotherapeutic agents. Doses given here are for metronidazole and should be adjusted to give the equivalent amount of other compounds. Two regimens are used—the original one of 250 mg three times a day for 7 days, or a single 1.6 or 2 g dose. Cure rates in women are similar (about 95 per cent) with both regimens if male sexual partners are also treated, but appear to be lower with the single-dose regimen if they are not. Only the 7-day regimen has been extensively evaluated in males, where it is equally effective. Treatment failures with any of the 5-nitroimidazole drugs are rare, but a proportion is due to resistant parasites.

7.14.1Cutaneous filariasis

G. M. Burnham

Filarial infections of the skin and soft tissues

Filarial infections of man and animal are worldwide. Of the filarias which primarily affect the skin or subcutaneous tissues of man— *Onchocerca volvulus*, *Loa loa*, and *Mansonella streptocerca*— the burden imposed by *O. volvulus* is by far the greatest. *Loa loa* produces self-limited swellings of the extremities and the migrating adult worm may be seen subcutaneously. *Mansonella perstans* and *Mansonella ozzardi* cause minimal if any symptoms.

Onchocerciasis

Onchocerciasis, or river blindness, occurs in 34 countries in Africa, Latin America, and the Arabian Peninsula. An estimated 17.7 million people are infected, the vast majority in Africa. Infection has caused blindness in 270 000 and left another 500 000 with severe visual impairment. Besides eye changes, onchocerciasis has chronic systemic effects, causing extensive and disfiguring skin changes, musculoskeletal complaints, weight loss, changes to the immune system, and perhaps epilepsy and growth arrest as well. Of all the manifestations of onchocerciasis, skin lesions are the most common. These include acute and chronic itchy papular disease, and intensely pruritic lichenification. Lesions may be localized or widespread. In later stages, degenerative skin disease develops with a loss of elastic tissue, and extensive pigmentory changes.

The disease, endemic to some of the world's poorest areas, has great impact on the economic and social fabric of communities. A complex human–parasite tolerance allows people who host millions of parasites to continue daily existence. The discovery of ivermectin treatment has brought untold benefits to victims of the disease and to their communities.

Epidemiology

The microfilariae of *O. volvulus* were first observed by O'Neill in Ghana in 1875 in an intensely pruritic chronic skin condition called 'Craw-craw,' Leuckart described the adult worm 20 years later, and in 1923 Blacklock in Sierra Leone showed the blackfly, *Simulium damnosum*, to be the vector. Hissette in the Congo, and Robles in Guatemala linked blindness with onchocerciasis. Long before, Ghanians along the Red Volta river had associated the biting flies with skin lesions and blindness.

Vector control has now interrupted onchocerciasis transmission in the Volta river basin of West Africa, leaving the largest numbers of infected people in Nigeria, Cameroon, Chad, Ethiopia, Uganda, and the Congo. Most African foci are fairly stable, but in South America, foci continue to enlarge and new ones are found. Within foci, the disease may occur unevenly due to differences in both distribution of flies and exposure to bites. In the Americas, onchocerciasis is most common in the highland areas of Guatemala. Other countries with disease foci are Mexico, Venezuela, Colombia, Brazil, and Ecuador

In Africa, blindness was noted to be more common in savannah and woodland than rain forest areas, but people in forest areas had more depigmented skin disease. Parasite DNA probes have shown the existence of different strains or forms of the parasite, particularly in West Africa, although migration may now be blurring this geographical distribution. Other factors such as population density, genetic factors, transmission patterns, and perhaps nutrition may contribute to the risk of blindness. Onchocercal skin disease may reduce marital prospects (and dowry size), disrupt social relationships, and decrease the productivity of agricultural workers.

Experimental studies suggested considerable variation in the efficiency with which sibling species of *Simulium* flies transmitted forest and savannah strains of the parasite. This has given rise to the concept of vector–parasite complexes in which forest strains of parasites are preferentially transmitted by forest sibling species of flies and savannah strains by savannah sibling species. However, recent studies using polymerase chain reaction (**PCR**)-amplified *O. volvulus* larval DNA have questioned the importance of transmission complexes.

Parasitology

Larvae of *O. volvulus* enter the human during the blood meal taken by an infected female *Simulium* fly. Within 1 to 3 months larvae develop into male or female adult worms within palpable nodules commonly located over bony prominences of the thorax, pelvic girdle, or the knees (Fig. 1 and Plate 1). Nodules may be found on the head, particularly among children. These average 3 cm in diameter and are easily palpable, but some are deep, particularly around the pelvis.

Fig. 1 A 3-cm subcutaneous nodule. (See also Plate 1.)

A female worm may release 1300 to 1900 microfilariae per day for 9 to 11 years. From the nodules, these microfilariae find their way mainly to the skin and eye. In the skin they are found predominantly in the lymphatics of the subepidermis. In the eye, most are in the anterior chamber, but they are also found in the retina and optic nerve. When an infected human is bitten, anticoagulants from the *Simulium* fly create a pool of blood from which blood and microfilariae are ingested. Within the fly, those microfilariae that survive moult twice over the following 6 to 12 days to become infective larvae.

Microfilariae are about 250 to 300 µm in length and may live up to 2 years. They move easily through the skin and connective tissue ordinarily remaining within lymphatic vessels and provoking little reaction while alive. They have been seen in blood, urine, cerebrospinal fluid, and internal organs. One hundred million or more microfilariae may be present in heavily infected people. While live microfilariae are tolerated by their human hosts, dead and dying microfilariae may evoke intense inflammatory reactions which are responsible for the eye and skin damage. Tolerance of microfilariae may be regulated by MHC-encoded molecules.

Important species of *Simulium* are really complexes made up of sibling species, identifiable through banding patterns of their larval chromosomes. In Africa the main vectors are members of the *S. damnosum* complex or *sensu lato* (*s.l.*), which can fly long distances. The vector in areas of Uganda, Tanzania, Ethiopia, and the Congo are members of the *S. neavei* complex. In the Americas complexes of *S. ochraceum*, *S. metallicum*, and *S. exiguum* are the principal vectors, and these cover shorter distances. Some *Simulium* will bite humans almost exclusively while others are to varying degrees zoophilic.

Simulium develop in water courses varying from broad rivers to small streams, depending on the individual sibling species. Rapid flowing water provides the oxygenation needed for development of the immature stages. Most larvae and pupae develop on rocks or vegetation just below the water surface, but those of *S. neavei* develop on amphibious *Potamonautes* crabs. During this development period, the larvae are susceptible to insecticides.

Clinical features

Manifestations of onchocerciasis are almost entirely due to localized host inflammatory responses to dead or dying microfilariae. In a heavily infected person, 100 000 or more microfilariae die every day. The predominant immune response in onchocerciasis is antibody mediated, but with an important cellular component. Inflammatory responses may vary considerably between groups of people depending on length of exposure to antigens and the down-regulating activities by the host's immune system.

Eosinophils play an important role in the inflammatory responses. Cellular proteins derived from eosinophils are deposited on connective tissues throughout the dermis and are attached to elastic fibres causing skin changes.

In the eye, eosinophils are present in the anterior segment but lymphocytes and macrophages are more numerous. There is an activation of vascular endothelium, pericytes, and fibroblasts in people with chronic eye changes. Autoantibodies have been found to cells in the inner retina and to the retinal photoreceptors. The roll of these antibodies in causing retinal damage is uncertain. There is extensive evidence for a down-regulating of the immune response in chronically infected eye tissue by suppressor T cells and lymphocytes secreting interleukin 4.

Adult worms elaborate substances that inhibit the host's normal immune response. Exposure to filarial antigens *in utero* and through breast milk may induce an immune tolerance in residents of endemic areas. This could explain the difference in the disease patterns seen in people from non-endemic areas who become infected.

Among those coinfected with HIV, there is a lessened reactivity to *O. volvulus* antigens, but no difference in adverse reactions following ivermectin treatment.

Eye damage

The risks of visual impairment increase as prevalence and intensity of infection rises in a community. Microfilariae enter the cornea from the skin and conjunctiva, and a punctate keratitis develops around dead microfilariae which clears when inflammation settles. In those exposed to years of heavy infection, sclerosing keratitis and iridocyclitis are likely to develop, causing permanent visual impairment or blindness (Fig. 2).

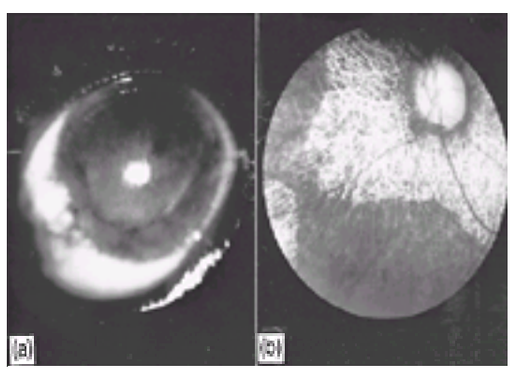

Fig. 2 (a) Sclerosing keratitis in a distorted eccentric pupil from anterior uveitis in a person blind from onchocerciasis. (b)Onchocerciasis producing a Hissette–Ridley fundus and optic atrophy in a person with central keyhole vision remaining.

The first sign of sclerosing keratitis appears as a haziness at the medial and lateral margins of the cornea. This is followed by a migration of pigment on to the cornea accompanied by a progressive ingrowth of vessels. Gradually the cornea becomes opacified. The central and superior areas are the last involved. Although eye lesions can be found wherever onchocerciasis occurs, in West Africa blindness is most common in savannah areas. Before control efforts began in Burkina Faso, 46 per cent of men and 35 per cent of women would eventually become blind.

Posterior segment lesions, which can coexist with anterior eye lesions, may be caused by inflammation around microfilariae entering the retina along the posterior ciliary vessels. Choroidoretinal lesions are commonly seen at the outer side of the macula or encircling the optic disc. Active optic neuritis is reported as an important cause of blindness in Nigeria. Optic atrophy has been reported to be present in 1 to 4 per cent of people with onchocerciasis in Cameroon and 6 to 9 per cent in northern Nigeria. Loss of peripheral vision is well recognized in onchocerciasis.

Skin disease

Of all the consequences of onchocerciasis, skin lesions are the most pervasive. Surveys of seven endemic sites in five African countries reported that between 40 and 50 per cent of adults had troublesome itching, which in some cases was so intense that people slept on their elbows and knees to minimize this symptom.

In its mildest form, onchocerciasis presents as itching with a localized maculopapular rash. These reactive lesions and itching may be evanescent, clearing completely without treatment in a few months. In other instances the papular lesions may become chronic and generalized, and accompanied by severe itching (Fig. 3 and Plate 2). Oedema and excoriations can be associated, and lesions may heal with hyperpigmentation. Particularly distressing are lichenified, hyperkeratotic lesions which may be widespread, and intensely itchy (Fig. 4 and Plate 3). A localized form of chronic papular dermatitis, often confined to one extremity, is known as *Sowdah*,

Arabic for dark. In this condition, first described from Yemen, there is an exceptionally strong IgG antibody response.

Fig. 3 Excoriated papular lesions of onchocerciasis with hyperpigmentation. (See also Plate 2.)

Fig. 4 Lichenified skin lesions with atrophy. (See also Plate 3.)

Light-skinned expatriates infected while visiting an endemic area may present a year or later with intensely itchy and red macular or maculopapular lesions. These may be confined to one area of the body or be more generalized, and may be associated with fever, muscle, joint pain, and sometimes oedema. Rash may sometimes persist for several months following ivermectin treatment.

In endemic areas, degenerative skin changes may develop in some people with long-standing infection. Elastic fibres are destroyed leaving the skin thinned with a wrinkled cigarette-paper appearance. The atrophied skin begins to sag, the most extreme state being 'hanging groin' with its apron-like skin folds. Depigmentation of the pretibial areas, or 'leopard skin', is a characteristic finding in older people living in endemic areas (Fig. 5 and Plate 4).

Fig. 5 Depigmented 'leopard skin'. (See also Plate 4.)

Other conditions associated with onchocerciasis

Both men and women with onchocerciasis weigh less than an uninfected cohort, and report more musculoskeletal pains. Evidence from Uganda and Burundi have suggested a possible association between epilepsy and onchocerciasis.

A peculiar pattern of growth arrest beginning between the age of 6 to 10 years was reported from a Ugandan onchocerciasis focus near Jinja in 1951. This Naklanaga syndrome, as it was called, now seems to have disappeared from there following elimination of onchocerciasis, but has been noted in western Uganda, and perhaps in Burundi.

Diagnosis

Finding microfilariae in skin snips is the time-honoured, though not very sensitive, method of diagnosis. Microfilariae lie close to the surface and are most plentiful in the iliac crest area, except in Latin America where they are more common in the shoulder and scapular areas. Using either a scalpel blade or a sclerocorneal punch, four to six snips (about 5 mg each) are taken under sterile conditions and immersed in normal saline. Microfilariae swimming free of the skin fragments can be counted easily with a dissecting microscope at 24 h or sooner. Examination of excised onchocercal nodules shows sections of adult worms. Enzyme immunoassay and PCR diagnostic methods have a high degree of sensitivity and specificity. Eosinophilia is common in onchocerciasis.

The Mazzotti test, in which people with onchocerciasis react with itching and a skin rash to 50 mg of diethylcarbamazine (DEC or Banocide), is seldom needed for diagnosis and is dangerous in heavy infections.

For community assessment, the prevalence of nodules in 30 to 50 males over the age of 20 years multiplied by 1.5 gives the approximate community prevalence of onchocerciasis. Where the prevalence of nodules is over 40 per cent the risk of blinding disease is high.

Treatment

The introduction of ivermectin for onchocerciasis in 1987 was one of the milestones of tropical disease treatment. Symptoms of onchocerciasis can be controlled effectively in individuals in a clinic or through mass treatment of endemic communities.

Ivermectin is derived from *Streptomyces avermitilis*. A single dose of 150 µg/kg clears microfilariae from the skin for several months. Annual treatment controls microfilarial counts and prevents progression of clinical findings, though in some locations it is given twice yearly. Treatment can be repeated if itching returns before

the next dose is due. In the absence of reinfection, treatment should probably be continued for 10 or more years, or until adult worms stop producing microfilariae. In Ghana, after 5 years of annual ivermectin, the number of microfilariae was reduced to 7 per cent of the pretreatment baseline count.

Limiting the numbers of microfilariae through annual treatment improves early and advanced anterior-segment eye lesions, halts development of optic nerve disease, and improves severe onchocercal skin lesions. Adverse reactions to ivermectin commonly consist of increased itching, swelling of the face or extremities, and headache and body pains. Hypotension has been reported rarely after treatment in heavily infected people. Bullas have been seen occasionally. The most pronounced adverse reactions occur after the first ivermectin treatment, decreasing after subsequent treatment cycles. Ivermectin has no adverse effects in uninfected people. Although ivermectin temporarily reduces the release of microfilariae by adult worms, it does not destroy the adults. Care should be exercised in treating people coinfected with *Loa loa*, particularly those with counts above 10 000 microfilariae/ml blood, as potentially fatal central nervous system events can occur.

Ivermectin acts primarily on parasite neurotransmitters producing paralysis. This action appears to be mediated by potentiation or direct opening of glutamate-gated chloride channels. Although some ivermectin resistance has developed in animal parasites, no drug resistance has been reported in humans .

Prevention and control

Methods have included insecticides added to rivers to interrupt *Simulium* breeding, mass distribution of ivermectin, and nodulectomy in an attempt to prevent blindness.

Vector control

Killing *Simulium* larvae by adding DDT to rivers eliminated onchocerciasis in Kenya and the Mabari forest of Uganda. In 1974 the Onchocerciasis Control Programme (OCP) was formed to control *Simulium* through the larviciding of rivers in the Volta basin of West Africa with ecologically suitable compounds. This highly successful vector control programme, later supplemented with ivermectin distribution, has now permitted tens of millions of people to live free of disease. Mass distribution of ivermectin is now the principal method for onchocerciasis control, though vector control may still be appropriate in some locations.

Ivermectin mass distribution

After the effectiveness of ivermectin had been shown, its manufacturers, Merck and Co., established the Mectizan® Donation Program to provide the drug free 'for as long as necessary to as many as necessary'. By mid-1998 over 100 million ivermectin treatments had been given in 33 of 34 endemic countries.

The goal of a control programme may be either complete eradication of the parasite reservoir or elimination of the public health and socio-economic consequences of continuing infection. In Guatemala, where high population coverage with 6-monthly treatment has reduced parasite transmission by 80 to 100 per cent after 3 years, eradication may ultimately be possible, and this could be true elsewhere in Latin America where sustained treatment is implemented.

The Onchocerciasis Elimination Program in the Americas (OEPA) and the African Programme for Onchocerciasis Control (APOC) have been formed with support by the World Bank and other United Nations agencies to eliminate the public consequences of infection. These programmes focus on regular mass administration of ivermectin through community-based distributors and mobile teams.

Because of the lifespan of adult worms, ivermectin distribution programmes must be sustained for a period of 15 years or more. In some places, the duration may have to be longer because of the difficulty in achieving good coverage, often because of insecurity.

Nodulectomy

A third form of onchocerciasis control has been the nodulectomy programmes of Mexico and Guatemala. For many years health workers have moved from village to village removing nodules, especially around the head. The evidence for this preventing blindness is not strong.

Areas needing further research

Although ivermectin brings great relief to the individual, and has a clear impact on the disease in mass distribution programmes, its does not kill adult worms. While symptoms and risks are controlled through annual treatment, the disease itself is not eradicated. A number of macrofilaricidal drugs, capable of killing adult worms, have been tested, but none has so far proved suitable for either individual or mass treatment. Diagnostic methods, although dramatically improved in recent years, are still not in a form suitable for practitioners in developing countries. Our basic knowledge of *O. volvulus* and the disease it causes still contains many gaps. These include a fuller understanding of the parasite and its relationship with the host, the nature of the systemic effects of *O. volvulus* infection, and better knowledge of the natural history of a disease which continues to affect millions worldwide.

Loa loa

Introduction

Loa loa is a filaria transmitted by the *Chrysops* fly in West Africa. The adult worm migrates beneath the skin, and sometimes across the eye, moving at about 1 cm/min. Periodically the infection causes sudden but transient localized inflammatory oedema known as Calabar swellings.

Parasitology

Larvae of *L. loa* burrow into the human skin during feeding of the *Chrysops* or 'mangrove fly' (*C. silacea* or *C. dimidiata*). In humans the parasites mature and live in the fascial layers. After a year or more, microfilariae are produced. Microfilariae are present in the blood during the day, when the *Chrysops* fly bites. Once taken up by the fly, microfilariae go through developmental stages in the fly's thoracic muscles. After 10 days the fly is able to infect a human, and can do so for another 5 days.

Epidemiology

Infection is most common around the Gulf of Guinea, particularly in Nigeria and Cameroon, but extends through Central Africa into Sudan, and Uganda, and south to Angola and the Congo (Fig. 6). Man is the only host, although a similar parasite is found in monkeys in the same areas. The fly lives in the rain forest canopy, and descends to bite humans, attracted perhaps by movement. Transmission may be most intense during the rainy season when flies are breeding on the muddy banks of forest streams.

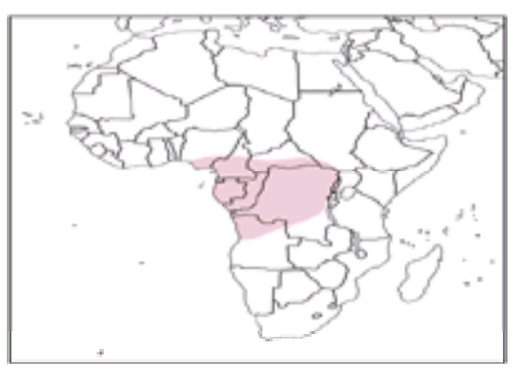

Fig. 6 Map of the approximate distribution of *Loa loa.*

Clinical features

The first clinical symptoms of loiasis may be delayed for several years after infection. Calabar swellings appear suddenly, most commonly in the forearms or wrists, and sometimes following heavy exercise. These oedematous lesions are red and itchy, and may be associated with fever and irritability. After a few hours, or 1 to 2 days at most, the affected part returns to normal. Swellings are not confined to the arms, but may be present in the face, breasts, or legs. They appear more commonly in hot seasons.

Calabar swellings are a hypersensitivity reaction to worm antigens which may be released in the process of migration or perhaps during the maturation of the worm. A high proportion of eosinophils are seen in peripheral blood smears, often exceeding 70 per cent.

A second common feature is the appearance of a migrating worm (Fig. 7 and Plate 5). This may be under the skin in any location, but is most dramatic when it crosses the eye ('eye worm', Fig. 8). Other than local irritation of the conjunctiva while the worm is passing, and the obvious concern of the host, there are no serious consequences.

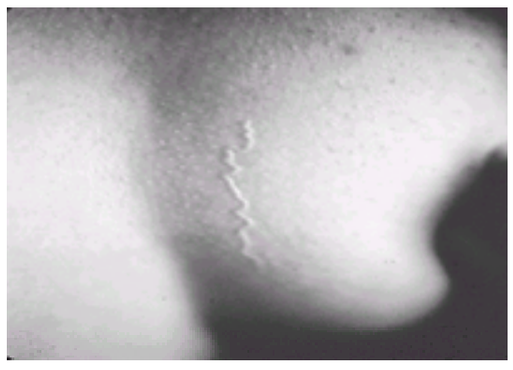

Fig. 7 Migrating *Loa loa. (See also Plate 5.)*

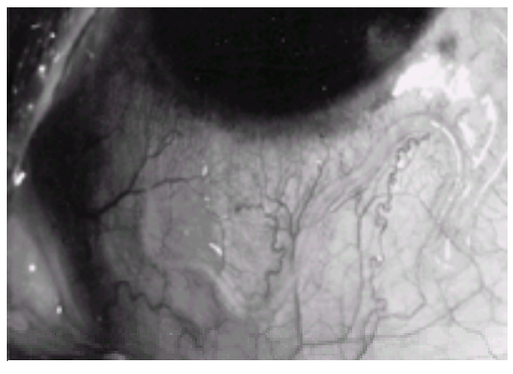

Fig. 8 *Loa loa* crossing the bulbar conjunctiva.

Rare but potentially serious consequences of *L. loa* are meningioencephalitis, renal disease, and endomyocardial fibrosis. The meningioencephalitis may occur spontaneously, though usually after treatment with diethycarbamazine or ivermectin. Recovery is common following supportive treatment, although fatalities have been reported. Those at most risk have microfilarial counts above 10 000/ml of blood. The renal and endocardial complications of loiasis may have an immune origin.

Laboratory diagnosis

Diagnosis has traditionally been by the finding of microfilariae in a daytime blood sample, or by a history or typical clinical findings. Use of more sensitive PCR methods has shown that many, even perhaps the majority of those infected, do not have microfilariae in their peripheral blood.

Treatment

The standard treatment has been diethycarbamazine (DEC), which kills microfilariae and many adult worms. The treatment is given as 50 mg on the first day, and the dose doubled each subsequent day until 2 to 3 mg/kg is reached (maximum 600 mg). This is then continued for up to 21 days. During treatment, fever, arthralgias, and itching can occur. Ivermectin at 200 µg/kg dramatically decreases the number of microfilariae and decreases some of the loiasis symptoms. As with diethycarbamazine, there is a risk of potentially fatal meningioencephalitis in those with high microfilarial counts. It might be prudent to initiate any ivermectin treatment at half dose, particularly in those with higher (more than 10 000 microfilariae/ml) parasite counts. Since many people with loiasis also have onchocerciasis, careful monitoring for severe eye and skin inflammation is important when giving diethycarbamazine. Treatment is unlikely to eradicate all adult worms, and in endemic areas reinfection is probable. Blood films for microfilariae or PCR examinations should be followed to indicate the need for retreatment.

Prevention

The best prevention is avoiding *Chrysops* fly bites. Having window screens on dwellings, wearing clothing to protect legs and forearms, and avoiding high biting areas can reduce risks.

The Mansonellas

Introduction

The mansonellas are a group of filarial infections common to many countries, and are of negligible clinical importance under most circumstances. Infection is transmitted by *Culicoides* midges.

Epidemiology

Mansonella (formerly *Dipetalonema*) *perstans* is found in much of tropical Africa as well as Trinidad and several parts of South America. Adult worms live free in the abdominal cavity, and microfilariae are found in the blood. *Mansonella ozzardi* is found in the West Indies and Central and South America. Microfilariae are found in the blood and skin. Adult worms have been found in the peritoneal cavity. In addition to *Culicoides*, *Simulium* flies have been reported to transmit *M. ozzardi* in the Amazon basis. *Mansonella* (formerly *Dipetalonema*) *streptocerca* is a common infection in West and Central Africa extending into western Uganda. Both microfilariae and adult worms are found in the skin, but without the nodules seen in onchocerciasis. Unless *M. streptocerca* microfilariae are differentiated parasitologically from those of *O. volvulus*, inappropriate mass treatment programmes for onchocerciasis could be implemented.

Clinical manifestions

Of the mansonellas, only *M. streptocerca* produces clear-cut symptoms, although even these can be confused with those of *O. volvulus* which may be a coinfection. Chronic papular lesions are commonly present, often associated with postinflammatory hyperpigmentation. Lichenification may occur less commonly. Hypopigmentation has been noted in areas of skin overlying the location of adult worms in the skin. In general these findings are not easily distinguishable from those of onchocerciasis.

M. perstans has been reported to produce Calabar-like swellings, and in Zimbabwe, central nervous system symptoms. *M. ozzardi* infections are generally without symptoms, though fever, arthralgias, headache, and itching have been associated in the Amazon area.

Diagnosis

A diagnosis is made by the finding of characteristic microfilariae in the blood or the skin. The microfilaria has a distinctive 'walking stick' shape to its tail, and four prominent nuclei in the tail, both of which distinguish it from the microfilaria of *O. volvulus.* Recently a PCR assay has been described for *M. streptocerca* and both QBC-fluorescence and ELISA methods for *M. perstans.* Eosinophilia is a characteristic finding.

Treatment

In asymptomatic persons no treatment is required. *M. streptocerca* responds well to ivermectin, often with mild reactions similar to those seen in onchocerciasis. Treatments of *M. perstans* with diethycarbamazine, and albendazole, have all been disappointing, though mebendazole given as 100 mg once or twice daily for 28 to 45 days has been reported to clear microfilariae. Ivermectin was able to lower microfilarial counts to 60 per cent of pretreatment values.

Further research

Little attention has been given to the mansonellas, ubiquitous in many places. A reliable, inexpensive field test kit for mass screening could help determine the extent of infection and any association with the ill-defined clinical symptoms often reported.

7.14.2 Lymphatic filariasis

R. Knight

Wuchereria bancrofti, *Brugia malayi*, and *Brugia timori* are mosquito-borne nematodes. They are important causes of morbidity in the tropics and subtropics between latitudes 41°N and 28°S in the Old World and 30°N and 30°S in the Americas (Fig. 1). Bancroftian filariasis due to *W. bancrofti* infects 110 million people; it was introduced into the Americas from Africa by the Atlantic slave trade. The two *Brugia* species infect about 13 million people in South and South-East Asia. Approximately 700 million people live in countries where these infections are endemic. *Brugia timori*, which was first described in 1964, has a very localized distribution but causes severe disease.

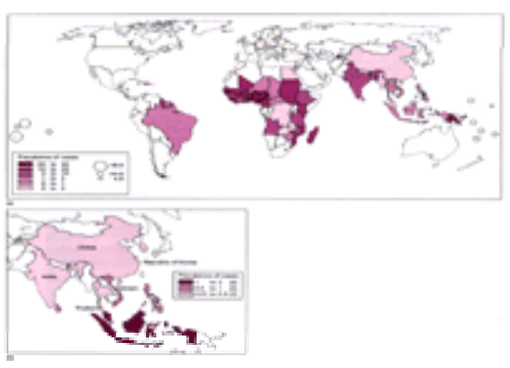

Fig. 1 Distribution of lymphatic filariasis; case prevalences (percentages) due to (a) *Wuchereria bancrofti* and (b) *Brugia* spp. The figures in parentheses indicate the number of countries. Circles denote Pacific Island prevalences. (By courtesy of E.Michael and D.A.P. Bundy.)

Aetiology—the biology of the parasite

Adult worms live in the larger lymphatic vessels and lymph nodes. They are smooth, creamy-white, and threadlike; females measure 80 to 100 mm in length, and males 40 mm; their lifespan is normally 2 to 5 years, but exceptionally much more. Mated females produce numerous microfilariae throughout their lives; these actively motile embryonic worms are sheathed by the remnants of the egg shell. They are 180 to 290 µm in length and 7 to 10 µm in diameter. Different species can be distinguished morphologically in stained films. Microfilariae migrate via the lymphatic system to the blood where they have a lifespan of up to 12 months (Plate 1). Their numbers in the peripheral blood vary during the day and night—a phenomenon known as periodicity; when not circulating they are sequestered in lung and reticuloendothelial capillaries. Maximal counts in the blood coincide with the biting cycle of the vector. The species and strain of parasite determine the periodicity; most common is nocturnally periodic with maximal counts between 22.00 and 02.00 h and virtual absence during the day. Alternatively, microfilariae may be present throughout the 24 h cycle with prominent peaks during the day or the night: diurnally and nocturnally subperiodic, respectively.

After uptake by the vector, microfilariae penetrate the gut and migrate to thoracic muscles where they mature over 9 to 15 days to infective third-stage larvae, which then migrate to the mosquito head and escape from the proboscis during a blood meal. Larval worms enter the puncture wound made by the vector, reach the peripheral lymphatic system, and move to larger lymph vessels below a lymph node. Sexual maturity and appearance of microfilariae in the blood usually takes 8 to 18 months, but sometimes only 3 months.

Epidemiology and transmission

In endemic areas microfilarial prevalence rates increase steadily from early childhood to reach a maximum in early adult life, when in highly endemic areas 10 to 30 per cent prevalences are not unusual; rates in males are generally higher, perhaps due to greater vector exposure. The cord blood of some infants shows microfilariae.

In some locations *Brugia malayi* is a zoonosis with an animal reservoir; elsewhere it is an anthroponosis with only a human source of infection.

Geographical distribution and mosquito vectors

W. bancrofti infection

Culex transmission

This vector breeds mostly in organically polluted water, usually in urban and suburban areas but also villages when there are suitable latrine and cesspit habitats. This is the commonest type of transmission and is increasing with urbanization; it occurs in India, Sri Lanka, Central and South America, some Caribbean Islands, urban and coastal villages in East Africa, Egypt, and parts of China. *Culex* bites at night, mostly on the legs, the microfilariae are nocturnally periodic. *Culex* is the most efficient vector and can maintain transmission at low microfilarial densities, making control difficult.

Anopheles transmission

The same vector species commonly transmit both filariasis and malaria. This occurs in East and West Africa, Papua New Guinea and Vanuatu, limited areas in South America, and parts of China. *Anopheles* bites nocturnally, mainly on the legs; microfilariae are nocturnally periodic.

Aedes transmission

This is limited to Southern Oceania, especially Fiji, Samoa, Tonga, the Cook Islands, and New Caledonia, but also patchily in Thailand, the Philippines, Vietnam, and the Nicobar Islands. *Aedes* feeds throughout the 24 h cycle with a daytime peak, and bites all over the body; the microfilariae are diurnally subperiodic.

B. malayi infection

Zoonotic *Mansonia* transmission in swamp forests

This occurs in Malaysia, Indonesia, and southern Thailand; monkeys and carnivores are reservoir hosts. *Mansonia* bites mainly by night but also by day, usually on legs below the knee; the microfilariae are nocturnally subperiodic.

Transmission in agricultural areas

In parts of Malaysia, Buru in Indonesia, and southern Thailand a mixed anthroponosis and zoonosis occurs in transitional zones with monkeys and cats as reservoirs, and both *Anopheles* and *Mansonia* as vectors. Microfilariae have periodicities intermediate between nocturnally periodic and nocturnally subperiodic.

In India (mainly Kerala), Malaysia, Sulawesi, southern Thailand, Vietnam, China, and Korea infection involves humans only with *Anopheles* as the main vector and *Mansonia* as the accessory vector; the microfilariae are nocturnally periodic.

B. timori infection

This is confined to Timor and other islands in the Lesser Sundas group in eastern Indonesia. *Anopheles barbirostris* is the vector. The microfilariae are nocturnally periodic.

Pathogenesis

Local immunological reactions to worm antigens provoke acute and subacute responses with oedema of lymphatic tissue and infiltration with eosinophils and monocytes. Antigens derive from moulting fluids of developing worms, excretory products, microfilariae trapped within the lymphatic system, and also dying worms including those killed by chemotherapy. Dead and disintegrating worms become surrounded by granulation tissue with giant cells and epithelioid cells. Stenosis or blockage of lymph vessels leads to distal dilatation with varicosities and valve incompetence. Prolonged or recurrent lymph stasis leads to accumulation of protein-rich interstitial fluid and fibroblast proliferation, dilated dermal lymphatics, and epithelial acanthosis and hyperkeratosis.

Determinants of pathology include duration of exposure, intensity of transmission, anatomical sites of infective mosquito bites, and the species and strain of parasite. Prenatal exposure to filarial antigen is of great importance and induces immunological tolerance. Residents in high-transmission areas often show patent microfilariaemia but little immunopathology. However, in many adults a later decline in microfilarial prevalence parallels increased host immunological reactivity and pathology. New residents and visitors show marked local reactivity to worms and often no blood microfilariae; the latter situation was well documented among American troops in the Pacific in 1942 to 1944 and French troops in former Indochina.

Clinical manifestations

Acute lymphatic filariasis

In endemic areas acute episodes are recurrent from the age of 10 years and most frequent 4 to 8 months after the peak of seasonal transmission. Episodes last several days or weeks; fever and malaise are common but blood eosinophilia is not marked. People leaving endemic areas cease to have acute episodes after 1 year although they may experience recurrent pain in previously affected tissues, especially after unusual exercise.

Filarial lymphadenitis and lymphangitis

Tender lymphadenopathy is most common in the inguinal and femoral nodes, but axillary and epitrochlear nodes are also affected. Tender retrograde lymphangitis typically spreads peripherally below the node.

Acute genital filariasis

This is uncommon in boys before puberty but common thereafter. The typical lesion is funiculitis with a tender fusiform or cylindrical swelling of the spermatic cord; epididymitis and orchitis are less common.

Filarial abscess and filarial fever

Affected nodes in the groin or elsewhere may break down producing an open ulcer that heals slowly leaving characteristic scars. Pelvic and retroperitoneal lymphadenitis can produce a febrile illness that is difficult to diagnose.

Chronic lymphatic filariasis

Lymphoedema and elephantiasis

Initially, transient pitting oedema occurs during inflammatory episodes in proximal nodes. Later, oedema persists between episodes becoming non-pitting distally. Eventually, brawny non-pitting oedema becomes permanent (Fig. 2). In patients with leg involvement epidermal thickening, papillomatosis, and fissuring are common (Fig. 3), and bacterial infection becomes an important complication.

Fig. 2 Chronic elephantiasis in a man in Belém, northern Brazil. Note the scars of unsuccessful surgery. (Copyright Pedro Pardal.)

Fig. 3 Chronic elephantiasis with epidermal thickening, fissuring, and papillomatosis in a man in north-east Nigeria. (Copyright D.A. Warrell.)

Chronic genital filariasis

Hydrocele is the commonest lesion and prevalence rates may reach 30 per cent in men over 35 years in highly endemic areas; many patients give a history of preceding episodes of funiculitis or epididymitis. The tunica vaginalis is often thickened. Nodular lesions of the spermatic cord and epididymis are common and the testis itself becomes enlarged and indurated. Lymphoceles occur on the cord. Dilated dermal lymphatics in the scrotal wall associated with atrophic epidermis produce lymph scrotum, the skin having a velvety appearance. Rupture of these lymphatics leads to weeping skin lesions and often secondary infection, occasionally complicated by Fournier's gangrene.

Lymphoedema of the scrotum is a late sequel (Fig. 4), often the testes are unaffected; penile lesions are rare. Vulval lymphoedema is under-recognized; it is associaeted with dilated retroperitoneal lymphatics and must be distinguished from lymphogranuloma venereum.

Fig. 4 Gross hydrocele in a patient with chronic filariasis. (By courtesy of the late P.E.C. Manson-Bahr.)

Chronic lymphadenitis and lymphangitis

Recurrent episodes of acute inflammation lead to persisting and sometimes massive lymph node enlargement. Thickened lymphatic cords may be palpable connecting the axillary and epitrochlear, or the femoral and popliteal nodes. Varicose lymph vessels may be visible in these areas. Lymph varices are fluctuant sacs of lymphatic tissue derived usually from the capsule of a node, hence the alternative term lymphadenocele. They partially empty when the part is raised; aspiration reveals lymph or occasionally chyle. They occur in the medial thigh, groin, axilla, and sometimes even the neck.

Chyluria and lymphuria

Dilated pelvic and retroperitoneal lymphatics may rupture into the urinary tract in the renal pelvis, ureter, or bladder. When there is lymph stasis above the cisterna chyli then small bowel chyle may reflux into the urine postprandially. Chyluria is often intermittent and blood stained (Fig. 5). Continued loss of protein and lipids in the urine may lead to weight loss and cachexia. Chyluria may eventually be self-limited.

Fig. 5 Chyluria and haematuria in a patient with chronic filariasis. (By courtesy of the late P.E.C. Manson-Bahr).

Non-lymphatic pathology

Tropical pulmonary eosinophilia

This presents as a subacute or chronic illness with cough, wheezing, and reticular or miliary pulmonary shadowing. Microfilariae are absent from the blood, but eosinophilia is marked and titres of filarial antibody are very high. Some patients have features of lymphadenopathic or genital filariasis, but many do not. Lung functional loss is restrictive. Response to antifilarial treatment is good but untreated the condition leads to pulmonary fibrosis and pulmonary hypertension. The syndrome is due to a heightened immunological response to dead microfilariae which may be found, in biopsies of lung and other tissue, surrounded by eosinophilic microabscesses. It occurs in most endemic areas, but is rare in Africa; it is commoner in men and rare in children; many patients are not long-term residents.

Filarial arthritis

Joint involvement is subacute and often recurrent with effusion; it usually affects the knee.

Filarial glomerulonephritis

The incidence of clinically significant disease is uncertain; it results from immune complex deposition on the glomerular basement membrane. Recurrent streptococcal infection associated with filarial lymphoedema is also implicated.

Diagnosis

Clinical

Many patients will have several clinical features that, together with history of preceding acute episodes, will be strongly suggestive diagnostically: manifestations such as varicose lymphatics, lymphadenocele, retrograde lymphangitis, and lymph scrotum are highly specific to filariasis. Genital lesions are rare in *Brugia* infections, which usually present with lymphoedema below the knee. In *B. timori* infections lymph node pathology in the legs is often severe, sometimes with skin ulceration. Upper limb and breast lesions are common in diurnally subperiodic *W. bancrofti* infections in the Pacific; but they do occur elsewhere with other strains of this parasite.

Parasitological

Microfilariae are typically found in blood films but also in aspirates from a lymph varix, hydrocele, lymphocele of the cord, or in urine. Blood should be taken to coincide with the expected microfilarial periodicity. Measured 10 or 20 µl volumes are used to prepare thick blood films stained by Giemsa. Counting chambers taking 100 µl of lysed blood can be used or larger volumes may be lysed and the spun deposit examined. Alternatively, 1 ml of lysed or unlysed blood is passed through a Millepore filter; the filter is then stained. Nocturnally periodic *W. bancrofti* microfilariae appear transiently in the blood 30 to 60 min after a 100 mg dose of diethylcarbamazine and this forms the basis of the 'provocation test'. Stained microfilariae can be identified by their sheaths, but these may be lost by *Brugia* parasites during staining; *B. timori* has distinctive sheath staining. The arrangement of nuclei at the caudal end allows species diagnosis; *B. malayi* has two subterminal nuclei separated by a space. The microfilariae of *Loa loa* also have sheaths and must be distinguished from those of species causing lymphatic filariasis.

Immunodiagnosis

Positive skin tests and filarial antibody are common in those exposed to infection and may be of value in visitors to an endemic area. Several tests for filarial antigen in serum are now available and a positive test indicates persisting adult worms. Antigen may be present in the absence of microfilariaemia.

Imaging of lymphatic vessels

Lymphangiography will delineate anatomical details of abnormal lymphatic tissues such as lymph varices and lymphatic connections to the urinary tract in chyluria. They are not usually diagnostic for filariasis. Scrotal ultrasound can show live worms—the 'filarial dance' sign.

Lymphoscintigraphy using technetium-labelled dextran or albumin is a less invasive and useful technique that can demonstrate lymphatic pathology. Abnormal dermal lymphatics occur in many asymptomatic infected persons in endemic areas but, so far, few local control subjects have been examined and comparisons with normal lymphatic studies in Western countries may not be justified.

Treatment

Individual chemotherapy

Diethylcarbamazine remains the treatment of choice. Adequate dosage will kill adult worms. Even a small single dose will clear blood microfilariae temporarily. Sensitivity reactions to filarial antigen, both local and systemic, are common in infected people and simulate some of the acute manifestations of the infection; they necessitate care and supervision in the initial stages, especially in *Brugia* infections. Treatment should be started at 1 mg/kg on the first day, increasing over 3 or more days to 6 mg/kg in divided doses; this dose then being continued for 21 days. Coinfection with *Loa loa* and *Onchocerca volvulus* must be excluded before diethylcarbamazine is given to avoid dangerous reactions.

Indications for curative treatment are acute manifestations with or without microfilariaemia, and chronic disease in patients who are either microfilaria positive or positive for filarial antigen identified serologically. Treatment often reduces the size of hydroceles but has little effect on chronic lymphoedema.

Surgical and supportive treatment

Acute manifestations of filariasis can mimic strangulated hernia and testicular torsion. Surgical treatment of filarial hydrocele is the same as that for non-filarial disease. Scrotal lymphoedema can be treated surgically, usually with preservation of the testes. Lymphosaphenous anastomosis is being used for leg elephantiasis; many other procedures have been used in the past, often with disappointing results (Fig. 2).

Bacterial infection is common in those with lymphoedema, especially when the skin is fissured, breached in an interdigital cleft, or when there is minor injury, ulcer, or insect bite. Early use of antibiotics and resting of the affected limb lessens the risk of increasing lymphoedema; supportive bandaging applied each morning or wearing elastic stockings reduces chronic oedema.

Filariasis at the community level

Surveys for lymphatic filariasis

These are carried out to assess the importance to public health and plan intervention programmes. Current clinical features together with history of acute features in the preceding 6 months are documented, and blood is taken to measure microfilarial density. Serum collected on such surveys has been the source of many immunopathological studies. The following disease groups are recognized, but the availabilty of tests for filarial antigen will add a new dimension to such surveys.

1. Asymptomatic without microfilariaemia—in highly endemic areas most of these people will have been exposed to infection; they are sometimes called 'endemic normals';
2. asymptomatic with microfilariaemia;
3. acute filariasis—many will show microfilariaemia, but this is absent in prepatent infections and in people with strong immunological responses, including visitors; and
4. chronic filariasis—in some geographical areas many subjects will be microfilaria negative, especially those with chronic lymphoedema; in other areas they are positive; negativity may be due to a decline in transmission over several years or to host immune responses.

Social and economic consequences of lymphatic filariasis

Surgical care of patients with hydrocele and other manifestations places a great burden on health care in highly endemic areas. In agricultural communities acute manifestations and episodes of secondary bacterial infection impair productivity. Social stigma is a major problem and may lead to divorce or make a woman unable to marry.

Vector control

These campaigns are targeted at the local vector. Larval *Aedes* breeding sites such a discarded tins, tyres, or coconut shells can be removed. *Culex* numbers can be reduced by improved sanitation, larvicides, and polystyrene beads applied to the water surface of latrines and cesspits. Bednets and repellants are universally applicable. Where *Anopheles* is the vector, malaria control can interrupt filariasis transmission as in Samoa, Vanuatu, and parts of southern China.

Population-based chemotherapy

Different dosage regimens of diethylcarbamazine have been used in many endemic areas; with annual or 6-monthly administration either to the whole population or to those found to be infected; medicated salt is an alternative. The main aim is to eliminate microfilariaemia and hence transmission; however, with repeated and higher doses many adult worms are eventually killed. Ivermectin offers an alternative method of reducing microfilaraemia. A single dose of 6 mg/kg of diethylcarbamazine is as effective as one 200 or 400 µg/kg dose of ivermectin. Both will reduce microfilariaemia to almost nil for 6 or 12 months. Sensitivity reactions are much commoner with diethylcarbamazine. Annual dosage with both of these drugs continued for 4 or 6 years—the lifespan of adult worms—should interrupt transmission. Albendazole is also effective as a microfilaricide and has some activity against adult worms; a 600 mg dose can replace either diethylcarbamazine or ivermectin in a two-drug annual regimen; diethylcarbamazine must not be used where onchocerciasis is co-endemic.

7.14.3Guinea worm disease: dracunculiasis

R. Knight

The clinical manifestations of Guinea worm and its surgical removal were known in antiquity. Attention was drawn to the seasonal occurrence of painful limb blisters that broke down to reveal a 'worm' in the floor of an ulcer. *Dracunculus medinensis* is the longest nematode infecting humans; in the Bible it is described as the 'fiery serpent'. It was the first human parasite to be shown to have an arthropod intermediate host: in 1869 the Russian naturalist Fedtschenko described the worm's early development in *Cyclops*—the 'water flea'. Recent attention is directed at eradication, for despite its complex lifecycle this can be achieved by public health measures alone.

Aetiology—the biology of the parasite Fig. 1)

Mature female worms, 70 to 120 cm in length, migrate along fascial planes and subcutaneous tissue to reach the skin, usually below the knee. Tissue damage caused by worm products produces a blister that soon ulcerates. Immersion of the affected part in water causes the worm to contract and expel numerous rhabditiform first-stage larvae from the uterus at the ruptured anterior end of the worm. Larvae swim vigorously in water for up to 7 days and some are ingested by predatory copepod crustaceans of the genus *Cyclops*. They penetrate the gut of the intermediate host and develop with two moults in the haemocele over a period of 14 days to become infective third-stage larvae. When water containing infected *Cyclops* is swallowed, the released infective larvae burrow though the wall of the duodenum to reach retroperitoneal tissue. After about 100 days the worms mate and the females begin their migration towards the limbs; the male worms die and may later calcify. Ten months after infection most female worms, containing fully formed larvae, have reached their destination; within the next month they will rupture through the skin to begin the cycle anew (Plate 1).

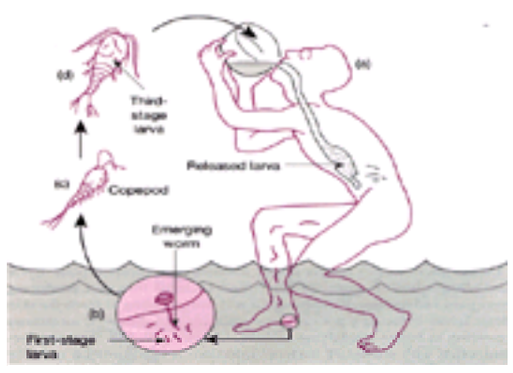

Fig. 1 Lifecycle of Guinea worm in man. (a) Copepods infected with third-stage larvae are ingested in drinking water; larvae are released in the intestine, migrate to the body cavity, mature, and mate. (b) Gravid female worms migrate to the limbs, cause a blister to form and release first-stage larvae into water. (c) First-stage larvae are ingested by copepods. (d) Larvae undergo two moults in the copepod and are infective after 2 weeks.

Epidemiology

Guinea worm transmission is predominantly rural with an annual cycle that often coincides with the planting or harvesting season. The seasonal morbidity causes great economic hardship. Water sources containing *Cyclops* are easily contaminated by infected people, including those seeking relief by immersion of their painful lesion. In semi-arid areas, transmission occurs in temporary ponds during the rainy season; in wetter areas, flooding and water turbidity limits transmission during the rains and infection occurs in shallow wells during the dry season. For practical purposes there is no zoonotic reservoir although infected dogs have been found in endemic areas and primates can be experimentally infected. Related species of *Dracunculus* are found in mink, raccoons, and otters in North America.

Geographic distribution

This infection was previously endemic over wide areas of the Middle East and the Indian subcontinent. Largely as a result of improved and protected water sources the infection disappeared from the Central Asian Republics between 1926 and 1933, from Iran in the 1970s, and Yemen and Saudi Arabia in the 1980s; India and Pakistan have recently become free of infection. It is now limited to the Sahel and Guinea savannah, between 2° and 18° north, in sub-Saharan Africa with most cases in southern Sudan, Niger, Nigeria, Mali, Burkina Faso, Chad, Ghana, and Uganda (Fig. 2). Formerly it was also present in the Americas having been introduced with the slave trade. By the 1880s it disappeared.

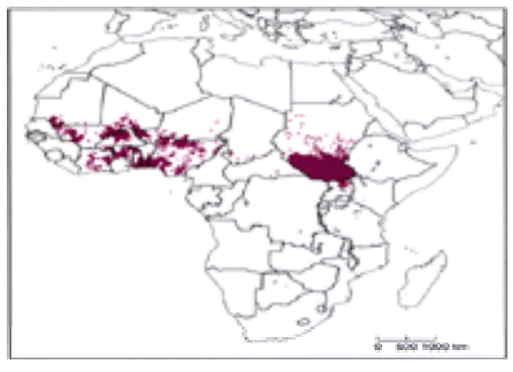

Fig. 2 Distribution of dracunculiasis – endemic villages in Africa. (Reproduced from Peries H, Cairncross S (1997). *Parasitology Today* **13**, 434, with permission: data from Joint WHO-UNICEF Programme on Mapping and Geographic Information Systems for Dracunculiasis Eradication (Health Map), WHO/CTD, Geneva.)

Clinical features

The blister is the first sign of infection in most patients (Plate 1). In others pre-emergent worms may be seen or felt under the dermis, some are actively motile. Allergic prodromal symptoms with urticaria, facial oedema, dyspnoea, and gastrointestinal manifestations may precede the blister by a few days; they disappear when the blister ruptures. Most patients have one or two worms each season, but up to 50 have been recorded. While most gravid worms emerge from a limb, other sites

include the trunk, scrotum, and vulva (Plate 3).

Uncomplicated cases resolve within 4 weeks; local complications derive from sensitization to worm products and bacterial infection producing severe pain and prolonged disability. Gravid worms failing to reach the skin release larvae inducing vigorous tissue reactions and abscesses, sometimes presenting as bubos, epididymo-orchitis, or acute arthritis. Joint involvement, often with secondary bacterial infection, is also common near the site of emergence: this leads to ankylosis and tendon contractures with deformities and permanent disability. Immature female worms may die before reaching the skin and become encapsulated by host tissue, where some calcify; they may also enter ectopic sites including the orbit, pericardium, and central nervous system. Mortality is usually less than 1 per cent. It results from systemic or local bacterial infection; tetanus is a significant risk when spores contaminate open lesions.

Diagnosis

Most patients in endemic areas recognize their condition. Worms release larvae on contact with water and these can be seen as a milky cloud. When the worm is not visible, ulcers may be irrigated with saline and the centrifuged deposit examined for larvae.

Patient management

Local treatment can be very painful and often must be repeated. Warm moist packs should be applied for several hours, followed by gentle massage along the tract of the worm towards the ulcer. Light traction is then applied to the worm; breakage must be avoided as this greatly aggravates the situation. Analgesics and antibacterial soaks are useful; oral antibiotics are often necessary. Between local treatments the lesion must be bandaged to reduce the risk of bacterial infection and contamination of water sources.

Pre-emergent worms can be surgically removed, a practice originating in India. A small incision is made adjacent to the worm near its mid-point, and a loop of worm is lifted out with a blunt curved probe (Plate 2). Massage is applied along the length of the worm towards the incision and by gentle traction the whole worm can usually be removed; in the event of breakage the worm ends should be ligated to minimize contact between host tissue and worm antigens. Deep abscesses require surgical treatment. Anthelmintics have no role in the treatment of Guinea worm.

Control and eradication

Several factors facilitate control: Guinea worm is recognized by local communities as a major health problem, there are no carriers beyond the annual cycle, and there is no animal reservoir. Provision of save water for drinking is the key to control; piped water supplies are unrealistic in most endemic areas, but covered tube wells or hand dug wells provided with parapets are appropriate. Additional measures are filtration of household water with finely woven cloth and the application of temephos (Abate) to ponds to kill copepods.

National programmes have played a major role in many endemic areas. Case detection surveys and health education can be integrated into existing primary health care systems. Unhygienic local treatments such as mud or leaf poultices and crude methods of worm extraction must be discouraged.

Several international health agencies took up the challenge of Guinea worm eradication in the mid-1980s with the target eradication date of 1995. Much has been achieved but the target was missed. Initial expensive hydrological programmes were later replaced by training of local cadres who could conduct health education, case detection, and management, partly independent of local health care services. In some areas private sector initiatives have been able to gain commercially from the publicity achieved by adopting control in a defined area.

There has been a decline of about 95 per cent in the incidence of Guinea worm in the last 15 years. The last stages of eradication will be the most difficult as vertical programmes then become inefficient. Unfortunately many of the major residual foci are in situations of civil disorder and mobile refugees; in others, lack of resources or an absence of democratic institutions will slow progress.

7.14.4 Strongyloidiasis, hookworm, and other gut strongyloid nematodes

R. Knight

Strongyloidiasis

The parasitic female *Strongyloides* worms are parthenogenetic. They measure 2 to 2.5 mm in length and normally live in tunnels between the enterocytes of the crypts of Lieberkühn in the duodenum and jejunum. In the external environment larvae may develop directly, through two moults, into infective larvae, in a manner similar to that of the hookworm (Fig. 1). Alternatively, they may follow the indirect cycle, develping into free-living male and female adult worms, about 1 mm in length, that produce a second generation of infective larvae. In either case the cycle is completed when infective filariform larvae penetrate the skin and are carried in the venous circulation to the lungs, from where they ascend the bronchi to be swallowed and so reach the upper small bowel, where they mature.

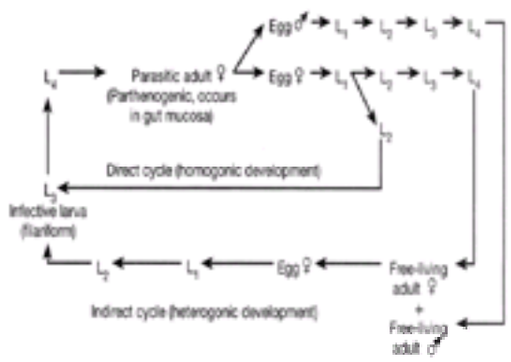

Fig. 1 Basic lifecycle in the genus *Strongyloides*; L_1, L_2, L_3, and L_4 are the larval stages. The indirect cycle occurs in the soil or faecal mass. Eggs of the parasitic female *S. stercoralis* hatch in the gut lumen and direct development may occur not only in the external environment but also on the perianal skin to produce external autoinfection, or in the gut lumen to produce internal autoinfection. The eggs of the parasitic female *S. fuelleborni* appear in the faeces and internal autoinfection is not possible.

Strongyloides stercoralis

Biology and epidemiology

Eggs hatch immediately on reaching the gut lumen, and the first-stage larvae (Fig. 2) then normally pass down the gut without moulting. Direct development in faecally contaminated soil takes 24 to 48 h; free-living adults mature in 72 to 96 h, and live for up to 10 days. Infective larvae can persist in the soil for 3 weeks. There is no second generation of free-living adults. Two types of autoinfection enable infection to persist in the host for long periods. In external autoinfection, infective larvae penetrate the perianal skin after rapid direct development on soiled skin. In internal autoinfection, larvae mature to the infective stage within the lumen of the gut and invade the mucosa of the small intestine or colon, they then pass via the gut lymphatics and portal vein to the lungs and back to the gut. In some patients, uncontrolled internal autoinfection leads to hyperinfection with massive worm loads and severe pathology.

Fig. 2 First-stage larvae of *S. stercoralis* in stool.

S. stercoralis is widely distributed in the tropics, where prevalence may be 5 to 10 per cent or higher in humid lowlands. It remains endemic in the southern United States, Japan, and in parts of southern Europe, for example, among Swiss and Italian horticulturalists. It also occurs in institutions when soil temperatures are high enough. Transmission among male homosexuals is very rare. Host risk factors are of great importance for internal autoinfection. Patients on steroid and cytotoxic therapy are at most risk, but also those with lymphomas and some other malignancies, hypochlorhydria, diabetic ketosis, hypogammaglobulinaemia, and malnutrition. Despite coprevalence with human immunodeficiency virus type 1 over much of its range, this viral infection does not predispose significantly to *S. stercoralis*

hyperinfection, except in patients with advanced AIDS. Servicemen in the Second World War became infected in Thailand and other parts of South-East Asia, mostly as prisoners of war. Many of these infections still persist and such people are at risk of hyperinfection if given steroids.

Pathology

In most persistent infections the parasite load is very low, evokes little pathological response, and the patient is free of symptoms. In some primary infections and when worm loads are higher there is villous blunting with oedema and cellular infiltration of the mucosa, leading to malabsorption and protein-losing enteropathy. In more severe infections and in hyperinfection the small-gut wall becomes oedematous and thickened with impaired motility, and the mesenteric lymph nodes are enlarged. In massive autoinfection there is patchy mucosal loss and some adult worms are found deep in the mucosa from where larvae may invade directly without entering the gut lumen (Plate 1). Invading infective larvae can produce a diffuse or haemorrhagic colitis; migrating or ectopic larvae may be found in any organ of the body. Rarely, adult female worms develop ectopically in the lungs, and these account for the occasional presence of eggs and rhabditiform larvae in sputum.

Clinical manifestations

Light persistent infections

Symptoms, if any, are usually intermittent, with episodes of upper abdominal pain, wheezy cough, and pruritus ani. Blood eosinophilia is common, and may be the only clinical finding. A pathognomonic sign is a rapidly migrating urticaria known as 'larva currens' that occurs on the buttocks, thighs, and lower trunk; it is a form of cutaneous larva migrans, arising from external autoinfection (Plate 2).

Moderate infections

Gut symptoms predominate, with diarrhoea and malabsorption. Weight loss and anorexia are prominent and not infrequently there is leg oedema. Pulmonary and skin lesions are not common. In primary infections a Loeffler's pneumonitis can occur, with high eosinophilia.

Hyperinfection

Diarrhoea is often severe, and sometimes bloody if there is colitis. Vomiting and abdominal distension may progress to pseudo-obstruction. Other manifestations are upper gastrointestinal bleeding, perforation, peritoneal and pleural effusions, pneumonitis (Fig. 3), and terminally, alveolar haemorrhages. Patients are often afebrile and without blood eosinophilia; they can deteriorate rapidly and develop Gram-negative septicaemia with shock, or meningitis, especially if they are immunosuppressed. Hypoglycaemia is a feature of autoinfection in malnourished children.

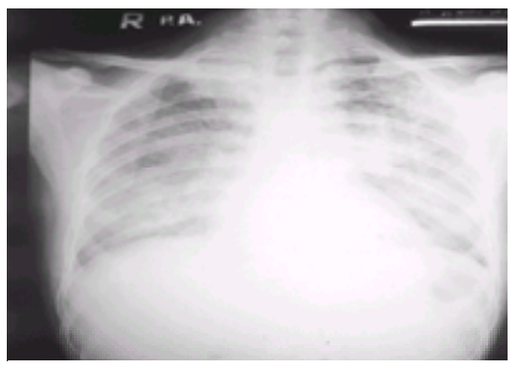

Fig. 3 Chest radiograph of a Thai patient who developed pneumonia as part of hyperinfection precipitated by corticosteroid treatment. (Copyright A.J.H. Simpson.)

Diagnosis

Rhabditiform larvae should be sought in the stool (Fig. 2). They may be scanty and numbers do not necessarily correlate with symptoms. Live larvae are seen in fresh, wet, preparations or Baermann concentrates. Agar-plate coprocultures give a result in 48 h, earlier than with conventional charcoal cultures. Formol-ether concentrates are useful, but sensitivity can be low. When stool specimens are not fresh, filariform *Strongyloides* larvae may be found. Duodenal aspiration is another useful technique. In hyperinfection, larvae may be found in sputum (Fig. 4) and in pleural, peritoneal, or cerebrospinal fluids.

Fig. 4 Gram stain of sputum from the patient whose chest radiograph is shown in Fig. 3, showing larvae of *S. stercoralis*. (Copyright A.J.H. Simpson.)

Serodiagnosis is useful, especially as a screening test in non-endemic areas. In heavy infections, small-bowel barium studies show segmental dilatation, narrowing, and abnormal motility; in hyperinfection, plain abdominal films may show fluid levels.

Treatment

Thiabendazole remains the drug of choice; 25 mg/kg is given twice daily (maximum 3 g/day), usually for 3 days. Intolerance is common and drug-induced hepatitis is reported. Treatment may fail in hyperinfection, which continues to have a high mortality. Such patients need supportive care and parenteral antimicrobials. Invermectin kills adult worms but not migrating tissue larvae; a single oral dose of 200 µg/kg, repeated after 1 week, or 200 µg/kg daily for 3 days are used, but experience in patients with hyperinfection remains limited. Albendazole is an alternative in non-urgent cases but cure rates are rather low.

Strongyloides fuelleborni

In this species eggs do not hatch in the gut lumen so there can be no internal autoinfection. The eggs are thin-walled and contain a larva. In Africa this parasite is common in non-human primates. In the forests of West and Central Africa, particularly Zaire, people are commonly infected, mainly from zoonotic sources. Elsewhere, for instance in Zambia and adjacent countries, there is person-to-person transmission. Infected volunteers have developed wheezing, upper abdominal pain, and loose stools, but symptomatology in natural human infections is poorly defined.

In Papua New Guinea a subspecies of this parasite, *S. f. kellyi*, is focally common in both children and adults. In a few communities a distinctive 'swollen belly syndrome' is associated with enormously high faecal egg counts and protein-losing enteropathy. Infants aged 2 weeks to 6 months are affected and show abdominal distension, diarrhoea, breathing difficulties, weight loss, hypoproteinaemia, and peripheral oedema; untreated, the mortality is high. There are no non-human primates in Papua New Guinea and no animal reservoir for this parasite is known. In infants, external autoinfection occurs when they are nursed in soiled string-bag cradles; transmammary transmission is suspected.

S. fuelleborni infection should be treated with thiabendazole. Supportive care including plasma infusion or blood transfusion, plus antibiotic cover, is needed for 'swollen belly syndrome' in Papua New Guinea.

Hookworm and other gut strongyloid nematodes

Adult strongyloid worms live attached to, or buried within, the bowel mucosa (Fig. 5). The ovoid eggs of all genera are similar in appearance, with thin, transparent shells containing a segmented embryo, commonly a 4-, 8- or 16-cell morula. Eggs hatch in the soil and development proceeds through three stages with two moults. The first and second larval stages feed upon bacteria. They are described as rhabditiform, because of resemblance to the soil nematode *Rhabditis*; the pharynx is short, muscular, and constricted in the posterior third, just anterior to a posterior bulb. The third stage, the infective filariform larva, does not feed and may retain the cuticle of the second stage; the pharynx is long and slender, without any constriction. In adults the buccal capsule and its oral armature, and the male copulatory bursa and spicules are used for species identification. Filariform larvae from cultures are generically distinct.

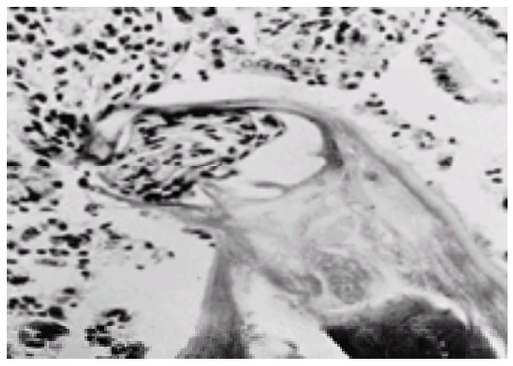

Fig. 5 Adult worm of *Necator americanus* showing relationship of its pharynx to a jejunal villus.

The hookworms

Aetiology—the biology of the parasites

Adult worm infections are due to *Ancylostoma duodenale* and *Necator americanus*. Several species that normally infect carnivores may accidentally infect humans and produce zoonotic cutaneous larva migrans or an eosinophilic enteritis in the case of *A. caninum*.

Adult worms measure 8 to 13 mm in length and taper at both ends (Plate 3). Anteriorly the worms are flexed dorsally, giving them their hooked appearance. They attach themselves to the jejunum by drawing mucosa into the buccal cavity (Fig. 5). A vigorous pharyngeal pump enables blood and tissue fluids to be ingested. Worms move frequently in response to host immunological responses. Females produce 5000 to 20 000 eggs per day, but output per worm declines as worm load rises. In the soil, development is temperature dependent. Under optimum conditions eggs hatch within 2 days and larvae develop to the infective stage in 5 days; they can persist in sandy soil for up to a month. Larvae penetrate host skin after soil contact, most commonly between the toes. After entry into dermal venules and lymphatics they are carried to the lung, ascend the bronchi and trachea, and after being swallowed, re-enter the gut where the final moult occurs. Eggs (Fig. 6) can appear in the faeces 50 to 60 days after cutaneous exposure.

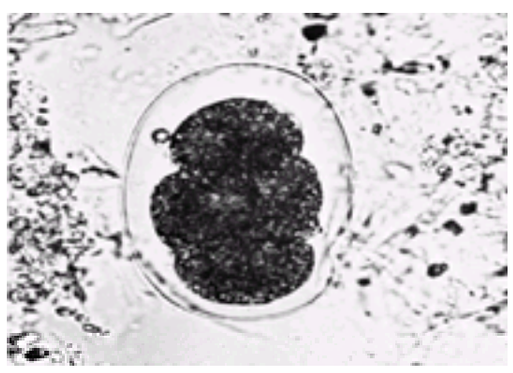

Fig. 6 Egg of *N. americanus*.

Epidemiology

N. americanus is found in the warm, moist tropics where transmission is sometimes perennial. Its introduction to the Americas dates from the transatlantic slave trade. It is a smaller worm than *A. duodenale* and the mouth is guarded by two cutting plates. The mean egg output per female is 8000 per day and the lifespan may exceed 5 years; transmission is exclusively by the percutaneous route.

A. duodenale is primarily a subtropical and temperate species with development in the soil at lower temperatures. It is widely distributed in North Africa, the Middle East, the Indian subcontinent, central and northern China, and in parts of Latin America. Formerly, it was endemic in southern Europe and Japan; it was responsible for 'miner's anaemia' in Cornish tin mines and the Gotthard tunnel. The mouth is guarded by two pairs of sharp teeth. Females produce 15 000 eggs per day. The lifespan is usually less than 2 years. In addition to the percutaneous route, larvae on vegetables can penetrate the buccal mucosa and undergo transpulmonary migration, or they can be swallowed and develop directly within the gut mucosa. Infection may also be transplacental; in China severe hookworm disease is reported in very young infants. Another lifecycle feature is arrested development when larval maturation is delayed at the third or fourth stage within skeletal muscle, or more commonly, in the gut mucosa. This postpones the onset of patent infection and is an adaptive mechanism to irregular or seasonal transmission.

In most populations where these parasites are endemic the prevalence and worm load both rise with age to reach a plateau in adults. Prevalence is highest in rural agricultural communities. Aridity and coolness at higher altitudes limit transmission, but irrigation schemes favour it by raising the water table. Children commonly acquire clinically significant infections between the ages of 5 and 10 years. Within communities, individuals differ greatly in worm load; behavioural factors are important but immune responses, including IgE antibody and eosinophils, limit the proportion of larval worms that mature to adults, the adult lifespan, and also female fecundity.

Pathogenesis of hookworm anaemia

Hookworms damage the mucosa mechanically and by the inflammatory response they evoke; bleeding continues at former attachment sites. Gut motility is affected, especially in primary infections and in children, and this may affect digestive and absorptive function. The major pathogenic mechanism is ingestion of plasma, interstitial fluid, and red cells by the adult worms. *A. duodenale* ingests about 0.15 ml of blood daily, and *N. americanus* 0.05 ml. Most red cells pass through the worm's gut and a proportion of the iron content, variously estimated at 10 to 50 per cent, is reabsorbed by the host. Because worm loads are commonly above 50, and may reach 500 or more, the cumulative effect can be serious. The main nutritional effects are iron deficiency and hypoproteinaemia. The rate at which blood loss leads to anaemia is determined by worm load, the duration of infection, iron stores, other blood loss, and dietary iron. Children, and pregnant or lactating women, with little reserve iron, can become anaemic in a few months; in a previously healthy adult male it can take 2 years or more. Loss of albumin into the gut may exceed the capacity of the liver to replace it; synthesis is depressed by low dietary protein, and by the anaemia. Hypoproteinaemia limits the normal, compensatory expansion of plasma volume that occurs in chronic anaemia. While the risk of pulmonary oedema is less, transition to a state of low cardiac output is made more likely.

Clinical features attributable to adult worms

In acute primary infections and in children, epigastric pain is common and may be associated with poor appetite and sometimes diarrhoea. Anorexia is an important mechanism leading to nutritional deficit in children. A few patients develop overt gut bleeding, and melaena is reported in transplacentally infected infants in China.

Most patients present with slowly progressive iron-deficiency anaemia, many have no gut symptoms. Exertional dyspnoea may begin at a haemoglobin level of 8 g/dl, but may not be noted until it falls to 5 g/dl. Palpitations, weakness, and faintness on exertion are common; and sometimes precordial pain or leg claudication. A puffy oedema of the face, arms, and hands is typical, and often unaccompanied by dependent oedema. Other features in heavy infections are mental apathy and depression, and in adults, amenorrhoea or impotence. Pica is common, especially in pregnancy.

Milder degrees of anaemia reduce physical work performance in adults. In children, growth and development may be slowed and cognitive impairment leads to reduced scholastic achievement.

Assessment of cardiovascular status is essential in anaemic patients, to differentiate a well-compensated, high-output state from a dangerous low-output one.

Clinical features attributable to larval worms: cutaneous larva migrans

Cutaneous lesions take the form of migrating, itchy, red, serpiginous papules, known as creeping eruption or cutaneous larva migrans (Plate 4). They commonly become vesiculated and excoriated, with bacterial pyoderma. *A. duodenale* or *N. americanus* cause 'ground itch' among estate workers and prominent lesions occur in experimental human infections; however, in many endemic areas they are unnoticed.

Zoonotic hookworms produce more vigorous lesions that may continue to move for several months. Most infections are due to *A. braziliense*, which is common in dogs throughout the tropics, subtropics, and warmer temperate regions. Less common are infections by two other dog parasites, *A. caninum* and *Uncinaria stenocephala*, and the cattle hookworm *Bunostomum phlebotomum*. Infections occur on sandy bathing beaches, in children's play areas, and by contact with pet sandboxes. Lesions are most common on the lower legs and buttocks, but also occur on the arms, hands, and face.

Wheezy cough due to pneumonitis is more common with *A. duodenale*; symptoms can continue for many months after one exposure, owing to remobilization of larvae arrested in muscle. Lung symptoms are most prominent in heavy primary infections.

In Queensland it is now recognized that larvae of the dog hookworm *A. caninum* can reach the gut to produce an eosinophilic enteritis with abdominal pain and vomiting; immature adult worms are found at laparotomy or colonoscopy.

Diagnosis

Stool microscopy will reveal eggs (Fig. 6), except in prepatent infections; examination of stool concentrates is rarely necessary. Faecal egg counts per gram of stool enable the intensity of infection to be estimated. The simplest method is a semiquantitative wet smear, using 2 mg of stool. For more precise results the use of the McMaster counting chamber is recommended. An alternative is the modified Kato technique, but this requires special care as hookworm eggs can overclear and become invisible. Isotope studies indicate that, with either species, 1000 eggs per gram is equivalent to 2.2 ml of blood loss per day. Culture to the infective larval stage, using the Harada Mori technique, will differentiate the two major species and the other genera of gut strongyloid nematodes.

Treatment

A single 400-mg dose of albendazole, or mebendazole at 100 mg twice daily for 3 days, are both very effective. Alternatives are pyrantel at 10 mg/kg daily for three or four doses, or bephenium at 5 g daily for three doses, the latter being less effective for *N. americanus.*

To replace iron reserves, oral ferrous sulphate will suffice in most patients, but several weeks of medication may be necessary. When compliance is doubted, consideration should be given to intramuscular iron or total-dose intravenous infusion of iron dextran.

Transfusion of packed or sedimented red cells may be necessary in pregnancy and when cardiac output is compromised. Frusemide may be necessary to cover the transfusion, but in other circumstances diuretics should be used with caution. Depletion of plasma volume in patients with hookworm anaemia together with hypoproteinaemia can compromise cardiac output. Even bed rest in formerly ambulant patients can lead to significant diuresis. Chemotherapy should generally be avoided in pregnancy.

Cutaneous lesions can be treated with thiabendazole at 25 mg/kg in two divided doses, for 2 days, and, if necessary, after 2 days' rest a further 5 days at the same dose. Alternatively, a single dose of ivermectin at 200 µg/kg may be given; this is more effective than a single dose of 400 mg albendazole.

Topical treatment avoids systemic effects (usually nausea). One 0.5-g tablet of thiabendazole can be ground up in 5 g of petroleum jelly or dimethylsulphoxide base and applied daily over the worm track for 5 days.

Control

Population-based measures are necessary when endemicity and morbidity are high. Latrines are generally beneficial, but can create foci for transmission when the water table is high. Provision of piped water reduces contact with soil polluted by promiscuous defaecation. Where human excreta is used as fertilizer, composting and chemical ovicides are needed. Cash-crop estates, plantations, and irrigation schemes should provide safe latrines and subsidized footwear.

Anthelmintic drugs can be deployed in several ways. Certain target groups such as agricultural and sewage workers, clinic outpatients with pallor, and anaemic blood donors can be treated empirically because of their likelihood of infection. Population chemotherapy, repeated twice yearly, aims to reduce both prevalence and mean worm load. It may include those with positive stool tests—selective chemotherapy; or whole communities—mass chemotherapy. The relative costs of drugs and diagnosis will change during the course of a programme. Single-dose medication is best and possible with mebendazole at a dose of 600 mg or albendazole at 400 mg.

Other gut strongyloids

Trichostrongylus spp.

These are common and economically important gut parasites of domestic ungulates. Infection is by ingestion of filariform larvae on vegetation. Development in the gut is direct, without lung migration. Adults are reddish-brown, 5 to 10 mm in length, and live with their anterior ends embedded in the jejunal mucosa where they feed on tissue fluid, not blood.

Human infection has been recorded with eight species; *T. colubriformis* and *T. orientalis* being the most important. Prevalence rates are highest in Iran, Iraq, Egypt, and Japan. Most infection is derived from sheep, goats, cattle, and camels, but in Iran *T. orientalis* is non-zoonotic. Worms cause mucosal damage, and loss of protein and some blood. Clinical features include abdominal pain, eosinophilia, and sometimes anaemia. The eggs are longer and narrower than those of hookworm, but larval culture is required for reliable differentiation. Infections respond to drugs used for hookworm.

Ternidens deminutus

Human infection is locally common in parts of Central and southern Africa. Infection is direct following oral ingestion of larvae; adult worms are 8 to 16 mm long. They live partly embedded in the colonic mucosa, where they produce superficial ulceration and cystic nodules. The worm is sometimes referred to as 'false hookworm', because of the similarity of its eggs; differentiation is important both clinically and epidemiologically. Non-human primates are infected in much of Africa, but most human infections are non-zoonotic. Infections respond to drugs used for hookworm.

Oesophagostomum spp.

These are important parasites of primates and ungulates: in veterinary practice they are known as the 'nodular worms'. Fourth-stage larvae and immature adults live in the colonic wall, often deeply situated or in the subserosa; lesions may become bacterially infected or perforate. Normally, adult worms return to the gut lumen. Most human infections are reported from forested parts of West and Central Africa. In some remote villages of north Togo and Ghana faecal surveys, using larval culture, have shown prevalences reaching 30 per cent. Most cases have presented surgically with masses, or abscesses, located in the caecum or other parts of the colon; or with bowel obstruction, or ectopic lesions in the peritoneum or abdominal wall. Clinically the lesions simulate carcinoma, tuberculosis, appendicitis, and amoeboma. Diagnosis in such cases has been histological.

The eggs resemble those of hookworm and are absent in prepatent surgical cases. Chemotherapy has been little studied in man, but albendazole has been successfully used. In Africa most human infections are with the monkey parasite *O. bifurcatum*, or *O. stephanostomum*, a parasite of anthropoid apes; in Asia, *O. aculeatum* is the likely cause. The ungulate species do not appear to infect humans.

7.14.5 Nematode infections of lesser importance

David I. Grove

Further reading

From time to time, a patient may be encountered who harbours an unusual nematode. Some of these organisms are free-living parasites and the patient has a spurious infection, usually as the result of ingestion of the worm or following the *in vitro* contamination of a clinical specimen such as faeces or urine. Other individuals may have true infections with worms being found either in the gastrointestinal tract or in the tissues. Many of these infections are with parasites of animals that are adapted poorly to the human host and are unable to complete their development in man. Thus, worms in varying stages of development including larvae, adults, and eggs may be found in specimens. Some parasites may be recovered from fluids and are viewed intact whereas others are seen only in histological sections. If there is uncertainty in identifying the worm in the former circumstance, help may often be obtained from a veterinary parasitologist who may be more used to dealing with the species concerned. In the latter instance, definitive diagnosis may be very difficult but excellent resources are available. [13,39] A summary of rarely reported nematodes is shown in Table 1. *Dirofilaria* species and unusual microfilariae in blood and tissues have been reviewed elsewhere. [40]

Nematodes found in the gastrointestinal tract may respond to a benzimidazole agent such as mebendazole (100 mg orally, twice daily, for up to 3 days) or albendazole (10 mg/kg orally, daily, for up to 1 week). Thiabendazole (25 mg/kg twice daily for several days) has been used traditionally orally for the treatment of systemic larval infections but its effectiveness is very variable; albendazole may be more active than thiabendazole and is absorbed better from the gut than mebendazole. If these drugs fail, ivermectin (0.15 mg/kg orally, daily, for several days) may be tried. Other drugs that have been used in these unusual nematode infections include levamisole and diethylcarbamazine. Unfortunately, some infections are refractory to all anthelmintics. Nevertheless, these worms generally cannot multiply in humans and the parasites will die spontaneously after months or years.

Ascariasis (roundworm)

Ascariasis is an infection caused by *Ascaris lumbricoides*. Normally, the adult worms are located in the small intestine. In unusual circumstances, such as fever, irritation due to drugs, anaesthesia, and bowel manipulation during surgery, the worms may migrate to ectopic sites where they may give rise to severe disease.

Geographical distribution

The distribution is cosmopolitan but the parasite occurs more frequently in moist and warm climates. In some rural tropical areas, the entire population may be infected. It is relatively more common in children, who also carry higher worm loads.

Morphology

The mature worm is cylindrical with tapering ends (Plate 1). It is creamy white to light brown in colour. The female measures 20 to 35 cm in length and 3 to 6 mm in breadth. The male measures 12 to 31 cm in length and 2 to 4 mm in breadth and has a curved tail. The head has three lips at the anterior end, which carry minute teeth or denticles along their margins. The lips can be closed or extended, allowing the worm to ingest food. In cross section, the worm reveals a thick cuticle, adjacent to which is the hypodermis which projects into the body cavity in the form of lateral cords (Fig. 1(a)). The somatic muscle cells are large and elongated and lie adjacent to the hypodermis. The worm is able to maintain its position in the small intestine by the activity of these muscles. If the somatic muscles are paralysed by anthelminthics, it is expelled by peristalsis.

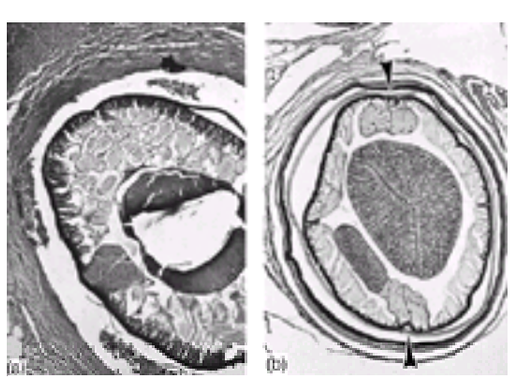

Fig. 1 (a) *Ascaris lumbricoides* in the bile duct (× 125). (b) Anisakis larva in cross section in the human stomach showing large bulbous lateral cords.

The fertilized eggs are ovoidal and measure 60 to 70 by 30 to 50 µm. When freshly passed they are not infective and contain a single cell. The larva becomes infective in the soil. The cell is surrounded by a thin vitelline membrane. Around the membrane is a thick, translucent shell, which in turn is surrounded by an irregular, albuminous coat (Fig. 2). The albuminous coat is sometimes lost or can be removed by chemical treatment, resulting in a decorticated egg. It was once assumed that the brown coloration of the egg was due to bile pigment, but tannins in the egg shell are probably responsible. The unfertilized eggs are 88 to 94 by 40 to 44 µm and

have disorganized contents. The larvae of *A. lumbricoides* may be seen in infected lungs and measure up to 2 mm in length, and 75 µm in diameter (Fig. 3). The larvae have a central intestine, paired excretory columns, and prominent lateral alae.

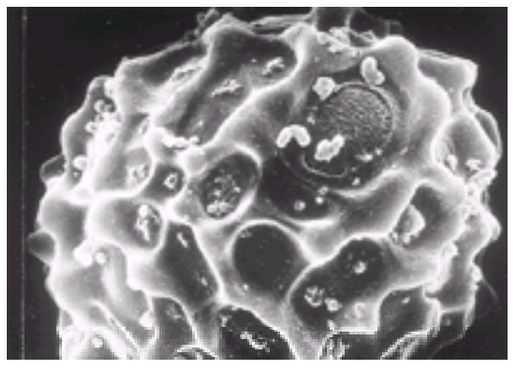

Fig. 2 Ascaris ovum seen by scanning electron micrography. (Copyright Viqar Zaman.)

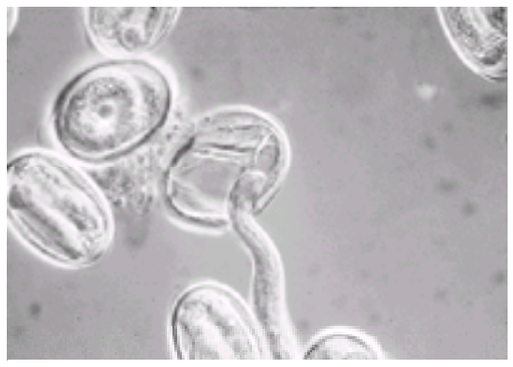

Fig. 3 Decorticated ova of Ascaris showing emergence of larvae. (Copyright Viqar Zaman.)

Lifecycle (see Fig. 4)

The gravid female produces 200 000 to 250 000 eggs daily. These take 3 or 4 weeks to develop into the infective stage, which is probably the third-stage rather than the second-stage larva as was previously thought. The eggs are resistant to chemicals and low temperatures and may remain viable for years in moist soil. On ingestion, the infective larva hatches out in the small intestine and penetrates the intestinal wall to enter the portal circulation. From the liver it is carried to the heart and via the pulmonary artery to the lungs. In the lungs, it breaks out of the capillaries into the alveoli and undergoes another moult to become a fourth-stage larva. From the lungs the larva moves up to the bronchi and then crawls over the epiglottis to enter the digestive tract. In the intestine, it moults again to become a sexually mature worm. The lifespan of an adult worm is approximately 1 year, after which it is spontaneously expelled. In hyperendemic areas, children are being continuously infected so that as some worms are being expelled, others are maturing to take their place.

Fig. 4 Lifecycle of *Ascaris lumbricoides*. (Adapted from Centers for Disease Control, Atlanta, Georgia, United States.)

Clinical aspects

In most cases, the infected person remains asymptomatic. However, there is much evidence to indicate that the presence of *Ascaris* causes nutritional problems and hinders the normal development of children. Occasionally, patients may develop fever, malaise, urticaria, intestinal colic, nausea, vomiting, diarrhoea, and central nervous system disorders.

The migration of larval *Ascaris* through the lungs may produce varying degrees of pneumonitis and bronchospasm known as Loeffler's syndrome (Plate 2). Chest radiographs may show diffuse mottling and increased prominence of peribronchial markings. There is generally high eosinophilia and the condition subsides after 7 to 10 days unless reinfection occurs. In areas where pig farming is common the larvae of *A. suum* (pig *Ascaris*) may also produce severe pneumonitis and bronchospasm.

Occasionally, ascariasis can cause severe, life-threatening disease. This could happen in the following situations.

1. When large numbers of worms get entangled to form a bolus and block the intestinal lumen producing signs and symptoms of acute intestinal obstruction.
2. When ectopic migration results in the entry of the worm into the appendix, common bile duct, or pancreatic duct. When the biliary tract is invaded, there is severe abdominal pain, often followed by suppurative cholangitis and multiple liver abscesses resulting from the disintegration of the trapped worm and secondary bacterial infection. Disintegration of the female worm releases a large number of eggs in the liver that can be recognized on histological examination.
3. When a worm blocks in the ampulla of Vater causing acute pancreatitis and pancreatic necrosis.

Diagnosis

This is usually made by detecting *Ascaris* eggs in the faeces. Sometimes, the patient brings developing or adult worms that have been passed in the faeces or have emerged from the anus or the nose in a sick child. They are roughly the same size as and have the appearance of earthworms. Occasionally, adult worms are outlined in the intestines during barium-meal examination.

Treatment

Whenever possible, all positive cases, irrespective of the worm load, should be treated, as even a few worms can undergo ectopic migration with dangerous

consequences.

Pyrantel pamoate

A single dose of 11 mg/kg body weight (maximum 1 g) is effective in curing over 90 per cent of cases of ascariasis. Side-effects are mild, if any, and the drug is well tolerated. It is also active against *Enterobius vermicularis* and hookworms (*Ancylostoma duodenale* and *Necator americanus*) but not against *Trichuris trichiura*. Its use in pregnant women and children of under 2 years is not recommended.

Mebendazole

This drug is a broad-spectrum anthelminthic with good host tolerance. It is active against *Ascaris*, *Trichuris*, *Enterobius*, and hookworms. This broad-spectrum activity is useful in endemic areas where multiple nematode infections are common. It is given as 100 mg twice daily for 3 days, for both adults and children of more than 2 years of age. Mebendazole should not be given to pregnant women, especially in the first trimester.

Albendazole

Like mebendazole this drug is also safe and effective against infections with *Ascaris*, *Trichuris*, *Enterobius*, and hookworms. The drug is given as a single oral dose of 400 mg for adults and children of more than 2 years of age. It should not be given to pregnant women.

Piperazine salts

These are old anthelminthics but still widely used because of their low cost and high degree of efficacy against *Ascaris* and *Enterobius*. The dose is 75 mg/kg (maximum of 3.5 g) given as a single dose daily for two consecutive days. It is not necessary to fast beforehand. Occasionally, symptoms involving the central nervous system, such as unsteadiness and vertigo, have been reported.

If signs of intestinal obstruction develop in a child living in an endemic area, ascariasis is a distinct possibility. The child should be admitted to hospital and prepared for surgical intervention. To start with the measures should be:

1. Decompression of the bowel through an intestinal tube with constant suction.
2. Rehydration and restoration of electrolyte balance by intravenous drip.
3. Antipyretics if fever is present.
4. Introduction of an appropriate dose of piperazine citrate through an intestinal tube. This induces flaccid paralysis of the worm.

In most cases this conservative therapy will relieve the obstruction and the child will rapidly recover. If, however, the signs of obstruction persist and the child's general condition worsens, laparotomy is required. Acute obstructive jaundice or pancreatitis due to obstruction of the common bile duct by *Ascaris* also requires urgent surgical intervention.

Prevention and control

As *Ascaris* eggs can survive in the soil for many years, prevention and control in endemic areas is difficult. Mass chemotherapy given at intervals of 6 months along with environmental sanitation can break the cycle. The prevalence of ascariasis and other soil-transmitted helminths is greatly reduced by improving housing. Infection is prevented by eating only cooked food and by avoiding green vegetables and salads in countries where human faeces are used as a fertilizer and where this parasite is endemic.

Anisakiasis

Anisakiasis is an infection caused by the larvae of nematodes belonging to the family Anisakidae.

Geographical distribution

The adult worms are commonly found in cetaceans (whales, dolphins, and porpoises) in many parts of the world. Human beings are infected when they eat raw or improperly cooked fish or squid. The incidence is highest in Japan, followed by Holland, Scandinavia, and countries along the Pacific coast of South America. A few cases have also been reported from California and the western United States.

Morphology

Complete speciation of the adults and larvae of this large group of parasites has not been done. In larval stages found in man the presence of large lateral cords which are bulbous in cross section is diagnostic of the family Anisakidae (Fig. 1(b)). Scanning electron microscopy shows the ventral side of the mouth to have a triangular boring tooth (Fig. 5).

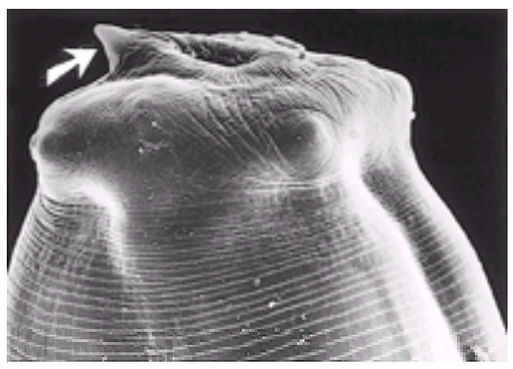

Fig. 5 Anisakis larva: third-stage larva of *A. simplex* showing the tip of the boring tooth (arrow) (× 400).

Lifecycle

Adults live in the lumen of the intestine of cetaceans. Eggs are passed in water and second-stage larvae are ingested by crustaceans, which are then ingested by fish or squid where they enter the muscles; cetaceans and man become infected by eating the fish or squid. In man, larvae do not develop to maturity but attach themselves to the mucosa of the stomach or intestine.

Clinical aspects

Most patients present with gastric symptoms that develop 4 to 24 h after eating infected fish. The symptoms are due to ulceration produced by the larvae as they burrow into the mucous membrane. There is epigastric pain, nausea, and vomiting, and sometimes haematemesis during the acute stage of the disease. If symptoms are mild and the patient is left untreated, the infection can become chronic with tumour formation. The small intestine may be involved, resulting in severe pain in the

lower abdomen, which may be misdiagnosed as appendicitis.

Diagnosis

Gastroscopy often reveals the lesion and the presence of larvae attached to the mucous membrane. Radiographs with a barium meal may show the presence of single or multiple ulcers and outline the worm. Serological tests are now available in some specialized centres.

Treatment

In acute infection an attempt should be made to remove all the larvae through a gastroscope. In chronic cases, surgical removal of the ulcerated areas or the tumour may be required. No effective chemotherapy is available. Prevention is by not eating raw fish and squid.

Capillariasis

Capillariasis is an infection by parasites belonging to the genus *Capillaria*. Two species infect man, *C. philippinensis*, which produces intestinal capillariasis, and *C. hepatica*, which produces hepatic capillariasis.

Geographical distribution

C. philippinensis has been described from the Philippines and Thailand. In the Philippines, the distribution of the disease includes the western and northern coastal areas of Luzon and the northeast of Mindanao. In Thailand, the infection is mostly sporadic and widely scattered. Infection has also been reported from Japan and recently from Dubai in the Middle East. *C. hepatica* is a rare human parasite but is commonly found in rodents in many parts of the world.

Morphology

Adult *C. philippinensis* are thin, small worms measuring 2.5 to 4.3 mm in length. They have a row of stichocytes at the anterior end, as in *Trichuris*. The eggs measure 36 to 45 µm in length and 19 to 21 µm in breadth, and have bipolar plugs, also like *Trichuris* (Fig. 6). However, unlike *Trichuris*, the eggs are not barrel shaped and the plugs do not protrude from the lateral ends. The adults of *C. hepatica* measure 52 to 104 mm in length and the anterior region contains the stichocytes. The eggs measure 48 to 66 by 28 to 36 µm and have bipolar plugs. The eggshell is thick and distinctly striated.

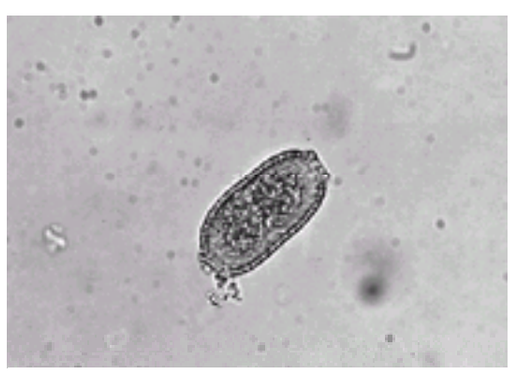

Fig. 6 *Capillaria philippinensis* egg (× 1400).

Lifecycle

The lifecycle of *C. philippinensis* has not been completely worked out. Humans are infected by eating freshwater fish and especially their succus entericus containing the infective larvae. Fish-eating birds act as a natural or reservoir host. Humans become involved accidentally in this natural fish–bird cycle. The main danger is of autoinfection, leading to very heavy worm loads.

C. hepatica is found in the liver of rodents and other mammals. The eggs are discharged in the liver tissue and remain there until the animal dies (Fig. 7). They eventually reach the soil by the decay of the carcass. Human beings are infected by accidentally swallowing embryonated eggs from the soil.

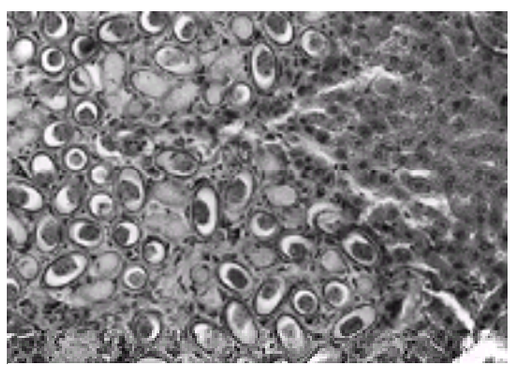

Fig. 7 *Capillaria hepatica* eggs in the liver (× 250).

Clinical aspects

C. philippinensis can produce severe and even fatal disease. Patients often present with abdominal pain, diarrhoea, and borborygmi. As the worm load increases through autoinfection, diarrhoea becomes more severe, with anorexia, nausea, and vomiting. Prolonged diarrhoea leads to cachexia and muscular wasting. There may also be signs of hypotension and cardiac failure. In untreated cases, the mortality rate approaches 20 per cent.

In *C. hepatica* infection, symptoms of visceral larva migrans may be present. The patient may have an enlarged tender liver with low-grade fever and eosinophilia.

Diagnosis

With *C. philippinensis*, diagnosis is made by finding the typical eggs in the faeces. Larvae or adult worms may also be present and repeated stool examination may be required in some cases. The parasite may also be found in jejunal aspirate or biopsy. With *C. hepatica*, diagnosis is made by identifying the parasite or eggs in a liver biopsy.

Treatment

All cases of *C. philippinensis* should be treated with mebendazole 200 mg, twice daily, until the symptoms subside and the eggs completely disappear from the faeces after repeated stool examination. This may take up to 20 days or more. Alternatively, albendazole 400 mg can be given daily for 10 days. Supportive measures to overcome malnutrition and diarrhoea will be required in severely ill patients. There is no specific treatment for *C. hepatica* infection. Infection with *C. philippinensis* is prevented by not eating raw fish in the endemic regions of Southeast Asia.

Trichinosis

Trichinosis is an infection caused by *Trichinella spiralis*.

Geographical distribution

The infection is endemic in many parts of the world where pork is consumed, including Central and Eastern Europe, Central, South, and North America, and parts of Africa and Asia. Infection is also endemic in the Arctic regions resulting from eating polar bear meat.

Morphology

The adult males are small nematodes measuring 1.4 to 1.6 mm. The female is viviparous and about twice as long as the male. The anterior part contains a row of glandular cells (stichocytes) as in *Trichuris trichiura*. The male worm lacks a spicule but has two copulatory papillae on the sides of the cloacal opening.

Lifecycle (see Fig. 8)

Human beings become infected by eating improperly cooked pork or pork products such as sausages. In some parts of the world, wild boars are heavily infected. After ingestion, the larvae are liberated in the small intestine and mature into adults. The female deposits larvae in the intestinal tissues from where they find their way into the bloodstream and then into the striated muscles of the body (Fig. 9). The most heavily parasitized muscles are the diaphragm, tongue, laryngeal, and abdominal muscles. After penetration, the larva undergoes three moults and coils into a spiral, which eventually becomes enclosed in a thick-walled cyst. In this form, the larva may remain viable for many years.

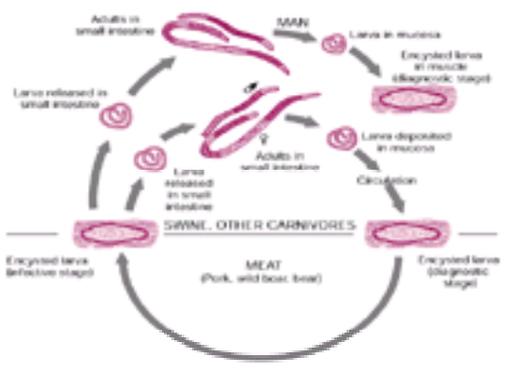

Fig. 8 Lifecycle of *Trichinella spiralis*. (Adapted from Centers for Disease Control, Atlanta, Georgia, United States.)

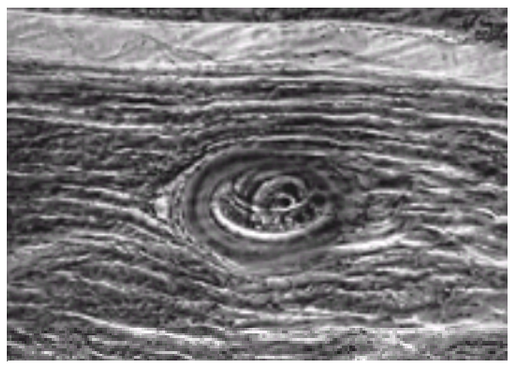

Fig. 9 *Trichinella spiralis* in human muscle (× 100).

Pigs become infected by eating infected scrap and garbage from slaughterhouses or farms. Occasionally, they may become infected by eating carcasses of infected rats.

Clinical aspects

Most people with light infections remain asymptomatic. In cases of heavy infection, there are three clinical stages.

The invasion stage

This is seen during the first week of infection and is due to juveniles and adults burrowing into the intestinal tissues. The patient complains of abdominal pain, nausea and vomiting, and diarrhoea of varying intensity. There may be fever, profuse sweating, and tachycardia.

The migration stage

This usually begins after the first week of infection. During this period, the larvae are liberated into the circulation by the gravid female and find their way to the muscles. Symptoms are attributable to toxic effects of the larvae and hypersensitivity reactions triggered by the liberation of parasite antigens. There is oedema of the face and periorbital tissues, fever, muscular tenderness, and hypereosinophilia. Complications involving the myocardium, lungs, and the central nervous system may occur due to the migrating larvae. However, the larvae do not encyst in the myocardium. A fine, macular skin rash, particularly on the trunk, may appear and last for a few days.

The encystment stage

This usually begins after the third week of infection. There is usually a gradual recovery from the symptoms. In a few cases with heavy infection, the symptoms may get worse and death may occur due to myocardiac failure, and respiratory and central nervous involvement. All serological tests become positive during this stage.

Diagnosis

This is based on a combination of clinical and epidemiological evidence. In a characteristic case, the patient will give a history of gastrointestinal disturbances (invasion stage) within 48 h of eating pork products, wild boar, or bear meat. If the patient presents in the later stage (migration stage), there is periorbital oedema,

myositis, irregular fever, and hyperosinophilia.

Among the various tests that become positive during the encystment stage, the two most commonly used are the skin test and the slide flocculation test. Recently, enzyme immunoassay has also been used. The skin test antigen is made from larvae and gives an immediate type reaction in positive cases. The test is very good for surveys but unsuitable for the detection of acute disease as it remains positive for many years after infection. The slide flocculation test is also prepared from larval antigen, which is attached to cholesterol particles. In a positive reaction, flocculation is seen under the microscope. The test remains positive for about 10 months after infection. Serum enzymes such as aminotransferases are elevated. Muscle biopsy is positive in approximately 90 per cent of clinically positive cases.

Treatment

The prognosis is good and most patients recover after the larvae have encysted. The mainstays of treatment are bedrest and salicylates. For myocarditis and severe myalgia, oral prednisone for 3 to 5 days (0.5–1.0 mg/kg per day) is useful and provides symptomatic relief. In experimental animals, thiabendazole is able to kill encysted larvae. In man, its efficacy against larvae is doubtful but a dose of 25 to 50 mg/kg per day for 2 to 5 days usually brings down the fever and eosinophilia. Mebendazole appears to be a good alternative to thiabendazole as it has fewer side-effects, and is given at a dosage of 300 mg daily for 7 days. A higher dose of 1000 mg daily for 10 to 14 days is recommended by some authorities to ensure complete killing of the larvae. Even with this high dosage, side-effects appear not to be serious, consisting of mild Jarisch–Herxheimer type reactions at the start of therapy. The manufacturer does not recommend giving mebendazole to children under 2 years of age or pregnant women.

Control and prevention

Trichinosis in the pig population can be greatly reduced or eliminated by hygienic rearing methods. Larvae in pork can be killed by freezing at – 18 °C for 24 h. Thorough cooking of pork is the best safeguard against infection in all endemic areas.

Enterobiasis (pinworm, threadworm)

Enterobiasis is an infection caused by *Enterobius vermicularis*.

Geographical distribution

This is one of the few parasites that is more prevalent in the temperate regions of the world than in the tropics. Children are more often involved than adults. It occurs in groups such as families living together, inmates of hostels, and in army camps.

Morphology

The male is approximately 5 mm long and 0.1 to 0.2 mm in diameter (Plate 3). The female is approximately 13 mm long and 0.3 to 0.5 mm in diameter. The gravid female has two distended uteri that practically fill the whole body. The male has a single spicule and a curved tail. The cervical alae of the cuticle allows easy recognition. The eggs are generally flattened on one side and measure approximately 50 to 60 µm in length and 20 to 30 µm in breadth. They have a thick, transparent shell. The eggs are unembryonated when passed but become infective within a few hours.

Lifecycle

The adults are mainly located in the caecal region (Fig. 10). The female deposits its eggs on the anus and perianal skin. Direct person-to-person infection occurs by inhalation and swallowing of the eggs. In addition, autoinfection occurs by contamination of fingers. It may occur as a sexually transmitted disease among male homosexuals. There is no visceral migration and the larva matures into an adult in the lumen of the intestinal tract. The lifecycle of the parasite is completed in about 6 weeks. Unlike *Ascaris* and *Trichuris* eggs, which need many days of development in soil before becoming embryonated, *Enterobius* eggs are embryonated when passed, hence there is rapid transmission from person to person.

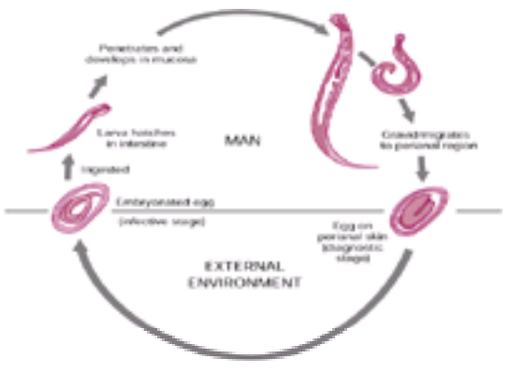

Fig. 10 Lifecycle of *Enterobius vermicularis*. (Adapted from Centers for Disease Control, Atlanta, Georgia, United States.)

Clinical aspects

The most common presenting symptom is pruritus ani. This can be very troublesome and occurs more often during the night. Persistent itching may lead to inflammation and secondary bacterial infection of the perianal region. Infected children may suffer from insomnia, emotional disturbance, anorexia, weight loss, and enuresis. Occasionally, adult worms may migrate, entering the female genital tract. Inside the uterus or the Fallopian tube they may get encapsulated and produce symptoms of salpingitis. In adolescents and children it is an important cause of vulvovaginitis. The parasite may also get lodged in the lumen of the appendix, leading to appendicitis (Fig. 11). The lifespan of the parasite is 3 to 6 weeks.

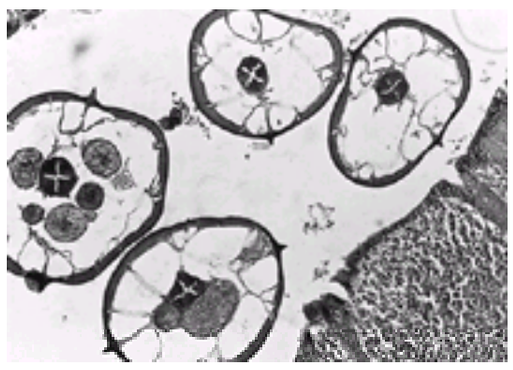

Fig. 11 *Enterobius vermicularis* in the lumen of the appendix (× 250).

Diagnosis

The eggs are not usually found in the faeces. They are most easily found around the anus, by swabbing or using cellulose adhesive tape. The anal examination for eggs should be done before defaecation or bathing. Sometimes intact worms are passed in the faeces and can be easily recognized by their size and shape.

Treatment

Attention to personal hygiene is an important part of treatment and prevention. The patient should be instructed to keep nails short and wash hands with soap and water after defaecating. The bed cover and sleeping garments should be changed every day and the floor in the bedroom kept clean. With these simple hygienic measures, infection will disappear on its own, due to the short lifespan of the parasite.

All the children and adults in a household should be treated at the same time. Many drugs are available to treat the infection. Piperazine citrate is given in a dose of 65 mg/kg for 7 days. The course is repeated after 2 weeks. Piperazine is contraindicated in renal and liver disease and epilepsy. Pyrantel pamoate is equally effective in a single dose of 11 mg/kg (maximum 1 g) and its side-effect profile is better than piperazine. The drug is repeated after 2 weeks. Mebendazole is effective in a single dose of 100 mg, repeated after 2 weeks. Alternately, albendazole in a single does of 400 mg can be given, repeated after 2 weeks. Both mebendazole and albandazole should not be given to pregnant women.

Trichuriasis (whip worm)

Trichuriasis is an infection caused by *Trichuris trichiura*.

Geographical distribution

It has a worldwide distribution and is the most common intestinal nematode in some tropical regions such as Southeast Asia.

Morphology

The adult male measures 30 to 45 mm and the female 35 to 50 mm in length. The parasite is commonly known as the whip worm because the anterior three-fifths is thin and elongated and the posterior two-fifths is bulbous and fleshy. One important feature of this group of worms is the possession of a thin, elongated oesophagus that is surrounded by gland cells known as stichocytes. The adults are mainly located in the caecum and produce barrel-shaped eggs, 22 to 50 µm long. At the lateral ends, they have transparent, blister-like plugs, which are single celled when freshly passed. In the soil the eggs become infective in about 3 weeks.

Lifecycle (see Fig. 12)

Infection occurs by the ingestion of the embryonated egg. The larva does not undergo visceral migration but penetrates the gut for a short period before returning to the lumen to mature into the adult stage. The worms attach themselves to the large intestine by threading their anterior end into the epithelium (Fig. 13). The posterior end hangs free in the lumen of the bowel. The whole period of development in the host takes about 3 months to complete.

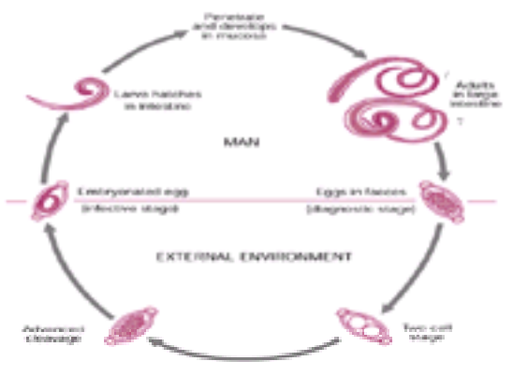

Fig. 12 Lifecycle of *Trichuris trichiura*. (Adapted from Centers for Disease Control, Atlanta, Georgia, United States.)

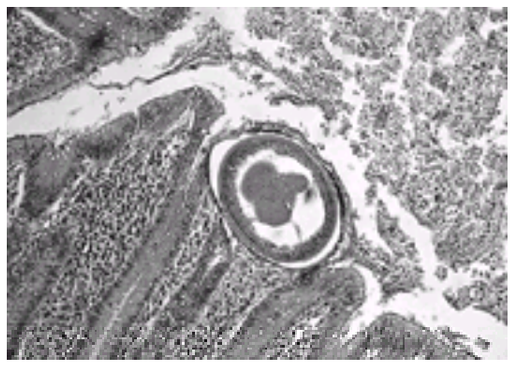

Fig. 13 *Trichuris trichiura*: anterior end embedded in the superficial layer of intestinal epithelium (× 250).

Clinical aspects

Light infections are generally asymptomatic. In heavy infections, there is colitis with the passage of blood and mucus in faeces. The clinical picture is often similar to that of amoebic dysentery. Heavy infection in children leads to anaemia that may cause oedema, and cardiac failure. There may be marked clubbing of the fingers. The anaemia is probably due to bleeding from the damaged and inflamed mucous membrane rather than sucking of blood by the parasite itself. In some cases, prolapse of the rectum occurs, probably due to constant irritation produced by the worms and the weakness of the levator ani muscle. Occasionally, the worm may lodge itself in the lumen of the appendix and cause acute appendicitis. The subtler form of trichuriasis is associated with long-term failure of children to grown in height, although they may not appear emaciated.

Diagnosis

This is based on finding characteristic barrel-shaped eggs in the faeces. Eosinophils and Charcot–Leyden crystals are often present. Sigmoidoscopy or proctoscopy may show worms attached to the mucous membrane and sometimes intact worms may be passed out in the faeces.

Treatment

Mebendazole

Mebendazole is the drug of choice and is given in a dose of 100 mg, twice daily for 3 days for both adults and children of not less than 2 years of age. Side-effects are few and it is well tolerated. During therapy, abnormal *Trichuris* eggs are produced as the drug interferes with embryogenesis of the worm. The drug should not be given to pregnant women, especially in the first trimester.

Albendazole

Albendazole is effective in a single dose of 400 mg for both adult and children of not less than 2 years of age. It should not be given the pregnant women. As with mebendazole, abnormal parasite eggs are produced during therapy.

Oxantel plus pyrantel pamoate

Oxantel is an analogue of pyrantel and a combination is effective against *Ascaris*, *Enterobius*, hookworms, and *Trichuris*. Dosage is 10 to 20 mg/kg body weight of each component as a single dose. In heavy infections, the drug may be repeated two or three times.

Preventive measures are the same as in ascariasis.

7.14.7Toxocariasis and visceral larva migrans

V. Zaman

Visceral larva migrans is the name given to a syndrome characterized by hepatomegaly, fever, respiratory symptoms, and high eosinophilia. It is caused mainly by the migrating larvae of *Toxocara canis* and *T. cati*. Other parasites that may cause this syndrome are *Ancylostoma* spp., *Spirometra*, *Gnathostoma*, and *Alaria*.

Geographical distribution

Toxocarial infection occurs wherever there are large domestic dog and cat populations. Many cases have been reported from the United States and other Western countries. They result from close association between these animals and man. Surveys in Great Britain have shown that approximately 2 to 3 per cent of the population possess antibodies to these parasites.

Lifecycle

Infection with *T. canis* is maintained in the dog population by direct transmission from the soil containing embryonated eggs, from transplacental transmission from bitch to puppies, through the maternal milk to puppies, and by dogs eating infected meat containing larvae. These multiple routes of infection ensure that almost all puppies are born infected. Human beings become infected by ingesting embryonated eggs from the soil. Toddlers and young children are usually involved because of their habit of eating soil and dirt. The larvae hatch out in the small intestine and migrate to various organs of the body including the liver, lungs, eye, and brain. They do not mature into adult worms in man. After some time a granuloma forms around the larvae.

Morphology

The larva of *T. canis* is approximately 18 to 20 µm in diameter and that of *T. cati* is about 15 to 17 µm in diameter; they are otherwise indistinguishable. Both species have pointed lateral alae and two lateral excretory columns. The posterior region of the larva contains the intestinal tract. Larvae of *Toxocara* spp. are much smaller than these *Ascaris* spp. This may be the reason why *Ascaris* larvae are not widely dispersed in the tissues as they are unable to enter the small blood vessels. Eggs of *Toxocara* spp. are similar in size to those of *Ascaris* but their surface is pitted, making identification easy. Eggs are never seen in human faeces as adults mature only in dogs and cats.

In animals and man the migrating toxocarae larvae eventually became surrounded by a granuloma. Various cell types are involved in granuloma formation, including macrophages, lymphocytes, eosinophils, and fibroblasts. In a fully formed granuloma the larvae are surrounded by layers of fibrous tissue and inflammation subsides. It is now accepted that granuloma formation is caused by the immune system, especially T cells. It is an attempt by the host to limit disease, but it also favours the larva by ensuring its survival for a long time in a circumscribed area (Fig. 1 and Fig. 2).

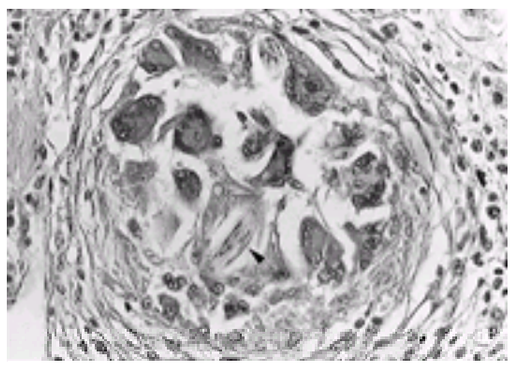

Fig. 1 Granuloma formation in an experimentally infected monkey showing a large number of giant cells and some fibroblastic reaction. The arrow marks the larva. Haematoxylin and eosin, × 400.

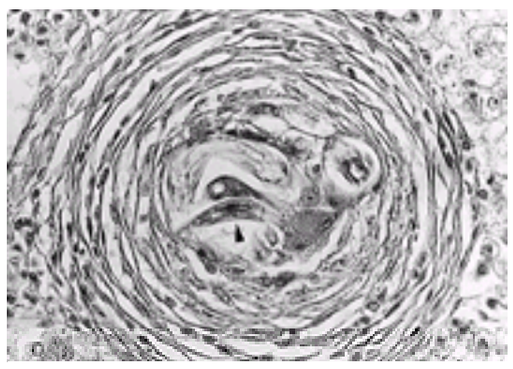

Fig. 2 Granuloma formation in the same animal as in Fig. 1 at a later stage, when the larva is completely surrounded by fibroblasts. Haematoxylin and eosin, × 400.

Clinical aspects

Toxocariasis may cause two different clinical pictures: classical visceral larva migrans syndrome and ocular toxocariasis.

Classical visceral larva migrans

This is seen most often in young children because of pica (dirt or soil eating). Most people remain asymptomatic. In a minority, symptoms consist of muscular pain, lassitude, anorexia, cough, and urticarial rashes. Physical signs include rhonchi, hepatomegaly, splenomegaly, and enlargement of the lymph glands. The acute phase generally lasts for 2 to 3 weeks followed by recovery. Sometimes the resolution of all the signs may take up to 18 months. Convulsions, paralysis, and other

neurological disorders result when larvae enter the central nervous system. Rarely the infection may end fatally if a massive dose of parasites has been ingested.

Ocular larva migrans

This is caused by granuloma formation in the eye. If this is near to the macula, impairment of vision or even blindness may result. Patients may present visual difficulty in one eye, with or without strabismus. As the generalized manifestation of visceral larva migrans may not be present, diagnosis is often difficult. Unlike in visceral larva migrans, eosinophilia may be absent. On fundoscopy a rounded swelling, often near the optic disc, may be detected.

Diagnosis

In classical visceral larva migrans there is leucocytosis with marked eosinophilia (20 to 80 per cent). In ocular larva migrans there may be no peripheral eosinophilia.

Serological tests are useful. An enzyme immunoassay using extracts of excretory–secretory products of *T. canis* larvae is positive in the majority of patients with visceral larva migrans. In ocular larva migrans the vitreous fluid is shown to have antibodies to the parasite.

Biopsy of the liver may show larvae with granulomas and eosinophilic infiltration. However, biopsy is rarely done because the chances of obtaining the appropriate specimen are remote, unless it is a massive infection. If facilities are available, laparoscopy may permit direct biopsy of a granuloma, which appears as a white dot on the surface of the liver.

Treatment

No antihelminthic drug is completely effective in killing the larvae and most patients recover without specific therapy. Diethylcarbamazine in a dosage of 6 mg/kg a day in three divided doses for 2 to 3 weeks has given equivocal results. Albendazole 400 mg twice a day for 3 to 5 days for both adults and children of more than 2 years of age, and mebendazole 100 to 200 mg twice a day for 5 days for both adults and children of more than 2 years of age may be of some value. The use of antihelminthics may sometimes provoke a greater inflammatory response, with worsening of the clinical picture, due to injury of the parasite. In severe cases, corticosteroids have been used with reports of improvement.

In ocular larva migrans, visible larvae can be photocoagulated by laser. Vitrectomy has been used in some cases, and local and intraocular steroids also appear to be of some value.

Prevention and control

Most cases of human toxocariasis are preventable by careful personal hygiene, not allowing children to play in environment likely to contain parasite eggs, and eliminating roundworms from pets, especially puppies and kittens. Unfortunately, people are often not aware that the infection can be transmitted from pets to humans. Efforts must be directed towards increasing this awareness.

7.14.8 Angiostrongyliasis

R. Knight

Human disease caused by two nematode species of the genus *Angiostrongylus* has been recognized comparatively recently. Both parasites normally infect rodents; molluscs are the primary intermediate hosts. They were initially thought to be rare and of limited distribution in humans, but these assumptions have proved incorrect. The epidemiology is complex because of multiple potential routes of transmission.

Angiostrongylus cantonensis

This is the rat lungworm; it causes cerebrospinal angiostrongyliasis. The first known case, reported in 1944, was a 15-year-old Taiwanese boy with meningoencephalitis in whose cerebrospinal fluid an immature adult worm was found. Detailed clinicopathological studies were made in 1962 during epidemics of eosinophilic meningitis in Tahiti.

Aetiology—the biology of the parasite

Adult worms live in the pulmonary arteries of rats; larvae from hatched eggs ascend the airways and so reach the faeces. Molluscs ingest these larvae and after two moults they are infective when eaten by a rodent. In the rat, infective larval worms migrate to the cerebral grey matter where they start to mature, move to the meninges, and then enter the venous sinuses and so reach the pulmonary arteries where maturation is completed. Infective larvae from a mollusc can also enter a second or third intermediate host in which they undergo no further development until they enter a mammalian host; such supernumerary hosts are termed paratenic or transport hosts, they are important sources of infection to humans.

Development in humans reaches the immature adult stage, measuring 11 to 15 mm in length. Nearly all will die in the superficial cortex, brainstem, and meninges causing vigorous tissue reactions; very few reach the lungs.

Epidemiology

Human infections occur throughout Oceania, especially Hawaii, Samoa, the Solomons, Papua New Guinea, Indonesia, the Philippines, and Northern Australia; and in south-east Asia, especially Thailand, Taiwan, and south Japan, but also India; a few infections are reported from Ivory Coast, Egypt, Madagascar, Cuba, the Caribbean, and South America. All ages can be affected and outbreaks have occurred after weddings and feasts; infections are often seasonal.

The principal rodent hosts are *Rattus rattus*, *R.norvegicus*, *R.alexandrinus*, and *R.exulans*. The prevalence in rats in endemic areas may be 40 per cent or more. The geographic spread and population increase of these peridomestic rodents has increased the zoonotic reservoir. Another factor leading to the increase in human infection has been the dispersal by human agency of the edible giant African snail *Achatina fulica* eastwards across the Indian Ocean and the Pacific, from Madagascar in 1800 to reach Hawai in 1936.

Many species of snail and slug act as intermediate hosts, and paratenic hosts include freshwater prawns, land and coconut crabs, frogs, and land planarians; in Thailand the yellow tree monitor is an important paratenic host. Common modes of transmission to humans include eating raw *Achatina* snails as a delicacy and for medicinal purposes; eating salads containing small undetected molluscs, their slime trails, or planarians; eating raw freshwater prawns and crabs; or drinking water containing tiny immature prawns, especially after heavy rains.

The modes of transmission differ geographically, by age and social group, and with time. In Thailand, *Pila* snails are a seasonal delicacy eaten by all the family, but young men take them raw with alcohol; another edible snail *Ampullaria canaliculatus* is infected in Taiwan and Japan. In the Ryuku islands of Japan, patients are usually infected by eating raw snails or toad liver for medicinal purposes.

Pathology

Inflammatory, granulomatous, and sometimes track-like lesions occur predominantly in the cortical grey matter and the meninges, but also in the brainstem and cerebellum; nerve roots and spinal cord may also be affected. Live worms are occasionally found at autopsy and dead worms are found in many of the lesions. The number of worms found varies greatly and may reach several hundred; worm tracks in the tissue and meninges are surrounded by a cuff of eosinophils; Charcot–Leyden crystal derived from eosinophils are numerous. Rarely adult worms have been found in human lung at autopsy. Ocular infection derives from worms that have migrated across the cribriform plate.

Clinical features

After an incubation period of 2 to 4 weeks the onset is acute with headache, intermittent at first, together with nausea and vomiting. There is constitutional upset and frequently meningism; fever is unusual. The illness is often self-limiting over a period of 4 weeks. Cranial nerve lesions include optic, abducens, and facial nerve damage. Less common are seizures, confusion, or radiculopathy with parasthesias, root pains, or weakness. Long tract signs and impaired consciousness are uncommon except in severe cases, but spinal cord damage can cause sphincter disturbance.

Ocular complications include retinal haemorrhages and larval worms in the vitreous or anterior chamber (Plate 1). Rarely migration to the lungs produces clinical evidence of pneumonitis. Numerous eosinophils occur in the cerebrospinal fluid and there is a blood eosinophilia.

Diagnosis

Lumbar puncture reveals high opening pressure with a clear or lightly turbid cerebrospinal fluid containing 500 to 2000 cells/mm of which 10 to over 90 per cent are eosinophils. Protein levels are high with normal glucose. Detailed examination at low power reveals larval or immature adult worms in up to 25 per cent of cases; they measure 5 to 15 mm in length. Cerebrospinal fluid changes may persist for up to 3 months. Computed tomography or magnetic resonance imaging may reveal focal cortical abnormalities. Serology using antigens from fourth-stage larvae is useful, but cross-reactions with other nematodes can cause difficulty. Techniques to detect worm antigen in cerebrospinal fluid and serum have also been developed.

Differential diagnosis is from other helminthic infections affecting the nervous system as eosinophils are otherwise rare in cerebrospinal fluid. A detailed geographic and dietary history is essential; conditions to be considered include gnathostomiasis, paragonimiasis, schistosomiasis, and neurocysticercosis. Confusion with

Gnathostoma spinigerum is a particular problem in Thailand, the latter more commonly causes long tract signs, bloody or xanthochromic cerebrospinal fluid, neck stiffness, and clouding of consciousness.

Treatment, prognosis, and control

Specific anthelmintic treatment is not useful and worm death aggravates the clinical condition. Headache can be relieved by repeated lumbar tap, analgesics, and sedatives. Steroids have been used in patients with focal neurological signs, but benefit is poorly substantiated. Larvae in the eye chambers should be removed surgically. Reported mortality rates vary from 0.5 to 30 per cent and depend mainly on the number of infective larvae ingested; some patients pass into coma after about 2 weeks and their prognosis is then very poor. Most patients improve in 2 to 4 weeks, but focal neurological deficits can persist longer; partial relapse after 2 months of illness may represent a reaction to dying worms. Some patients have relatively mild illnesses and can be discharged within a few days; during epidemics these patients may need only outpatient care.

Control measures include health education to limit ingestion of raw high-risk dietary items and unwashed salads. Warnings may be necessary regarding raw molluscs, amphibians, and reptiles used for medicinal purposes. Rodents in vegetable gardens and the peridomestic environment should be controlled.

Angiostrongylus costaricensis

This causes abdominal angiostrongyliasis. It was first recognized in Costa Rica in 1950 in surgical specimens simulating bowel malignancy. The parasite was described from such specimens in 1967 and the complete lifecycle in rodents was elucidated during the next 3 years.

Aetiology—the biology of the parasite

In both the rodent and human hosts the worms are located in the ileocaecal mesenteric arteries. The cotton rat *Sigmodon hispidus* is the principal reservoir host, but other species of rodents including the coatimundi are also involved, and even dogs and marmosets. In the rodent hosts, worm eggs embolize to gut wall capillaries and the hatched larvae pass into the gut lumen. Veronicellid slugs, especially *Vaginalus plebeius*, eat rodent faeces containing larvae and these develop with two moults in fibromuscular tissue of the mollusc into infective larvae over a period of 18 days. Infective larvae can persist in the slug for several months or be shed in slime trails. The prepatent period in rats eating infected slugs is 24 days.

In human infections the worms reach maturity but the embryonated eggs do not hatch.

Epidemiology

Infections occur especially in Costa Rica, Nicaragua, Guatemala, and Honduras, but also sporadically in the Americas from the United States to Argentina, and some Caribbean Islands. Recently, infections are being increasingly recognized from Brazil. Small veronicellid slugs are the main source of infection to humans; infection rates in these hosts can reach 85 per cent. Slugs may be unnoticed on fallen fruits or in salads, especially when small or chopped; their mucus also contains infective larvae. Many cases are in school children, but infants and older persons are also affected; an outbreak after eating mint is reported. Seropositivity in endemic areas suggests that there are unrecognized infections.

Pathology and clinical features

Lesions primarily affect small arteries; they produce subacute or chronic granulomatous inflammatory masses in the wall of the caecum (Fig. 1) and right colon; sometimes the predominant feature is ischaemic infarction. The finding of an adult nematode measuring 18 to 42 mm in length within a gut arterial vessel is diagnostic of this infection; eggs may be seen in vessels or in tissue where they are surrounded by eosinophil granulomas. Lesions also occur elsewhere in the colon or terminal ileum, in regional abdominal lymph nodes, or the omentum. Some larvae enter the hepatic artery and cause granulomatous or necrotic lesions in the liver; others enter testicular arteries causing similar lesions of the testis.

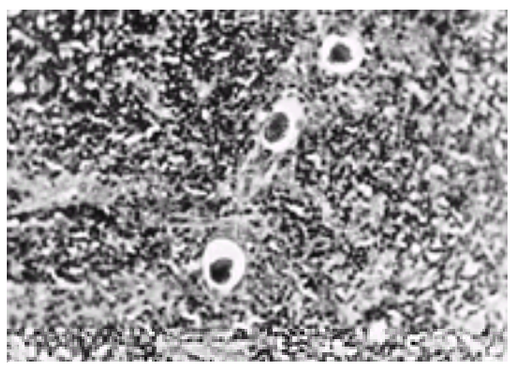

Fig. 1 Section of a human caecum showing three eggs of *A. costaricensis* with cellular infiltration mostly of eosinophils (by courtesy of Dr Pedro Morera, University of Costa Rica).

Clinically, most patients present with right-sided or right iliac fossa pain, with tenderness and sometimes a palpable mass in this region. Other features are eosinophilia, fever, diarrhoea, or rectal bleeding. Tender hepatomegaly with high blood eosinophilia occurs in some patients and sometimes focal necrotic lesions in the liver. Serious complications are bowel obstruction and perforation, and testicular infarction.

Diagnosis and treatment

Confirmation of diagnosis is usually made histologically on resected material. The condition can mimic appendicitis, bowel neoplasm, Meckel's diverticulitis, testicular torsion, or other surgical problems. Parasite eggs are not found in faeces, but serology using enzyme immunoassay or latex agglutination is useful. Contrast radiology reveals filling defects and altered motility of terminal ileum, caecum, or ascending colon. Laparoscopy can reveal the bowel and hepatic lesions; biopsy may be diagnostic.

The value of anthelmintic treatment remains unproven; thiabendazole or high doses of mebendazole have been used. Surgery is often necessary but can sometimes be deferred in uncomplicated cases when the diagnosis is strongly suspected, as spontaneous remission is common.

Preventive measures include washing and careful inspection of vegetables, and hand washing before meals by children and those preparing salads.

7.14.9 Gnathostomiasis

Pravan Suntharasamai

Gnathostomiasis is an extraintestinal infection with larval or immature nematodes of the genus *Gnathostoma* (order Spirurida). It is characterized by intermittent and migratory space-occupying lesions in the skin or the internal organs, resulting in inflammation and/or haemorrhage.

Aetiology

Four species of gnathostomes are known to infect man. Adult parasites live in the upper gastrointestinal tract of the definitive hosts: *Gnathostoma spinigerum*, the most common infection, in dogs, cats, and other mammals; *G. hispidum* and *G. doleresi* in pigs; and *G. nipponicum* in weasels. Larvae, hatched in water from ova shed with the host's faeces and ingested by cyclops, are eaten by freshwater fish, amphibians, reptiles, crustaceans, birds, or mammals. Third-stage larvae are found in the walls of the viscera and in the muscles of these second intermediate hosts. Unless they are eaten by definitive hosts, the parasites cannot developed into reproductive adults but they remain infectious to man and other paratenic hosts.

Consumption of the raw or undercooked flesh of second intermediate and paratenic hosts is the most common mode of transmission. Skin penetration after contact with infected material is less important. Prenatal transmission can occur, as larvae have been recovered in neonates as young as 3 days old.

Epidemiology

Isolated cases of *G. spinigerum* infections have been reported frequently in Thailand and Japan and sporadically in Australia, Bangladesh, Cameroon, China, Ecuador, India, Mexico, Southeast Asian countries, and Sri Lanka. Infections with the other three species have been reported from Japan.

Gnathostomiasis can present in places far away from these endemic areas due to migration of the latently infected human host or importation of the infective flesh of paratenic hosts. Consumption of a raw fish dish at a party can result in an outbreak.

Pathogenesis

The ingested larva penetrates the gut wall and migrates to the liver before wandering through almost any tissue except bone. Symptoms and signs vary according to the sites and sizes of the inflammatory or haemorrhagic lesions induced intermittently along the migratory route.

Clinical features

Nausea, vomiting, and epigastric pain may develop within 1 or 2 days after consumption of the infective food. Fever, pain in the right upper quadrant of the abdomen, chest pain, dry cough, and hypereosinophilia may develop within 1 to 2 weeks.

The primary invasive illness usually passes unnoticed and so the incubation period is not known in most cases. General health is scarcely impared and fever is uncommon. The illnesses can be categorized according to the affected organs as follows.

Cutaneous forms

Gnathostomal creeping eruption (Fig. 1)

This is rare in *G. spinigerum* infection but frequent with the other three species. The serpiginous track (Fig. 1) is similar to but bigger and more variable in depth than that caused by dog or cat hookworm larvae (see Chapter 7.14.9). A trail of subcutaneous haemorrhage is sometimes observed.

Fig. 1 Creeping eruption around the left thigh. (Reproduced from Bhaibulya and Charoenlarp (1983), with permission.)

Cutaneous migratory swelling

This most common manifestation of human gnathostomiasis is usually intermittent. The first swelling may develop 3 to 4 weeks after infection. Swelling can occur anywhere and may recur close to or distant from the original site (Fig. 2). It develops rapidly and usually lasts for about 1 to 2 weeks. Frequently it is extensive, involving the whole wrist or hand for example. Swelling of digits or plantar surfaces can be very painful and incapacitating. Itching is the main associated symptom. Regional lymphadenitis is usually absent. When swelling involves the eyelid, chemosis and conjunctival haemorrhage may be observed.

Fig. 2 Migratory swelling in a 23-year-old male. (a) At the eyelids for 5 days when seen on 5 June 1986. (b) At the right side of the upper lip on 9 June 1986 when the larva was picked out by needle puncture and squeezing.

The worms can escape spontaneously through the skin or the conjunctiva. The interval between episodes of swelling varies from a few days to a few months and rarely 1 to 2 years. Intermittent cutaneous migratory swelling can go on for more than 5 years.

Visceral forms

Visceral invasion as described below for *G. spinigerum* infection has not been reported in infections with other *Gnathostoma* species.

Spinocerebral gnathostomiasis

Involvement of the spinal cord commonly starts with intermittent, agonizing, shooting pains in a limb or a segment of trunk, followed by paraplegia with urinary retention and, rarely, quadriplegia. Sensation is correspondingly impaired and the Brown–Séquard syndrome is sometimes seen. A few patients with haematoma and inflammation due to brain invasion (Fig. 3) present with severe headache and vomiting, followed very quickly by coma, cranial nerve palsies, and/or hemiplegia. A rapidly advancing or changing pattern of neurological deficits is characteristic of the infection. Eosinophilic meningitis without focal neurological deficit or subarachnoid haemorrhage occasionally occurs.

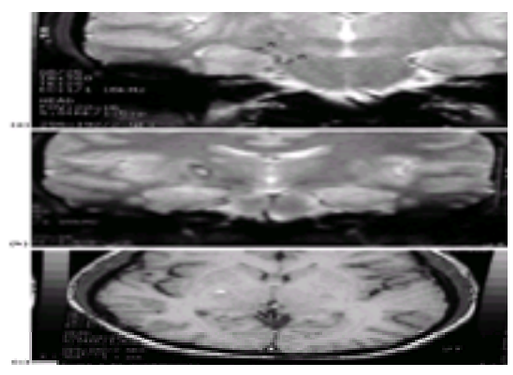

Fig. 3 Magnetic resonance image of a case of cerebral gnathostomiasis. (a), (b) Coronal T_2-weighted sections at the level of the brainstem and basal ganglion demonstrate a serpiginous mixed hyposignal with a hypersignal track (* *) along the right lateral upper pons and midbrain penetrating into the lentiform nucleus (arrow head). (c) Axial T_1-weighted section of the brain at the basal ganglion level demonstrates a small hypersignal T_1 subacute haemorrhage (short arrow) along the track of the parasite at the posterior limb of the internal capsule and adjacent serpiginous hyposignal T_1 track (long arrows). (By courtesy of Dr Jiraporn Laothamatas, Ramathibodi Hospital, Bangkok, Thailand.)

The cerebrospinal fluid can be bloody, xanthochromic, or slightly turbid with a minor increase in protein content. The proportion of eosinophils is higher than expected from haemorrhage *per se.*

Ocular gnathostomiasis

The gnathostome can be found in the anterior chamber (Fig. 4) and the vitreous. The parasite usually migrates through the sclera or the cornea. It can induce uveitis, iritis, intraocular haemorrhage, retinal detachment and scarring, and blindness.

Fig. 4 Gnathostome larva in the anterior chamber. (By courtesy of Dr Nesit Leelawong.)

Intra-abdominal and oral gnathostomiasis

These uncommon forms can present with intestinal obstruction or a painful intra-abdominal mass. Worms may emerge from the tongue, soft palate, gum, and cheek mucosa.

Pulmonary gnathostomiasis

Worms may be found in the sputum of patients with bronchitis, eosinophilis pneumonitis, pleurisy, pleural effusion, or pneumohaemothorax.

Genitourinary gnathostomiasis

The parasites have been recovered from blood-stained urethral discharge and urine, the glans penis, adnexal masses, and the cervix.

Auditory gnathostomiasis

The worms have been found in the external auditory canal in a patient with hearing loss and tinnitus, and penetrating the tympanic membrane in another patient.

Laboratory diagnosis

The diagnosis is definitive if the worm can be identified in sections of surgical specimens. The whole worm may be available if it emerges through the skin, in excretions and discharges, or from eye operations. Their sizes ranged from 0.34 × 2.2 mm to 1.0 × 16.25 mm. Their stage of development does not correlate with the duration of clinical illness. Infections with more than one worm are uncommon.

Enzyme immunoassay and Western blot tests are sometimes available in Thailand and Japan. Western blot is specific.

Blood eosinophilia (7 to 76 per cent) occurs irregularly in about 60 per cent of cases and therefore is not necessary for presumptive diagnosis.

Magnetic resonance imaging can show tortuous tracks and haemorrhage in cerebral gnathostomiasis (Fig. 3).

Differential diagnosis

Diagnosis of cutaneous forms is based on clinical characteristics, geographical and dietary history, and by excluding other causes. Differential diagnoses include contact dermatitis, angioedema and urticaria, Calabar swellings (caused by *Loa loa*), fascioliasis, paragonimiasis, sparganosis, dirofilariasis, and from non-infectious causes.

Gnathostomal aetiology is highly likely if rapidly advancing myelitis follows root pain, or if features of cerebral or subarachnoid haemorrhage occur in a person who is healthy apart from a history of cutaneous migratory swelling. Eosinophil pleocytosis is essential for the diagnosis, as is exclusion of eosinophilic meningoencephalitis caused by *Angiostronglus cantonensis*, *Baylisascaris procyonis*, and non-helminthic encephalomyelitis.

In intraocular infections, the larvae of *A. cantonensis* can be distinguished as they are thinner, longer, and folding. They usually appear in the eyeball 2 to 3 weeks after the manifestation of eosinophilic meningoencephalitis.

Visceral gnathostamiasis usually depends on identifying the worm in surgical specimens (at autopsy the worms may have migrated away from the site of the main pathological lesion), or in secretions such as sputum, urine, or vaginal discharge.

Treatment

Surgical removal is curative but advisable only in accessible areas such as the eye or skin. Blind exploration of subcutaneous tissues in areas of diffuse swelling is not productive.

Oral therapy with albendazole at an adult dosage of 400 mg twice daily for 2 to 3 weeks induces migration of the gnathostome to the skin. The worms are frequently recovered between days 2 and 14 of treatment by picking with a needle, excisional biopsy, or even by pinching with the patient's nails. However, the success rate is only 6 to 7 per cent. Recurrence of swelling in patients whose worms do not migrate to the skin is less frequent after albendazole treatment. Aminotransferases should be measured before this treatment even though hepatotoxicity at this dosage is usually mild and reversible.

Prognosis

Cerebral gnathostomiasis can be fatal and blindness is frequent after intraocular gnathostomiasis. Patients can be reassured that central nervous or intraocular involvement occur in less than 1 per cent of patients with cutaneous migratory swelling.

Prevention

All dishes that contain raw or poorly cooked flesh of animals in or imported from endemic areas must be avoided. Those who prepare potentially infected flesh should use gloves if prolonged exposure is likely.

7.15.1 Cystic hydatid disease (*echinococcus granulosus*)

Armando E. Gonzalez, Pedro L. Moro, and Hector H. Garcia

Introduction

Cystic hydatid disease is a zoonotic disease caused by infection with the larval stage (hydatid cyst) of the tapeworm *Echinococcus granulosus*. Hydatid cysts in liver and lung are frequent causes of human morbidity in endemic zones.

Aetiology

The lifecycle of *E. granulosus* requires two hosts. The adult tapeworm is found in the small intestine of the definitive host, usually dogs or other canids. It consists of only three to five proglottids, and measures between 3 and 7 mm long when fully mature. *E. granulosus* has remarkable biological potential; there may be as many as 40 000 worms in a heavily infected dog, each one of which sheds about 1000 eggs every 2 weeks. Dogs infected with *Echinococcus* tapeworms pass eggs in their faeces that contaminate the soil and vegetation and remain viable for long periods in cold humid places. Intermediate hosts (sheep, cattle, horses, pigs, and other mammals, including man) acquire hydatid disease by ingesting viable eggs of *E. granulosus*. Eggs hatch in the intestine freeing oncospheres which penetrate the intestinal mucosa and are transported by the blood and lymphatic systems to the liver, lungs, and other organs, where they develop into unilocular cysts.

Taxonomic studies have identified different strains of *Echinococcus*. Tapeworms developed from horse and sheep cysts are distinguishable, and *E. granulosus* from horse cysts is unlikely to infect humans. Wild cycles involving wolves with moose, caribou, and reindeer have been described in North America. In Africa, adult tapeworms have been identified in lions, hyenas, and jackals and cysts in antelopes and wild pigs.

Epidemiology

Hydatid disease is an important cause of human morbidity requiring costly surgical treatment. The infection is widely distributed in most parts of the world where sheep are raised and dogs are used to herd livestock. In the Americas most cases have been reported from Argentina, Chile, Uruguay, Peru, and southern Brazil. Recent studies in Peru have revealed prevalences of hydatid disease ranging from 5.7 to 8.9 per cent in highland villagers, and as high as 32 and 89 per cent in dogs and sheep, respectively. High prevalence of liver hydatid disease, with rates of up to 5.6 per cent, have also been reported in north-western Turkana in Kenya. *Echinococcus* is widespread in the Old World, particularly in Greece, Cyprus, Bulgaria, Lebanon, and Turkey. In the United States, most infections are seen in immigrants from endemic countries. However, sporadic autochthonous transmission is currently recognized in Alaska, California, Utah, Arizona, and New Mexico.

Communities at higher risk of infection include those where sheep are raised extensively and where dogs are used to care for large flocks of livestock. Known risk factors for infection include feeding dogs with raw offal and access of dogs to sheep that die in the field (Fig. 1). The risk of infection is also linked to poor hygiene and intimate contact with dogs. In north-western Turkana, dogs are allowed to stay within the house, and are used to clean up women's menses and lick vomit from faces and diarrhoea from the anal regions of their children.

Fig. 1 Epidemiological conditions for completion of the lifecycle of *Echinoccocus*: free dog waiting for sheep offal at a slaughterhouse.

Pathogenesis

The incubation period of human hydatid infections is highly variable and often prolonged for several years. Cysts have been reported to grow continuously between 1 and 5 cm per year. However, recent studies suggest that cyst growth is highly variable. Some cysts grow as much as 1 cm per year while other viable cysts showed no growth during 3 to 12 years of follow-up.

Most human infections remain asymptomatic; hydatid cysts are found incidentally at autopsy much more frequently than the reported local morbidity rates. The locality of the cysts, their size, and their condition determine the particular manifestations.

Clinical features

Hydatid cysts are most frequently seen in the liver (60 to 70 per cent) followed by the lungs (30 to 40 per cent). Signs of hepatic hydatid disease include hepatomegaly with or without the presence of a mass in the upper right quadrant. Obstructive jaundice, mild epigastric pain, indigestion, and nausea may occur occasionally. Hydatid cysts may become secondarily infected with bacteria presenting as a hepatic abscess. Features of lung involvement (Fig. 2) are cough, haemoptysis, dyspnoea, and fever. The ratio of liver to lung cysts may vary from one geographical region to another: a liver to lung ratio of 1.4:1 has been observed in Peru, in contrast to the 3:1 to 13:1 ratio reported in Argentina and Uruguay. Differences in *Echinococcus* strains may account for this variation. Brain cysts produce intracranial hypertension and epilepsy. Vertebral cysts compress the spinal cord causing paraplegia; bone cysts produce spontaneous fractures (Fig. 3 and Plate 1) and deformity. Sudden rupture of cysts in the peritoneal cavity may result in peritonitis, and rupture in the lungs may cause pneumothorax and empyema. Rupture may also cause allergic manifestations such as pruritus, oedema, dyspnoea, anaphylactic shock, and even death.

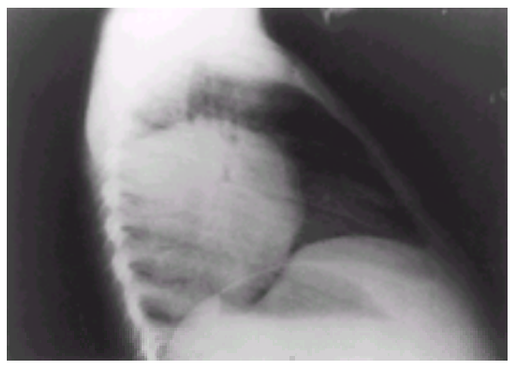

Fig. 2 Plain chest radiographs showing a lung hydatid cyst.

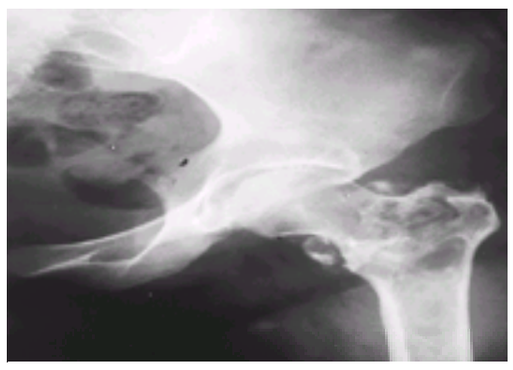

Fig. 3 Pathological fracture of the femur caused by hydatid infection (copyright D.A. Warrell).

Diagnosis

Clinical findings such as a space-occupying lesion and residence in an endemic region are suggestive of hydatid disease. Abdominal ultrasonography is an important aid to the diagnosis of abdominal cysts. Portable ultrasonography machines are used with good results in field surveys. Chest radiography is useful for diagnosis of lung cysts. CT scanning is very helpful, especially for diagnosis of non-typical lesions.

Serology

Efforts to develop sensitive and specific immunodiagnostic tests in humans have been relatively successful. A number of serological tests have been developed for diagnosis of hydatid disease, including an enzyme immunoassay, which identify antibodies against antigen B or components of this antigen. A Western blot assay based on the identification of three specific antigens of 8, 16, and 21 kDa is currently used. Major drawbacks in serological diagnosis are low sensitivity for detection of lung hydatid cysts and cross-reactivity with sera of patients with *Taenia solium* infection. In field surveys, serological tests should be used in combination with imaging techniques in order to detect most cases of hydatid disease.

Parasitological diagnosis

Although uncommon, this can be done from sputum samples of patients whose lung cysts have recently ruptured. Scolices have four spherical suckers and a rostellum with two rows of hooks.

Treatment

Surgery

Surgical removal of hydatid cysts remains the treatment of choice in many countries. The usual surgical approach involves injection of a protoscolicidal agent into the cyst, usually 20 per cent hypertonic saline solution or 90 per cent alcohol, followed by evacuation of the fluid, prior to surgical excision. Major risks of surgical treatment include accidental spillage of fluid and scolices into the peritoneal cavity, which may lead to anaphylaxis or secondary peritoneal hydatidosis. Recurrence rates following surgery may be as high as 30 per cent. Antihistamines are given as prophylxis and suction cones have been used to prevent spillage. The efficacy of these methods is uncertain.

Chemotherapy

Benzimidazole compounds have been shown to be effective against hydatid disease. Courses of albendazole in a dose of 10 to 15 mg/kg body weight per day for 28 days are interspersed with drug-free periods of 2 weeks. This regime cures approximately one-third of cases of liver hydatid disease and causes partial regression of cysts in another third of patients. However, many courses may be needed to achieve complete or partial cyst regression. Small liver or lung hydatid cysts should be treated with albendazole. Because of its high scolicidal activity, albendazole is recommended as a prophylactic agent 1 to 3 months prior to surgical intervention. Albendazole is indicated when surgery is contraindicated. Mebendazole may also be used, although it is less effective than albendazole. Albendazole, mebendazole, and other benzimidazole compounds should not be used in pregnant women because of their potentially teratogenic effects. Since benzimidazoles are potentially hepatotoxic, liver enzymes should be monitored before and during treatment.

Recent experimental studies in animals have shown that another benzimidazole compound, oxfendazole, has strong parasiticidal activity. Intermittent weekly therapy with oxfendazole was effective in sheep hydatid disease, suggesting the possibility that daily therapy as currently used with albendazole may not be needed. Future studies will explore the effect of oxfendazole in the treatment of human hydatid disease.

PAIR (percutaneous aspiration, injection, reaspiration)

PAIR consists of percutaneous puncture using sonographic guidance, aspiration of substantial amounts of the cyst fluid, and injection of a protoscolicidal agent, usually hypertonic saline for at least 15 min, followed by reaspiration of cyst contents. Albendazole should be administered before PAIR treatment, and antihistamines should be given to reduce the risk of allergic reactions if there is spillage of fluid. Good results have been reported with this procedure with no major complications. A recent study comparing the use of PAIR and surgical treatment for liver hydatid cysts found less complications and a shorter hospital stay in the PAIR-treated group.

Prevention and control

The earliest successful programme against echinococcosis was carried out in Iceland. It was based on a health educational campaign that eradicated the parasite. Control programmes have been aimed at educating dog owners to prevent their animals from having access to infected offal. This approach includes periodic treatment of sheepdogs with praziquantel (every 45 days), reduction in the dog population, close veterinary inspection of slaughterhouse facilities for the presence of dogs, and cremation of infected offal. Control programmes are in force in Argentina, Chile, and Uruguay. Partial success has been achieved in the first two countries. However, hydatid disease remains a serious problem in Uruguay. Control programmes in New Zealand and Tasmania have reduced the number of infected animals

and the incidence of human infection.

Serological tests such as the Western blot for diagnosis of sheep hydatidosis and the coproantigen ELISA for canine echinococcosis are potentially useful for measuring the burden of disease and monitoring control programmes in endemic regions. A recent major advance has been the development of a recombinant vaccine (EG95) which seems to confer 96 to 98 per cent protection against challenge infection. Recent trials in Australia and Argentina using this vaccine have reported that 86 per cent of immunized sheep were completely free of viable hydatid cysts when examined 1 year later. The number of viable cysts was reduced by 99.3 per cent. Although the results of these initial trials seem promising, further research is needed to assess the cost-benefit of using this vaccine.

7.15.2Gut cestodes

R. Knight

Two groups of tapeworms infect man: the cyclophyllidean species which are covered in this chapter, and the pseudophyllidea (see Chapter 7.15.4).

The cyclophyllidean tapeworms maintain anchorage to the host small-gut mucosa by means of the scolex, a holdfast structure bearing a circlet of four suckers and usually a central evertible rostellum with one or more circlets of minute hooks (Fig. 1(a) and Fig. 1(b)). The rest of the body forms the strobila and consists of a chain of flattened proglottids, which bud behind the scolex. The worms change their site of attachment regularly, and are surprisingly motile. Gravid proglottids are lost from the end of the worm and are replaced by others that have matured as they pass down the strobila. Each proglottid possesses a complete set of hermaphroditic sex organs and marginal genital openings. Eggs accumulate in the uterus of gravid proglottids and only enter the faecal stream when the proglottids are disrupted. In many species the eggs enter the environment within intact proglottids. In either case the eggs are embryonated and contain a hexacanth embryo (onchosphere) that bears three pairs of hooks. The egg shells have two membranes; but in *Taenia* the outer is lost early and the inner forms the thick embryophore.

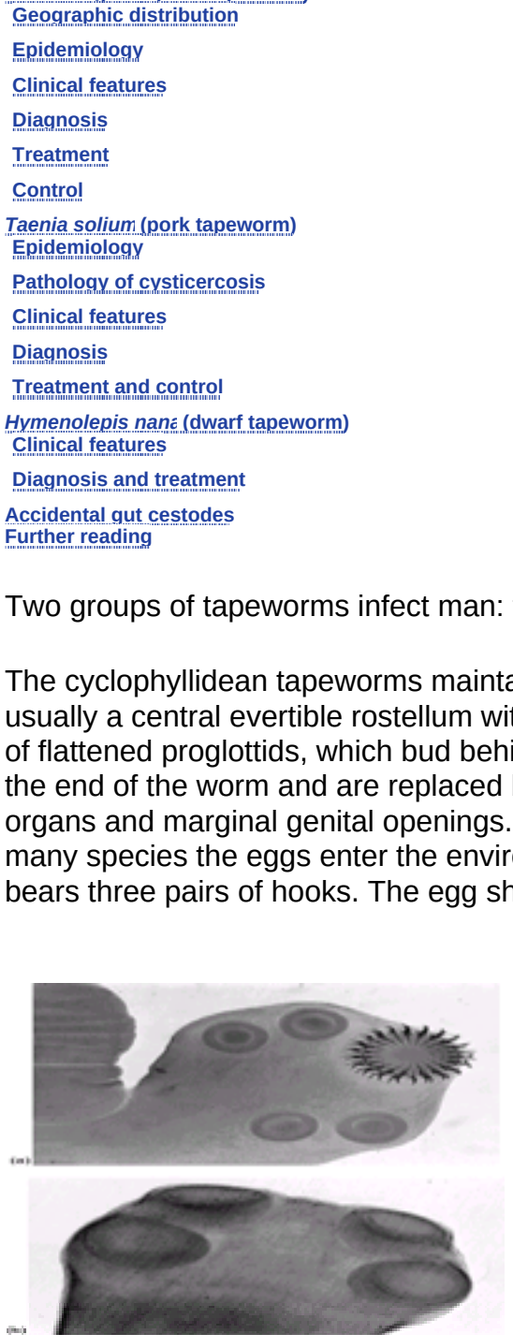

Fig. 1 (a) *Taenia solium* showing scolex with four suckers and a double row of hooks (× 250). (b) *Taenia saginata* showing scolex with four suckers and no hooks (× 250). (By courtesy of Professor V. Zaman.)

After ingestion by the intermediate host, eggs hatch and the released hexacanth embryos bore their way into the mucosa. The larval stages of the parasite are generally cystic with an invaginated embryonic scolex—the protoscolex. The cycle is completed when the larval stage, within the intermediate host or its tissues, is eaten by the definitive host; the protoscolex evaginates and attaches to the gut mucosa.

In three species, humans are an obligatory part of the lifecycle (Table 1; Fig. 2, Fig. 3, and Fig. 4), in the rest they are an accidental host (see Table 2). The two *Taenia* species cause anthropozoonoses because the cycle is maintained by an obligatory alternation between human and non-human hosts. Symptoms result from local hypersensitivity reactions to the worm and its scolex, and altered gut motility due to the physical mass of the worm. Patients often become aware of proglottids in their faeces. Some patients report poorly defined systemic symptoms, which may have an immunological basis. A blood eosinophilia up to 10 per cent can occur with any gut cestode.

Taenia saginata (beef tapeworm)

Geographic distribution

The beef tapeworm is prevalent where cattle have access to human faeces and where humans eat undercooked beef. The highest prevalence is in Africa, particularly in eastern and north-eastern parts; it is also common in many countries in the Middle East, South America, and South-East Asia. Prevalence is now very low in the United States, Canada, and Australia. It still persists endemically in Western Europe; but eastwards prevalence increases progressively across Europe and into the former USSR.

Epidemiology

Gravid proglottids are passed at defaecation, often in short chains; free eggs also occur in faeces. The whitish proglottids, approximately 2 to 3 cm long, are actively motile, elongating and contracting (Fig. 5). Viable eggs persist on pasture for many months and can survive most forms of sewage treatment. Cattle have access to human faeces on farms, at camp sites and recreation areas, and on railway lines. Infected herdsmen can initiate epizootics. Eggs may be dispersed by flies and dung beetles, and seabirds can ingest proglottids in estuarine waters and deposit them in their faeces on inland pastures.

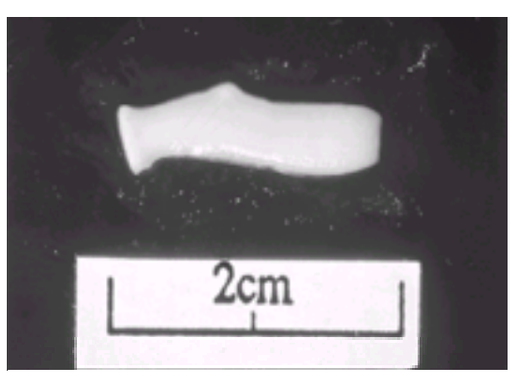

Fig. 5 Actively motile, contracting proglottid of *Taenia saginata* found by a patient in the stool. (Copyright D.A. Warrell.)

In cattle, cysticerci occur in striated muscle; they are whitish, ovoid, and measure 8 by 5 mm; they contain an invaginated protoscolex with no hooks. They become infective within 12 weeks and remain viable in the living host for 2 years; they are viable in stored, chilled meat for several weeks but are killed at –20°C within 1 week. The prepatent period in humans is 3 months and worms may live 30 years. Cattle develop protective immunity to new infection.

A subspecies *T. saginata asiatica* occurs in Taiwan, Korea, Indonesia, Thailand, and Burma. Infection follows ingestion of raw pig or wild boar liver; the protoscolex of the cysticercus bears hooks.

Clinical features

Most worms are solitary. Multiple worms are smaller, more common in high-transmission areas, and probably arise by simultaneous infection. Most patients are first aware of the worm by seeing proglottids on faeces (Fig. 5). Many will experience active worm migration through the anus, and this may induce an anxiety response. Many have no other symptoms, but others complain of nausea and upper abdominal pains, often relieved by food. A few patients eat to relieve symptoms. In children, impaired appetite can have nutritional consequences. Some patients have symptoms suggestive of hypoglycaemia, namely dizziness and sweating. Pruritus ani is common. The worm may be visible on small-bowel barium studies.

Proglottids have been found in a variety of surgical specimens including resected appendices, but a pathogenic role is usually difficult to establish. They occasionally obstruct the small intestine, pancreatic duct, or bile duct. After gut perforation they can occur in the peritoneum. Proglottids are recorded in the gallbladder, and eggs have been found in gallstones.

Diagnosis

The typical eggs may be found in faeces, but this is an insensitive method; perianal swabs are also useful. Eggs are indistinguishable from those of *T. solium*; patients should be asked to bring worm specimens. Unless the proglottid is fully gravid the number of uterine branches is an unreliable diagnostic character. A better morphological distinction is the presence of a vaginal sphincter; this is absent in *T. solium*. In human surveys in endemic areas a 24-h faecal collection after an anthelmintic will give the most reliable prevalence.

Treatment

A single morning dose of 2 g niclosamide is given to adults and older children on an empty stomach; the tablets should be chewed. Children of 2 to 6 years should receive 1 g, and those below 2 years, 500 mg. The alternative is praziquantel given in a single dose of 10 to 20 mg/kg after a light breakfast. After either drug the proximal part of the worm disintegrates in the gut and the scolex cannot be found. Failure of proglottids to reappear within 3 to 4 months indicates cure.

Control

This includes health education about raw beef, meat inspection, sanitation and hygiene on cattle farms, and proper sewage treatment and disposal. Mass treatments

of herd contacts, or whole adult populations, are the most effective short-term measures when endemicity is high. *T. saginata* causes great economic loss to the beef industry in some developing countries.

Taenia solium (pork tapeworm)

The clinical importance of the pork tapeworm relates mainly to cysticercosis, the occurrence of larval forms in human tissue (see Chapter 7.15.3). This arises when eggs hatch in the upper gut and humans become an accidental intermediate host. The source of such eggs is the faeces of persons infected with adult worms.

T. solium is generally less common than the beef tapeworm; it is now very rare in North America and Western Europe, but it remains common in much of sub-Saharan Africa, Mexico, South America, and in China, India, and other parts of Asia.

Epidemiology

In the pig muscle cysticerci produce 'measly pork' (Fig. 6). The cysts are most numerous in the tongue, masseter, heart, and diaphragm, but also occur in the brain. When eaten by humans in undercooked pork the worms mature in 5 to 12 weeks. The eggs have the same resistant qualities as *T.saginata*.

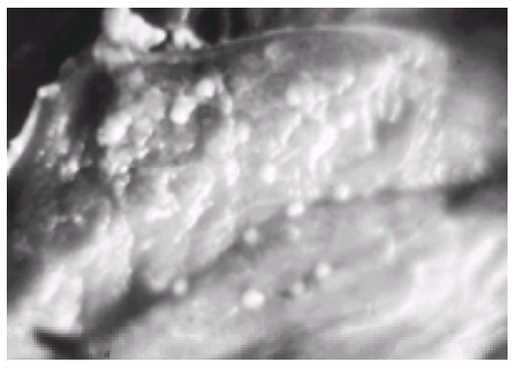

Fig. 6 'Measly pork' showing numerous cysts in the pig's muscle. (Copyright Sornchai Looareesuwan.)

Human cysticercosis is much more limited geographically than *T. solium* implying that internal autoinfection from disrupted proglottids is rare. Conditions favouring cysticercosis include poor personal hygiene, which facilitates external autoinfection and contaminated fingers among food handlers. Faecal pollution of the peridomestic environment, irrigation water, or cultivated vegetables is also important. In parts of Africa, tapeworm proglottids are used in traditional medicine. In the absence of these factors, cases of cysticercosis may be very sporadic even when *T. solium* is common. Cysticercosis is a major health problem in Mexico, some South American countries, and to a lesser extent in Africa and Asia. In 1969, *T. solium* was introduced from Bali into the highlands of Irian Jaya, New Guinea, where the disease is now of great importance.

Pathology of cysticercosis

Cysts occur especially in striated muscle, subcutaneous tissue, the nervous system, and the eye. Many remain clinically silent until the parasite dies after 3 to 5 years, when vigorous inflammatory and hypersensitivity reactions can occur; later lesions may calcify. In the brain, particularly in the subarachnoid and the ventricular system, atypical racemose cysts may occur. They appear as irregular or grape-like clusters of cysts that have no protoscolex; they can be mistaken pathologically for non-parasitic cysts.

Clinical features

Symptoms due to the adult worms are similar to those of *T. saginata* but are often milder and not associated with pruritus ani. The proglottids do not migrate actively *per anum*.

Diagnosis

Adult worm infection is detected as for *T. saginata*. Methods for detecting faecal antigen are available and have great potential use in epidemiological studies. Proglottid fragments can be identified using DNA probes.

Treatment and control

Adult worms are treated as for *T. saginata*. Vomiting must be avoided and an antiemetic is recommended, together with a purgative 2 h after the medication, which should be given after a light breakfast. It should be remembered that the faeces will be potentially highly infective for several days, both for the patient and attendants. Control measures are similar to those of *T. saginata* but local risk factors for human cysticercosis must receive special attention.

Hymenolepis nana (dwarf tapeworm)

The dwarf tapeworm is the most common cestode in man; it is also the smallest. When worm loads are high it causes more gut pathology than any other species. It is common in most developing and tropical countries. The lifecycle normally involves only humans (Fig. 4). Fully embryonated infective eggs are passed in the faeces; gravid proglottids normally disintegrate completely in the gut. Infection is commonly direct, but also by the other faecal–oral routes. Eggs hatch in the jejunum and the hexacanth embryo bores into a villus where it transforms into a cysticercoid larva. After 4 to 6 days it re-enters the gut, everts the scolex, and attaches to the mucosa; eggs appear in the faeces within 12 days. The lifespan is 3 months. The eggs are delicate and survive less than 10 days in the environment. Prevalence is usually much higher in children than adults; outbreaks can occur in families and institutions. External autoinfection is common in high-risk groups and enables high worm loads to build up. In addition, internal autoinfection occurs when there is gut stasis or retroperistalsis. Because of the importance of direct transmission, this infection may be common even in arid environments such as Western Australia.

Clinical features

In heavily infected people, especially children, up to 1000 or more worms may be present. Mucosal damage caused by both larval and adult worms leads to protein loss and sometimes malabsorption. Abdominal pains and anorexia are common.

Immunosuppressant or steroid therapy, particularly in patients with lymphoma, can lead to the development of bizarre cystic larval forms in the gut wall, mesenteric nodes, liver, and lungs. A similar condition can be produced in immunosuppressed mice.

Diagnosis and treatment

Eggs can be detected in faeces using concentration methods. Proglottids are rarely found in faeces, except after treatment.

Praziquantel in a single dose of 25 mg/kg is the most effective drug. If niclosamide is used, a 7-day course is needed to ensure that larval stages are killed when they re-enter the gut lumen. The dose on the first day is as for *T. saginata*; on the remaining days one-half of this dose is given. Relapses often result from persistence of

eggs in the patient's environment.

Accidental gut cestodes

Many species have been recorded in humans (see Table 2). All have arthropods as intermediate hosts, the larval cysticercoid stage being in the haemocele; the full lifecycles of some species are still uncertain. The normal definitive host becomes infected by eating the arthropod intentionally or accidentally. The means by which humans become infected is sometimes not clear, but fleas, small beetles, and mites are easily overlooked in food. *Dipylidium caninum* infection occurs in children who have groomed their pet. Infections with *Bertiella* are mostly in owners of pet monkeys, but oribatid mites are common in fallen fruit, especially mangoes. Children may eat insects deliberately, and this appears to be the mode of infection by *Raillietina siriraji* in Bangkok. Beetles are used for medicinal purposes in parts of Thailand and Malaysia, and this is the most likely route by which *Mathevotaenia* is acquired.

Hymenolepis nana fraterna is the murine strain of the human parasite and *H. diminuta* also infects rodents; both are rare in human beings. Both human and murine subspecies of *H. nana* will infect *Tribolium* beetles. In many of these species the eggs are in capsules that are released when the proglottid disintegrates in the gut, or more commonly, in the faecal mass. *Mesocestoides* is unique among these parasites in three respects: two intermediate hosts are required; the genital opening is medioventral rather than at the margin of the proglottid as in all other cyclophyllidean tapeworms; and larval worms can occur in man when mites are ingested.

Many patients will present because they have passed proglottids. *Dipylidium caninum* actively migrates out of the anus, like *T. saginata*. Faecal examinations of persons with abdominal complaints may reveal unusual eggs or egg capsules. Poorly defined systemic and allergic complaints are common. Treatment is as for *T. saginata*.

Recognition of these parasites is of epidemiological interest and may indicate potential transmission of other zoonotic pathogens. It is certain that all these parasites are underreported. Unusual proglottids or eggs should be preserved in formol saline and sent to a parasitologist.

7.15.3 Cysticercosis

Hector H. Garcia and Robert H. Gilman

Introduction

Known since the Hippocratic era, cysticercosis is the commonest helminthic infection of the human central nervous system. It is probable that the suspicion of its origins led some religions expressly to forbid the consumption of pork. Socio-economic improvements eradicated the infection in Europe and North America. However, endemic *Taenia solium* taeniasis/cysticercosis persists in most developing countries, where human cysticercosis is an important cause of epilepsy and other neurological morbidity, and porcine infections cause important economical losses to peasants.

Aetiology

Cysticercosis is infection with the larval stage (cysticercus) of *T. solium*, the pork tapeworm. In the lifecycle (Fig. 1) of this two-host zoonotic cestode, humans are the only definitive host and harbour the adult tapeworm, whereas pigs are intermediate hosts. The hermaphroditic adult *T. solium* inhabits the small intestine. Its head or scolex bears four suckers and a double crown of hooks, connected by a narrow neck to a large body (strobila) between 2 and 4 m long, composed of several hundred proglottids. Gravid proglottids, each containing 50 000 to 60 000 fertile eggs, detach from the distal end of the worm and are excreted in the faeces. The cycle is completed when pigs ingest stools contaminated with *T. solium* eggs. Once ingested by the pig, the invasive oncospheres in the eggs are liberated by the action of gastric acid and intestinal fluids and actively penetrate the bowel wall, enter the bloodstream, and are carried to the muscles and other tissues where they develop into larval cysts. When humans ingest undercooked pork containing cysticerci, the larvae evaginate in the small intestine, their scolices attach to the intestinal mucosa, and they begin forming proglottids. By accidentally ingesting *Taenia* eggs, humans may also act as intermediate hosts for *T. solium* and develop cysticercosis.

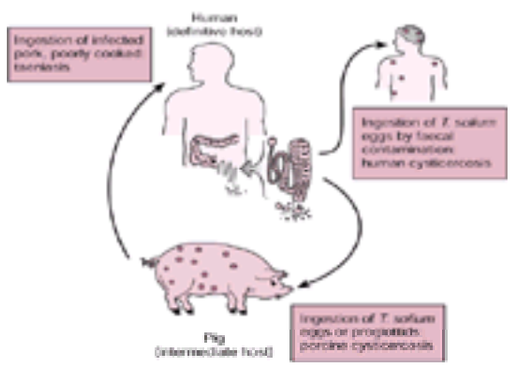

Fig. 1 Lifecycle of *T. solium*.

Epidemiology

The availability of neuroimaging studies and the subsequent development of specific serodiagnostic tests resulted in identification of neurocysticercosis as a frequent neurological disorder in Latin America, Africa, and Asia, where the prevalence of active epilepsy is almost twice that in Western countries. Neurocysticercosis is an emerging problem in industrialized countries, seen mainly in immigrants from endemic areas, some of whom may spread the infection as tapeworm carriers.

The main sources of human cysticercosis are ingestion of food contaminated with *T. solium* eggs and faecal–oral contamination in those carrying the tapeworm. Epidemiological studies suggest that almost every newly diagnosed patient with cysticercosis has been infected by someone in their close environment who is harbouring a *T. solium* and tends to dismiss the role of environment or water in transmission. Airborne transmission of *T. solium* eggs or internal autoinfection by regurgitation of proglottids into the stomach have been suggested but not proved.

Pathogenesis

Any organ may be infected but parasites survive more frequently in the nervous system, possibly because the immune response there is limited. Signs and symptoms are caused by perilesional inflammation and oedema, mass effect, or obstruction of cerebrospinal fluid circulation. Although complete development of cysts takes about 2 months, symptoms usually develop years after the initial infection. This clinically silent period and finding inflammation around cysts in symptomatic cases suggest that symptoms are due to inflammatory processes associated with death of the parasite rather than to the presence of the parasite itself.

Meningeal cysticerci elicit an intense inflammatory reaction causing thickening of basal leptomeninges. The optic chiasma and other cranial nerves are usually entrapped within this dense exudate, resulting in visual field defects and other cranial nerve dysfunctions. The foramens of Luschka and Magendie may be occluded by the thickened leptomeninges leading to hydrocephalus. Blood vessels may be affected by the inflammatory reaction. The walls of small penetrating arteries are invaded by inflammatory cells, leading to a proliferative endarteritis with occlusion of the lumen, and which may result in cerebral infarction.

Clinical features

Neurocysticercosis is a pleomorphic disease, whose manifestations vary with the number, size, and topography of the lesions and the intensity of the host's immune response to the parasites. Patients can be classified by the number and location of the cysticerci, and the presence or absence of associated inflammation or calcifications.

Epilepsy, the most common presentation of neurocysticercosis, is usually the primary or sole manifestation of the disease. Seizures occur in 50 to 80 per cent of patients with parenchymal brain cysts or calcifications but are less common in other forms of the disease. Other common focal signs include pyramidal tract signs, sensory deficits, signs of brainstem dysfunction, and involuntary movements. These manifestations usually follow a subacute or chronic course, making neurocysticercosis difficult to differentiate clinically from neoplasms or other infections of the central nervous system. Focal signs may occur abruptly in patients who develop a cerebral infarct as a complication of subarachnoid neurocysticercosis. Subarachnoid cysticerci may reach 10 cm or more in diameter ('giant' cysticercosis,

Fig. 2), and exert a mass effect.

Fig. 2 Giant cysticercotic cyst (brain CT).

Neurocysticercosis may present with increased intracranial pressure, usually from hydrocephalus secondary to cysticercotic arachnoiditis, granular ependymitis, or ventricular cysts. In these cases, intracranial hypertension develops subacutely and progresses slowly. An encephalitic picture may result from overwhelming inflammation around many parasitic cysts, a syndrome that occurs more frequently in younger people, especially women. In contrast, some patients may tolerate hundreds of intraparenchymal cysticerci with only minor symptoms.

Muscular pseudohypertrophy, a rare presentation, is caused by heavy cysticercal infection of skeletal muscles (Fig. 3) giving a 'Herculean' appearance. The few cases reported are all from India. Other apparent differences in clinical manifestations between Asia and Latin America include a high frequency of subcutaneous cysts and single degenerating brain lesions in Asia.

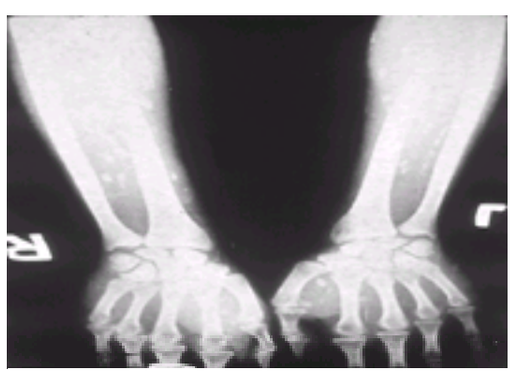

Fig. 3 Heavy cysticercal infection of skeletal muscles (copyright Sornchai Looareesuwan).

Pathology

The cysticerci are liquid-filled vesicles consisting of vesicular wall and scolex (Fig. 4). The vesicular wall is composed of an outer or cuticular layer, a middle or cellular layer with pseudoepithelial structure, and an inner or reticular layer. The invaginated scolex has a head or rostellum armed with suckers and hooks, and a rudimentary body or strobila that includes the spiral canal.

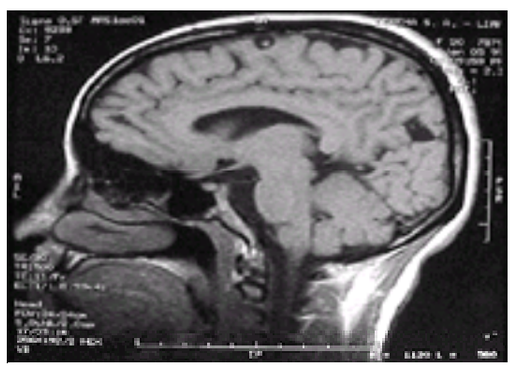

Fig. 4 Uncontrasted T_1 MR image showing two intraparenchymal cysticerci with visible scolices.

The macroscopic appearance of cysticerci varies in different locations within the central nervous system. Cysticerci within the brain parenchyma are usually small and tend to lodge in the cerebral cortex or basal ganglia. Subarachnoid cysts may be small if located in the depths of cortical sulci, or grow to 5 cm or more in the basal cisterns or sylvian fissures. Ventricular cysticerci are usually single, may or may not have a visible scolex, and may be attached to the choroid plexus or float freely in the ventricle. Spinal cysticerci are usually located in the subarachnoid space (rarely intramedullary). Their morphology is similar to cysts located within the brain.

Basal cysticerci may undergo a disproportionate growth of their membrane, with extension processes, resembling a brunch of grapes (racemose cysticercosis, Fig. 5). In these cases, the scolex is frequently unidentifiable even by microscopy.

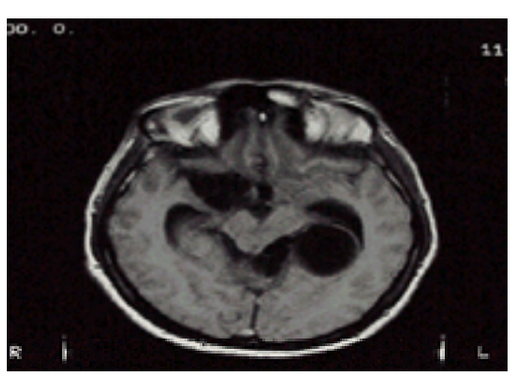

Fig. 5 Basal 'racemose' cysticercosis.

Viable, vesicular cysticerci elicit little inflammatory change in surrounding tissues because of active immune evasion mechanisms. The appearance of symptoms is interpreted as the result of immunological attack from the host, in a process of degeneration that ends with the death of the parasite. Inflammatory changes in the parasite membrane and increased density of cyst fluid mark the transition between four defined stages: viable, colloidal, granular nodular, and calcified cyst. Viable cysts may coexist with degenerating cysts or calcifications.

Laboratory/imaging diagnosis

The pleomorphism of neurocysticercosis makes it impossible to diagnose on clinical grounds alone. In endemic regions, late-onset seizures in otherwise healthy individuals are highly suggestive of neurocysticercosis. Most of these patients are normal on neurological examinations. Routine neuroimaging and serological studies are, therefore, mandatory. Finding cysticerci outside the central nervous system (eye, subcutaneous tissue, muscle) assists the diagnosis of neurocysticercosis. Muscular and subcutaneous cysticerci are far less common in American than in African or Asian patients with neurocysticercosis.

Neuroimaging

CT and MRI have drastically improved diagnostic accuracy by providing objective evidence about the topography of the lesions and the degree of the host inflammatory response to the parasite. Imaging findings in parenchymal neurocysticercosis depend on the stage of involution of cysticerci. Viable cysticerci appear as rounded cystic lesions on CT (Fig. 2), hypointense on MRI (Fig. 4), without associated enhancement, whereas degenerating parasites are seen as focal enhancing lesions surrounded by oedema, and calcifications as hyperdense dots or nodules (Fig. 6). Disappearance of cyst fluid signals the degenerative phase and calcified nodules the residual phase. Single or multiple ring-like or nodular enhancing lesions are non-specific and present a diagnostic challenge. Pyogenic brain abscesses, fungal abscesses, tuberculomas, toxoplasma abscesses, and primary or metastatic brain tumours may produce similar findings on CT or MRI.

Fig. 6 Calcified neurocysticercosis.

CT and MRI findings in subarachnoid neurocysticercosis are less specific. They include hydrocephalus, abnormal meningeal enhancement, and subarachnoid cysts. Cerebral angiography may show segmental narrowing or occlusion of major intracranial arteries in patients with cerebral infarcts secondary to parasitic vasculitis. In neurocysticercosis there is rarely fever or signs of meningeal irritation; glucose levels of cerebrospinal fluid are usually normal. MRI is generally better than CT for the diagnosis of neurocysticercosis, particularly in patients with basal lesions, brainstem or intraventricular cysts, and spinal lesions. MRI is, however, less sensitive than CT for the detection of small calcifications.

Immunological tests

Immunoblot (Western blot) is the best available serological test for *T. solium* antibodies. It is 98 per cent sensitive in cases with more than one active lesion, and 100 per cent specific. Its sensitivity may drop in patients with a single cyst. Other assays using unfractionated antigens (e.g. enzyme immunoassay) suffer from poor specificity but are more reliable when performed with cerebrospinal fluid than serum. Antigen-detection tests may provide a tool for serological monitoring of antiparasitic therapy. Although results of serology and imaging studies may be similar, they evaluate different aspects of the disease and may be discordant in some patients. Intestinal tapeworm carriers, naturally cured patients, or non-neurological infections may have normal brain images but be positive serologically. Those with only inactive lesions or a single cerebral lesion may be seronegative.

A proportion (about 10 to 15 per cent) of patients with neurocysticercosis are tapeworm carriers at the time of diagnosis, and in another 10 per cent or so a carrier can be detected in the household. Parasitological diagnosis is difficult: eggs and proglottids are shed only intermittently in stool and are usually missed by routine stool examination. Stool assays to detect parasite antigens are more sensitive than microscopy, but are not widely available. A recently described serological test for tapeworm carriers may improve detection.

A set of diagnostic criteria based on neuroimaging studies, serological tests, clinical presentation, and exposure history has been proposed by Del Brutto and colleagues. Besides absolute demonstration of the presence of the parasite, 'major' criteria (including typical findings on neuroimaging, demonstration of specific anticysticercal antibodies, or the presence of typical cigar-shaped calcifications in muscle) are combined with 'minor' criteria and epidemiological data to suggest a probable or possible diagnosis. Application of these criteria should improve the consistency of diagnosis.

Treatment

Because of the clinical and pathological pleomorphism of neurocysticercosis, precise assessment of the viability and size of cysts, the location of parasites, and the severity of the host's immune response is important before planning treatment.

Symptomatic treatment is very important. Seizures secondary to parenchymal neurocysticercosis can usually be controlled with anticonvulsants. However, the optimal length of anticonvulsant therapy in patients with neurocysticercosis has not been determined, and it is difficult to withdraw this treatment. Prognostic factors associated with recurrence of seizures include the development of parenchymal brain calcifications, and occurrence of recurrent seizures or multiple brain cysts before starting antiparasitic therapy.

Antiparasitic agents destroy viable cysts, although their long-term clinical benefit in seizures due to parenchymal neurocysticercosis has not been proved. Currently, albendazole is the drug of choice for antiparasitic treatment of cerebral cysticercosis (15 mg/kg.day for 7 days, with steroids), although a recently described single-day praziquantel regimen (75 to 100 mg/kg, in three doses at 2-h intervals, followed by steroids 6 h later) demonstrated similar cestocidal activity with few cysts. Longer courses may be required in patients with many lesions or subarachnoid cysticercosis. Transient worsening of neurological symptoms can be expected during antiparasitc therapy, secondary to the perilesional inflammatory reaction. There is no role for antiparasitic drugs in inactive neurocysticercosis (i.e. calcifications with or without enhancement on CT scan) since the parasites are dead.

Between the second and fifth day of antiparasitic therapy there is usually an exacerbation of neurological symptoms, attributed to local inflammation caused by the death of the larvae. For this reason, albendazole or praziquantel are generally given simultaneously with steroids in order to control the oedema and intracranial hypertension. Serum levels of praziquantel decrease when steroids are administered simultaneously, an effect that does not occur with albendazole. However, there is no evidence that cysticidal efficacy is decreased. Serum levels of phenytoin and carbamazepine may be lowered by simultaneous praziquantel administration. There are no data in patients receiving albendazole.

Some forms of neurocysticercosis should not be treated with antiparasitic agents. In patients with severe cysticercotic encephalitis these drugs may result in

worsening cerebral oedema and fatal herniation. In this case, the mainstay of therapy is high doses of corticosteroids to decrease the inflammatory response. In patients with both hydrocephalus and parenchymal brain cysts, antiparasitic drugs should be started only after placement of a ventricular shunt in case the intracranial pressure increases as a result of drug therapy. Antiparasitic drugs must be used with caution in patients with giant subarachnoid cysticerci. In such patients, concomitant steroid administration is mandatory to avoid cerebral infarction. Albendazole can successfully destroy ventricular cysts, but the surrounding inflammatory reaction may cause acute hydrocephalus if the cysts are located within the fourth ventricle or near the foramens of Monro and Luschka.

Surgery is limited to ventriculoperitoneal shunts to relieve obstructive hydrocephalus, and excision of single cysticerci (in the fourth ventricle or giant intraparenchymal cysts). However, shunts frequently dysfunction. The protracted course in these patients and their high mortality rates (up to 50 per cent in 2 years) is directly related to the number of surgical interventions required to change the shunts. Recently, neuroventriculoscopy has been employed as a less invasive option for resection of ventricular cysticerci.

Prognosis

Parenchymal cysticercosis has a good prognosis. Seizures usually subside in time without sequelae. In contrast, extraparenchymal cysticercosis and especially racemose cysticercosis have a poor prognosis, responding poorly to antiparasitic therapy, and leading to progressively deteriorating disease and death.

Prevention and control

Cysticercosis would not exist if pigs had no access to human faeces. However, this approach is hampered in endemic zones by the lack of sanitary facilities, veterinary inspection, and more importantly, because farmers tend to raise pigs under free-range conditions in order to reduce the cost of feeding them. Intervention programmes have concentrated on mass chemotherapy to eliminate human taeniasis, but their results have not been sustained. New tools for controls are oxfendazole, an effective and cheap single-dose therapy for porcine cysticercosis, and the candidate porcine vaccines under trial by several groups.

Monitoring the effect of an intervention requires suitable indicators. Human seroprevalence does not reflect changes in infection patterns because antibodies persist for years, even after successful treatment. Studies in Peru have shown that serological monitoring of porcine infection is a useful marker for both prevalence and changes in infection intensity over time. Similarly, the rate of infection in uninfected (sentinel) pigs over time can be used to estimate intensity of *T. solium* infection in the community. The prevalences of human and porcine infection are strongly correlated.

Areas of uncertainty/controversy

Although most cysts disappear after antiparasitic treatment, it remains uncertain whether this is associated with better control of seizures. Retrospective trials suggested that seizures were better controlled in treated patients. An open-label controlled trial failed to find a beneficial effect for albendazole or praziquantel in either clinical control or radiological evolution. However, the methodology of this study has been questioned, and data from double-blind randomized studies are not yet available.

Areas needing further research

A recent report suggests an association between brain calcifications secondary to cysticercosis and glial neoplasms. This has not yet been confirmed or rejected. Systematic long-term evaluation is needed to determine whether hydrocephalus is a late complication of antiparasitic therapy. The efficacy and costs of comprehensive human–porcine eradication programmes must be assessed.

7.15.4 Pseudophyllidean tapeworms: diphyllobothriasis and sparganosis

Seung-Yull Cho

Diphyllobothriasis

Diphyllobothriasis is a fish-borne infection of the intestine with tapeworms that belong to the genus *Diphyllobothrium*. The type species is *D. latum*.

Plerocercoid larvae of *D. latum* in fish can infect humans. In the intestine, the 1 cm long plerocercoid develops into a 5–6 m long adult, which produces a million eggs each day. In fresh water, a cycle is maintained—the egg embryonates to a coracidium, which becomes a procercoid larva in the copepod *Cyclops strenuus*, and then a plerocercoid in fish.

Human infections occur worldwide. The incidence is high in Siberia and in Baltic countries such as Finland. In Switzerland, the Lake Regions of North America, and in East Asia, cases of diphyllobothriasis are not uncommon. Humans may also be infected by zoonotic species of *Diphyllobothrium*. For instance, *D. yonagoense* and *D. nihonkaiense* in Japan and *D. pacificum* in Chile and Peru are intestinal parasites of seals while *D. ursi* and *D. dendriticum* in Alaska are parasites of bears and birds respectively. The habit of eating sliced raw fish, such as pike, burbot, perch, salmon, and other freshwater fish, creates the opportunity for infection. Prevention is achieved by freezing fish for 1 day at – 18 °C or lower.

Infection usually causes few symptoms. Abdominal discomfort, fatigue, diarrhoea, and urticaria may be the vague presenting symptoms. Vomiting up a tapeworm and intestinal obstruction due to a mass of worms occurs very rarely. A strip of gravid segments may pass out through the anus. Tapeworm pernicious anaemia may be associated with *D. latum* infection. In these patients, elimination of the tapeworm results in improvement of the anaemia. Clinically, haematological and neurological manifestations are the same as in pernicious anaemia.

Clinical symptoms are rarely responsible for raising the suspicion of diphyllobothriasis. The diagnosis can be confirmed by identifying eggs in the stool by microscopy. Discharged chains of gravid segments are also diagnostic. In endemic areas, all patients with pernicious anaemia should have their stools examined. Treatment is simple and effective. Niclosamide in a single adult dose of 2 g or praziquantel in a single dose of 10 mg/kg body weight are the drugs of choice.

Sparganosis

Sparganosis is a zoonotic infection caused by the larval tapeworm of *Spirometra mansoni* or *S. mansonoides.* The larvae invade a variety of human tissues (Fig. 1).

Fig. 1 A sparganum surgically removed from a subcutaneous mass.

The sparganum (plerocercoid) is a 1–30 cm long, white, slender tapeworm larva without round suckers. It is found in terrestrial vertebrates. Carnivorous mammals are infected with the adult stage in their small intestine. In fresh water, the egg embryonates, becoming a coracidium. The swimming coracidium is taken up by zooplankton, such as *Cyclops leuckarti*, and develops into a procercoid larva. When terrestrial vertebrates including man ingest the procercoid, it transforms into a tissue-invading sparganum.

Human sparganosis occurs sporadically worldwide. The procercoid larva in *Cyclops* can be inadvertently drunk in unfiltered water. Sparganum-infected frog, snake, poultry, or pork meat are important sources of human infection in endemic areas such as Japan, Korea, China, Vietnam, and Southeast Asian countries due to traditional habits. Some people believe that eating raw meat is a tonic or is beneficial for patients with tuberculosis. Rural people in Vietnam practise applying poultices of frog or snake skin to an inflamed eye. In this case a sparganum in the frog or snake skin can directly penetrate the conjunctiva.

Ingested larvae penetrate the intestinal wall and migrate systemically. The worm usually lodges in subcutaneous tissue or muscle of the chest or abdominal walls, breast, limbs, or scrotum. A lump may appear and then spontaneously disappear, only to reappear some weeks or months later at a site remote from the first. The sparganum secretes at least six different serine and cysteine proteases, which facilitate worm migration and evasion of the host's immune response. Orbital, chest, and abdominal cavities are involved. Sparganosis of the central nervous system is increasingly recognized.

A granuloma is formed along the tortuous migration track. Zones of necrosis and intense lymphohistiocytic reaction with eosinophilic infiltration surround the larva and its track. The disintegrated worm may be found in a granuloma, leaving behind calcareous corpuscles. Local bleeding and suppuration may complicate sparganosis. The sparganum can survive for more than 5 years. In general, one or only a few infect each patient.

Sparganum proliferum is an acephalic, branched, proliferating larva that is histologically similar to a non-proliferating sparganum. In very rare human infections the larvae are found in thousands in subcutaneous tissue and internal organs. The human infection has been found in Japan, the United States, and Venezuela. The biology of this larva is still unknown. The patient's serum reacts with sparganum antigen.

Diagnosis of sparganosis is rarely made preoperatively. Incidental recovery of the worm at surgery makes a definitive diagnosis. Preoperative diagnosis of cerebral sparganosis is made with high confidence when computed tomography or magnetic resonance imaging of the brain shows an enhancing nodule with changing shape or position in the sequential images, degeneration of white matter, and ventricular dilatation together with positive antibody tests in serum and cerebrospinal fluid (Fig. 2).

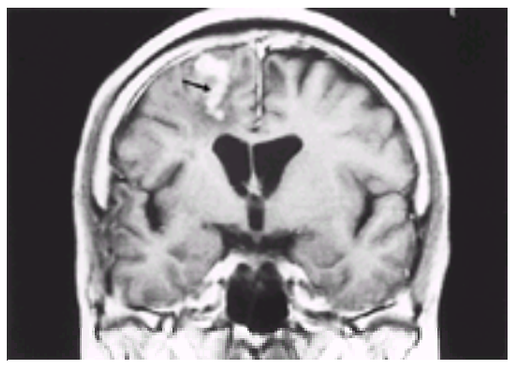

Fig. 2 A MRI finding of cerebral sparganosis. Coronal contrast-enhanced T_1-weighted image shows a tortuous curvilinear enhancing lesion (arrow) with surrounding low density of oedema and degeneration in right frontal lobe.

Excision of the mass or removal of the worm from the lesion is curative. Repeated surgery is necessary when the patient has multiple lesions. There are no drugs which are are known to be effective against sparganosis. The prognosis is excellent in almost all cases when treated surgically. However, all cases of *S. proliferum* infection have proved fatal.

7.16.1 Schistosomiasis

D. W. Dunne and B. J. Vennervald

Introduction

Schistosomiasis, also known as bilharzia, is caused by infection with parasitic trematode worms (flukes) of the genus *Schistosoma*. Disease is usually associated with chronic infections contracted by exposure to fresh water containing infective cercarial larvae that penetrate intact skin and develop into blood-dwelling worms. Most human infections are caused by one of three species, *S. mansoni*, *S. haematobium*, or *S. japonicum*. Two species, *S. intercalatum* and *S. mekongi*, are less important. Schistosomiasis is patchily distributed in parts of South America, Africa, the Middle East, China, and Southeast Asia. An estimated 600 million people in 74 countries are at risk of infection and some 200 million are infected. Of these, the World Health Organization estimates that 120 million may be symptomatic, while 20 million are suffering severe consequences of infection. Although simple diagnosis and effective drug treatment is available for individual uncomplicated cases, the world disease burden caused by these parasites has increased from the estimated 114 million human infections in 1947. Diagnosis and treatment are often not available to exposed rural populations, and drug-based control programmes are hampered by the continued susceptibility of treated individuals, particularly children, to reinfection. Human schistosomiasis is most often an insidious and chronic disease with a range of pathological manifestations involving the intestine and liver, or the urogenital tract. Mortality estimates are difficult, but 20 000 to 200 000 deaths may be directly associated with schistosomiasis each year.

Parasite lifecycle

The schistosome lifecycle requires two host species: a 'definitive' vertebrate host, in which adult male and female worms develop and sexual reproduction occurs, and an 'intermediate' freshwater snail host, in which the parasite multiplies asexually. Transmission between these hosts is achieved by two different free-swimming larval stages. For species that infect man, miracidia hatch from eggs excreted in the faeces or urine of the vertebrate host, and then seek out and infect snails. Cercariae are released from the snail and are able actively to penetrate intact human skin. Different schistosome species have their own, often very restricted, range of snail hosts. Schistosomiasis is thus closely associated with particular freshwater habitats, and its geographical distribution is restricted by the availability of particular snail species. *S. mansoni* and *S. haematobium* are confined to aquatic snails (genera *Biomphalaria* and *Bulinus* respectively) that inhabit ponds, lakes, irrigation canals, slow-flowing streams, and rivers. *S. japonicum* is transmitted by amphibious snails of the genus *Oncomelania* that, in addition to a variety of freshwater habitats, are also present in damp soil and vegetation, such as paddy fields. Schistosomes that infect man can also infect other mammals. This is important in the transmission of *S. japonicum*, a zoonotic infection in which cattle, water buffalo, pigs, dogs, and rodents can act as reservoir hosts of the human parasite. *S. mansoni* infects a narrower range of mammals and only a few rodent species and baboons have any potential to act as occasional reservoirs. In nature *S. haematobium* is essentially specific to man. The sites of maturation of the adult worms vary between schistosome species, affecting both the transmission of the infection and its clinical sequelae.

Once shed from freshwater snails, cercariae (Fig. 1) live for about 24 h, but their effective period of infectivity is probably shorter under field conditions. Cercarial behaviour and the timing of their release enhance their chance of contacting their vertebrate host of choice. Light and increasing temperature trigger the release of *S. mansoni* and *S. haematobium* cercariae during the day and their tails are used actively to maintain their position near the water surface. *S. japonicum* cercariae are shed late in the day and are closely associated with the meniscus, perhaps reflecting their wider host range, as species specific for rodents are shed at night. Contact with skin triggers adherence mechanisms and proteolytic enzymes and muscular movements allow penetration of the skin in minutes. Penetration initiates transformation into a schistosomular larva, with loss of the tail and of the protective outer glycocalyx layer, and the addition of an extra lipid bilayer to the surface membrane of the parasite's syncytial outer tegument. This tegument now forms the main parasite–host interface and so has physiological and immunological functions vital to long-term survival in the hostile environment of the bloodstream. These include uptake of nutrients, response to injury, and surface adsorption of host antigens to provide an immunological disguise.

Fig. 1 The infective larva (cerceria) of *Schistosoma mansoni*, length approximately 200 µm. The head region has characteristic suckers; the muscular forked tail propels the free-swimming larva, but is discarded during skin penetration. This larva will develop into an adult worm in a human host.

Newly transformed schistosomula remain in the epidermis for several days before migrating, via the bloodstream, lungs, and systemic circulation, to the hepatic portal system. Here the schistosomula mature and differentiate into adult worms, pair, and migrate against the portal blood flow to the small venules draining the genitourinary tract (*S. haematobium*) or the large and, to a lesser extent, small intestine (*S. mansoni*, *S. japonicum*, *S. intercalatum*, *S. mekongi)*. Male and female worms are 1 to 2 cm long and morphologically distinct. Paired worms remain permanently coupled, with the shorter, flatter, more muscular male gripping the female in its gynaecophoric canal (Fig. 2). Worms ingest blood cells into their blind-ending bifurcated gut, producing a haematin-like pigment that is regurgitated into the blood. Adult worms have average lifespans in man of 3 (*S. haematobium*) to 7 (*S. mansoni*) years, although active infections are reported in individuals who have left endemic areas more than 20 years previously. Female worms start to produce eggs between 5 and 12 weeks after infection, at rates of 300 (*S. mansoni*) to 3000 (*S. japonicum*) per day. A few days after an egg is laid, a single miracidium develops within the rigid eggshell, the shape and size of which is characteristic for each species. *S. mansoni* (Fig. 3) and *S. haematobium* eggs are ellipsoid, 65 by 150 µm, the former having a lateral spine and the latter a terminal spine. *S. japonicum* eggs are more spherical, 70 by 90 µm, with a small lateral knob that is not always apparent microscopically. Embryonated eggs pass from the venules into the gut or bladder lumen. This is facilitated by host immune responses to secreted egg antigens, as egg excretion is inhibited in immunosuppressed experimental hosts. The passage of the eggs causes tissue damage, as does the granulomatous reactions to eggs that fail to escape from the bloodstream and get swept into the liver by the

portal blood flow.

Fig. 2 Adult worms of *S. mansoni*. The shorter male encloses the female in its gynaecophoric canal, the characteristic haematin-like pigment can be seen in the female worm's gut.

Fig. 3 Egg of *S. mansoni* containing a fully developed miracidium and showing the characteristic lateral spine of this species.

Eggs deposited in fresh water rapidly hatch in response to osmotic changes, releasing the miracidium. This ciliated and actively swimming larva lives for about 6 h, and is able to detect chemically the proximity of snails, modifying its swimming behaviour as it approaches a potential host. The parasite actively penetrates the snail's tissues and transforms into a primary sporocyst. Asexual replication gives rise to daughter sporocysts that migrate to the snail's hepatopancreas where cercariae are asexually generated within each sporocyst. Thus, snails infected with a single miracidium release cercariae that are all of the same sex. Cercariae are first released from snails 3 to 6 weeks after infection, depending on parasite species and ambient temperature. Infected snails can shed hundreds of cercariae daily over several months.

Distribution (Fig. 4)

Schistosomiasis is associated with poor living conditions and inadequate sanitation and water supply. Its distribution has changed over the last 50 years. In some areas sustained control strategies have been successful. However, environmental changes, development of water resources, population increases, and migration, have led to its spread into previously non-endemic areas or areas with a low rate of infection. *S. japonicum* and *S. haematobium* have decreased, whereas *S. mansoni* has increased to become the most prevalent and widespread species. *S. japonicum* has been controlled effectively in many areas and is now endemic only in China, where it is much reduced, Indonesia, the Philippines, and Thailand. *S. mekongi* is found in Kampuchea and Laos, while *S. intercalatum* is found in 10 countries within the rainforest belt of central Africa. *S. mansoni* is present in most countries of sub-Saharan Africa, and in Madagascar, the Nile delta and valley, as well as Saudi Arabia, Yemen, Oman, Libya, northern and eastern Brazil, Surinam, Venezuela, and some Caribbean islands. *S. haematobium* is widespread in sub-Saharan Africa and Madagascar, and is more prevalent than *S. mansoni* in North Africa and the Middle East. Information on the geographical distribution of schistosomiasis is available from the World Health Organization website: http://www.who.int/ctd/html/schistoepidat.html.

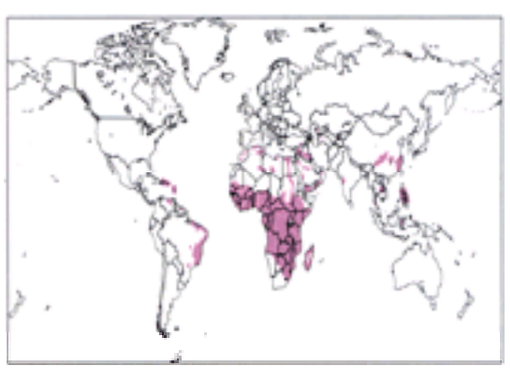

Fig. 4 Global distribution of the schistosomes that affect humans.

Clinical features

Stage of invasion: cercarial dermatitis or 'swimmer's itch'

When cercariae penetrate the skin they can cause a skin reaction, called cercarial dermatitis or 'swimmer's itch'. This is frequently seen after exposure to avian schistosomes, and is associated with the death of cercariae in the skin. It is seen both in areas endemic for human schistosomiasis and in non-endemic areas. In previously unexposed people, the invasion causes a transient immediate hypersensitivity reaction with intense itching. Within 12 to 24 h it is followed by a delayed reaction characterized by a small, red, pruritic, macular rash progressing to papules after 24 h. The rash may persist for up to 15 days and residual pigmentation may persist for months. Following repeated exposure, the signs and symptoms increase dramatically and start earlier. A similar reaction can be seen after re-exposure to human cercariae, predominantly *S. mansoni* and *S. japonicum.* Treatment, if needed, is symptomatic.

Stage of maturation: acute schistosomiasis or Katayama fever

The early stages of a primary infection can be associated with a severe systemic reaction that resembles serum sickness. This acute illness, called acute toxaemic schistosomiasis or Katayama fever, can occur following initial infection with any schistosome infecting humans, although it is more common in *S. japonicum* and *S. mansoni* infections. Acute schistosomiasis is most marked in primary infections in non-immune adults, but acute *S. japonicum* infection can occur in re-exposed individuals. Symptoms appear 2 to 6 weeks after exposure. The clinical picture resembles an acute pyrexial illness with fever as a prime characteristic. The patient feels ill, and may have rigors, sweating, headache, malaise, muscular aches, profound weakness, weight loss, and a non-productive irritating cough. Anorexia, nausea, abdominal pain, and diarrhoea can occur. Physical examination may reveal a generalized lymphadenopathy, an enlarged tender liver, and, sometimes, a

slightly enlarged spleen and an urticarial rash (Plate 1). Eosinophilia is almost always present. Patients may become confused or stuporose or present with visual impairment or papilloedema. Severe cerebral or spinal cord manifestations may occur, and this is an indication for urgent investigative measures. Even light infections may cause severe illness and the syndrome can, in rare cases, be fatal.

Differential diagnosis includes infections such as typhoid (leucopenia, no eosinophilia), brucellosis, malaria, infectious mononucleosis, miliary tuberculosis, leptospirosis, and other conditions with fever of unknown origin. Fever and eosinophilia occur in trichinosis, tropical eosinophilia, invasive ankylostomiasis, strongyloidiasis, visceral larva migrans, and infections with *Opisthorchis* and *Clonorchis* species.

Established infections

Urinary schistosomiasis (*Schistosoma haematobium*)

The signs and symptoms due to *S. haematobium* infection relate to the worms' predilection for the veins of the genitourinary tract, and result from deposition of eggs in the bladder, ureters, and to some extent the genital organs. In the phase of established infection two stages can be recognized:

a. An active stage mainly in children, adolescents, and younger adults with egg deposition in the urinary tract, egg excretion in the urine with proteinuria and macroscopic or microscopic haematuria.
b. A chronic stage in older patients with sparse or absent urinary egg excretion but the presence of urinary tract pathology.

In the active stage many patients will have minimal symptoms. The most frequently encountered complaint is a painless, characteristically terminal, haematuria, the prevalence and severity of which is related to the intensity of infection. In communities where *S. haematobium* is highly endemic, macroscopic haematuria among boys is considered a natural sign of puberty. Dysuria, frequency, and suprapubic discomfort or pain is associated with schistosomal cystitis and may continue throughout the course of active infection. Initially the eggs may give rise to an intense inflammatory response in the mucosa. This may cause ureteric obstruction leading to hydroureter and hydronephrosis. Cytoscopy reveals friable masses or polyps extending into the bladder, petechiae, and granulomas. These early inflammatory lesions, including the obstructive uropathy, are usually reversible after treatment with antischistosomal drugs. The bladder lesions and obstructive uropathy can be visualized by ultrasonography (Fig. 5).

Fig. 5 Bladder pseudopolyps as seen by ultrasound in *S. haematobium* infection. (Photograph by courtesy of Dr J. Richter, Heinrich-Heine-Universität Düsseldorf, Germany.)

As the infection progresses, the inflammatory component decreases, possibly due to modulation by the host immune response, and fibrosis increases. Various changes occur in the bladder including calcification, ulceration, and the development of papillomas. Cytoscopy reveals 'sandy patches' composed of large numbers of calcified eggs surrounded by fibrous tissue and an atrophic mucosal surface. The bladder lesions may lead to nocturia, precipitancy, retention of urine, dribbling, and incontinence. Calculus formation is common, as is secondary bacterial infection, usually due to *Escherichia coli*, *Pseudomonas*, *Klebsiella*, *Enterobacter*, or *Salmonella* species. The ureters are less commonly involved, but ureteric fibrosis can cause irreversible obstructive uropathy which can progress to uraemia. Bilateral ureteric involvement is common, although lesions may predominate on one side. Despite damage to the ureters, symptoms may be absent or minimal.

Egg deposition may also cause granulomas and lesions to develop in the genital organs, most commonly in the cervix and vagina in females and the seminal vessels in males. Dyspareunia, contact bleeding, and lower back pain may result in women, and perineal pain and painful ejaculation in males. Symptoms such as haematospermia and perineal discomfort have been described in travellers returning from Mali. In some of these patients, eggs have been demonstrated in seminal fluid but not in urine. The impact of genital lesions caused by *S. haematobium* infection on the spread of HIV needs to be elucidated. Although small numbers of *S. haematobium* eggs are frequently detected in faeces and rectal biopsies, intestinal symptoms are uncommon.

In some areas in Africa an association between *S. haematobium* infection and squamous cell carcinoma of the urinary bladder has been described. The aetiological significance of the parasite in the causation of this cancer is not proven, but is suggested by the finding that the prevalence of carcinoma of the bladder is correlated with intensity of *S. haematobium* infection. In the established stage *S. haematobium* should be distinguished from renal tuberculosis with haematuria, haemoglobinuria, and cancer of the urogenital tract.

Intestinal schistosomiasis

In most early *S. mansoni* and *S. japonicum* infections few, if any, minimal symptoms are apparent. Clinical features are generally encountered in those with high-intensity infections, and are diarrhoea, sometimes with blood or mucus in the stool, abdominal discomfort, and hypogastric pain or colicky cramps. Severe dysentery is rare, but can occur. The liver, especially the left lobe, may be enlarged and tender; the spleen may also be enlarged, but is usually soft. At this stage, the condition is entirely reversible by antischistosomal treatment, but the relative lack of symptoms may cause it to pass unnoticed until irreversible complications set in. Later stages present as intestinal or hepatosplenic disease. Intestinal schistosomiasis is associated with granuloma formation (Plate 2), inflammation, and fibrosis, primarily in the large intestine. Focal dense deposits of eggs of *S. mansoni* or *S. japonicum* in the large intestine can induce the formation of inflammatory polyps. The major clinical manifestation is intermittent diarrhoea with or without passage of blood or mucus, occasionally associated with protein-losing enteropathy and anaemia. Intestinal schistosomiasis in *S. japonicum* infection may also involve the stomach, with gastric bleeding and pyloric obstruction.

The differential diagnosis includes irritable bowel syndrome, amoebiasis, giardiasis, intestinal helminth infection, ulcerative colitis, Crohn's disease, and tuberculosis.

Hepatosplenic disease is the most severe chronic manifestation of *S. mansoni* and *S. japonicum* infection. The development of presinusoidal periportal fibrosis (clay pipe stem or Symmers' fibrosis) (Fig. 6) leads to portal hypertension, but hepatic function usually remains normal (Plate 3). Patients with periportal fibrosis may not excrete eggs in faeces. During the early stages the liver is enlarged, especially the left lobe; it is smooth, firm, and sometimes tender. Later, in many cases, it becomes small firm and nodular. The spleen is enlarged, often massively, due to passive congestion and reticuloendothelial hyperplasia (Fig. 7). The patient may be asymptomatic or may complain of a left hypochondrial mass with discomfort and anorexia. Anaemia may be present. Ascites, attributable both to the portal hypertension and to hypoalbuminaemia, may be seen, especially in *S. japonicum* infection. There may be reduced growth, infantilism, and amenorrhoea. Most importantly, 80 per cent of patients with hepatosplenic disease have oesophageal varices detectable by endoscopy. These patients may experience repeated bouts of haematemesis, melaena, or both. This is the most severe, potentially fatal, complication of hepatosplenic schistosomiasis, and death may result from massive loss of blood.

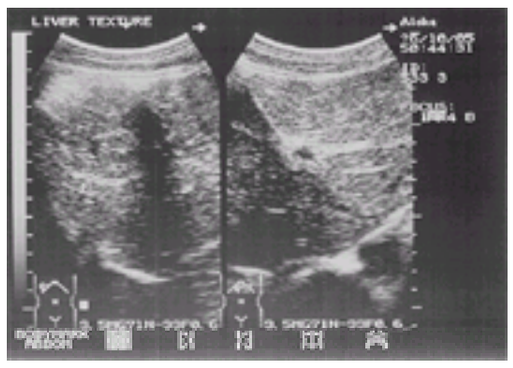

Fig. 6 Periportal fibrosis as seen by ultrasound in *S. mansoni* infection.

Fig. 7 Kenyan child with severe hepatosplenic schistosomiasis mansoni.

The differential diagnosis of hepatosplenic schistosomiasis includes kala-azar (visceral leishmaniasis), tropical splenomegaly syndrome associated with malaria, leukaemia, lymphoma, alcoholic, or viral cirrhosis, and some of the haemoglobinopathies. Some regression of periportal fibrosis may occur after specific antischistosomal therapy, as judged by ultrasonography examination of the liver, but in most individuals with periportal fibrosis and clinical manifestations of hepatosplenic disease, regression does not occur.

In comparison with *S. japonicum* and *S. mansoni* infections, clinical symptoms of disease in *S. intercalatum* infection are commonly mild or absent, and it is not regarded as a serious public health problem. Active infection is seen in children and adolescents and pathology is detected only in those with egg excretion exceeding 400 eggs per gram of faeces. The usual clinical presentation is one of diarrhoea, often with blood in the stool and lower abdominal pain or discomfort. *S. mekongi* infections are usually asymptomatic but may produce a clinical picture similar to that of *S. japonicum*, although the infections are usually milder. Hepatosplenomegaly can occur.

Other manifestations

Central nervous system manifestations

Central nervous system involvement in *S. mansoni* and *S. haematobium* infections most frequently affect the spinal cord following acute infection. This manifestation is not related to the intensity of infection. A myelopathy results from the inflammatory reaction, caused by the deposition of eggs around the spinal cord, and presents with ascending motor and sensory symptoms.The lesion is usually in the region of the canda equina. Although paraparesis is seen most commonly during acute schistosomiasis, it may also be a late stage complication of *S. mansoni* infection in endemic areas with high rates of transmission. Myelography, computed tomography, and magnetic resonance imaging are of diagnostic value. In acute cases lesions are seen on magnetic resonance imaging scans as a diffuse swelling of the lumbar cord with central softening or cyst formation.

The brain is the major site of central nervous system involvement in *S. japonicum* infections, with about 2 per cent of acutely infected patients experiencing symptoms that mimic acute encephalitis or a focal neurological process. Computed tomography shows multiple enhancing lesions. In chronic infections, patients may present with focal brain lesions that can resemble tumours and present as focal epilepsy. These lesions contain masses of eggs and granulomas. Uncontrolled studies suggest that treatment with a combination of antischistosomal drugs and glucocorticoids is effective.

Pulmonary manifestations

Deposition of eggs can also occur in the lungs. Granulomatous reactions and fibrosis develop in the pulmonary vasculature leading to pulmonary hypertension and/or cor pulmonale (Plate 4). This is normally seen secondary to hepatosplenic schistosomiasis in patients with portal fibrosis and portal hypertension, but pulmonary hypertension may also result from accumulation of *S. haematobium* eggs in the lungs. A syndrome of cough with multiple small radiographic lesions and eosinophilia has been described. Symptoms include fatigue, palpitations, dyspnoea, cough, and sometimes haemoptysis. Patients may progress to decompensation with congestive cardiac failure. In endemic areas schistosomiasis must always be considered as a possible cause of cor pulmonale.

Renal manifestations

Glomerulonephritis is a common occurrence in chronic *S. mansoni* infection in Brazil, especially in patients with hepatosplenic disease. Immunoglobulins, complement components, and schistosome antigens are deposited in the mesangial area. The condition is manifested clinically as proteinuria and/or nephrotic syndrome, sometimes with hypertension.

Miscellaneous manifestations

Patients infected with any of the three major schistosome species and subsequently infected with *Salmonella* may develop a prolonged intermittent febrile illness. Prolonged excretion of *Salmonella* in the urine and intermittent bacteraemia has been demonstrated in *S. haematobium* infection. Treatment for the *Salmonella* infection alone is often not effective without treatment of the underlying schistosome infection.

Diagnosis and investigations

Information about geographical area and history of exposure to potentially contaminated fresh water is important for diagnosis of schistosomiasis, especially in travellers. This can indicate the likelihood of infection and point to the schistosome species involved. A definitive diagnosis is made by the direct demonstration of schistosome eggs by microscopy of urine or stool samples, biopsies or, on rare occasions, secretions such as seminal fluid. In epidemiological studies it is usually important to obtain quantitative estimates of egg output to provide information about intensity of infection within a population.

Direct parasitological methods

In *S. haematobium* infection eggs can be detected in urine after filtration, sedimentation, or centrifugation followed by microscopy. Ideally, urine should be passed around midday and the terminal part of the stream examined. The most commonly used method in epidemiological studies in endemic areas is filtration of 10 to 20 ml

of urine using a syringe and a polycarbonate (Nucleopore®), polyamide (Nytrel®), or paper filter. Infection intensity is expressed as eggs per 10 ml of urine. This may not be sufficiently sensitive for detection of low-intensity infections in travellers. In such cases, diagnosis is often based on filtration of 24-h urine samples.

For *S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum* eggs in the faeces, sedimentation of the eggs followed by microscopy is a useful and simple technique. However, the Kato thick smear technique is the most widely used method in epidemiological studies. This is based on microscopic examination of a smear of a small but fixed amount of faecal sample (usually 20 to 50 mg). Coarse particles and fibrous material are first removed from the sample by passing it through a sieve. A fixed sample volume is obtained by the use of a template. This is placed on a microscope slide and squashed with either a piece of cellophane soaked in glycerol or a glass coverslip. After leaving the slide for 6 to 24 h to allow the preparation to clear, the eggs are counted and the level of infection expressed as eggs per gram of faeces. Unfortunately, watery or diarrhoeal stools cannot be processed this way, and low-intensity infections may not be detected, since only small faecal samples are examined and eggs may be clumped unevenly in the stool. Increased sensitivity is obtained by increasing the number of samples examined. For diagnosis of light infections in previously unexposed travellers, microscopic examination of a rectal tissue snip crushed between glass slides is often the most sensitive direct diagnostic method. This method can also be used for biopsies. The crushed tissue sample is far better than a sectioned biopsy for the detection and identification of eggs.

Other direct methods

Recently, sensitive enzyme immune assays have been developed to detect circulating schistosome antigens in serum or urine. These antigens, circulating anodic antigen and circulating cathodic antigen, are derived from the gut of the adult schistosomes. The assays have almost 100 per cent specificity and very high sensitivity, and are excellent epidemiological tools as they provide a direct estimate of worm burden and can be used to monitor the efficacy of chemotherapy. They are less well suited for diagnosis of light infections in travellers.

Indirect diagnostic techniques

In *S. haematobium* infections, chemical reagent strips for detection of microhaematuria are widely used in endemic areas as a diagnostic measure. The method can be used in areas of both high and low transmission and there is a consistent significant correlation between microhaematuria and intensity of infection. In intestinal schistosomiasis, blood may be found in the stools, but it is not as useful an indicator of infection. In urinary schistosomiasis, eosinophiluria, with high numbers of eosinophil granulocytes in the urine, is a characteristic finding. Recently, detection of the eosinophil granule protein **ECP** (eosinophil cationic protein) in urine has been used for the qualitative assessment of eosinophil infiltration of the bladder mucosa, and hence local inflammation. Measurement of ECP in urine has proved useful in following post-treatment resolution of urinary tract morbidity in endemic areas. Eosinophilia is often found in acutely infected travellers. In cases where eggs are difficult to find, eosinophilia plus a history of exposure may suggest the need for further examination for schistosomiasis including serodiagnosis.

Immunodiagnosis

In cases of suspected schistosomiasis in which eggs have not been detected, serology can be used to demonstrate specific antibodies. An indirect immunofluorescence test using sections of adult worms for detection of specific immunoglobulins (IgM and IgG) is widely used. For travellers, a positive antibody result combined with a history of exposure should lead to treatment. Serodiagnosis is not useful in endemic areas because of the high levels of specific antibodies found in naturally exposed populations.

Ultrasonography

Ultrasonography is non-invasive, portable, has no biological hazards for the patient, and can be used to either complement or replace many invasive diagnostic techniques. It is the technique of choice for grading schistosomal periportal fibrosis, portal hypertension, hydronephrosis, and urinary bladder lesions. A protocol for standardized investigations and methods of reporting has been produced by the World Health Organization. Ultrasonography is especially useful for monitoring decreases in morbidity after chemotherapy programmes.

Pathophysiology/pathogenesis

Schistosome eggs can be trapped in the tissues, often the walls of the intestines or, depending on species, the urinary bladder or ureters. The eggs of *S. mansoni* and *S. japonicum* are swept into the liver via the portal system, where they embolize into the portal radicles and give rise to vascular and granulomatous changes. Granulomatous pyelophlebitis and peripyelophlebitis is responsible for development of portal hypertension, while granulomata with subsequent fibrosis may be responsible for the periportal fibrosis. The characteristic lesion in the liver is a presinusoidal periportal fibrosis (Symmers' fibrosis). There is typically no bridging between the fibrous tracts, no nodule formation, and no hepatic cell damage. Increased portal pressure can result in the development of portosystemic collaterals and eggs may pass directly from the portal vein to the pulmonary circulation. Here the combination of vascular and granulomatous changes is responsible for pulmonary hypertension.

Treatment

Today the drug of choice is praziquantel, available as 600 mg tablets (e.g. Biltricide®, Distocide®). It is administered orally, normally in a single dose, and is effective against all schistosome species infecting man. It is also effective for most other trematode infections and against adult cestodes. The drug is safe and well tolerated. Drug dosages are shown in Table 1. Complete cure is achieved in up to 85 per cent of those treated, and egg counts are reduced by 95 per cent or more in others. In endemic areas, this level of efficacy is acceptable since very light residual infections do not lead to severe morbidity. In patients who are not cured by the initial treatment, the same dose can be repeated at weekly intervals for 2 weeks or on two successive days.

Although praziquantel has not been shown to be teratogenic, it is not recommended for use during pregnancy. Apart from this there are no contraindications. Any side-effects are generally mild, resolving spontaneously over a few hours and rarely requiring medication. Gastrointestinal side-effects include abdominal pain or discomfort and sometimes vomiting. They occur more frequently in individuals with high infection intensities. Urticarial skin reactions and periorbital oedema may occur in about 2 per cent of treated individuals. General side-effects including headache, dizziness, fever, and fatigue can also occur, but less frequently. As a general principle, all patients with acute schistosomiasis should be treated with praziquantel. It is disputed whether steroids should be added to specific drug treatments. A beneficial effect has been demonstrated in some studies where corticosteroids have been added to praziquantel treatment. Use of praziquantel for cerebral *S. japonicum* infections is safe and effective, resulting in rapid dissipation of cerebral oedema and resolution of cerebral masses. Chemotherapy is only part of the management of schistosomiasis-associated portal hypertension, since the main complications are due to obstructive pathology. Management of portal hypertension and prevention of bleeding from oesophageal varices is beyond the scope of this chapter. Praziquantel has largely replaced other drugs for treatment of schistosomiasis. However, metrifonate (Biarcil®) and oxamniquine (Mansil® (South America), Vansil® (Africa)) are still used sometimes.

Prognosis

Most infected people have few, if any, overt symptoms. Acute schistosomiasis can be fatal or can lead to severe residual damage to the nervous system if not treated, but responds well to antischistosomal therapy if started early. Early infections respond extremely well to treatment and the pathological lesions regress leaving little residual damage. However, in endemic areas individuals, particularly young children, are rapidly re-exposed and reinfected unless control measures are taken at the community level. Chronic infections with fibrosis respond less well to specific antischistosomal treatment, although some regression of hepatosplenic disease has been seen after treatment. The lifetime prognosis is worst in patients with severe hepatosplenic schistosomiasis and oesophageal varices. Previous episodes of haematemesis indicates a 70 per cent risk of rebleeding.

Transmission and epidemiology

Each successful cercarial penetration of human skin has the potential to give rise to a single male or female adult worm, but it is probable that many cercariae die naturally in the epidermis. People tend to accumulate worms with continued exposure to infection. However, human populations in endemic areas do not just continue to accumulate worms with age. Intensities of infection increase in children during their younger years (as estimated by numbers of excreted eggs), peaking around the age of 12 years, before falling to lower levels in adulthood (Fig. 8(a)). This is probably due to the death of older worms, which are not replaced at a similar rate in older people. This age–infection intensity profile is more pronounced if study populations are given chemotherapy to remove existing infections and then monitored for

levels of reinfection over several subsequent years. In these circumstances, it is clear that young children are much more susceptible to reinfection than older children or adults, and that a striking change in susceptibility to reinfection occurs after 12 years of age. The slower acquisition of worms in adulthood could be due to reduced exposure to infection or to age-dependent changes in innate resistance or acquired immunity. In many endemic areas children have more contact with water than adults, but careful observation of water-associated behaviour has shown that age profiles of water contact are variable between communities, whereas profiles of reinfection intensities are remarkably consistent (Fig. 8(b)). This suggests that host-related factors other than exposure influence susceptibility to reinfection. This has been most convincingly shown in fishing communities in areas with high *S. mansoni* transmission on Lake Albert, Uganda. Here occupational water contact results in adults having greater exposure to infection than their children, yet, within 12 months of treatment, it is the children under 12 years of age that suffer much higher reinfection intensities. Current research is focused on assessing the relative roles of innate resistance and acquired immunity in this age-dependent resistance and whether the onset of puberty or the length of time spent living in endemic areas might be important. For example, it is not known if this age-dependent resistance to infection holds true for travellers exposed to infection for the first time. Immune responses to schistosomes also differ between children and adults. Specific IgE and other characteristically T helper 2 type responses against the parasite are associated with resistance to reinfection. Whatever mechanisms underlie the contrasting susceptibilities of children and adults, continued exposure can be expected to result in reinfection, especially amongst younger children.

(b) Age–reinfection intensity profiles of *S. mansoni* after chemotherapy in the same six communities in Kenya, assessed between 12 and 36 months after treatment. (By courtesy of AJC Fulford.)

Prevention and control

Despite the high risk of reinfection, chemotherapy is usually highly beneficial at both the individual and population levels, as those suffering high intensities of infection are at greatest risk of the more severe forms of schistosomiasis. Various chemotherapy-based control strategies can be employed depending on intensity of transmission and the available resources. In areas of high transmission, population-based chemotherapy can avoid the time and expense required for diagnosis and reduce the prevalence and severity of morbidity. Alternatively, schoolchildren can be targeted for treatment, as they invariably have the heaviest worm burdens and contribute most to on-going transmission. In areas of less intense transmission, treatment can be restricted to diagnosed cases. The provision of safe water supplies and sanitation, where it can be achieved, will make an important additional contribution. Mortality can be prevented and morbidity best controlled by a combination of health education, chemotherapy, provision of safe water supplies and sanitation, and, where appropriate, snail control. Health education should be aimed at improving practices of water use and preventing indiscriminate urination and defaecation. The role of molluscicides in control programmes depends on the local epidemiological and ecological circumstances and the resources available. Within the context of a larger concerted intervention, focal mollusciciding of major transmission sites can be useful. Eradication of host snail species is not usually feasible, although modification of the environment to eliminate snails has been successful in parts of China. In general, it has only been through sustained effort with integrated control strategies that disease control has been achieved. Schistosomiasis control strategies are guided by the Second Report of the WHO Expert Committee on the Control of Schistosomiasis (1993). Recognition that the available control methods, including effective chemotherapy, have failed to reduce the world burden of schistosomiasis has led to renewed efforts to develop an effective vaccine. Recombinant schistosome antigens have been partially successful in protecting experimental animals and several are progressing towards phase I and II human trials.

7.16.2Liver fluke infections

David I. Grove

Liver flukes, otherwise known as trematodes, are leaf-like hermaphroditic flatworms. The hepatobiliary system of humans is commonly infected by flukes of the genera *Clonorchis* and *Opisthorchis* and occasionally by other species (Table 1). In addition, *Eurytrema pancreaticum* has been found rarely in the pancreatic duct. These infections are usually diagnosed by finding eggs in the faeces. Unfortunately, eggs of many of these species cannot be differentiated from each other nor can they be distinguished reliably from the eggs of certain intestinal trematodes. In such cases, definitive diagnosis can only be made if adult worms are recovered from the stools after anthelmintic treatment, at surgery, or at autopsy; parasitological textbooks should be consulted for diagnostic details.

Clonorchiasis

Lifecycle

Clonorchis sinensis adult worms, 10 to 25 mm long by 3 to 5 mm wide, live in the bile ducts or occasionally the gallbladder attached to the mucosa. They produce eggs which are passed in the faeces (Fig. 1). The miracidium within the egg hatches after ingestion by a suitable species of aquatic snail; nine species belonging to the families Hydrobidae, Melanidae, Assimineidae, and Thiaridae are known to be susceptible but *Parafossarulus manchouricus* is perhaps the most common. The miracidia develop into sporocysts then in turn become rediae which produce larvae known as cercariae. After 6 to 8 weeks, the cercariae emerge from the snail and swim about in the water until they encounter certain freshwater fishes (over 100 species, mostly of the family Cyprinidae, i.e. carp, are susceptible). They attach to the surface of the fish, lose their tails, penetrate under the scales, encyst in the skin or flesh, and develop into infective metacercariae over several weeks. When raw or undercooked infected fish is eaten by humans, the metacercariae excyst in the stomach, enter the common bile duct through the ampulla of Vater, and ascend into the biliary passages where they mature in 1 month. Adult worms may live for up to 40 years.

Fig. 1 Egg of *Clonorchis sinensis*: this is identical with that of *Opisthorchis viverrini*. (By courtesy of Prayong Radomyos, Faculty of Tropical Medicine, Mahidol University, Bangkok.)

Epidemiology and control

Fish-eating mammals including humans, dogs, cats, and rats may be infected with *C. sinensis*. Human clonorchiasis is endemic in Japan, Korea, China, and Vietnam where the first and second intermediate hosts are found and where the population habitually consumes raw fish. In endemic areas, fish are kept in ponds and fertilized with human and animal faeces. Over 20 million people are thought to be infected in China. Control programmes include proper waste disposal, measures to control snail numbers, and mass treatment with praziquantel, but the most important is health education to discourage the habit of eating raw or undercooked fish.

Pathology

Pathological changes are related to the intensity and duration of infection. They are produced by mechanical irritation, toxin production, immunological responses, and secondary bacterial infection. Inspection of the cut surface of the liver often reveals dilated, thick-walled bile ducts with adult worms visible within their lumens. Adult flukes may be found in the gallbladder but they are usually killed by bile. Histologically, there is desquamation and hyperplasia of epithelial cells, formation of adenomatous tissue and proliferation of periductal connective tissue, and infiltration with eosinophils and mononuclear cells. This may be complicated by epithelial metaplasia then mucinous cholangiocarcinoma. Recurrent pyogenic cholangitis is a common complication and the worms and eggs act as a nidus for gallstone formation. Some patients have flukes in the pancreatic duct which may cause pancreatitis.

Clinical features

Most patients are asymptomatic and are diagnosed incidentally on stool examination. Symptoms are more common in older patients with heavy worm burdens. It is difficult to differentiate these symptoms from other conditions but they include right hypochondrial or epigastric pain or discomfort, lassitude, anorexia, and flatulence. Some patients complain of a peculiar, hot sensation on the skin of the abdomen or back. Cholangitis causes fever, right upper quadrant pain, and jaundice. Cholangiocarcinoma is associated with pain, jaundice, and weight loss.

Diagnosis

The diagnosis is suggested by finding eggs in faeces or in duodenal aspirates. They are yellow-brown, 25 to 35 µm long by 12 to 19 µm wide, and have a seated operculum with a small knob at the other end (Fig. 2). They cannot be differentiated from ova of *Opisthorchis* species. Furthermore, they are extremely difficult to differentiate from eggs of flukes in the family Heterophyidae (see Chapter 7.16.4), although the latter tend to have a smoother egg shell, a less prominent shoulder at

the operculum, and the knob may be absent. The diagnosis can only be confirmed by examination of adult flukes. Serological tests have been described but are not routinely used for individual patient diagnosis. Imaging techniques such as ultrasound or computed tomography may disclose adult worms in the gallbladder or bile ducts, which are often dilated and may contain sludge. Liver function tests may be abnormal, often with an obstructive picture.

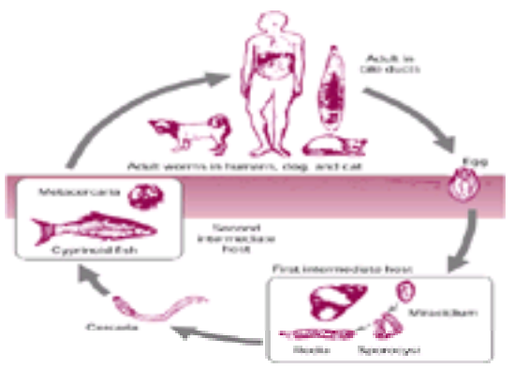

Fig. 2 Lifecycle of *Clonorchis sinensis* and *Opisthorchis* species.

Treatment

Praziquantel is the treatment of choice and in a dose of 25 mg/kg three times daily after meals for 2 days has a cure rate of close to 100 per cent; eggs should disappear from the stool within 1 week. Biliary tract abnormalities may reverse after treatment as this has been shown in opisthorchiasis. Triclabendazole may prove to be useful but there is insufficient documentation at present. Bacterial cholangitis is treated with antibiotic therapy such as a combination of amoxicillin, gentamicin, and metronidazole. Surgery may be required in some patients with obstructive jaundice.

Opisthorchiasis viverrini

This infection is very similar to clonorchiasis. The adult *Opisthorchis viverrini* is smaller than *C. sinensis*, measuring 7 to 12 mm by 2 to 3 mm, although there is some discrepancy in the literature over its size, perhaps reflecting different methods of preparation and fixation. It may live for over 10 years. The lifecycle is similar to that of *Clonorchis* with various species of the genus *Bithynia*, particularly *B. goniomphalus*, *B. funiculata*, and *B. siamensis* (= *laevis*), being the snail first intermediate host. Many species of carp serve as the second intermediate host. Humans, dogs, cats, and other fish-eating mammals are definitive hosts. This parasite is endemic in northern Thailand and adjacent Laos and Cambodia where 10 million people are estimated to be infected because of the popularity of chopped raw cyprinoid fish as a foodstuff.

The pathology and clinical features are similar to those induced by *C. sinensis.* The association with cholangiocarcinoma may be even more striking with this infection. The diagnosis is made as discussed under clonorchiasis. Praziquantel is the drug of choice; 25 mg/kg three times after meals for 1 day gives close to 100 per cent cure rate. Mebendazole (30 mg/kg daily) or albendazole (400 mg twice daily) may be effective if given for several weeks. Triclabendazole may prove to be useful but there is insufficient documentation at present. A control programme is underway in Thailand which includes detection and treatment of infected people together with intensive health education.

Opisthorchiasis felineus

This infection is very similar to clonorchiasis. The adult *Opisthorchis felineus* is morphologically very similar if not identical to *O. viverrini* (the two species have been distinguished by the pattern of flame cells in the cercariae). The lifecycle is similar with *Bithynia leachi* being the only known molluscan intermediate host. Many species of carp serve as the second intermediate host. Humans, dogs, cats, rats, foxes, seals, and other fish-eating mammals are definitive hosts. Infection is acquired by eating raw or undercooked fish; in Siberia, raw, slightly salted, and frozen fish is often consumed. This parasite is endemic particularly in Russia and adjacent countries but also in parts of southern Europe and eastern Asia with several million people probably being infected overall. Eggs are indistinguishable from those of *O. viverrini* and *C. sinensis*. The pathology, clinical features, diagnosis, and treatment are similar to *O. viverrini* and *C. sinensis* infections.

Fascioliasis

Lifecycle

Fascioliasis is due to infection with the sheep liver fluke, *Fasciola hepatica* or with *F. gigantica*. Adult *F. hepatica* flukes, 20 to 30 mm by 8 to 13 mm in size, live in the large bile ducts and produce eggs which are passed in the stools. The eggs require a period of 9 to 15 days for the miracidia to develop and hatch in water at 22 to 25°C, but remain viable for up to 9 months if kept moist and cool. The miracidia penetrate the tissues of various species of amphibious snails of the family Lymnaeidae and develop over the next 4 to 5 weeks through the stages of sporocyst, rediae, daughter rediae, and cercariae. The cercariae emerge from the snails and encyst on various kinds of aquatic vegetation to become metacercariae. A wide range of mammals is susceptible to infection, but sheep and cattle are the most important. Human infections are usually acquired by eating watercress or by drinking water contaminated with metacercariae. Metacercariae excyst in the duodenum, penetrate the intestinal wall, and pass into the peritoneal cavity. They then invade the liver capsule and migrate through the hepatic parenchyma to the bile ducts where they mature in about 3 to 4 months. The lifespan of these flukes is several years.

F. gigantica is large attaining a size of up to 7.5 cm. The eggs are difficult to distinguish from those of *F. hepatica* and the lifecycle of the two parasites is similar.

Epidemiology and control

Because of the wide range of susceptible definitive and intermediate hosts, the infection is geographically widespread. Human infections with *F. hepatica* have been reported from all continents. Fascioliasis gigantica is less frequent and has been seen in Africa and Asia. Infection is prevented by not eating fresh aquatic plants, particularly watercress (*Nasturtium officinale*) and by boiling drinking water. Veterinary control measures include elimination of the snail intermediate hosts by drainage of pastures and treatment with molluscicides and by eradication of infection from infected herds.

Pathology

In the early stages of infection, larvae migrating through the liver parenchyma may cause considerable destruction with necrosis, abscess formation, and haemorrhage. The number of tunnels lined by ragged walls of necrotic, bleeding, and inflamed liver tissue is proportional to the number of worms. In the chronic stages, the walls of the bile ducts become thickened by fibrous tissue and inflammatory infiltration, the epithelium becomes hyperplastic, and the bile ducts dilate. Occasionally the lumina of the bile ducts may become obliterated causing obstructive jaundice. These structural changes predispose to secondary bacterial infection which exacerbates the problem. Sclerosing cholangitis and biliary cirrhosis may follow prolonged heavy infection. There is no apparent association with cholangiocarcinoma.

Clinical features

Human fascioliasis is usually mild and related to the phase of infection. There are three phases.

1. In the migratory phase, symptoms usually begin about 1 month after infection. Patients may develop abdominal discomfort or pain (especially in the epigastrium and right upper quadrant), anorexia, nausea, vomiting, fever, headache, tender hepatomegaly, and urticaria. These initial symptoms may persist for several months.

2. The latent phase is asymptomatic and may last for months to years.
3. The obstructive phase is characterized by the recurrence or appearance for the first time of epigastric and right upper quadrant abdominal pain, biliary colic, anorexia, nausea, vomiting, tender hepatomegaly, fever, and jaundice. These features are frequently due to complicating bacterial cholangitis or cholecystitis and may be associated with bacteraemia.

Flukes occasionally migrate to other sites, especially the anterior abdominal wall. Acute oedematous nasopharyngitis ('halziun') may be an allergic response to larval flukes which attach to the pharyngeal wall after ingestion of infected, raw sheep or goat liver.

Diagnosis

In enzootic areas, early fascioliasis is suspected in patients with fever, tender hepatomegaly, and eosinophilia who give a history of consuming freshwater plants. If available, serological tests may be useful early in the illness before egg production begins. Liver biopsy may be helpful in some cases.

Chronic fascioliasis is diagnosed by finding the characteristic eggs in stools or fluid obtained by duodenal or biliary drainage. The eggs of *F. hepatica* and *F. gigantica* cannot be distinguished reliably from each other or from those of the intestinal fluke, *Fasciolopsis buski*; differentiation of these two infections requires identification of adult flukes. Liver function tests are often abnormal and may show an obstructive picture. Radiolucent shadows of flukes may be seen by cholangiography. Ultrasonography and computed tomography are useful in the demonstration of lesions in the liver and biliary tracts. If the patient has recently consumed liver, spurious infection (ingestion of eggs) should be ruled out by placing the patient on a liver-free diet for a few days and repeating the stool examination.

Treatment

The treatment of fascioliasis has been problematic. Success has been claimed for bithiniol and emetine but these drugs are not generally available. Chloroquine at 5 mg/kg per day orally for 3 weeks has limited effectiveness. Praziquantel, which is active against many trematodes, is often ineffective in fascioliasis but may be tried if other agents are not available. Recent studies have shown that triclabendazole in a single oral dose of 10 mg/kg is very effective although some patients require a second dose after a few weeks. This drug appears to have few side-effects. It is available in some countries but not others; further information can be sought from the manufacturer (Novartis, Basle, Switzerland). Flukes are evacuated through the intestinal tract. Another drug under investigation which shows promise is nitazoxanide administered in a dose of 500 mg orally twice daily for 6 days.

Dicrocoeliasis

Dicrocoelium dendriticum adult worms measuring 5 to 15 mm by 1.5 to 2.5 mm live in the biliary passages. Eggs passed in the stools are ingested by certain land snails (e.g. species of *Zebrina* and *Helicella*) in which they develop through two stages of sporocysts with the eventual production of cercariae. The snail leaves slime balls of cercariae on the ground and these are ingested by ants (*Formica* species) in which they develop into metacercariae.

This organism is primarily an infection of sheep, goats, deer, and other herbivores which ingest ants. Humans are rarely infected, usually by accident. Cases have been reported from Europe, Asia, and Africa. Spurious infections result from the consumption of raw, infected liver. Patients may be asymptomatic but may complain of dyspepsia, flatulence, and abdominal colic. The diagnosis is made by finding the eggs in faeces, bile, or duodenal fluid; they cannot be differentiated from those of *Eurytrema pancreaticum*. Definitive diagnosis is made by identification of adult worms. Treatment is with praziquantel at 25 mg/kg three times after meals for 1 day.

Metorchiasis

Many fish-eating mammals of North America serve as definitive hosts for *Metorchis conjunctus*. The aquatic snail *Amnicola limosa* is the first intermediate host; eggs are ingested, hatch into miracidia, and ultimately release cercariae. Metacercariae develop in the flesh of several species of freshwater fish. Ingested metacercariae hatch in the duodenum and migrate up the biliary tree.

A point source outbreak of this disease has been reported in 19 people who ate raw fish prepared from the white sucker (*Catostomus commersoni*) caught in a river north of Montreal. The illness was characterized by upper abdominal pain, low-grade fever, eosinophilia, and abnormal liver function tests. Ten days after ingestion of infected fish, eggs indistinguishable from those of *O. viverrini* were seen in the stools. The patients responded to treatment with praziquantel.

7.16.3Lung flukes (paragonimiasis)

Sirivan Vanijanonta

Lung fluke infection is caused by *Paragonimus* spp. At least 15 species cause disease in humans (Table 1). *Paragonimus westermani* is the most common and widespread, but *P. africanus*, *P. uterobilateralis* (West Africa), *P. ilokstuenensis* (China), and *P. peruvianus* (South America) are also causative. *P. heterotremus* (Thailand, Laos, Vietnam), *P. szechuanensis*, and *P. hueitungensis* also cause cutaneous paragonimiasis.

The adult flukes are reddish-brown and pea-shaped (Plate 1). They are 0. 8 to 1. 6 cm in length, 0. 4 to 0. 8 cm in width, and 0. 3 to 0. 5 cm thick with cuticular spines on the integument. Typically they are encapsulated in cysts adjacent to the bronchi. The eggs are golden brown and ovoid in shape (80–120 × 50–60 µm) (Plate 2).

Lifecycle

Adult flukes encyst in the lung. Ova are expelled through the bronchi and expectorated with sputum or swallowed and passed with faeces. They hatch in fresh water after a few weeks. The resulting miracidia then infect various species of freshwater snail in which they form sporocysts, rediae, and daughter rediae. Metacercariae develop in susceptible freshwater crabs and crayfish (Plate 3, Plate 4). Infection results from ingestion of viable metacercariae in raw or insufficiently cooked crabs and crayfish. Metacercariae excyst in the peritoneal cavity, where they grow and become young flukes. Most of these will then reach the lung by passing through the peritoneal cavity, diaphragm, and pleural cavity, before finally encysting in the lung parenchyma. Tunnels may be formed during their migration. Encysted flukes mature over a period of 6 to 8 weeks and eggs are produced in 10 to 12 weeks. The circuitous routes of migration allow young flukes to lodge and mature in ectopic locations. The reservoir hosts are wild and domestic felines that feed on crabs and crayfish. Freshwater snails that serve as the first intermediate hosts belong to the Thiaridae, Hydrobilidae, and Pleuroceridae families. The second intermediate hosts are the freshwater and brackish-water crabs *Eriocheir japonicus*, *Larnaudia beusekomae* (*Tiwaripotamon beusekomae*), and *Potamon smithiasis*, or crayfish of the genus *Cambaroides*, such as *C. japonicus* in Japan, and *C. similis*, *C. dauricus*, and *C. sckrenki* in China and Korea.

Epidemiology

Paragonimiasis is an important zoonosis. Human beings enter the lifecycle accidentally. However, in some areas human paragonimiasis may be common enough for person-to-person transmission to occur. Human infection is limited in its distribution to places where there are contributory factors that facilitate the lifecycle: reservoir hosts, suitable environment, first and second intermediate hosts, and permissive dietary habits. The three major foci of this disease are in Asia, Africa, and Central and South America. In Asia, endemic areas are to be found in China, Japan, Taiwan, Korea, The Philippines, Thailand, Laos, Vietnam, and Burma, in which the principal parasites are *P. westermani*, *P. skjabini*, and *P. heterotremus*. In Africa, the disease is endemic in eastern Nigeria, the Cameroons, the Congo valley, and the Republic of Congo. In Nigeria the dominant parasite is *P. uterobilateralis*, while in the Cameroons and the Republic of Congo, *P. africanus* predominates. *P. mexicanus*, *P. peruvianus*, and *P. caliensis* are causative agents in Mexico, Guatemala, Honduras, Costa Rica, Ecuador, Colombia, Peru, and Paraguay.

Transmission of *Paragonimus* spp. to man occurs mostly through ingestion of metacercariae in the second intermediate host. Paratenic hosts infected with immature worms also contribute to animal and human disease.

Pathology and pathogenesis

The pathogenesis of human paragonimiasis is unknown. In experimental animals the larval flukes penetrate the intestinal wall and reach the peritoneal cavity, then pass through the diaphragm and pleura to the lung. They cause irritation, acute inflammatory reactions, traumatic tracts, pressure effects, haemorrhage, and necrosis in affected tissues. Pathological findings in the pleural cavity include turbid and haemorrhagic fluid containing numerous pus cells and eosinophils. Acute, diffuse, fibrinoexudative peritonitis may also occur. Abscess cavities containing young flukes are then formed and become enclosed in a fibrous capsule. Mature cysts adjacent to the bronchial system may rupture into it and the cystic contents are then expectorated with sputum or swallowed and passed with faeces. Single or multiple cysts may occur, usually in the lower lobes of the lungs.

Extrapulmonary pathological changes may be caused by aberrant migratory flukes. Cysts, abscesses, and granulomas may be found in the abdominal viscera, subcutaneous tissue, muscles, genital organs, and the brain. *P. heterotremus* and *P. skjabini* also create migratory subcutaneous swellings.

Clinical manifestation

The clinical manifestations are divided into acute and chronic phases. The acute phase occurs after the consumption of an improperly cooked, infected crab or crayfish. The incubation period varies from a few days to weeks. The severity of symptoms usually correlates with the worm load. Invasion and migration by young flukes cause inflammatory and allergic responses such as fever, rashes, urticaria, abdominal pain and discomfort, and a feeling of tightness in the chest. Acute symptoms are rarely serious and patients progress to the chronic stage.

Chronic manifestations are classified as pulmonary and extrapulmonary.

Pulmonary paragonimiasis

The most remarkable clinical feature is a chronic, productive cough with jam-like, brownish-red sputum. Other symptoms include breathlessness, chest pain, unilateral or bilateral pleural effusions, and empyema. Occasionally patients may experience haemoptysis following heavy work or exertion, while pneumothorax occurs rarely.

Pulmonary paragonimiasis is an insidious and persistent lung disease. Patients have surprisingly good general health and usually show few abnormalities on physical examination. A minority of symptomatic patients have normal chest radiographs. Abnormal findings include linear infiltrations, exudative pneumonia, localized pleural effusion, and nodular or cystic lesions. These lesions are predominantly found in the basilar and peripheral regions of both lower lung fields. Cysts may be single or multiple; the most characteristic radiographic feature is a ring shadow with a crescent-shaped opacity along one side of the border resembling the corona phase of a solar eclipse. Other findings are pleural effusion, pleural thickening, and calcification. Long-standing, extensive lesions with fibroatelectasis resemble the lesions of chronic pulmonary tuberculosis.

Extrapulmonary paragonimiasis

Extrapulmonary paragonimiasis is caused by the aberrant migration of larval and young adult flukes to any organ. Migratory swelling of cutaneous or subcutaneous tissues may also occur.

Cerebral paragonimiasis

The clinical symptoms are similar to those of a cerebral space-occupying lesion and are related to the site of the lesion. However, one or more syndromes may be present. Epileptic seizures are common, and patients may develop mental disturbances of the schizoid and paranoid type. Increased intracranial pressure induces persistent intense headache, nausea, vomiting, papilloedema, diplopia, and loss of visual acuity. Patients with paragonimus cysts in the basal meninges will present with meningeal symptoms that include increased intracranial pressure, obstructive hydrocephalus, arterial thrombosis, and stroke. On rare occasions, patients may suffer from cerebellopontine-angle syndrome with tinnitus, progressive deafness, nystagmus, dysphagia, and hiccups.

Spinal-cord paragonimiasis

Spinal involvement produces progressive weakness, sensory impairment of the lower extremities, paralysis, and back pain.

Intra-abdominal paragonimiasis

Paragonimus spp. may create migratory tracts or pressure effects leading to necrosis of the spleen, liver, small and large intestinal wall, and cause non-specific abdominal signs and symptoms.

Subcutaneous paragonimiasis

P. skjabini, *P. westermani*, and *P. heterotremus* cause migratory subcutaneous nodules or asymptomatic subcutaneous nodule(s) at any part of the body.

Diagnosis

Pulmonary paragonimiasis should be excluded in any patient from an endemic area who presents with a chronic productive cough and jam-like, brownish-red or 'rusty' sputum. The definitive diagnosis is made by observing the characteristic ova in sputum, pleural effusion, or stool, or flukes in biopsy specimens. Expectoration of intact flukes has been reported. Other supportive evidence is obtained by chest radiographs, which show the characteristic shadows of single or multiple cysts in the lungs (Fig. 1) Computed tomography of the chest is also helpful (Fig. 2).

Fig. 1 Pulmonary paragonimiasis posteroanterior radiograph showing thick-walled cystic lesion in the right lower lobe and left lower lobe with pericystic fibrosis. (Copyright Professor Sirivan Vanijanonta.)

Fig. 2 Pulmonary paragonimiasis' CT scan, howing thick-walled lesion with pericystic fibrosis in the left upper lobe and a fibrocalcific lesion in the right upper lobe. (Copyright Professor Sirivan Vanijanonta.)

Serology is essential for the diagnosis of extrapulmonary paragonimiasis. Enzyme immunoassay, and dot enzyme immunoassay, and monoclonal antibody tests are highly sensitive and specific, as is counterimmunoelectrophoresis using adult or free metacercariae as a source of antigen. Other less sensitive but more specific tests include complement fixation and indirect haemagglutination. Intradermal skin tests have been used for epidemiological surveys.

Differential diagnosis

Pulmonary paragonimiasis should be differentiated from pulmonary tuberculosis, melioidosis, lung abscesses, and lung tumours.

Extrapulmonary paragonimiasis should be differentiated from other diseases that produce similar clinical manifestations in affected organs. For example, cerebral paragonimiasis should be differentiated from cerebral cysticercosis, hydatidosis, meningoencephalitis, brain abscesses, and tumours. Subcutaneous paragonimiasis may resemble gnathostomiasis, sparganosis, loiasis, or onchocerciasis.

Treatment

Specific

The drug of choice is praziquantel at a dosage of 75 mg/kg per day in three divided doses for 2 to 3 days. A cure rate of nearly 100 per cent has been reported in multicentre studies. Albendazole and tricarbendazole are also effective. The symptoms rapidly improve in a few days. Eggs disappear from the sputum in a few weeks. Radiological improvement takes months, depending on the extent and chronicity of the disease. Convulsions, seizures, coma, and behavioural changes may develop during treatment of cerebral paragonimiasis. As a result of parasite death, brain oedema and host–parasite interaction may cause increased intracranial

pressure. Therefore, treatment should proceed with caution and the dose adjusted if necessary. Dexamethasone cover has been suggested in some cases.

Symptomatic and supportive treatment

These treatments, including blood transfusion, bronchodilators, anticonvulsants, and analgesics, are also important.

Prognosis

Pulmonary paragonimiasis is rarely fatal and the lesions may calcify or completely resolve in a few years. Cerebral paragonimiasis may cause chronic morbidity such as epilepsy, mental changes, and neurological sequelae.

Prevention and control

Effective control measures are directed towards interruption of the lifecycle. However, control and eradication of intermediate hosts is impracticable; therefore, health education, changes in social and dietary customs, and the mass treatment of infected people in an endemic area are more effective for prevention and control.

7.16.4 Intestinal trematode infections

David I. Grove

Intestinal trematode infections of humans other than intestinal schistosomiasis are widespread but are most common in Asia. This is a reflection of cultural factors, particularly the consumption of raw or undercooked vectors, most frequently freshwater fish and molluscs, but also water plants. More than 50 million people are estimated to harbour one or more species of these hermaphroditic flukes. In many instances, the extent of morbidity due to these infections is uncertain.

Diagnosis

The diagnosis of intestinal fluke infections is usually based upon recovery of eggs from stools. Unfortunately, ova from species within a given family often look very similar and it may be possible when using routine laboratory methods to identify an infection only to family level, such as a heterophyid or echinostomatid egg. Definitive identification relies upon recovery of adult worms after anthelmintic treatment. Identifying characteristics are provided in parasitology texts.

Treatment

Praziquantel has been shown to be effective with a number of these infections and is the drug of first choice. It is given in a dose of 20 mg/kg orally after a meal, perhaps repeated once or twice. Flukes are usually expelled the following day. The role of triclabendazole, for instance in a dose of 10 mg/kg orally, in the treatment of intestinal trematodiases is not yet clear. Other possibilities which are less likely to be effective include niclosamide at 150 mg/kg orally for 1 or 2 days and albendazole at a dose of 200 mg orally for 2 days.

Prevention

These fluke infections can be prevented by thoroughly cooking potentially infected foodstuffs.

Echinostomiasis

This term may be conveniently used to include all infections with flukes of the family Echinostomatidae. There are more than 30 genera in this family and so far 18 species have been reported to infect humans (Table 1). These species vary in size from 1 to 20 mm in length. Echinostomes live in the intestines of various birds and mammals. When eggs are passed in the stools and reach water, the miracidium develops, hatches, and enters a snail, the first intermediate host. It then develops through the stages of sporocyst, mother redia, and daughter redia to release cercariae. The cercariae in turn infect second intermediate hosts which include various species of snails, tadpoles, and fish or they encyst on vegetation. Humans are infected after ingestion of inadequately cooked food containing these metacercariae.

In humans, they live in the small bowel, particularly the jejunum, and attach to the mucosa where they may cause a variable amount of damage. Heavy worm loads may cause abdominal discomfort, flatulence, and diarrhoea. Eggs 80 to 150 by 50 to 75 µm in size are passed in the stools (Fig. 1). They are yellow-brown, ellipsoidal, thin-shelled, and operculate and contain an immature embryo; eggs of the various species cannot be reliably differentiated from each other or from those of the intestinal fluke *Fasciolopsis buski* or the liver flukes *Fasciola hepatica* and *F. gigantica*.

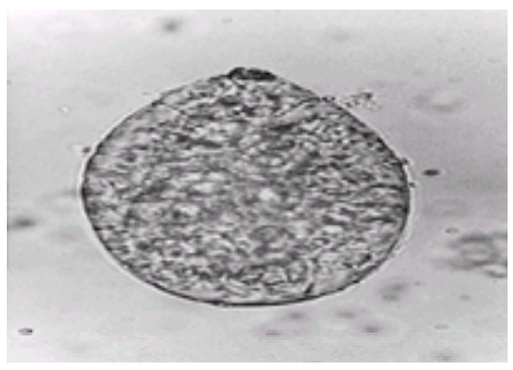

Fig. 1 Egg of *Echinostoma ilocanum* (by courtesy of P. Radomyos). All echinostome eggs look similar, as do those of *Fasciolopsis* and *Fasciola* species.

Fasciolopsiasis

This infection is caused by *Fasciolopsis buski* (see Table 3). The adult fluke (Fig. 2) is found in the small intestine of humans and pigs. When eggs are passed in the stools and reach water, the miracidium develops, hatches, and enters a snail, the first intermediate host; snail hosts include species of *Segmentina*, *Hippeutis*, and *Gyraulus*. The miracidium then develops through the stages of sporocyst and redia to release cercariae after 8 weeks or so. The cercariae swim out and encyst on water plants and develop into metacercariae over 4 weeks. Infection is acquired by ingestion of infected uncooked edible plants such as water caltrop (*Trapa bicornis*), water chestnut (*Eliocharis tuberosa*), water bamboo (*Zizania aquatica*), and watercress (*Neptunia oleracea*).

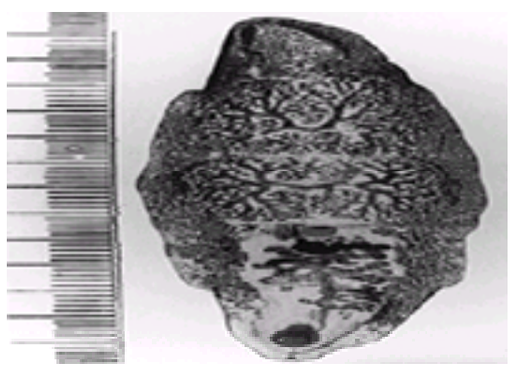

Fig. 2 Adult *Fasciolopsis buski*, 6.5 cm in length (by courtesy of P. Radomyos).

Fifty years ago it was estimated that 10 million people were infected with this parasite. The current prevalence is unknown. Fasciolopsiasis occurs most commonly in areas where people keep pigs and raise and eat freshwater lants.

The adult worms attach themselves to the mucosa of the upper small bowel where they may cause inflammation and erosion and provoke a mucous intestinal discharge. Light infections are generally asymptomatic but heavy worm burdens may be associated with anorexia, nausea, abdominal discomfort, and diarrhoea or even intestinal obstruction. Stools may be foul-smelling and contain undigested food. In severe cases, a protein-losing enteropathy is associated with ascites, generalized oedema, and prostration.

Eggs 130 to 140 by 80 to 85 µm in size are passed in the stools (Fig. 3). They are yellow-brown, ellipsoid, thin-shelled, and operculate and contain an immature embryo; they cannot be reliably differentiated from those of the intestinal echinostomes or of the liver flukes *Fasciola hepatica* and *F. gigantica*.

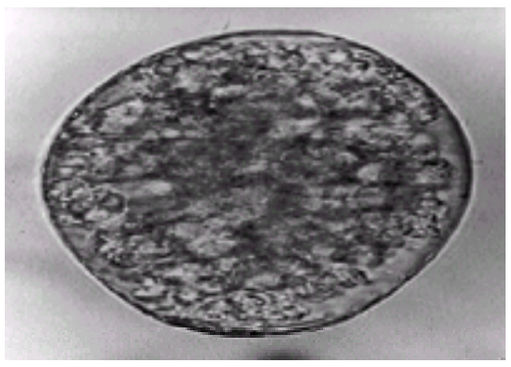

Fig. 3 Egg of *Fasciolopsis buski* (by courtesy of P. Radomyos). Note its similarity to ova of *Fasciola* species and echinostomes.

Heterophyiasis

This term may be conveniently used to include all infections with flukes of the family Heterophyidae although some infections are more precisely known by the generic name of the infecting organism, for instance metagonimiasis. These are small flukes, generally less than 1 to 2 mm in length. So far 37 species in this family have been reported to infect humans (Table 2). These infections are found in many places but are most common in Asia. *Metagonimus yokogawai* is believed to be the most common heterophyid infection.

Heterophyids live in the intestines of various mammals and birds. When eggs are passed in the stools, they contain a ciliated miracidium which hatches when ingested by a freshwater or brackish-water snail, the first intermediate host. Snails susceptible to *Heterophyes* include *Pirenella conica*, *Cerithidea cingulata*, and *Tympanotonus micropterus* while *Semisulcospira libertina* and *Thiara granifera* are host to *Metagonimus*. The miracidium then develops through the stages of sporocyst and one or two generations of rediae to release cercariae. The cercariae in turn infect various species of salmonoid and cyprinoid fish as the second intermediate hosts. These include mullet (e.g. *Mugil cephalus*) and minnow (*Gambusia* spp.) for *Heterophyes* species and carp (e.g. *Carassius carrasius*) and sweet fish (*Plecoglossus altivelis*) in the case of *Metagonimus* species. Humans are infected after ingestion of inadequately cooked fish containing metacercariae which mature in the flesh or scales of the fish.

The adult worms attach to or invade the mucosa of the upper small bowel where they may cause granulomatous inflammation and erosion. Light infections are generally asymptomatic but heavy worm burdens may be associated with anorexia, nausea, abdominal discomfort, and mucous diarrhoea. Occasionally ova deposited in the bowel wall enter blood vessels and embolize to other tissues. Eggs have been found in the heart and central nervous system. In cases of heterophyiasis described in the Philippines, cardiac failure was associated with subepicardial haemorrhages, myocardial damage caused by occlusion of vessels by ova, and eggs were stuck to a thickened, calcified mitral valve. Neurological features include focal cerebral disturbances and transverse myelitis.

Eggs 20 to 40 by 10 to 20 µm in size are passed in the stools (Fig. 4). They are yellow-brown, elongated, operculate, and contain a miracidium. Eggs of members of the family Heterophyidae cannot be reliably differentiated from each other. Furthermore, they are extremely difficult to differentiate from eggs of *Clonorchis sinensis* and *Opisthorchis* species although heterophyids tend to have a smoother egg shell, a less prominent shoulder at the operculum, and the abopercular knob may be absent.

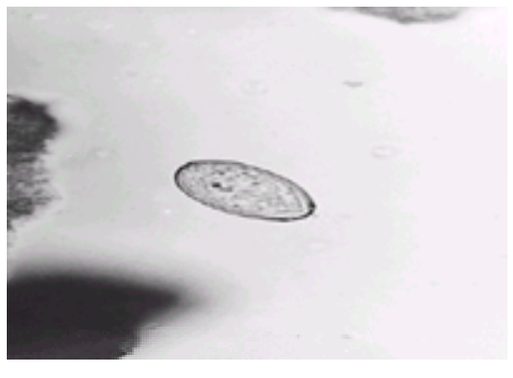

Fig. 4 Egg of *Metagonimus yokogawai* (by courtesy of P. Radomyos). All heterophyid eggs look similar, as do those of *Clonorchis sinensis* and *Opisthorchis viverrini.*

Other intestinal fluke infections

There are another dozen or so species of intestinal fluke belonging to various families that have been reported to infect humans (Table 3). As with other fluke infections, definitive diagnosis depends upon recovery of the adult worms; this is most commonly achieved by treatment with praziquantel. *Gastrodiscoides hominis* is unusual in that it attaches to the mucosa of the large bowel.

Alariasis

In North America, various species of the fluke *Alaria* are found in the intestines of wild carnivores such as wolves, foxes, bobcats, and skunks. The first intermediate hosts are snails and the second intermediate hosts are frogs and tadpoles. Cases of visceral larva migrans (sometimes fatal), ocular disease, and subcutaneous nodules due to *Alaria* mesocercariae have been described, usually following ingestion of undercooked frogs' legs. Other than surgical excision, no treatment has been described.

7.17 Non-venomous arthropods

J. Paul

Almost one million arthropod species have been described and it is likely that millions more await description. Most arthropods are of no medical importance. Medical problems they pose include envenoming, biting, transmission of infectious agents, allergy, infestation, and phobias. Arthropods may act as intermediate hosts of parasites and may cause nuisance by crawling over the skin, by making loud monotonous noises, or by invading dwellings. Most medically important arthropods are in the classes Insecta or Arachnida. Arthropod-related problems commonly present either as a particular clinical manifestation, such as bites or infestation, without an obviously visible causative agent, or as a problem visibly related to a specific kind of arthropod. Schemes of classification based on clinical manifestations and their likely causes and on the taxonomic arrangement of arthropods and their medical significance provide two useful approaches towards understanding arthropod-related problems.

Bites

Arthropod bites are common. They may be important because of the immediate physical discomfort of the bite, sensitization leading to pruritus, excoriation and secondary infection, other immunological phenomena including anaphylaxis, the transmission of infectious agents, and in exceptional circumstances blood loss. Reaction to bites varies with age, past exposure, and other factors which influence immune response. When the patient is able to associate bites with a particular kind of arthropod, management may be directed towards treatment of the bite if necessary (topical corticosteroids, systemic antihistamines), consideration of the risk of transmitted infection, and prevention of further bites (eradication of ectoparasites, change in behaviour to avoid exposure, repellents, special clothing, insecticide-impregnated bednets). It is often possible to associate bites with infesting ectoparasites, to arthropods which remain attached (ticks), and to predatory bloodsuckers which are highly visible (mosquitoes, midges, and black flies, when swarming) and which cause immediately painful bites (tsetse flies, some mosquitoes, tabanid flies). In is harder to ascribe a cause to bites from arthropods which bite at night or when the patient is asleep (some mosquitoes, sand flies, bedbugs, triatomine bugs) or from arthropods which are inconspicuous and which do not cause immediately painful bites (harvest mites, some fleas, some biting flies). Bites of larger arthropods typically have a central punctum and a surrounding area of inflammation and are pruritic. In cases of uncertainty it may be necessary to obtain a dermatological opinion to exclude other diagnoses, including organic disorders, artefact, and delusion.

Blood-sucking flies (Diptera)

Many flies are haematophagous (Table 1). Most blood-sucking flies are in the suborder Nematocera (mosquitoes, sand flies, black flies, biting midges) and the family Tabanidae of the suborder Brachycera (horse flies, clegs). The tsetse flies, *Glossina* spp., are in the suborder Cyclorrhapha. All blood-sucking flies are at least a nuisance: the bites are often painful and associated with sensitization. More importantly, biting flies may transmit infection. Mosquitoes (Culicidae) are vectors of filariasis and numerous viral diseases, including yellow fever and dengue. Mosquitoes of the genus *Anopheles* transmit malaria. Depending on species and location, mosquitoes bite at different times of the day. Mosquitoes need stagnant water for the development of their larval stages. Mosquitoes may be controlled by reducing their access to stagnant water and by application of insecticides to dwellings. Use of permethrin-impregnated bednets has been shown to reduce malaria transmission. Sand flies (Phlebotominae) are mainly tropical and subtropical in distribution and transmit leishmaniasis. In South America, sand flies of the genus *Lutzomyia* transmit *Bartonella bacilliformis*. Black flies (Simuliidae) occur worldwide but in Britain are rarely troublesome to humans except in certain localities, notably by the River Stour, Dorset. In Africa, simuliids transmit onchocerciasis, and in South America they are associated with the haemorrhagic syndrome of Altimira, but in Britain they are merely a nuisance (Blandford fly, *Simulium posticatum*). Black flies pierce the skin and suck blood from the edge of the puncture. The bites, oozing blood, have a characteristic appearance and may be associated with severe reaction by the host. Black fly larvae require fast-flowing water. Biting midges (Ceratopgonidae) are vectors of the filarial worms *Dipetalonema perstans* and *Mansonella ozzardi*. In Africa, tabanid flies transmit *Loa loa*. Tsetse flies, are vectors of African trypanosomiasis. When visiting locations where biting flies are troublesome, bites may be avoided to some extent by wearing clothing which covers the skin and by use of repellents.

True bugs (Hemiptera)

The two main groups of medically important Hemiptera are the bedbugs, *Cimex* spp., and the triatomine reduviid bugs, including *Rhodnius prolixus* and *Triatoma infestans*. The common bedbug *Cimex lectularius* (Plate 1) is cosmopolitan. The tropical bedbug *Cimex hemipterus* occurs in tropical and subtropical countries. There is no clear evidence to implicate bedbugs as vectors of disease. Bedbugs are nocturnal, hiding during the day and feeding at night. Although in some cases, bites may go unnoticed and there may be no allergic reaction, bedbugs may cause sleeplessness and the bites may cause pain and swelling (Fig. 1). Where a room is heavily infested, patients may complain of an unpleasant odour produced by the bugs. Bugs may be found by making special searches at night or by searching their hiding places during the day. Bedbugs superficially resemble lentils, being round and flat. Adults reach a length of about 5 mm. Nymphs pass through five instars to reach adulthood after about 4 months. Bedbugs can live for 6 months without feeding, becoming paper-thin. Bedbugs may be translocated in furniture and personal effects. Control relies on removal or steam cleaning of infested mattresses and treatment of infested rooms with insecticides. Related bugs which occasionally bite humans are the pigeon bug *Cimex columbarius*, the bat bug *Cimex pipistrelli*, and the martin bug, *Oeciacus hirundinis*. Infestation may be managed by restricting the access of host species to dwellings. In Britain, bats are protected under the Wildlife and Countryside Act.

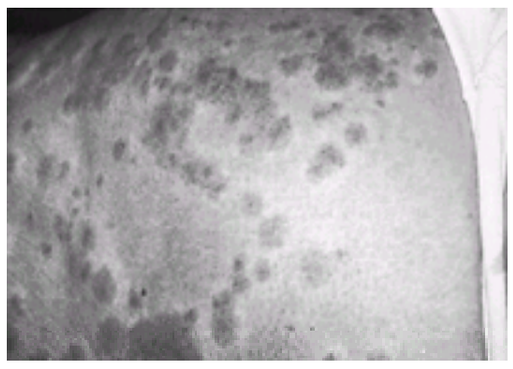

Fig. 1 Erythematous macules of bedbugs. (Reproduced by courtesy of D. Hill, Adelaide.)

Most of the 129 species of cone-nose bugs (family Reduviidae, subfamily Triatominae) occur in the Americas. Seven species occur in Asia and one species, *Triatoma rubrofasciata*, is cosmotropical. Many triatomines are obligate feeders on the blood of vertebrates. Triatomines transmit South American trypanosomiasis. Important vector species are *Rhodnius prolixus*, *Triatoma infestans*, *Triatoma brasiliensis*, *Triatoma dimidiata*, and *Panstrongylus megistus*. The bugs infest dwellings, hiding in crevices during the day and biting at night. Dwellings may be heavily infested: in Colombia, 11 403 specimens of *Rhodnius prolixus* were reported from one house, occupied by nine people, all seropositive for trypanosomiasis. As well as transmitting trypanosomiasis, triatomines may cause significant blood loss to occupants of infested buildings. Control depends on deinfestation of dwellings with insecticides and on the construction of buildings which offer few hiding places for the bugs.

Ticks (Ixodoidea)

Ticks bites are often recognized as such because ticks may remain attached to the skin for days. Hard ticks (Ixodidae) and soft ticks (Argasidae) occur worldwide. Stages of the lifecycle are egg, larva (six-legged), and nymph and adult (both eight-legged). Ticks attach and feed with a barbed hypostome and detach when engorged. Smaller stages and ticks in inconspicuous sites, such as on the perineum, may feed unobserved. Bites are usually painless but may result in local sensitization, secondary infection, and transmission of infectious agents, including numerous viruses, rickettsias, and Lyme disease (Table 2). Local reaction to bites may be confused with erythema migrans of Lyme disease, (which expands and typically develops a cyanosed centre). Ticks may be removed by gripping with forceps (or in the field, with finger and thumbnail), between the skin and the tick's head and pulling gently. One should avoid squeezing the tick. Careless removal may detach the hypostome, a potential source of secondary infection or inflammation. In Britain, ticks most often found on humans are the sheep tick *Ixodes ricinus* (a vector of Lyme disease), and the hedgehog tick *Ixodes hexagonus* (Plate 3). When visiting tick-infested places, bites may be avoided by tucking trousers into boots and by wearing light-coloured clothing which makes ticks highly visible. After visiting tick-infested habitats, searches of the body allow prompt removal of ticks which reduces the chance of disease transmission.

Harvest mites (Trombiculidae)

In Britain, larvae of the harvest mite *Neotrombicula autumnalis* are a common cause of bites in late summer. The mites are tiny and seldom noticed. They crawl rapidly on to the body, attach (often under tight-fitting clothes), inject proteolytic enzymes, feed on tissue fluid and detach, causing pruritic, sometimes bullous lesions hours later. Red bugs or chiggers (a term also applied to *Tunga penetrans*) are names given to trombiculids in the Americas. In Asia, trombolucids are vectors of scrub typhus. Where trombiculids are troublesome, tucking trousers into boots and application of diethyltoluamide and other repellents may be partially effective.

Accidental bites

Some arthropods which do not normally bite man can inflict painful but usually trivial bites when provoked by handling, as by children and entomologists: these include predatory true bugs such as the water boatman *Notonecta glauca* and the assasin bug *Reduvius personatus* in Britain and wheel bugs, *Arilus* spp., in the Americas; larger beetles (Coleoptera); dragonflies (Odonata); and bush-crickets (Orthoptera) such as the wartbiter *Decticus verrucivorus*. Spines used in defence by the great silver diving beetle *Hydrous piceus* and larger tropical grasshoppers of the subfamily Cyrtacanthridinae can cause penetrating injury when handled. Pincers of larger crabs and lobsters (Crustacea) can cause crushing injuries of digits and their spines may cause penetrating injury.

Infestation

Sites of infestation include the hair, body surface and immediate environment (ectoparasites: lice, fleas), the skin and subdermis (scabies, tungosis, dermal myiasis), wounds, tissues, and orifices (myiasis), and the gastrointestinal tract (myiasis, canthariasis). With ectoparasites, the main problems are related to their bites: diagnosis and management may be based on the identification of the ectoparasite. Delusory parasitosis is a condition in which the patient becomes convinced of infestation by parasites despite reassurance by the doctor and absence of clinical or laboratory evidence.

Scabies

The agent of human scabies, a chronic infestation, is the human scabies mite *Sarcoptes scabiei* var. *hominis*. Scabies mites adapted to other hosts, such as *Sarcoptes scabiei* var. *canis* cause a self-limiting pruritus in man. Clinical manifestations of scabies are caused by the adult female mite which burrows through the epidermis. The adult female is oval and about a third of a millimetre long (Fig. 2). The female lives for about a month, burrowing and ovipositing daily. The burrow may extend to a centimetre in length. Six-legged larvae hatch after a few days and moult to become eight-legged nymphs and later eight-legged adults. Adult males are smaller than females, do not burrow, and die after mating on the epidermis. Scabies is cosmopolitan in distribution. Prevalence rates vary but may be higher in conditions of overcrowing and following social disruption in wartime. Outbreaks may occur in nursing homes and in hospitals. Most cases must be acquired by close contact as the mites do not survive long away from the body. The main presenting symptom is pruritus which occurs with sensitization about a month after the onset of infestation. Symptoms may be worse at night and after a hot bath or shower. Burrows commonly occur in web spaces between the fingers and on the wrists but may be very widespread. There is often evidence of excoriation but the appearance of the skin is variable and may show secondary infection, eczematization, lichenification, and papulovesicles (Fig. 3). Careful examination may reveal burrows and mites. Diagnosis may be confirmed by microscopy of scrapings from affected areas, especially interdigital spaces, but many cases are atypical and a dermatological opinion may be required to exclude other causes (Fig. 4). Immunosuppressed patients, including transplant recipients and patients with AIDS, are prone to crusting or so-called Norwegian scabies in which crusting lesions of scales and mites accumulate over the hands, feet, and other sites such as the eyebrows, but the patient suffers relatively little discomfort. Such cases and presumably their fomites are highly contagious. Treatment of scabies is by topical application of acaricides. Malathion and permethrin are currently recommended, applied twice, one week apart, in the United Kingdom. Gamma benzene hexachloride is also effective. To prevent reinfection, close contacts should be treated simultaneously. During outbreaks, it may be necessary to treat whole cohorts of patients or healthcare teams. Ivermectin, by mouth, has been used to treat cases of crusting scabies in immunosuppressed patients. Occasionally, the mites *Dermanyssus gallinae* and *Ornithonyssus* spp. whose normal hosts are birds, bite humans, causing lesions which resemble scabies.

Louse infestation

Lice are obligate parasites of animals. They bite using piercing mouthparts to feed on blood or tissue fluids. Three species, of cosmopolitan distribution, are associated with man: *Pthirus pubis*, the pubic louse, the body louse (or clothing louse) *Pediculus humanus*, and the head louse *Pediculus capitis*. Body and head lice are morphologically similar and are treated by some authors as subspecies or forms of *P. humanus*. Lice complete their lifecycle on their host. Adult females deposit eggs (nits) on hairshafts (pubic and head lice) or on clothing (body louse). Larvae hatch after about 1 week, begin to feed, and over the course of about 2 weeks undergo several moults before reaching adulthood. Adult females live for about a month and may lay about a hundred eggs. Egg cases remain where attached and may persist after successful treatment of infestation. Most infestations are probably acquired through close contact with an infested case but some cases may result from contact with clothing, bedclothes, or hairbrushes containing living lice or their eggs which may be attached to shed hairs. In addition to the aesthetic and social drawbacks of louse infestation, medical problems common to all three taxa, relate to sensitization of the host to louse antigens from bites and the resulting pruritus which may lead to excoriation and secondary infection. Louse bites have a central punctum and surrounding small red macule. Body lice may transmit a number of agents, including those of endemic typhus (*Rickettsia prowazeki*), trench fever (*Bartonella quintana*), and relapsing fever (*Borrelia recurrentis*). Louse infestation may be treated by topical application of pediculocides. Pediculocides should be used with caution in children and asthmatics.

Pubic lice (crab lice)

The lice attach themselves to pubic hairs. Rarely they may be found on eyebrows, eyelashes (phthirus palpebrarum), axillary, head, or chest hair. Eggs are deposited on hair shafts. Most infestations are probably acquired through sexual contact with an infested case. Children may acquire phthirosis at atypical sites through close contact with adults. Lice seldom stray from the body. Transmission is possible but unlikely without close contact with an infested case. The main symptom is pruritus, sometimes with excoriation and secondary infection. Bluish-grey patches (maculae caeruleae) may occur on the skin. Diagnosis is by observation of the lice, which may be difficult to find, or of eggs or egg cases attached to hairshafts. Adults are 1 to 2 mm long. The anterior legs are smaller than the other two pairs. The body is squat and crablike (body length, excluding head, about 1.2 times body width) (Fig. 5). Infestation may be treated by topical application of carbaryl or malathion to the whole body, repeated a week later to kill newly hatched larvae. (The original description contained a printing error (*Pthirus*) for phthirus (Greek for 'louse').)

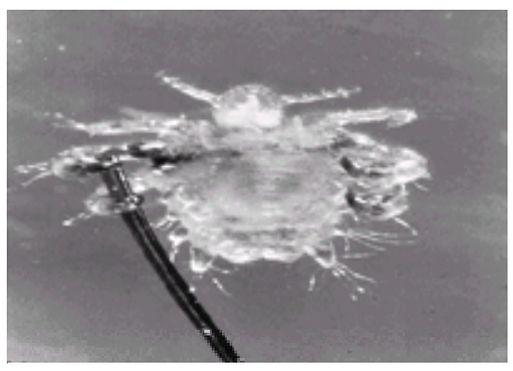

Fig. 5 Adult specimen of *Pthirus publis.* (Reproduced by courtesy of R.V. Southcott, Adelaide, South Australia.)

Head lice

Head lice infest the scalp and rarely other body sites. They lay their eggs at the base of hair shafts. Infestation is more common in children than in adults and more common in females than in males. Prevalence rates vary but may be very high in certain communities or institutions, such as schools. Prevalence rates may be high despite good standards of hygiene. Most cases occur probably as a result of close contact. The main symptom is pruritus which may be associated with excoriation, secondary infection, and lymphadenopathy. Diagnosis is by observation of lice, which generally remain close to the scalp, or of eggs or egg cases attached to hairs (Fig. 6). A fine comb (nit comb) may be used to collect material to make the diagnosis. Adults are 3 to 4 mm long. Infestation may be treated by application of pediculicide lotion to the scalp overnight and repeated a week later to destroy newly hatched larvae. Currently available pediculocides in the United Kingdom include malathion, permethrin, phenothrin, and carbaryl. Treatment failure with permethrin has been reported from many parts of the world. Compared with laboratory reference strains, lice collected from infestations failing to respond to permethrin have shown relative resistance to the agent. There is evidence that in Israel permethrin resistance may be due to mono-oxygenase plus nerve insensitivity resistance mechanisms. Malathion resistance has been reported and may be due to a

malathion-specific esterase. Regular and fastidious use of a nit comb may be used (on its own or in combination with a pediculocide) to treat infestation. There is much anecdotal evidence that combing can be effective. Combing avoids concerns of pediculocide toxicity and resistance, but a study in Wales showed combing to be less effective that chemical treatment. In institutions, co-ordinated treatment campaigns may be required to prevent reinfestation.

Fig. 6 Nits attached to hair. (Reproduced by courtesy of D. Hill, Adelaide.) Photograph from a patient with pediculosis showing several hair fibres with numerous egg cases attached.

Body lice

Body lice infest clothing and body hair. They lay their eggs on clothing, often along seams. Body lice are morphologically like head lice but they are slightly larger (Plate 4). Body louse infestation is associated with poor hygiene and social deprivation, as may occur in wartime. Transmission occurs as a result of close contact or through contact with infested clothing. Bites occur on the body, resulting in pruritus which may be associated with excoriation, eczematization, and secondary infection. Diagnosis is confirmed by finding lice, usually on the clothing. Infestation may be treated by topical application of carbaryl or malathion to the whole body, repeated a week later to kill newly hatched larvae. Hot washing of clothing will destroy adults and early stages.

Fleas (Siphonaptera)

Fleas are bloodsucking ectoparasites. There are thousands of species, adapted to various host animals. Adults are a few millimetres long, brown, laterally compressed, and typically very active. Adults move through the fur or under clothing but can survive in the environment for long periods without feeding. Eggs are dropped to the ground, where the larvae develop, feeding on organic matter. The pupa may remain in the environment for long periods before the adult emerges. Increasing standards of hygiene in developed countries have made the human flea, *Pulex irritans*, a rarity. Most flea bites in Britain are due to cat and dog fleas, *Ctenocephalides felis* (Plate 2) and *C. canis*, either through direct exposure to an infested animal or to an environment exposed to an infested animal, possibly months previously. Flea bites result in intense pruritus at the bite site. There is a central punctum and there may be bulla formation (Fig. 7). Flea bites often occur in groups. Although patients may not witness fleas, clues that bites have been caused by fleas include intense pruritus, the appearance of bites in small groups and a history of exposure to a flea-ridden animal or its domain. Troublesome bites may be treated with topical corticosteroids and systemic antihistamines. Prevention of bites is by good domestic hygiene and treatment of infested animals and environments with insecticides. Certain species of flea are vectors of a number of infectious diseases including plague and murine typhus.

Fig. 7 Fleabites. Erythematous macropapule with central bite point visible. (Reproduced by courtesy of D Hill, Adelaide.)

Tungosis

Tungosis is infestation by a flea, *Tunga penetrans*, the jigger, chigger, or chigoe (but popular names are shared with tromboculid mites). The gravid female, about 1 mm long, burrows into exposed skin (usually the foot) or under a toenail and swells to about 1 cm in diameter, causing local discomfort. Lesions may be enucleated surgically, the diagnosis being confirmed by histology. Local remedies in endemic areas (tropical Africa and the Americas) of shelling out fleas may leave cavities prone to secondary infection and tetanus. The wearing of footwear prevents infestation.

Myiasis

Myiasis is the infestation of living animals by the larvae of flies (Diptera). Useful schemes of classification of myiasis include those based on the anatomical site (dermal, subdermal, wound, nasopharyngeal, orbital, ophthalmic, aural, urogenital, pulmonary, intestinal) and on the species of fly involved. Myiasis caused by flies whose larvae are obligate parasites of living tissues may be termed specific or primary myiasis. Myiasis associated with larvae which feed on decaying organic matter may be termed opportunistic or secondary myiasis. Myiasis due to larvae which find there way into the body (especially the gastrointestinal tract) by chance may be called accidental myiasis. Of the many species listed as possible agents (Table 3), most are opportunists whose saprophagous larvae feed on decaying organic matter, which might include necrotic wound tissue. Opportunists usually confine themselves to dead tissue and may even benefit the healing process. There is no dipterous obligate intestinal parasite of man. Intestinal myiasis may be caused by coprophagous larvae which invade the rectum or by resilient maggots, such as those of the false stable fly *Muscina stabulans* and the cheese skipper *Piophila casei* which survive when swallowed in food and may cause intestinal disturbance and scarring. Intestinal myiasis may be spurious following diagnosis based on observation of rapidly hatching larvae on freshly passed faeces. Flies from several genera, notably *Fannia*, may cause urogenital myiasis. Scuttle flies (Phoridae) have been reported to cause pulmonary myiasis, possibly following inhalation of the gravid female fly. A small number of flies are obligate parasites of living tissues and a few species are closely associated with, but not specific to, humans. Many cases of myiasis are benign, self-limiting, and relatively harmless, but aural, nasopharyngeal, and malign wound myiasis are potentially lethal entities that may require removal of the larvae and possibly reconstructive surgery. Myiasis is diagnosed by observing dipterous larvae in a lesion. Identification of larvae may require entomological expertise but management of the patient, which depends on the type of lesion, may involve the removal of larvae, surgical exploration, debridement, or treatment of secondary infection and should be based on clinical assessment.

Dermal myiasis

Dermatobia hominis, the human bot fly, is a common cause of dermal myiasis in the American tropics. The female fly lays her eggs on biting arthropods such as mosquitoes. The eggs hatch when in contact with skin into which the larva burrows. The larval stage lasts about 10 weeks (Fig. 8), a boil with a small aperture forming as the larva grows. Such boils are not infrequently seen in Europeans returning from the neotropics. The larva may grow to more than a centimetre in length. An early symptom is sporadic pain caused by the spiny larva. Unless in an unusual anatomical site, such as close to the eye, infestation is generally harmless. Secondary

infection of the wound is the most common complication. Larvae may be removed through a simple incision. Remedies which include application of raw meat or glue to the lesion may not be successful. Squeezing may rupture the larva to evoke a local granulomatous reaction.

Fig. 8 Two third larval instars of the human bot fly (*Dermatobia hominis*) (approximately 13 mm long) extracted from a facial 'boil' in a European who had been visiting Guyana. (b) Larva of *Dermatobia hominis* initially infesting the scalp of a young child in Panama. The larva made a 4-mm hole in the anterior fontanelle and entered the frontal lobe of the brain. The child died of malaria. (Armed Forces Institute of Pathology photograph, neg. no. 50807.)

The tumbu fly, *Cordylobia anthropophaga*, is widespread in the Afrotropical region. The female oviposits on sand and also on drying clothes. Ironing destroys eggs. Contact with viable ova on clothing leads to infestation. The larvae (Plate 6) pierce the skin and grow rapidly. An uncomfortable boil forms which oozes serosanguinous fluid. Fever and lymphadenopathy may occur. Larvae reach maturity in about 10 days. Larvae may be removed through a simple incision, but with care it may be possible to express larvae following application of petroleum jelly.

The larvae of warble flies, *Hypoderma* spp., occasionally cause dermal myiasis in man. Larvae of horse bot flies, *Gasterophilus* spp., cannot complete their lifecycle in man but they can pierce human skin, where they wander for a week or so, causing intense itching (creeping eruption).

Wound myiasis

Many dipterous species are known to cause wound myiasis, but most of them are facultative feeders on necrotic tissue and are rarely destructive to the host, although the presence of maggots in a wound may cause distress. Debridement of nectrotic tissue will control such infestation. In contrast, under controlled conditions, clinicians may introduce maggots to promote healing.

Causes of malign myiasis include the New World screw-worm *Cochliomyia hominivorax*, in the Americas and the Old World screw-worm *Chrysomya bezziana* and Wohlfahrt's wound myiasis fly *Wohlfahrtia magnifica* in the Old World. Their larvae are obligate parasites of living tissue. Eggs are laid on wounds, in ears, and on mucous membranes. The larvae (Fig. 9) burrow in groups into healthy tissue, causing widespread destruction which may be mutilating or fatal (Fig. 10). Secondary bacterial infection or secondary wound myiasis may ensue. All species may cause nasopharyngeal, aural, orbital, genital, and malign wound myiasis. Infestation is best avoided by cleaning and dressing wounds as they occur. Treatment involves surgical removal of the larvae, debridement of affected tissue, and treatment of secondary infection. Reconstructive surgery may be required.

Fig. 9 Larvae of the New World screw-worm (*Cochliomyia hominivorax*) (approximately 8 mm long) extracted from the wound illustrated in Fig. 10. These were sent to the Natural History Museum, London, where they were identified. Larvae of the second myiasis species (*C. macellaria*) were also found in the sample and were probably collected from the edges of the wound. (By courtesy of Dr Martin JR. Hall, Medical and Veterinary Division, The Natural History Museum, London.)

Fig. 10 Fatal myiasis (New World screw-worm): historical illustration of a 50-year-old Honduran woman who complained of a small chronic ulcer on the right cheek; on admission to hospital she was found to have a huge ulcer exposing the bones of the face and forehead and destroying the tissues of the cheek and face, right eye, and orbit; more than 300 larvae were removed (see Fig. 9). (Harrison JHH (1908). A case of myiasis. *Journal of Tropical Medicine and Hygiene*, **XI**, 20.)

Ophthalmic myiasis

Nasal bot flies, *Oestrus* spp., naturally parasitize various herbivorous mammals. They are larviparous and drop their larvae into the nostrils of the host. Dropped into human eyes they cause a self-limiting conjunctivitis. Larvae of warble flies, *Hypoderma* spp., are more dangerous: they may burrow into the eye, resulting in pain, nausea, and much damage and must be surgically removed.

Canthariasis

Infestation of the body by beetles (Coleoptera) or their larvae is called canthariasis. Clinically, it may resemble myiasis but is much rarer. Larvae swallowed with food may dwell temporarilly in the intestines, causing discomfort and may be detected in excreta. Beetles occasionally invade orifices. In Sri Lanka, scarabid dung beetles have been reported to invade the rectum. A specimen of the ground beetle *Sciates sulcatus* was recovered from the vagina of a women complaining of vaginal

discharge who had visited Pakistan (Plate 5). In Israel, the dung beetle *Maladera matrida* has been reported to invade the external auditory canal. In Oman, two cases of invasion of the external auditory canal by the ground beetle *Crasydactylus punctatus* have been reported. In one case, the beetle reached the middle ear causing sensorineural hearing loss.

Allergy

A wide range of immunological responses to arthropod bites has been described, from local pruritus to anaphylaxis. The dead remains, cast skins (exuviae), and faeces of many arthropods include sensitizing agents. They may act as contact or inhalant allergens following domestic or occupational exposure, resulting in dermatitis, conjunctivitis, rhinitis, and asthma. Allergic patients may show specific IgE antibodies to a wide range of domestic pests including house flies, clothes moths, cockroaches, carpet beetles, *Anthrenus* spp., silverfish, *Ctenolepisma longicaudata*, and house dust mites *Dermatophagoides* spp. *Dermatophagoides* spp. are a common cause of allergy in Britain and exposure to cockroach allergens in household dust has been associated with asthma in the United States. Following mass emergence, the exuviae of mayflies (Ephemeroptera) and caddis flies (Trichoptera) may act as inhalant allergens. Entomologists who collect insects by sucking them into pooters may develop inhalant allergy to their subject of study. Larvae of the beetles *Tenebrio molitor* (mealworm) and *Alphitobius diaperinus* (lesser mealworm), which are reared for fish bait and animal food, have been associated with rhinoconjunctivitis, contact urticaria, and asthma. Beetles which infest stored grain, including *Tenebrio molitor*, *Tribolium confusum* (confused flour beetle), *Sitophilus* sp. (grain weevil), and *Alphitobius diaperinus* have been associated with occupational allergy in grain workers or bakers. Allergy has been associated with other beetles, including *Dermestes peruvianus* (hide beetle), *Gibbium psylloides* (mite beetle), and *Harmonia axyridis* (Asian ladybird). Insect allergy can be investigated by skin prick tests, measurement of allergen-specific serum IgE, and by monitoring respiratory function following allergen exposure.

Insects and hygiene

Synanthropic insects which feed or wander over faeces, wounds, and food may serve as passive vectors of bacterial and viral diseases. Such insects include pharaoh's ants, *Monomorium pharaonis*, flies, and cockroaches (Dictyoptera). Despite many reports of the isolation of pathogenic bacteria and viruses from these insects, there have been few epidemiological studies to define their importance as passive vectors but is generally accepted that the presence of these insects in hospitals should be monitored and controlled.

Flies

Many species of fly (especially of the suborder Cyclorrhapha), frequent human and animal food, wounds, eyes, and faeces. Such flies vomit and defaecate where they feed. Numerous pathogenic bacteria and viruses have been isolated from flies, suggesting that they may act as passive vectors of bacterial and viral diseases. A controlled study in The Gambia where fly control was associated with fewer new cases of trachoma, suggested that flies may act as vectors of the trachoma agent, *Chlamydia trachomatis*. In The Gambia *Musca sorbens* is the most common eye-visiting fly. In Pakistan, a controlled study showed fly control to be significantly associated with a reduction in incidence of childhood diarrhoeal illness. In Israel, fly control was associated with a reduction in cases of shigellosis. Flies may be controlled by using insecticides or fly traps in dwellings and latrines.

Pharaoh's ants

Pharaoh's ants, *Monomorium pharaonis* L., commonly infest hospitals, where they invade sterile packs and wound dressings. They are potential passive vectors: bacteria, including *Salmonella* spp. and *Staphylococcus* spp. have been isolated from these ants, which should, therefore, be controlled with insecticides.

Cockroaches

Cockroaches are omnivorous scavengers. A few of the 3500 described species have become cosmopolitan synanthropes. The main pest species are the common cockroach, *Blatta orientalis*, the American cockroach, *Periplaneta americana*, the German cockroach, *Blattella germanica*, and the banded cockroach, *Supella longipalpa*. Other species may be locally important, for example *Ectobius lapponicus*, described by Linnaeus as infesting dried fish in Lapland. The common pest species are mostly of tropical origin and require temperatures of 25 to 33 °C but *B. orientalis* will tolerate 20 °C. In cooler climates they are restricted to permanently heated areas and can occur in large numbers in hospitals and in sewers. Many pathogenic viruses, including poliomyelitis virus and Coxsackie A virus, and bacteria, including *Shigella* spp., have been isolated from cockroaches. There is evidence that cockroaches acted as vectors of hepatitis A during an outbreak in California and of *Salmonella typhimurium* on a paediatric ward in Belgium. Cockroaches are potential allergens, 7.5 per cent of healthy persons having a positive skin test in one study. Cockroaches wander over sleepers and are attracted to nasal and oral secretions. Herpes blattae is a dermatitis described from Réunion and attributed to cockroach allergy. Cockroaches sometimes wander into the ears and nostrils, where they become trapped or reluctant to leave. Lidocaine spray is reported to hasten the exit of such visitors.

Eye-frequenting moths and beetles

Some nocturnal moths of the families Pyralidae, Noctuidae, and Geometridae in Africa and Southeast Asia habitually feed on the lachrymal secretions of animals. They may visit human eyes, causing a certain amount of discomfort, and may transmit eye infections, including trachoma and viral conjunctivitis. They may also cause mechanical damage to the cornea. The moths stimulate the flow of secretions by vibrating and probing with their probosces. Implicated species include *Lobocraspis griseifulva*, *Arcyophora* spp., and *Filodes fulvidorsalis*. *Calyptra eustrigata* is a skin-piercing, blood-sucking noctuid moth from Malaya. Such Lepidoptera may be avoided by sleeping under a net. In Australia a beetle, *Orthoperus* sp., has been associated with corneal erosion.

7.18 Pentastomiasis (porocephalosis)

D. A. Warrell

The Pentastomida, pentastomes or 'tongue worms', inhabit the respiratory tracts of vertebrates where they feed on blood and other tissues. There are more than one hundred species, classified into two orders, Cephalobaenida (e.g. genus *Raillietiella*) and Porocephalida (e.g. genera *Linguatula*, *Armillifer*, *Leiperia*, and *Sebekia*). About ten species are known to be capable of causing zoonotic infections in humans. Pentastomida are probably arthropods, but they have also been classified as Branchiuran crustacea, annelids, and in a separate phylum. The name pentastome derives from their having two pairs of anterior hooks and a mouth, giving the impression of five stomata (Fig. 1). In humans, visceral pentastomiasis is most often caused by *Linguatula serrata* or *Armillifer armillatus* and nasopharyngeal pentastomiasis (halzoun or Marrara syndrome) by *L. serrata*.

Fig. 1 Adult pentastomid showing mouth (arrowed) and lateral hooks giving the appearance of five stomata. Scanning electron micrograph, 400 ×. (By courtesy of Professor Viqar Zaman.)

Aetiology

Linguatula species

Linguatula serrata occurs in Europe, the Middle East, Africa, and North, Central, and South America, but not Asia. The names 'Linguatula' and 'tongue worm' describe the flattened shape, particularly of the adult female. Their surface bears numerous annular grooves. Dogs, foxes, and wolves, the definitive hosts, harbour adults and nymphs in their upper respiratory tract and shed them in their nasal secretions, saliva, and faeces. Herbivorous animals ingest the ova which hatch in the lumen of the gut releasing larvae that burrow into the tissues and encyst. When these intermediate hosts are eaten by the definitive host, nymphs hatch from the cysts and migrate to the lungs and nasopharynx where they mature.

Clinical features

If humans ingest ova of *Linguatula* spp., cysts usually develop in the liver but do not cause symptoms unless they obstruct or compress, for example, the filtration angle of the anterior chamber of the eye (2nd- or 3rd-instar larvae), biliary, gastrointestinal or respiratory tracts, meninges, or brain. Ingestion of cysts containing third-stage larvae in raw liver and lymph-nodes of sheep, goats, cattle, and lagomorphs can result in acute nasopharyngitis, known as halzoun, Marrara syndrome, or nasopharyngeal pentostomiasis. This has been reported from the Middle East, especially Lebanon, Greece, and the Sudan. In the human stomach, larvae escape from the cysts and migrate up the oesophagus to the nasopharynx mucosa. Within a few hours of eating the infected viscera there is intense irritation of the upper respiratory and gastrointestinal tracts associated with coughing, sneezing, rhinorrhoea, retching, vomiting, lacrimation, haemoptysis, epistaxis, cervical lymphadenopathy, transient deafness, difficulty in speaking, dysphagia, wheezing, and dyspnoea. Larvae can be found in sputum and vomitus. Patients usually recover in 1 or 2 weeks, but deaths have resulted from acute upper airway obstruction. These features suggest a hypersensitivity reaction. Halzoun has also been attributed to flukes (*Fasciola hepatica*) and nematodes (*Mammomonogamus laryngeus*) ingested in raw sheep and goat liver and to leeches (*Limnatis nilotica* and *Dinobdella ferox*). Very rarely, larvae may develop into adults in the human nasal cavity.

Armillifer (*Porocephalus*) species

These are also annulated, non-segmented parasites (Fig. 2). The adults, up to 20 cm long, inhabit the respiratory and digestive tracts of snakes, especially those of the genera *Python*, *Boaedon*, *Naja*, and *Bitis*, and other vertebrates. Ova are shed in the snake's nasal secretions and are picked up by herbivorous mammals. Larvae encyst in the tissues of these intermediate hosts and will develop to the nymph stage if ingested by another animal, but develop to adults only in snakes. Humans may ingest ova by drinking water contaminated by snakes, or they may ingest living encysted larvae in raw snake meat eaten as part of *ju ju* rituals (West Africa), or from inadequately cooked snake (Temuan tribe of Malaysian aborigines and in Benin and other West African countries). Ingested eggs hatch in the gut releasing larvae which burrow into the tissues where they develop into nymphs. Hundreds of wriggling nymphs have been discovered beneath the visceral peritoneum at laparotomy.

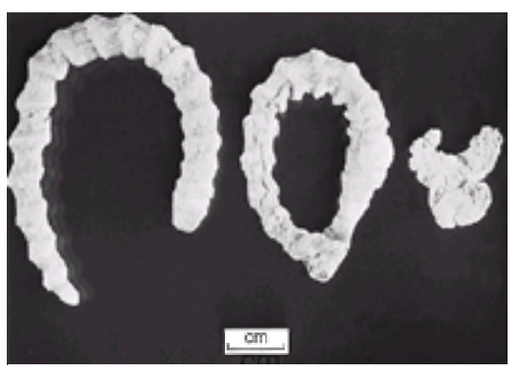

Fig. 2 *Armillifer armillatus*. Left: two adults found in the lungs of a Gaboon viper (*Bitis gabonica*). Right: calcified nymph from the mesentery of a Ghanaian patient. (By courtesy of Dr G. M. Ardran.)

Human infections with the larvae or nymphs of the following species of *Armillifer* have been reported:

- *A. agkistrodontis*—China (in the snake *Deinagkistrodon acutus*);
- *A. armillatus* (18–22 annular rings)—Africa: Egypt, Senegal, The Gambia, Ghana, Benin, Nigeria, Cameroon, Congo, and Zimbabwe;
- *A. grandis*—Congo;
- *A. moniliformis* (30 annular rings)—Malaysia, Philippines, Indonesia, Tibet, and Australia;
- *A. najae*—India.

Clinical features

The commonest evidence of infection by *Armillifer* spp. is the discovery of calcified nymphs (Fig. 2) on radiographs of the abdomen and chest (Fig. 3). These appear as discrete, crescent-shaped, soft tissue calcifications, 4 × 4 mm in size. In West Africa they are seen particularly in the right upper quadrant and are situated beneath the peritoneum covering the liver. In Ibadan, Nigeria, these shadows were seen in 2 per cent of adult males and 4 per cent of adult females. Hundreds of calcified encysted nymphs have been found in the peritoneum at laparotomy or at autopsy in the liver (Fig. 4), spleen, gut wall and lumen, lungs, cirrhosal cavities, central nervous system, eye, and elsewhere in 27 per cent of cases in The Congo (*A. armillatus* and *A. grandis*), in 6 to 13 per cent in Cameroon (*A. armillatus*), and in 45 per cent in Malaysian Orang Asli (*A. moniliformis*).

Fig. 3 Typical radiographic appearance of calcified nymphs of *Armillifer armillatus* in the abdominal cavity of a Ghanaian patient. (By courtesy of Dr G. M. Ardran.)

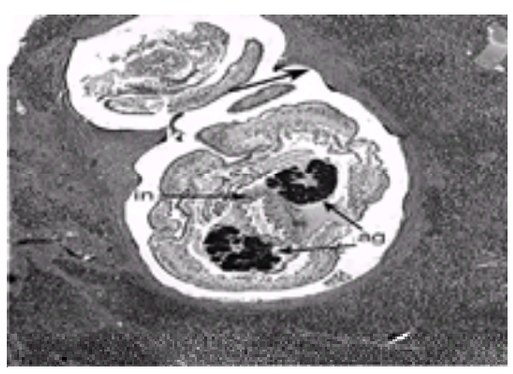

Fig. 4 Encysted nymph/larva of *Armillifer armillatus* in human liver. The outer layer of the parasite (arrowed) lines the cyst wall. Acidophilic glands (ag), intestine (in), 21 ×. (Armed Forces Institute of Pathology photograph, negative number 75–2703.)

Armillifer spp. infection is usually symptomless or causes vague abdominal pain. Serious inflammatory and obstructive effects have been described in the gut, lungs, biliary tract, pericardium, central nervous system, and anterior chamber of the eye. Severe acute reactions may be related to hypersensitivity or perhaps to massive infection such as might follow ingestion of a gravid female. Migration of large numbers of larvae from the gut into the tissue might produce abdominal pain and obstructive jaundice. A few fatal cases have been reported, including one patient who died from intestinal obstruction caused by nymphs of *A. armillatus*. It has been suggested (Nigeria and The Congo) that infection by *Armillifer* spp. might be associated with malignancy of the colon and elsewhere.

Other pentastomid infections

Human infections with *Leiperia cincinnalis* have been described in Africa, and subcutaneous infections by *Raillietiella gehyrae* and *R. hemidactyli* in Vietnam and by *Sebekia* species in Costa Rica. In Vietnam, infection with *Raillietiella* spp. follows the swallowing of small live lizards for medicinal purposes.

Diagnosis

The radiographical appearances of calcified pentastomid nymphs are distinctive (Fig. 3). Pentastomes may be discovered at surgery or autopsy. In the liver (Fig. 4), intestinal wall, mesentery, mesenteric lymph nodes, peritoneum, or lung, viable encysted larvae or granulomas containing necrotic pentastomes or their moulted cuticles may be identified. Initially, encysted larvae excite little or no tissue reaction, but the granulomas are surrounded by hyalinized or calcified fibrous tissue. In tissue sections, pentastomes can be distinguished from helminths. Antibodies to *Armillifer* spp. have been detected by fluorescence in infected patients.

Treatment

There is no specific treatment, although mebendazole has been suggested. Obstruction and compression should be relieved surgically. Hypersensitivity phenomena should be treated with adrenaline (epinephrine), antihistamines, and corticosteroids. Infections can be prevented if all meat is thoroughly cooked.

Other zoonoses transmitted from reptiles to humans

The most important of these is salmonellosis transmitted to humans by the faecal–oral route or by scratches and bites, from chelonians (tortoises, turtles, terrapins) and from snakes and lizards, especially iguanas. In Britain, 38 per cent of imported tortoises (*Testudo* species) contain *Salmonella* spp.; in the United States, where 8 million reptiles are kept as pets, 14 per cent of reported salmonellosis cases (280 000 per year) were attributable to pet terrapins, as were up to 17 per cent of cases of infant salmonellosis in Puerto Rico. The species include *S. typhimurium, S. muenchen, S. ealing, S. volta, S. alachua, S. stanley, S. marina, S. poona, S. pomona*, and *S. java*.

Other infections transmissible from reptiles to humans include *Arizona hinshawii* (in snake powder, Pulvo de Vibora, made from rattlesnakes), *Plesiomonas shigelloides, Edwardsiella tarda*, leptospirosis, Q fever, sparganosis, capillariasis, strongyloidiasis, mesocestoidiasis, and infestation with the mite *Ophionyssus natricis*. Potential zoonoses include *Mycobacteria, Pseudomonas*, other *Aeromonas* species, *Proteus* spp., and some togaviruses (such as western equine encephalitis in garter snakes in western North America) and herpesviruses.

7.19 Chronic fatigue syndrome (postviral fatigue syndrome, neurasthenia, and myalgic encephalomyelitis)

Michael Sharpe

Historical introduction

Illness characterized by chronic fatigue but without a clear pathological basis has a long history. In the nineteenth century it attracted a diagnosis of 'neurasthenia' but by the early twentieth century this diagnosis fell into disuse. It is probable that since that time patients have continued to present to doctors with similar symptoms but have received other diagnoses such as depression, brucellosis, and Epstein–Barr virus infection. Apparent epidemics of fatiguing illness have been occasionally reported over the last 50 years and attributed to infection by various agents. One occurred among staff at the Royal Free Hospital, London in 1955 giving rise to the term myalgic encephalomyelitis. More recently, it has become accepted that the cause of many cases of chronic disabling fatigue is not an infection. The purely descriptive term chronic fatigue syndrome was consequently introduced in 1988. The cause and treatment of chronic fatigue syndrome remain controversial.

Introduction

The terms chronic fatigue syndrome, postviral fatigue syndrome, neurasthenia, and myalgic encephalomyelitis have all been used to describe an idiopathic syndrome characterized by disabling fatigue occurring chronically after minimal exertion. The current international consensus definition is shown in Table 1. It is now clear that there is considerable overlap between chronic fatigue syndrome and other 'functional' syndromes such as irritable bowel syndrome and fibromyalgia.

- What is fatigue? Fatigue is an imprecise term with many meanings. In clinical medicine, the symptom of fatigue implies a subjective feeling of lack of both energy and endurance.
- When is fatigue abnormal? Fatigue after exertion is a normal phenomenon. It is abnormal when it is disproportionate to the exertion, persistent, and associated with impaired function.
- Why 6 months? Six months is used to define chronicity for purposes of research. It excludes the short-lived fatigue that can follow any illness.
- Which other symptoms? Patients with chronic fatigue syndrome commonly complain of additional symptoms, which are described below under clinical features.
- What conditions must be excluded? Chronic fatigue may be a symptom of many, if not most, medical and psychiatric illnesses. The term chronic fatigue syndrome has been reserved for patients in whom the fatigue remains medically unexplained or 'idiopathic' after clinical assessment.

Aetiology

No specific aetiology has been identified. However, a number of psychological and biological factors have been identified that may play a role in the onset and/or perpetuation of illness. It is likely that different and perhaps multiple factors operate in different cases.

Infection

Patients frequently give a history suggestive of acute infection at the outset. Fatigue states lasting several months can follow infections such as Epstein–Barr virus and Q fever. Infection may therefore trigger chronic fatigue syndrome, but the available evidence does not support the hypothesis that chronic infection is the cause of chronic fatigue syndrome.

Immune dysfunction

Minor immune abnormalities have been detected in a proportion of patients. Cytokines can cause fatigue. However, no consistent immune abnormality or casual link of these with symptoms has been established in patients with chronic fatigue syndrome. The role of immune factors remains of interest but is unclear.

Stress and emotional disorder

More than half of the patients seen in hospital clinics who meet criteria for chronic fatigue syndrome also meet criteria for depressive and anxiety disorders. Many patients describe major life stresses. It has therefore been suggested that at least some cases of chronic fatigue syndrome are due to emotional disorder that is expressed somatically (somatization). This is undoubtedly true in some cases, but in many others these syndromes are either absent or are an inadequate explanation of the illness.

Psychological and behavioural factors

There is evidence that psychological and behavioural factors play a role in perpetuating chronic fatigue syndrome. They include misconceptions about the nature of

the illness, excessive avoidance of physical activities so that the person becomes inactive, repeated seeking of (ineffective) medical care, and failure to resolve continuing psychological and social problems.

Inactivity

Some patients with chronic fatigue syndrome are profoundly inactive. This may lead to muscle wasting, changes in the cardiovascular response to exertion, and postural hypotension. The consequent intolerance of activity may perpetuate the illness.

Dysfunction of the central nervous system

Abnormalities have been found in tests of cognitive function. There is also evidence for abnormalities in neuroendocrine tests and in functional neuroimaging. However, abnormalities in similar domains have been found in patients with depression and anxiety disorders. Consequently the specificity and clinical utility of such tests remains to be established.

Endocrine dysfunction

A slightly reduced 24-h cortisol excretion has been reported. Replacement therapy with low-dose hydrocortisone has been reported to produce short-term symptomatic relief. However, the balance of risks and benefits of this treatment is not yet established.

Idiopathic postural hypotension (neurally mediated hypotension)

A tendency to postural hypotension has been reported in a proportion of patients with chronic fatigue syndrome. At present the aetiological and treatment implications of this observation remain unclear.

Sleep disorder

Various sleep abnormalities have been found in patients with chronic fatigue syndrome. They include both specific sleep disorders such as sleep apnoea syndrome and non-specific abnormalities such as fragmentation of sleep. These may contribute to daytime fatigue in at least some cases.

Social and iatrogenic factors

P>Information about chronic fatigue syndrome or myalgic encephalomyelitis, whether from doctors, patient groups, or the media, that leads patients to see their illness as mysterious with a hopeless prognosis and best treated by rest is likely to be unhelpful.

Epidemiology

Prevalence

One-quarter of the general population complain of persistent fatigue. In contrast, recent population studies in the United Kingdom and United States suggest that only approximately 0.5 per cent could be regarded as having chronic fatigue syndrome. Most of these persons are aged between 20 and 40 with a predominance of females. The syndrome is also seen in children and adolescents.

Epidemics

Epidemics of a chronic fatigue-like syndrome have been described from various parts of the globe. This observation is compatible with, but does not establish, an infective cause. It remains unclear whether these were true epidemics and also whether the clinical picture reported is similar to that of cases of sporadic chronic fatigue syndrome.

Pathogenesis

A number of explanations have been proposed (see section on aetiology above). These are best considered in the categories of predisposing, precipitating and perpetuating factors:

- Predisposing factors: Certain individuals may be predisposed to develop chronic fatigue syndrome by virtue of genetics, personality, or other vulnerability.
- Precipitating factors: The condition may be precipitated by factors such as infection or psychological stress (life events).
- Perpetuating factors: For practical management the most important factors are those that perpetuate the illness and consequently act as barriers to recovery. Perpetuating factors include the modifiable psychological and behavioural factors described above as well as biological factors.

Clinical features

Main symptoms

The principal symptom of chronic fatigue syndrome is chronic mental and physical fatigue, tiredness, or exhaustion that is exacerbated by activity. Patients often report being able to perform activities for brief periods, but subsequently experiencing severe fatigue for hours or days thereafter.

Other symptoms

Other common symptoms include muscular pain, unrefreshing sleep, dizziness and breathlessness, headache, tender lymph glands, and symptoms of irritable bowel syndrome. Patients often describe day-to-day fluctuations in their symptoms, irrespective of activity. Periods of almost complete recovery may be followed by relapse, often sufficiently severe to make normal daily activity impossible. Depression and anxiety are common, and a proportion of patients suffer panic attacks. Patients and their relatives may hold strong beliefs about the nature and aetiology of their illness (see section on aetiology), and these may be of importance when planning management.

Physical signs

Physical examination is typically unremarkable. Complaints of fever and lymphadenopathy are generally not confirmed on examination. The presence of definite physical signs (such as objectively measured fever) should not be ascribed to the syndrome and alternative diagnoses should be sought.

Differential diagnosis

Almost any disease may present with unexplained fatigue. The differential diagnosis of idiopathic chronic fatigue syndrome is correspondingly large (see Table 2). The nature of the fatigue may offer useful clues. Muscular disease should be considered if the patient has objective weakness, no psychological symptoms, and a family history. If the patient's complaint of fatigue includes prominent sleepiness, a sleep disorder should be considered. In particular, prominent snoring and morning headaches in the obese patient raise the possibility of obstructive sleep apnoea.

It is important to also assess the mental state. Depression is suggested by fatigue that is worse in the morning and accompanied by loss of motivation, interest, and pleasure. Other symptoms of depression should be sought including sadness, loss of appetite and weight, and feelings of pessimism and failure. If there is evidence of depression it is essential to ask about suicide plans. Chronic anxiety is also associated with fatigue and may also give rise to many of the somatic symptoms of

chronic fatigue syndrome such as muscle pain, impaired concentration, and poor sleep.

Pathology

There is no established pathology other than muscular and other changes associated with inactivity. Reports of abnormal structural brain scans have not been confirmed.

Laboratory diagnosis

There are no diagnostic tests and no characteristic abnormalities on laboratory investigation. These are conducted purely to exclude other diseases. All patients should have a full blood count, erythrocyte sedimentation rate or C-reactive protein, basic biochemistry screen, urine analysis, and possibly thyroid function and antinuclear antibody tests. Further investigation depends on the clinical findings and differential diagnoses under consideration.

Treatment

General management

The doctor should listen to the patient's story and ask about his or her own understanding of the illness in all cases. It is usually also worth seeing the partner or relevant family members. This provides opportunities to correct misconceptions. It is especially important to explain that the illness is not progressive or life threatening (see below). A more positive and less sinister explanation of chronic fatigue syndrome as a 'reversible dysfunction of the central nervous system' with a cautiously optimistic prognosis may be offered. The adverse physiological and psychological effects of prolonged bed rest should be explained if necessary. The patient should be encouraged to adopt a consistent but gradually increasing level of activity, avoiding extremes of both inactivity and exertion. An evidence-based self-help book may be useful (such as *CSF/ME: the facts*; see Further reading). An initial hospital appointment that achieves all the above usually requires at least 45 min.

Drug therapy

A trial of an antidepressant drug may be considered, especially if there is evidence of depression. It is advisable to choose a non-sedating type and to start with a low dose. Low doses of antidepressant drugs may reduce anxiety, improve the quality of sleep, and reduce pain. If there is evidence that the patient has a depressive disorder it is important to give an adequate dose for an adequate period.

Psychological aspects of care

Many patients have ongoing difficulties in their work or personal relationships. Whether contributors to or consequences of the illness, they may need help to improve their ability to cope with these. For some patients long-term follow-up provides an opportunity to encourage them to persevere with rehabilitation and to minimize the risk of multiple referrals and resulting iatrogenic harm from conflicting advice, repeated medical investigation, and failed attempts at treatment.

Rehabilitation and cognitive behavioural treatment

A systematic review has found that rehabilitative psychological therapy (cognitive behavioural therapy) is more effective than conventional management, with significant improvement rates of 60 per cent and 25 per cent respectively at 12 months. Two trials have suggested that supervised and gradually increased physical activity alone may be effective for willing patients. If available, a general hospital liaison psychiatry or psychology service may be best placed to offer treatment in a setting acceptable to the patient. General rehabilitation services are of value for chronic severe disability.

Other treatments

Many other treatments have been proposed but none has been adequately evaluated. Patients should be discouraged from pursuing unproven treatments unless they are part of a clinical trial.

Prognosis

The prognosis for functional recovery is relatively good for patients seen in general practice. It is poor for those severe enough to be referred to hospital clinics. A long history, multiple symptoms, and entrenched belief that the illness is irreversible predict a particularly poor prognosis. Effective treatment can improve the patient's ability to function. There is no mortality associated with chronic fatigue syndrome other than suicide, which may reflect unrecognized depressive illness.

Prevention

As the cause is unknown there is no specific primary prevention. Secondary prevention is important as it is likely that good early management and avoidance of iatrogenesis will reduce the risk of chronicity.

Other aspects

Occupational, quality of life, and psychological aspects

Chronic fatigue syndrome can be associated with a markedly reduced quality of life. Occupational issues are often prominent. Occupational stress may be an aetiological factor and having chronic fatigue syndrome makes it difficult to sustain employment. The ambiguous status of chronic fatigue syndrome as an accepted disease makes it especially difficult for patients with this diagnosis to negotiate with employers, insurers, and other agencies.

Areas of controversy

Almost all aspects of chronic fatigue syndrome are controversial. Most controversy has centred on whether it is most appropriately regarded as a medical or a psychiatric syndrome. This debate should be seen in the context of the stigma associated with psychiatric illness.

Areas needing further research

Further work is needed into both aetiology and treatment. In particular a refinement of the definition of the syndrome to enable the identification of more homogeneous groups will be important in developing effective treatment.

7.20 Infection in the immunocompromised host

J. Cohen

One of the most distressing experiences in medicine is to see a patient cured of a serious underlying disease only to die as a result of a complication of the treatment. While the benefits of immunosuppression have been enormous, there is no doubt that unwanted effects, and in particular serious infection, have proved to be a major drawback.

Classification

The term 'immunocompromised host' has no formal definition, but embraces a group of overlapping conditions in which the ability to respond normally to an infective challenge is in some way impaired. Nevertheless, it is helpful to think of such patients falling into one of four broad groups (Fig. 1).

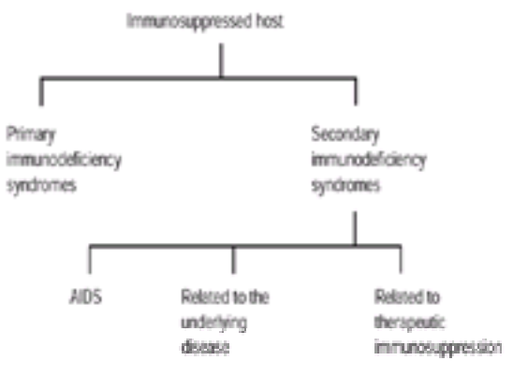

Fig. 1 A classification of the immunocompromised host.

Primary immunodeficiency syndromes

These are patients with congenital defects in immunity that render them more susceptible to infection. At the most extreme, children with severe combined immunodeficiency have virtually no functioning cellular or humoral immunity, and if unprotected will die from infection within a few months of birth. In contrast, some patients with chronic granulomatous disease, an inherited defect of neutrophil function, remain undiagnosed until early adult life. A complete description of the diagnosis and management of this group of disorders is given elsewhere.

Secondary immunodeficiency syndromes

AIDS

AIDS is a model for an acquired defect of immunity leading to an increased risk of infection. Although there are inevitably parallels with other groups of immunocompromised patients, there are particular issues both in the diagnosis and management of infection in AIDS that warrant separate discussion (see Chapter 7.10.21).

Infection related to the underlying condition

The notion of opportunistic infection in the immunocompromised host is most familiar with haematological malignancies or organ transplantation, discussed in detail below. Less obvious, but probably more numerous, are the many physiological conditions and other diseases associated with an increased incidence of infection (Table 1). These immune defects are usually mixed, and frequently poorly characterized, but the clinical problem is real enough. In malnutrition, for example, infection due to mycobacteria and *Salmonella* is more common, and *Pneumocystis carinii* pneumonia was first described in children with protein-calorie malnutrition. There is an extensive literature documenting multiple defects of host defence in association with alcohol abuse; clinically, this is reflected in an excess of lower respiratory tract infections with *Streptococcus pneumoniae*, *M. tuberculosis*, and *Klebsiella pneumoniae.* In Cushing's disease, the excess endogenous steroid production can result in a pattern of opportunistic infections that mirrors that seen in patients receiving steroid therapy (see below). Diabetes mellitus is good example of a disease that is frequently complicated by infection, typically with staphylococcal skin abscesses.

Patients who have had their spleen removed, or who have functional (or more rarely congenital) asplenia, are at increased risk of certain infections. The degree of risk is related to the underlying cause; overall, 4 to 12 per cent will suffer a serious infection, but this varies from 1.5 per cent following traumatic splenectomy to as high as 25 per cent in patients with thalassaemia. Serious infections are most common during the first 5 years following splenectomy, and particularly during the first year; recurrent infections occur in about 20 per cent of those affected. Approximately 50 per cent of infections are meningitis or bacteraemias, and most of the remainder are pneumonias (see Chapter 22.4.4).

In myeloma and chronic lymphocytic leukaemia the primary defect is hypogammaglobulinaemia, manifested clinically by an excess of bacterial infections, typically those caused by encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. These patients (and others, such as those with rheumatoid arthritis, systemic lupus erythematosus, or polyarteritis nodosa) all have impaired immunity as a consequence of their underlying disease, but because they also commonly receive treatment with immunosuppressive drugs it can be very difficult to attribute cause and effect.

Infection complicating therapeutic immunosuppression

In addition to the well-recognized risk groups such as those with haematological malignancy or allograft recipients, infective complications of immunosuppression are now being recognized in a much broader range of patients. Conditions as diverse as severe skin disease, asthma, inflammatory bowel disease, and rheumatoid arthritis are routinely treated with drugs such as prednisolone (typically at doses of 5 to 25 mg/day), azathioprine, cyclosporin, and cyclophosphamide. These patients are not so profoundly immunosuppressed as the recipient of a bone marrow transplant, but they are certainly at risk of opportunistic infections. Any failure to recognize the risk may mean that diagnosis is delayed.

Immunosuppressed patients have multiple risk factors; a recipient of a bone marrow transplant may have been neutropenic, receiving corticosteroids and cyclosporin

A for management of graft-versus-host disease, and have an indwelling right atrial catheter for feeding purposes. Clearly each of these factors represents a substantial and very different type of risk factor for infection, and it is important to remember that, in such patients, multiple pathogens can cause disease simultaneously. The following sections describe the management of some of the common clinical syndromes that present as infection in immunosuppressed patients.

Common clinical syndromes

A general approach to management

Infections in immunosuppressed patients can progress with frightening rapidity; the early physical signs are often muted and the microbiology can be confusing. Patients need to be reviewed frequently and will often need empirical therapy, but this need not be totally 'blind'; a structured and informed assessment will generally allow a logical response to what are the most likely pathogens.

The history

This may reveal exposure to community-acquired infections such as varicella zoster or tuberculosis, which can be particularly severe in the immunocompromised patient. Note should be made of any past history of infection; bronchiectasis, for instance, can be very troublesome in transplant recipients. A detailed travel history is important; patients who have visited certain parts of the United States may have been exposed to the systemic mycoses such as histoplasmosis or coccidioidomycosis, which are unfamiliar to many clinicians. Visitors to Central America or the Far East, even many years ago, may have acquired an asymptomatic infection with the helminth *Strongyloides stercoralis*; immunosuppression can lead to overt disease (the hyperinfection syndrome) with a high mortality (see below).

Physical examination

This may be unhelpful; immunosuppressed patients often do not mount a good inflammatory response. Thus there may only be a low-grade fever, a thin serous exudate may suffice for pus, and mild abdominal tenderness be the only sign of peritonitis. Nevertheless, careful, and if necessary repeated, clinical examination is worthwhile, as signs of inflammation may become apparent only when immune function returns. Particular attention should be paid to the presence of new skin lesions. In neutropenic patients bacteraemias may be accompanied by striking embolic lesions; *Pseudomonas* infections (and less commonly *Klebsiella* and *Aeromonas*) can cause a focal necrotic cellulitis called ecthyma gangrenosum. Fungal infections present as indolent, locally invasive lesions; *Aspergillus* infections often have a black eschar. The perianal area and the insertion sites of indwelling right atrial catheters repay careful examination. Aspiration and/or biopsy of any new skin lesion in immunosuppressed patients is well worthwhile, since it may quickly point to an otherwise inapparent diagnosis. Lymphadenopathy is always important and provides the opportunity for aspiration or biopsy. It is more usually seen as a feature of subacute or chronic complication of immunosuppression. It may be due to direct infection (for example tuberculosis), or as a manifestation of a lymphoproliferative condition secondary to Epstein–Barr virus. Post-transplant lymphoproliferative disease is emerging as one of the major causes of late death following renal transplantation.

Underlying disease

This can provide valuable clues. Neutropenia is a major risk factor for infection, conferring susceptibility to bacteraemias, particularly with Gram-negative organisms such as *Escherichia* and *Pseudomonas*. A patient with an obstructing bronchial neoplasm may develop a lung abscess due to inadequate drainage. Corticosteroids are used widely; when given in doses exceeding 15 to 20 mg daily for long periods they increase susceptibility to infections with viruses, fungi, parasites, and bacteria such as *M. tuberculosis*—all organisms normally associated with cellular immune defences.

Duration of immunosuppression

This often has a profound effect on the type of infection that occurs. This effect is well illustrated by comparing the 'timetables' of infections in renal transplant recipients with these receiving bone marrow transplants (Fig. 2). In the first 6 weeks after a renal transplant bacterial infections predominate, typically complicating the surgery or urinary infections. Between 6 weeks and 6 months post-transplant the patient is most at risk from the 'classical' opportunistic infections; as time continues and the intensity of immunosuppression declines, typical community-acquired infections become more common. In bone marrow transplantation, the initial period of neutropenia is characterized by bacterial infections; later, when many patients receive high-dose steroids for graft-versus-host disease, cytomegalovirus and fungal infections (*Candida* and *Aspergillus*) develop.

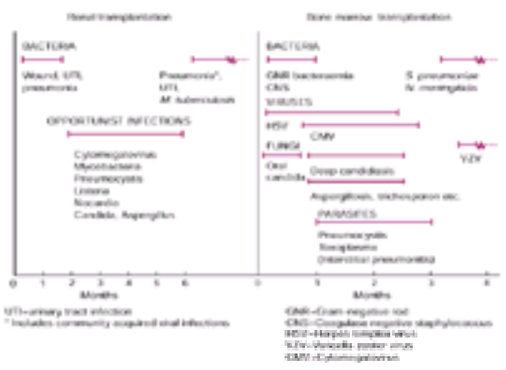

Fig. 2 A scheme representing a timetable for the development of infective complications in renal transplant and bone marrow transplant recipients.

Speed of progression

An assessment of this is helpful in both differential diagnosis and in deciding on empirical therapy. In neutropenic patients, the onset of fever is usually an indication for immediate empirical antibiotic therapy (see below). In contrast, the response to a fever and new pulmonary infiltrates in a patient 8 months after renal transplant will depend on the pace of the illness. Rapid deterioration over the space of a few hours will suggest a bacterial infection or a non-infectious cause, and will need urgent therapy; a more indolent presentation would point to a fungal or mycobacterial aetiology, and treatment can be delayed for a short period to try and establish the diagnosis.

Investigations

It is important that the diagnostic laboratories be made aware of the clinical problem, since handling of specimens from immunosuppressed patients—and interpretation of the results—will often differ substantially from routine procedures. In addition, routine screening of transplant recipients and donors should include serological tests for cytomegalovirus, hepatitis B, and HIV.

Pyrexia of unknown origin

In neutropenic patients, fever is often the first and only sign of bacteraemia, and prompt action is necessary. In this situation, a pyrexia of unknown origin is defined as a fever of over 38 °C sustained for 2 h, and not obviously due to an identifiable cause such as concomitant blood transfusion.

The risk of bacteraemia is directly related to the severity of neutropenia; the incidence is greatest at below 1×10^{9}/litre, and particularly when the count falls to less than 0.1×10^{9}/litre (Fig. 3). Some years ago, the commonest isolates were Gram-negative bacteria such as *E. coli* and *Klebsiella*, generally derived from the patient's gut flora, and *Ps. aeruginosa*, a common environmental pathogen, especially in hospitals. Gram-negative bacteraemia in neutropenic patients carried a very high mortality, and led to the introduction of a number of preventive strategies such as the use of prophylactic antibiotics and colony stimulating factors. Although these approaches have not been entirely successful, the incidence of Gram-negative bacteraemias has declined substantially, and in most units Gram-positive organisms,

notably coagulase negative staphylococci (*Staphylococcus epidermidis*) and viridans streptococci, are now the commonest isolates.

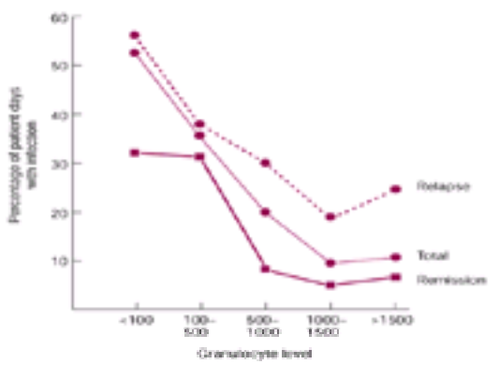

Fig. 3 The relationship between neutrophil count and the risk of invasive Gram-negative infection. (From Bodey G *et al*. (1966). *Annals of Internal Medicine* **64**, 328–40, with permission.)

The clinical features are entirely non-specific. Occasionally a focus will be suggested by erythema around the point of entry of an indwelling catheter, a finding often associated with staphylococcal infection. Septic shock is infrequent, although it can be associated with viridans streptococci; endocarditis is rare.

Blood cultures should be drawn before treatment is begun. Ideally two sets should be obtained, at least one of which should be from a peripheral vein (rather than an indwelling catheter), although this is not always possible. Culturing larger volumes of blood (for example 30 ml rather than the more conventional 10 ml) increases the yield. Appropriate samples must also be taken from other potential foci of infection. Nevertheless, it has been one of the enduring frustrations of this subject that even the most rigorous of microbiological investigations in the febrile neutropenic patient will yield only some 40 to 50 per cent of positive cultures. The explanation for this is unknown; some studies have suggested that it is due to endotoxaemia in the absence of bacteraemia, but the data are inconclusive. What is clear, however, is that treatment must begin before the results of the cultures are available; delay can kill.

The choice of the initial empirical antibiotic regimen for the febrile neutropenic patient has been the subject of intense investigation. The ideal regimen will be safe and have good bactericidal activity against all the common pathogens. No single regimen is perfect; much will depend on the availability (and cost) of antibiotics in a given institution, and on local patterns of antibiotic susceptibility. Well-validated regimens include the combination of an antipseudomonal penicillin plus an aminoglycoside (for example piperacillin plus gentamicin), or the use of single agents such as a third-generation cephalosporin (for example ceftazidime) or a penem such as meropenem. All these regimens are very active against the common Gram-negative organisms, but are relatively ineffective at treating Gram-positive bacteria such as coagulase negative staphylococci, nowadays a common problem. Unfortunately, the only drugs which are reliably active for these organisms are glycopeptides such as vancomycin, and some clinicians have advocated adding vancomycin to the initial empirical regimen. The disadvantage of this approach is the toxicity (and cost) of vancomycin, which may not be justified since unlike the Gram-negative infections, coagulase negative staphylococci rarely cause death. Several prospective clinical trials have concluded that vancomycin can usually be withheld until the results of blood cultures are known. An alternative strategy under investigation is to use a fourth-generation cephalosporin, such as cefepime, that has an improved spectrum of activity against Gram-positive bacteria while preserving good cover against Enterobacteriaceae and *Pseudomonas aeruginosa*.

In patients who respond to the initial regimen the treatment should be continued for at least 7 days, and ideally until the neutrophil count has returned to more than 0.5 × 10^9/litre. Sometimes this is not possible; the patient may have a persistent or unresponsive neutropenia (for example in aplastic anaemia or following bone marrow transplant). In these cases treatment is usually stopped cautiously after an arbitrary period such as 14 days; rebound bacteraemias will need further treatment.

A common problem is the patient who continues to have high swinging fevers in the absence of any obvious focus or positive microbiology. In this situation, deep fungal infection becomes more likely. The few clinical trials which have addressed this problem have concluded that persistent fever for 72 h should be treated by the addition of amphotericin B. For patients who are intolerant of amphotericin B or who develop nephrotoxicity, one of the liposomal formulations of the drug can be used; toxicity is greatly diminished and they are of at least equal efficacy, although they are extremely expensive.

Fever of unknown origin in the non-neutropenic immunosuppressed patient is a completely different problem. Fever in this situation is rarely immediately life-threatening, and since there is a wide differential diagnosis it is better to pursue the cause rather than embark on empirical therapy.

Fever and new pulmonary infiltrates

The development of fever and new pulmonary infiltrates is one of the most challenging clinical problems in this group of patients. Pneumonia is the commonest infective cause of death in immunocompromised patients. In the presence of diffuse airspace disease the mortality approaches 50 per cent irrespective of the underlying defect in host defence, although the epidemiology varies between different patient groups and with the intensity of the immunosuppression (Table 2).

The condition can progress extremely quickly, and conventional diagnostic procedures may be unhelpful. The list of possible causes is so daunting (Table 3) that clinicians can be tempted to use multiple empirical antimicrobial agents, sometimes to the patient's detriment. It is often not possible to 'guess' with any certainty the precise cause of the problem and multiple causes may be present. But considering the available information it may be possible to construct a 'short-list' to guide further investigation and treatment.

The initial evaluation should follow the approach outlined above, in particular making an assessment of the intensity of the immunosuppression and the speed of progression of the pulmonary disease. The main purpose is to determine the need for empirical therapy, either because the clinical picture is suggestive of a 'simple' bacterial pneumonia, or because of a potentially more serious, progressive cause of uncertain aetiology. Factors favouring bacterial aetiology include neutropenia, a rapidly developing clinical evolution (for example deterioration over a period of 12 h), progressive hypoxia, a sputum Gram stain showing a marked predominance of a single bacterial morphology (even in the absence of neutrophils), or a chest radiographic appearance that has worsened over a short period. High fever is not necessarily a part of this syndrome; it is important to emphasize that this rapidly evolving clinical picture is not inevitably due to infection. Non-infective causes such as acute lung haemorrhage or pulmonary oedema can present in an identical fashion, and the most appropriate therapy may be diuretics rather than antimicrobials. However, antimicrobials will often need to be given as well because of what has been termed 'infection-provoked relapse'. In immunologically mediated diseases such as systemic lupus erythematosus or antiglomerular basement membrane disease (Goodpasture's syndrome) infection can precipitate a relapse of the underlying disease. Thus, the development of fever and new pulmonary shadows in a patient with antiglomerular basement membrane disease may be primarily due to lung haemorrhage associated with a rise in antiglomerular basement membrane antibodies, but this in turn can be precipitated by an infection that need not necessarily be in the lung. Treatment must be directed both towards improving oxygenation and the underlying infection.

Blood cultures should always be obtained, and attempts made to obtain sputum. A chest radiograph and arterial blood gas analysis are essential. The initial treatment will be dictated by the clinical circumstances, but it is best to avoid a complex regimen to provide very broad spectrum cover. Rapid clinical deterioration is usually attributable to bacterial infections; if community acquired, a combination of an extended-spectrum cephalosporin plus erythromycin is appropriate. For hospital-acquired infections, a cephalosporin (combined with an aminoglycoside if there is strong evidence of *Pseudomonas* infection) is reasonable. Where staphylococcal infection is suspected, flucloxacillin plus an aminoglycoside should be used. Unusual ('opportunist') organisms such as mycobacteria, *Nocardia*, or cytomegalovirus rarely cause such a rapid clinical deterioration and are difficult to distinguish on clinical grounds alone. For these reasons, the addition of further empirical agents is usually not warranted.

In patients in whom immediate empirical therapy is not necessary, additional diagnostic procedures can be performed. These should include serological tests for atypical organisms, and examination of blood and urine for cytomegalovirus (tests for cytomegalovirus early antigen are very helpful). The chest radiograph should be repeated, but it is not as sensitive as arterial blood gas measurements, which should be done twice daily. The radiographic appearances are rarely sufficiently specific to suggest a precise diagnosis, although they can be suggestive. Thus a bilateral interstitial midzone infiltrate associated with marked hypoxia is typical of *Pneumocystis* pneumonia, and a pleural based infarct is suggestive of *Aspergillus*. However, there are pitfalls in relying on the radiographic appearance alone in

guiding the choice of therapy. First, no radiographic appearance is pathognomonic of any single pathological process; cytomegalovirus or pulmonary oedema can mimic *Pneumocystis* pneumonia, for example, and *Legionella* pneumonia cannot be distinguished from *Aspergillus*. Secondly, multiple agents can coexist, each requiring separate treatment. Other imaging techniques, such as computed tomography (**CT**), can often provide useful additional information on the extent of the process, and will sometimes point to the cause (for example the 'halo sign' associated with invasive aspergillosis).

It is often appropriate to try and make a specific diagnosis by obtaining material directly from the bronchial tree. In most cases the method of choice is bronchoscopy with bronchoalveolar lavage. This will provide adequate material without incurring a serious risk of bleeding (many such patients are thrombocytopenic) or pneumothorax. In most series, bronchial brush or transbronchial biopsy specimens produce only a marginal increase in the diagnostic yield, and are usually not done unless the clinical picture is suggestive of a non-infective process such as an infiltrating tumour. The highest yield is from open lung biopsy, but this should not usually be done as a first-line procedure.

Acute neurological syndromes

A large number of conventional and opportunist pathogens can lead to neurological infection in immunocompromised patients. Although there is some degree of overlap, the underlying defect in host defence is a often a good indicator of the likely cause (Table 4).

The clinical features may help suggest the diagnosis. Meningitic syndromes are more likely to be associated with conventional bacterial infections, listeriosis, and tuberculosis, as well as fungi such as *Cryptococcus* and *Candida*. In contrast, infections with *Toxoplasma*, *Aspergillus*, or *Nocardia* more commonly present as space-occupying lesions. Pure encephalitic syndromes are less common, but can occur with herpes simplex. Rhinocerebral mucormycosis is a progressive, destructive infection caused by *Mucor* and related moulds, that usually begins in the paranasal sinuses and spreads caudally to involve the orbits or the frontal lobes of the brain. It is seen particularly in patients with uncontrolled diabetes mellitus or as a complication of neutropenia.

Bacterial infections generally proceed rapidly, while fungi and parasites pursue a more indolent course. However, exceptions to this are common, and there is no substitute for obtaining a precise diagnosis. Examination of the skin (see below) and fundoscopy may be valuable. Retinitis is not usually a feature of systemic infection with toxoplasma or cytomegalovirus; in contrast, *Candida* endophthalmitis may be the only manifestation of deep-seated infection.

Examination of the cerebrospinal fluid is mandatory. A high index of suspicion is necessary, since the clinical features of meningitis are often muted in these patients. An unexplained low-grade fever and mild headache may be the only clues; frank meningism, photophobia, or focal neurological signs occur late. Examination of the cerebrospinal fluid should include direct microscopy (neutrophil, lymphocyte, or eosinophil pleocytosis) and culture for (myco)bacteria and fungi, a cryptococcal latex agglutination test, antigen tests for pneumococcus, and a search for specific antibody production (for example for coccidioidomycosis) or DNA sequences by the polymerase chain reaction (for example for herpes simplex and papovaviruses).

Some organisms are rarely seen by direct microscopy: Mycobacteria are seen in fewer than 10 per cent of cases, *Nocardia* and *Aspergillus* only very rarely. A predominance of lymphocytes suggests partially treated bacterial infection, tuberculosis, or a viral aetiology but not infection with *Listeria*, despite its name. A low cerebrospinal fluid glucose points to tuberculosis but is not specific. Sometimes the only abnormality is a modest elevation of the cerebrospinal fluid protein; this should never be ignored, even in the seeming absence of other features of neurological infection. Where appropriate, cytological examination of the cerebrospinal fluid should be done to exclude carcinomatous or leukaemic meningitis, which can mimic an acute infective presentation.

Certain neurological infections are often associated with pulmonary disease; these include *Legionella*, tuberculosis, *Aspergillus*, *Mucor*, and *Nocardia*. A brain CT scan, which should be contrast-enhanced, is valuable. Focal, usually enhancing, lesions are particularly associated with pyogenic abscesses and toxoplasmosis. Tuberculomas can appear as single lesions. Magnetic resonance imaging is better then CT scanning for detecting abnormalities of the brainstem (for example the basal meningitis associated with cryptococcal infection), and frequently reveals lesions in toxoplasmosis which are not seen on CT scans. It may pre-empt the need for brain biopsy when a diagnosis of progressive multifocal leucoencephalitis is considered.

Any new skin lesions should be biopsied. Nasal biopsy may reveal *Mucor*. An electroencephalogram is not helpful, unless herpes encephalitis is suspected. Brain biopsy is done rarely; it should not be considered unless empirical therapy has failed, or there is a real prospect of therapeutic benefit to the patient.

If the cerebrospinal fluid is non-diagnostic but bacterial infection cannot be excluded, empirical antibiotics should be given immediately. An extended spectrum cephalosporin such as cefotaxime is suitable. Serological tests for toxoplasmosis are not specific in this setting, and if the infection is suspected it is better to start empirical therapy with pyrimethamine and sulphadiazine. Cerebral aspergillosis and mucormycosis have a very poor prognosis; treatment should be begun with high-dose amphotericin B, and surgical debridement considered if possible. There is no effective treatment for progressive multifocal leucoencephalitis.

Acute gastrointestinal syndromes

The organisms associated with specific gastrointestinal syndromes in these patients are shown in Table 5.

Severe stomatitis is a common complaint in immunosuppressed patients. The three commonest causes: *Candida*, herpes simplex, and chemotherapy-induced mucositis are clinically indistinguishable and indeed can coexist and cause disease together. For these reasons, the diagnosis should always be confirmed by microscopy and culture. Herpetic stomatitis in particular can be atypical in these patients; the classical appearance of groups of small vesicles is unusual, and a more common presentation is ulceration, which can be extensive. In profoundly immunosuppressed patients such as bone marrow transplant recipients, oral candidiasis is very common, and in patients who are seropositive before transplant, reactivation of herpes simplex is almost universal. For these reasons, prophylaxis is usually given. Both herpes simplex and *Candida* can cause oesophagitis, generally (but not exclusively) as an extension of oral disease. Oesophagoscopy with brush cytology and/or biopsy is the investigation of choice. Proven oesophageal candidiasis should be regarded as 'invasive' disease and treated with systemic antifungals (amphotericin B or fluconazole).

A large number of organisms can cause acute diarrhoeal syndromes; in addition, non-infective conditions such as radiation enteritis, drugs, and graft-versus-host disease must be included in the differential diagnosis. There are no distinguishing clinical features of note, and diagnosis depends on microbiological examination of the faeces.

The diarrhoea caused by *Clostridium difficile* is usually due to a pseudomembranous colitis. However, patients with leukaemia or aplastic anaemia may develop neutropenic enterocolitis (previously called typhlitis), a fulminating invasive colitis characterized by diffuse dilation and oedema of the bowel walls, haemorrhage, ulceration, and a high mortality. Classically this has been associated with clostridial bacteraemia, in particular *C. septicum*, but other clostridia, including *C. difficile*, and even Gram-negative bacteria, can also be found.

Strongyloides stercoralis is a nematode that can be carried asymptomatically for many years after exposure (see Chapter 7.14.4). Strongyloidiasis has been recognized as a complication of HTLV-I infection, and also occurs secondary to immunosuppression (typically with high-dose steroids and in recipients of solid organ transplants). A rise in the worm burden results in the hyperinfection syndrome, which may present as pneumonitis or intermittent intestinal obstruction. Worms moving through the gut wall can carry with them enteric bacteria, resulting in polymicrobial bacteraemias and Gram-negative meningitis when the worms invade the cerebrospinal fluid.

Giardiasis is particularly associated with hypogammaglobulinaemia, and curiously is rarely seen in other groups. *Cryptosporidium*, *Microsporidia*, and *Isospora* are now well recognized causes of severe and sometimes chronic diarrhoea in AIDS patients, but may also occur in other less severely immunocompromised patients. Among the viruses, the most difficult problem is cytomegalovirus. Cytomegalovirus can cause a severe colitis, and in these cases ganciclovir is beneficial. The diagnosis should be confirmed by biopsy, but ultimately may depend on the result of a therapeutic trial since demonstration of the organism does not necessarily indicate that it is causing disease.

Mild abnormalities of liver function tests are a common accompaniment of many systemic infections, but hepatitis is a particular feature of both toxoplasmosis and cytomegalovirus infection. An increased prevalence of hepatitis B has been found in patients on chronic haemodialysis (10 per cent), and those with Hodgkin's disease (8 per cent) and lepromatous leprosy (20 per cent). The acute hepatitic episode is mild, often anicteric, and may pass unnoticed. However, persistent viral replication (hepatitis e antigenaemia) and the development of complications associated with chronic infection are more likely. Although it is likely that infection with the

other hepatitis viruses occurs in immunosuppressed patients there are as yet no detailed clinical or epidemiological data that define the problem.

A particular form of systemic candidiasis has been called chronic hepatosplenic candidiasis (although other organs can be involved, and the syndrome is better referred to as chronic systemic candidiasis). The patient presents with unremitting fever and occasionally abdominal pain; palpable hepatomegaly is unusual. Typically the neutrophil count has returned to normal after a recent course of chemotherapy for acute leukaemia; the liver function tests show a markedly raised alkaline phosphatase and there may be hyperbilirubinaemia, but microbiological investigations (including blood cultures) are negative. The diagnosis is made by ultrasonography or CT scan of the abdomen, which reveals multiple intrahepatic (or less commonly splenic) abscesses. Unfortunately biopsy of these lesions reveals histological or culture evidence of *Candida* in only about a third of cases. Treatment has been difficult; conventional therapy with amphotericin B (even with the addition of flucytosine) has often failed, but the use of a liposomal formulation of amphotericin B and fluconazole has produced encouraging results.

8.1 Poisoning by drugs and chemicals

A. T. Proudfoot and J. A. Vale

Introduction

In the minds of most people, not least those of doctors, the term poisoning suggests an acute event demanding immediate care and attention. This is often so, but poisoning may take other forms. The consequence is not always immediate even after a single dose—so-called acute poisoning. Prolonged uptake may result in accumulation, as with many heavy metals, and the damage may arise only after prolonged exposure—that is, chronic poisoning.

Exposure by oral, inhalational, cutaneous, or other routes, should not itself be equated with poisoning. Uptake is necessary for there to be a toxic effect, and even if this occurs, poisoning does not necessarily result, as the amount absorbed may be too small.

If true poisoning does occur, the ensuing clinical syndrome may be distinctive. For example, fixed dilated pupils, exaggerated tendon reflexes, extensor plantar responses, depressed respiration, and cardiac tachyarrhythmias suggest tricyclic antidepressant poisoning. Anaemia, constipation, colic, and motor nerve palsies are indicative of lead poisoning. However, with a whole range of psychotropic medications there may be only non-specific central nervous depression, respiratory impairment, and hypotension. In some instances, distinctive sequelae may not appear until many years have elapsed as, for example, with carcinoma of the

oesophagus following ingestion of corrosives or hepatic haemangiosarcoma from vinyl chloride exposure.

Poisoning may be accidental or deliberate. It is usually accidental in small children, but in adults it is invariably deliberate with parasuicidal, suicidal, or rarely, homicidal intent.

Thus, the medical approach to poisoning should never be confined to the poison and its effects. All the circumstances surrounding the episode must be taken into account, especially in cases where litigation may follow, for example in the event of an occupational mishap with a chemical. It is therefore important that the doctor concerned, having instituted any necessary life-saving measures, should take a careful history, retain all pertinent evidence such as suicide notes and biological specimens, and make a meticulous record of symptoms, signs, progress, and outcome.

Epidemiology

Few health-care professionals would deny that poisoning, accidental or deliberate, is a common problem in most countries throughout the world. Yet it is remarkably difficult to obtain reliable statistics on the morbidity or mortality it causes, even in countries with comparatively advanced systems for collection of population health data. In the developing world, about 600 000 deaths/year are attributed to deliberate self-harm, the majority from poisoning with pesticides such as organophosphorus insecticides. The following observations are based primarily on statistics from the United Kingdom and the United States but, wherever appropriate, observed variations in patterns of poisoning in other countries are noted.

Hospital admissions due to poisoning

Poisoning from accidental or deliberate ingestion or inhalation of drugs or chemicals is a common acute medical emergency requiring hospital admission. In the period 1957 to 1976, the annual number of hospital admissions due to acute poisoning in England and Wales rose steadily from less than 20 000 to more than 125 000. Since then, there has been a decline in the incidence of self-poisoning in England to approximately 100 000 admissions each year. Despite this decline, self-poisoning still accounts for more than 10 per cent of acute adult medical admissions in the United Kingdom. However, the true incidence of self poisoning may be as much as three times that of the hospital admission rate.

In the United Kingdom, with the exception of young children, females predominate in all age groups in those admitted to hospital because of acute poisoning and there is a marked preponderance in those aged 15 to 44 years. Many paediatric episodes are poisoning scares, rather than true poisonings, though this often only becomes clear in retrospect. The majority of adults who poison themselves are not suicidal.

In Western Europe and North America, drugs have always been the most common agents taken by adults and rank second only to household products as the substances most often ingested by children. In the United Kingdom, alcohol is taken in addition to the drug overdose in 60 per cent of males and 40 per cent of females, and at least one-third of self-poisoning episodes involve one or more drugs. Approximately two-thirds of adults ingest drugs that have been bought in retail outlets or prescribed for themselves or a close relative. Therefore, the pattern of pharmaceutical agents used for self-poisoning reflects prescribing habits (particularly for illnesses occurring in those aged 15 to 44 years) and common symptoms that are self-treated. Barbiturate and non-barbiturate hypnotics are now seldom encountered causes of poisoning, while use of other psychotropic agents such as the benzodiazepines, tricyclic antidepressants, and selective serotonin-specific reuptake inhibitors in overdose is now more frequent; analgesic poisoning also occurs much more commonly than previously.

Within Europe there are variations from country to country. In Finland, for example, alcohol, cardiovascular drugs, and psychotropics are the most common causes of poisoning. Outside Europe, and in developing countries in particular, the situation is often very different. In Sri Lanka, for example, agrochemicals account for nearly 60 per cent of all poisonings; such agents account for less than 1 per cent of hospital admissions for poisoning in England and Wales. In South Africa, the pattern of poisoning in the white population mirrors that in North America and Western Europe, whereas that observed in black South Africans is very different, with kerosene (paraffin) and traditional medicines accounting for the majority of hospital admissions (and deaths) attributable to poisoning. In countries where malaria is prevalent, poisoning by antimalarials is an additional cause of morbidity and mortality.

Deaths from poisoning

The number of deaths from poisoning is to some extent determined by the lethality of the agents involved. This, in turn, results in regional differences with rates that are often much higher in developing countries.

In contrast to the rise in the number of hospital admissions for poisoning in England and Wales, deaths from acute poisoning have decreased over the last 40 years and, since 1972, they have remained virtually constant at 4000 per annum. The lack of change over the last 30 years is particularly striking because this period follows the substitution of 'natural gas' for 'town gas', which led directly to a fall in carbon monoxide deaths from nearly 4000 in 1963 to just over 1000 per annum 10 years later.

Despite relatively little change in the overall mortality statistics for acute poisoning in England and Wales, there have been very substantial changes in the agents responsible. Deaths from barbiturate and non-barbiturate hypnotics have fallen, while those due to analgesics and psychotropic agents have risen. Deaths from carbon monoxide have shown a slow but steady increase since 1975, reaching just over 1500 in 1991. Increasing numbers of young men (14 to 24 years) in the United Kingdom are killing themselves. Self-poisoning with car exhaust fumes (containing carbon monoxide) is currently the most common means of doing so.

In England and Wales, about 80 per cent of individuals who die as a result of poisoning do so at home, the inpatient mortality being less than 1 per cent of all cases admitted to hospital. The age and sex distribution of deaths attributed to acute poisoning is significantly different from that for admissions—there are fewer patients in the age range 15 to 44 years and more in the older age categories where males predominate. A similar pattern of causes of death has been observed elsewhere in Western Europe and in North America, but in many developing agricultural countries, agrochemicals (cholinesterase inhibitors, paraquat, aluminium phosphide, and other pesticides) more commonly predominate. On a global scale, it has been estimated that pesticides account annually for 1 million serious unintentional poisonings and 2 million people admitted to hospital for suicide attempts, predominantly in developing countries.

Childhood poisoning

It is estimated that in the United Kingdom as many as 41 000 poison exposures occur in children aged 4 years or less each year. In the United States, the Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Centers for 2000 records 1 142 796 poison exposures in children less than 6 years of age.

Children aged less than 5 years are particularly active and exploratory and have a strong impulse to put things into their mouths. These characteristics predispose to accidental poisoning, which in Western Europe is particularly likely to occur when parents are inattentive or neglectful, as at times of family crises. The vast majority (80 to 85 per cent) of cases occur in the child's own home, and in many instances the substances involved are out of their usual storage place or have been put into some other container; grandparents, for example, may find it convenient to remove drugs from child-resistant closures or leave the caps off containers because they themselves have difficulty opening this type of packaging.

A child may also be poisoned by an adult who administers a toxic substance by mistake, and rarely a parent or carer may poison a child as a form of abuse, sometimes with fatal consequences. In addition, older (typically 10 to 16 years) emotionally disturbed children may deliberately poison themselves. Abuse of volatile substances is a continuing problem in adolescents.

Diagnosis

Ideally, the diagnosis of acute poisoning requires that the doctor establish the chemical composition of the poison, the magnitude of the exposure, and the route of exposure (whether by ingestion, injection, inhalation, or skin contamination), so that the features likely to develop can be anticipated and the risk assessed. As in any other branch of medicine, diagnosis of acute poisoning is based on the patient's history and on a combination of circumstantial evidence, the findings on physical examination, and appropriate investigations when a history is not available. However, in acute poisoning, there are many obstacles to establishing the information required. Young children may not be able to give a history and adults are often unreliable while physical signs are rarely diagnostic. Similarly, circumstantial evidence may not be available, be only tentative or misleading, and laboratory diagnosis can never be fully comprehensive.

History

Since accidental poison exposure in childhood is most common between the ages of 9 months and 5 years, an unequivocal history is unlikely to be forthcoming from the victim but may be obtainable from older witnesses. Clearly, however, statements about amounts must be interpreted with caution since knowledge of the quantities in original containers is frequently inaccurate or unknown.

In contrast, 90 per cent or more of adults presenting with acute poisoning are conscious or only slightly drowsy and there would seem little reason why diagnosis of self-poisoning on the basis of the history should be difficult. Indeed, while a small number of patients adamantly deny having taken a poison, the majority usually admit to it without hesitation, although problems often arise in trying to establish precisely the nature and quantity of what has been taken. Comparison of patients' statements with the agents detected by laboratory analysis of blood or urine consistently reveals major differences in about half the cases. In consequence, patients are often thought to be deliberately untruthful. However, surprise at these findings may merely reveal a lack of medical insight into the circumstances under which self-poisoning occurs. It is commonly an impulsive act; the patient ingests the contents of the first bottle that comes to hand, often when under the influence of alcohol. Moreover, although about 60 per cent of episodes involve drugs prescribed for the victims or their relatives, like many other patients, they are often ignorant of their names.

If these considerations make it difficult to establish the nature of the poison, it is hardly surprising that they should make the amounts involved even more suspect. Few patients count the number of tablets they consume and it is impossible for patient or doctor to know what constitutes a 'handful', 'bottleful', or similar arbitrary quantity.

Circumstantial evidence

Circumstantial evidence becomes important in the diagnosis of acute poisoning when patients are either unable to give a history (for example young children, adults who have severe learning difficulties or who are demented, and unconscious patients) or are unwilling to do so. However, although circumstantial evidence may strongly suggest poisoning, it is seldom incontrovertible. It takes several forms.

Circumstances under which found

The mother may return to the kitchen or bathroom to find her child with some substance all over his hands, face, and clothing, or surrounded by pills, one of which he is eating. The assumption that more has been ingested may or may not be correct and the amount swallowed is a matter of speculation. Similarly, adults may be found unconscious with tablet particles around the mouth or on clothing as the only clue to diagnosis. More often, the presence of empty drug containers with occasional tablets or capsules nearby suggests the diagnosis. Less commonly, they are found unconscious or dead in some remote location. The lack of personal effects to indicate who they are or where they live may suggest a desire not to be identified and should arouse suspicion of drug overdosage. Self-poisoning is a common cause of coma in previously healthy young adults. Protestations by relatives that patients would never take overdoses are usually wrong.

Suicide notes

Suicide notes are reliable indicators of drug overdose in the absence of physical violence as a cause of coma. The note may specify what has been taken in addition to expressing despair, futility, worthlessness, and remorse.

Features

There are few symptoms or physical signs that cannot be attributed to one poison or another. However, a clinical feature rarely arises in isolation and clusters of features are of much greater diagnostic value. Those most commonly encountered in present-day practice are given in Table 1.

Conscious patients with abnormal behaviour, who may be experiencing auditory and visual hallucinations, may have ingested amphetamines, phencyclidine, LSD (lysergic acid diethylamide), 'magic' (psilocybin-containing) mushrooms, and drugs such as the older antihistamines and tricyclic antidepressants that have marked anticholinergic actions. Occasionally a patient with severe salicylate intoxication, who cannot give a history despite being conscious, is hyperventilating, sweating, flushed, and tachycardic, suggesting a diagnosis which can then be confirmed analytically.

Drowsiness, ataxia, dysarthria, and nystagmus are common after ingestion of benzodiazepines. Coma with hypotonia and hyporeflexia may follow, particularly if alcohol has also been taken. Hypotension, hypothermia, and respiratory depression are rare. All of these features, however, may occur after overdosage with outmoded drugs such as barbiturates, methaqualone, meprobamate, and ethchlorvynol that are still occasionally prescribed. In present-day clinical practice, tricyclic antidepressants remain among the most common central nervous system (**CNS**) depressants encountered in overdose. They cause hypertonia, hyperreflexia, extensor plantar responses, and dilated pupils. Sinus tachycardia and prolongation of the QRS interval on the electrocardiogram support a diagnosis of intoxication with these drugs. Hypotension and hypothermia are less common features. Tricyclic antidepressants and non-steroidal anti-inflammatory agents, particularly mefenamic acid, are the most common causes of seizures after drug overdosage. Coma with pinpoint pupils and a reduced respiratory rate is virtually diagnostic of overdosage with opioid analgesics and is an indication for a therapeutic trial of naloxone. Many patients with opioid poisoning will be habitual drug abusers and have venepuncture marks and evidence of venous tracking in the antecubital fossae. Alcohol may be smelt on the breath, as may solvents such as toluene, acetone, or xylene as the result of 'sniffing' glues, cleaning agents, or other preparations. Skin blisters occur in poisoning by many drugs (see below) but rarely in coma due to other causes. Burns around the lips or in the buccal cavity or pharynx indicate ingestion of corrosives, including paraquat.

Lateralizing neurological signs

Since most serious poisonings are associated with impairment of consciousness, neurological signs are particularly important. Lateralizing signs (unless they are attributable to a known neurological disease) virtually exclude a diagnosis of acute poisoning. Such findings have been recorded with barbiturate and phenytoin overdose but so rarely that the general rule is not significantly compromised. A possible exception is transient inequality of pupil size. This has been reported only rarely in acute poisoning but is not an uncommon finding in normal individuals (for instance due to Holmes–Adie pupils); clinical experience suggests that it occurs more frequently in poisoning than seems apparent from the literature.

Decerebrate and decorticate movements

Unconscious poisoned patients may respond to painful stimuli with flexor and extensor limb movements of the type seen in decorticate and decerebrate states. However, in poisoning, these signs do not indicate irreversible brain damage and patients showing them can be expected to recover fully. Hypoglycaemia must be excluded in these cases.

Strabismus, and internuclear and external ophthalmoplegia

A variety of ocular signs including strabismus, internuclear ophthalmoplegia, and total external opthalmoplegia, may be found in acutely poisoned patients. They are also features of Wernicke's encephalopathy in chronic alcohol abusers.

Strabismus has been described in poisoning with phenytoin, carbamazepine, and tricyclic antidepressants. Usually the optic axes diverge in the horizontal plane but in some patients there is additional vertical deviation. It is present transiently and only in patients who are unconscious. Dysconjugate, roving eye movements may also be seen if both eyes are observed for a period of time. It is important to know that such abnormalities occur so that they are not misattributed to intracranial vascular lesions or some other pathology requiring surgical intervention.

Dysconjugate eye movements may become apparent only when vestibulo-ocular reflexes are examined by caloric stimuli. Installation of ice-cold water into the external auditory meatus should make both eyes turn to the side irrigated and failure of one eye to deviate is evidence of internuclear ophthalmoplegia and a lesion of the medial longitudinal fasciculus. This has been reported in poisoning with a variety of drugs including tricyclic antidepressants, phenothiazines, benzodiazepines, barbiturates, and ethanol and can be detected in 10 per cent of cases if caloric tests are carried out. Both sides are usually affected but internuclear ophthalmoplegia also occurs on one side only in acute poisoning.

In some cases, cold-induced lateral eye movements are followed after an interval of 5 to 15 s by forced downward gaze lasting several minutes, but the suggestion that the latter may be diagnostic of drug-induced coma requires further study before acceptance.

It is widely accepted that absence of oculocervical (abnormal 'doll's eye' responses) and vestibulo-ocular responses indicates severe brainstem damage and the likelihood that the patient will not

survive. However, this is not the case in acute poisoning where these reflexes may be abolished in patients who subsequently make a full recovery.

Management

Antidotes and methods to enhance elimination are available for very few poisons. Management of most poisoned patients is based on what has been called 'an orderly if unspectacular regimen of supportive therapy'.

Immediate treatment

A small but important number of poisoned patients arrive at hospital with respiratory obstruction, ventilatory failure, or in cardiorespiratory arrest. In these cases, conventional resuscitation takes precedence over detailed assessment of the patient and attempts to obtain a history. The opioid antagonist, naloxone, can be of inestimable value in emergency treatment. It is safe and should be used whenever there is the slightest suspicion that an opioid may be involved. Its use may transform a desperate situation for the better within seconds and even if it is given inappropriately, it is unlikely to have adverse effects.

Unconscious patients need scrupulous attention to respiration, hypotension, hypothermia, and other complications if they are to survive. Expert nursing is as important as medical measures.

Airway

Establishing and maintaining an adequate airway is of paramount importance in the management of the unconscious poisoned patient. The tongue falling back, dental plates being dislodged, other foreign bodies, buccal secretions, vomitus, and flexion of the neck may obstruct the airway. In the first instance, the neck should be extended and the tongue and jaw held forward. Secretions in the oropharynx must be removed and an oropharyngeal airway should be inserted before turning the patient into a semiprone position. If the cough reflex is absent, an endotracheal tube should be inserted to prevent aspiration into the lungs and allow regular aspiration of bronchial secretions. It is then important to ensure that the inspired air is adequately warmed and humidified.

Ventilation

Once a clear airway has been established the adequacy of spontaneous ventilation should be assessed from the results of arterial blood gas and pH measurements. These should be carried out in all patients who are unconscious irrespective of the presence or absence of features suggesting inadequate gas exchange. Unconscious poisoned patients often have a mild, mixed respiratory and metabolic acidosis with carbon dioxide tensions at the upper limit of normal and oxygen tensions that fall with increasing depth of coma. Increasing the oxygen content of the inspired air is often sufficient to correct hypoxia. Patients with acute respiratory failure should have an endotracheal tube inserted to reduce the respiratory dead space and thereby increase alveolar ventilation. If this does not reduce carbon dioxide tensions, assisted ventilation is indicated. High-inspired oxygen concentrations are imperative in patients with carbon monoxide and cyanide poisoning and in pulmonary oedema resulting from inhalation of irritant gases.

Hypotension

Hypotension in acute poisoning can be due to a variety of factors including a relative reduction in the intravascular volume secondary to expansion of the venous capacitance bed, metabolic acidosis, arrhythmias, the cardiodepressant effects of some drugs, and blood or fluid loss into the gut. Correct management of individual cases obviously depends on accurate identification of the causes. Young patients are generally not at risk of cerebral or renal damage unless the systolic blood pressure falls below 80 mmHg, but in those over the age of 40 years it is preferable to keep the systolic blood pressure above 90 mmHg. Hypotension often responds to elevation of the foot of the bed by 15 cm and, if this is unsuccessful, a central venous line should be inserted and the intravascular volume expanded as necessary. Dobutamine 2.5 to 10 µg/kg.min or adrenaline (epinephrine) at 1 to 10 µg/kg.min are indicated if hypotension is resistant to these measures.

Arrhythmias

Although many poisons are potentially cardiotoxic, the incidence of serious cardiac arrhythmias in acute poisoning is very low. Tricyclic antidepressants, b-adrenoceptor blocking drugs, chloral hydrate, cardiac glycosides, amphetamines, cocaine, bronchodilators (particularly theophylline and its derivatives), and antimalarial drugs are the most likely causes. Cardiotoxicity usually occurs together with other features of severe poisoning including metabolic acidosis, hypoxia, convulsions, respiratory depression, and abnormalities of electrolyte balance that should be corrected before considering the use of antiarrhythmic drugs. The latter have narrow therapeutic ratios and their use may further impair myocardial function. In general, drug therapy should only be given for persistent, life-threatening arrhythmias associated with peripheral circulatory failure. The drug used must be selected from a knowledge of the pharmacology and toxicology of the poison involved and in such a way that it will not further compromise cardiac function. Lignocaine is probably the drug of choice for clinically important ventricular tachydysrhythmias since its half-life is short and the dose can be adjusted readily.

Convulsions

Convulsions are potentially life-threatening because they cause hypoxia and metabolic acidosis and may precipitate cardiac arrhythmias and arrest. Short isolated convulsions do not require treatment but those that are recurrent or protracted should be suppressed with diazepam intravenously 10 mg in an adult, repeated as necessary. This drug is highly effective in adequate doses and alternatives are seldom needed. However, it is important to remember that giving benzodiazepines in this way may potentiate the respiratory depressant effects of other poisons and further complicate management. The combination of convulsions, coma, and vomiting, which may occur with overdosage of theophylline derivatives, is particularly dangerous and in these circumstances it may be preferable to paralyse the patient, insert an endotracheal tube, and start assisted ventilation. However, although this ensures control of the airway and oxygenation, thus avoiding the risk of inhalation of gastric contents, it does not suppress seizure activity; cerebral function must therefore be monitored and parenteral anticonvulsants given as required.

Hypothermia

Any poison that depresses the central nervous system may impair temperature regulation and cause hypothermia, especially when discovery of the patient is delayed and environmental temperatures are low. This important complication may be missed unless temperature is recorded rectally using a low-reading thermometer. In severe cases, peripheral and core temperatures should be monitored. Treatment includes nursing the patient in a warm room (27 to 29°C) and a heat conserving 'space blanket'. Cold intravenous fluids should be avoided and bottles for use should be stored in the room or the lines should pass through a heating device.

Hyperthermia

Rarely, body temperature may increase to potentially fatal levels after overdosage with central nervous system stimulants such as cocaine, amphetamines, phencyclidine, monoamine oxidase inhibitors, butyrophenomes, and theophylline and its derivatives. In such cases, muscle tone is often grossly increased and convulsions and rhabdomyolysis are common. Cooling measures, including administration of chlorpromazine, may be indicated and dantrolene should be given to reduce muscle tone.

Acid–base abnormalities

Acid–base disturbances commonly accompany coma due to drugs. Acute respiratory acidosis is less common than might be expected but some elevation of arterial carbon dioxide tensions towards the upper limit of normal is usual. This, in combination with mild hypoxia in the deeper grades of coma, produces overall acidaemia. In general, acidosis should be prevented and managed by ensuring adequate ventilation, oxygenation, and tissue perfusion, and control of convulsions rather than by giving bicarbonate. However, a number of poisons, particularly methanol and ethylene glycol, cause life-threatening metabolic acidosis, which should be corrected by infusion of sodium bicarbonate.

Acute respiratory alkalosis, often in combination with a minor metabolic acidosis, is commonly found in acute salicylate poisoning. The metabolic component may require treatment if it is the dominant feature and is causing overall acidaemia. Respiratory alkalosis should not be treated.

Electrolyte abnormalities

Electrolyte abnormalities may result from acid–base disturbances or the direct effects of poisons. Massive tissue damage, usually rhabdomyolysis, may allow potassium to leak from cells leading to potentially lethal hyperkalaemia. Cardiac glycosides cause hyperkalaemia secondary to loss from cells due to inhibition of the membrane sodium–potassium pump while the reverse occurs with sympathomimetic drugs. Ingestion of potassium salts, even in sustained release formulations, may lead to hyperkalaemia and fatal arrhythmias. Oxalic acid and ethylene glycol (which is metabolized to oxalic acid) may cause hypocalcaemia by leading to the formation of insoluble calcium oxalate that is deposited in tissues. Similarly, ingestion of fluorides is also a possible cause of hypocalcaemia, but the amounts children tend to ingest in the form of tablets to prevent dental caries seldom cause serious problems.

Bladder care

Urinary retention is a common complication of acute poisoning, particularly with tricyclic antidepressants and other drugs that have marked anticholinergic actions. However, bladder catheterization is all too often an unthinking measure in unconscious poisoned patients. Coma *per se* is not an indication for catheterization in poisoned patients, the great majority of whom regain consciousness within 12 h. The bladder can usually be induced to empty reflexly (provided it is not allowed to become grossly overdistended) by applying gentle suprapubic pressure. Catheterization should be reserved for those patients in whom suprapubic pressure is insufficient to empty the bladder, and in those thought to be developing renal failure.

Skin, muscle, and nerve lesions

Skin blisters may be found after poisoning with a wide variety of drugs including barbiturates, tricyclic antidepressants, and benzodiazepines, and non-drug toxins. They often occur over bony prominences that have been subjected to pressure and less frequently at sites where two skin areas have been in contact, such as the the inner aspects of the knees. They should be managed as partial thickness burns. Rhabdomyolysis is a further possible result of immobility and may occur in combination with skin lesions or independently. Drug overdose is the most common non-traumatic cause of this condition and it may lead to acute renal failure and, rarely, to ischaemic muscle contractures and long-term disability. Similarly, peripheral nerves such as the radial, ulnar, and common peroneal may be damaged by direct pressure while the patient is unconscious or by being entrapped in fibrosing muscle after rhabdomyolysis.

Antidotes

Naloxone for opioid analgesics, oxygen for carbon monoxide, and possibly, flumazenil for benzodiazepines are the only antidotes commonly needed in the management of unconscious poisoned patients. *N*-Acetylcysteine is used frequently for paracetamol poisoning. Other antidotes of proven value are listed in Table 2. They are seldom required and although their use in correct circumstances may be lifesaving, some are toxic in their own right and the reader is recommended to seek further advice from a poisons information service. Antivenoms for bites and stings by venomous animals are discussed in Chapter 8.2.

Reduction of poison absorption

Prevention of absorption of poisons through the lungs obviously requires removal from the toxic atmosphere and occasionally removal of soiled clothing as well. The latter is also necessary when absorption is thought to have been percutaneous. In addition, the contaminated skin should be thoroughly washed with soap and water.

While it appears logical to assume that removal of unabsorbed drug from the gastrointestinal tract ('gut decontamination') will be beneficial, the efficacy of current methods remains unproven and efforts to remove small amounts of 'safe' drugs are clearly not worthwhile or appropriate. The two major international societies of clinical toxicology (American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists) have produced Position Statements on each method. The Position Statements are summarized below.

Gastric lavage

Gastric lavage should not be employed routinely in the management of poisoned patients. In experimental studies, the amount of marker removed by gastric lavage was highly variable and diminished with time. There is no certain evidence that its use improves clinical outcome and it may cause significant morbidity. Gastric lavage should not be considered, therefore, unless a patient has ingested a potentially life-threatening amount of a poison and the procedure can be undertaken within 1 h of ingestion. Even then, clinical benefit has not been confirmed in controlled studies. Unless a patient is intubated, gastric lavage is contraindicated if airway protective reflexes are lost. It is also contraindicated if a hydrocarbon with high aspiration potential or a corrosive substance has been ingested.

Syrup of ipecacuanha

Syrup of ipecacuanha should not be administered routinely in the management of poisoned patients. In experimental studies the amount of marker removed by syrup of ipecacuanha was highly variable and diminished with time. There is no evidence from clinical studies that syrup of ipecacuanha improves the outcome of poisoned patients and its administration, even in children, should be abandoned. In particular, syrup of ipecacuanha should not be administered to a patient who has a decreased level or impending loss of consciousness as aspiration pneumonia might ensue. In addition, it should not be administered to a patient who has ingested a corrosive substance or hydrocarbon with high aspiration potential.

Single-dose activated charcoal

Single-dose activated charcoal should not be administered routinely in the management of poisoned patients. Based on volunteer studies, the effectiveness of activated charcoal decreases with time; the greatest benefit is within 1 h of ingestion. The administration of activated charcoal may be considered if a patient has ingested a potentially toxic amount of a poison (which is known to be adsorbed to charcoal) up to 1 h previously; there are insufficient data to support or exclude its use after 1 h of ingestion. However, there is no evidence that the administration of activated charcoal improves clinical outcome. Unless a patient has an intact or protected airway, the administration of charcoal is contraindicated.

Cathartics

The administration of a cathartic alone has no role in the management of the poisoned patient and is not recommended as a method of gut decontamination. Experimental data are conflicting regarding the use of cathartics in combination with activated charcoal. No clinical studies have been published to investigate the ability of a cathartic, with or without activated charcoal, to reduce the bioavailability of drugs or to improve the outcome of poisoned patients. Based on available data, the routine use of a cathartic in combination with activated charcoal is not endorsed. If a cathartic is used, it should be limited to a single dose in order to minimize adverse effects.

Whole bowel irrigation

Whole bowel irrigation should not be used routinely in the management of the poisoned patient. Although some volunteer studies have shown substantial decreases in the bioavailability of ingested drugs, no controlled clinical trials have been performed and there is no conclusive evidence that whole bowel irrigation improves the outcome of the poisoned patient. Based on volunteer studies, whole bowel irrigation may be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs. There are insufficient data to support or exclude its use for potentially toxic ingestions of iron, lead, zinc, or packets of illicit drugs, but it remains a theoretical option for these ingestions. Whole bowel irrigation is contraindicated in patients with bowel obstruction, perforation, ileus, and in patients with haemodynamic instability or a compromised airway. Whole bowel irrigation should be used cautiously in debilitated patients, or in patients with medical conditions that may be further compromised by its use.

Methods to increase poison elimination

Once a poison has been absorbed and providing there is no antidote, it is reasonable to consider the use of treatments that might speed its elimination from the body. Formerly, forced diuresis, peritoneal and haemodialysis, charcoal haemoperfusion and, less commonly, plasmapheresis were the techniques employed most commonly. In recent years, however, it has been shown that multiple doses of oral activated charcoal given over many hours significantly shortened the plasma half-life of many drugs, at least in volunteers.

Forced diuresis

In the past, forced diuresis enjoyed extensive use in the treatment of acute poisoning if only because it did not require special equipment and could be instituted rapidly and in any hospital. However, there was considerable ignorance of its rationale and its use for many poisons was not justified. The efficacy of forced diuresis depends on the poison being excreted unchanged by the kidney or as an active metabolite. However, most drugs are either degraded by the liver to non-toxic metabolites or have such large volumes of distribution that there is insufficient active drug elimination in urine for forced diuresis to be of any clinical value as the amount removed is insignificant compared with that removed by hepatic metabolism. Urine pH is more important than urine flow and in recent years there has been a trend away from forcing a diuresis (i.e. infusing large volumes of fluid) to attempting to alter urine pH alone.

Urine alkalinization

Most drugs are partly reabsorbed from the urine as it flows through the renal tubules. Reabsorption is confined to unionized, lipid-soluble molecules. Increasing the concentration of ionized drug in the urine should reduce reabsorption and further enhance elimination. This is achieved by manipulating urine pH. Thus, rendering the urine alkaline enhances elimination of weakly acidic compounds such as salicylates, phenobarbital, chlorpromamide, fluoride, and phenoxyacetate herbicides such as 2,4-D and mecoprop.

In practice, inducing an alkaline urine is only used in cases of poisoning due to salicylates and phenoxyacetate herbicides as phenobarbital poisoning may be treated effectively with multiple-dose activated charcoal.

Before alkalinizing the urine, it is important to correct plasma volume depletion and electrolyte and metabolic abnormalities. Sodium bicarbonate, most conveniently administered as an 8.4 per cent solution (1 mmol bicarbonate/ml), is infused intravenously to ensure that the pH of the urine, which is measured by narrow-range indicator paper or a pH meter, is more than 7.5 and preferably close to 8.5.

As urine alkalinization is a metabolically invasive procedure requiring frequent biochemical monitoring, and medical and nursing expertise, it should be performed in a critical care area.

Acid diuresis

Although, theoretically, induction of an acid diuresis should increase the elimination of basic drugs such as amphetamines, there is seldom any need to use it and no evidence that it is of value in cases of poisoning.

Multiple doses of oral activated charcoal

Multiple doses of activated charcoal aid the elimination of some drugs from the circulation by interrupting their enterohepatic circulation and adsorbing that which diffuses into the intestinal juices. The rate of transfer of the latter is dependent upon the blood supply to the gut, the area of mucosa available for transfer, and the concentration gradient of the drug across the mucosa. The adsorptive capacity of charcoal is such that zero drug concentrations are present in luminal fluid and that the diffusion gradient remains as high as possible. The process has been termed 'gut dialysis' since, in effect, the intestinal mucosa is being used as a semipermeable membrane.

The American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists have published a Position Statement on multiple-dose activated charcoal. This confirms that although many studies in animals and volunteers have demonstrated that multiple-dose activated charcoal increases drug elimination significantly, this therapy has not yet been shown in a controlled study in poisoned patients to reduce morbidity and mortality. Further studies are required to establish its role and the optimal dosage regimen of charcoal to be administered.

Based on experimental and clinical studies, multiple-dose activated charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. In all of these cases there are data to confirm enhanced elimination, though no controlled studies have demonstrated clinical benefit.

Although volunteer studies have demonstrated that multiple-dose activated charcoal increases the elimination of amitriptyline, dextropropoxyphene, digitoxin, digoxin, disopyramide, nadolol, phenylbutazone, phenytoin, piroxicam, and sotalol, there are insufficient clinical data to support or exclude the use of this therapy in patients poisoned with these drugs.

The use of multiple-dose charcoal in salicylate poisoning is controversial. One animal study and two of four volunteer studies did not demonstrate increased salicylate clearance with multiple-dose charcoal therapy. Data in poisoned patients are insufficient at present to recommend the use of multiple-dose charcoal therapy for salicylate poisoning.

Multiple-dose activated charcoal did not increase the elimination of astemizole, chlorpropamide, doxepin, imipramine, meprobamate, methotrexate, phenytoin, sodium valproate, tobramycin, and vancomycin in experimental and/or clinical studies.

Unless a patient has an intact or protected airway, the administration of multiple-dose activated charcoal is contraindicated. It should not be used in the presence of intestinal obstruction. The need for concurrent administration of cathartics remains unproven and is not recommended. In particular, cathartics should not be administered to young children because of their propensity to cause fluid and electrolyte imbalance.

In conclusion, based on experimental and clinical studies, multiple-dose activated charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.

Recommended adult doses of charcoal for this purpose are 50 to 100 g initially, followed by 50 g 4-hourly or 25 g 2-houly until charcoal appears in the faeces or recovery occurs.

American Academy of Clinical Toxicology/European Association of Poisons Centres and Clinical Toxicologists (1997/1999). Position Statem*Journal of Toxicology—Clinical Toxicolog* **35**, 699–762; **37**, 731–51.

Dialysis

Haemodialysis in acute poisoning is indicated most commonly for the treatment of acute renal failure and only infrequently to increase the elimination of poisons. The rate of elimination across the dialysis membrane depends upon a number of variables including the molecular weight of the poison, the extent to which it is protein bound, the concentration gradient, and pH of blood and dialysate. Haemodialysis is of little value in patients who ingest poisons with large volumes of distribution (such as tricyclic antidepressants) because the plasma contains only a small proportion of the total amount of drug in the body. Haemodialysis is indicated in patients with severe clinical features and high plasma concentrations of salicylate, lithium, methanol, isopropanol, ethylene glycol, and ethanol. Peritoneal dialysis increases the elimination of poisons such as ethylene glycol and methanol but is much less efficient than haemodialysis.

Haemoperfusion

Haemoperfusion involves the passage of blood through an adsorbent material that retains the poison. Activated charcoal is the most popular adsorbent. Within 4 to 6 h haemoperfusion can reduce significantly the body burden of compounds with a low volume of distribution (less than 1 litre/kg). The technique effectively removes barbiturates, carbamazepine, disopyramide, ethchlorvynol, glutethamide, meprobamate, methaqualone, theophylline, and trichloroethanol derivatives. However, there is now evidence that multiple-dose activated charcoal is as effective as haemoperfusion in phenobarbital, carbamazepine, and theophylline poisoning, and is simpler to use. Furthermore, barbiturate and non-barbiturate hypnotics are now prescribed only rarely.

Acetone

Acetone is a clear liquid with a characteristic pungent odour and sweet taste, used widely in industrial and household products. Once absorbed either through the lungs, skin, or gut, acetone is exhaled unchanged or metabolized to carbon dioxide.

Clinical features

Acetone has an irritating effect on the mucous membranes of the eyes, nose, and throat. Intoxication results in headache, excitement, restlessness, chest tightness, incoherent speech, nausea, and vomiting. Occasionally, gastrointestinal bleeding, coma, and convulsions have been reported.

Treatment

If toxicity has followed inhalation, remove from exposure and give supportive treatment. After ingestion, gut decontamination is not useful.

International Programme on Chemical Safety (1998). *Environmental Health Criteria 207. Acetone*. World Health Organization, Geneva.

Acids

Acids commonly involved in cases of poisoning include the inorganic acids such as hydrochloric, hydrofluoric, nitric, phosphoric, and sulphuric acids; and organic acids such as acetic, formic, lactic, and trichloroacetic acids. Car battery acid typically contains 28 per cent sulphuric acid. Proprietary cleaning agents and antirust compounds often contain a mixture of hydrochloric and phosphoric acids.

Clinical features

On the skin acids behave characteristically as corrosives leading to erythema and burns. In the eyes, intense pain and blepharospasm are common, and corneal burns may occur. When ingested, acids flow rapidly along the lesser curvature of the stomach to the prepyloric region where they pool because of spasm of the pylorus and antrum to cause almost instantaneous coagulative necrosis of one or more layers of the stomach. In many cases, acids spare the oesophagus because of rapid transit and resistant squamous epithelium.

There is immediate pain in the mouth, pharynx, and abdomen, intense thirst, vomiting, haematemesis, and diarrhoea. The pain and mucosal oedema cause dysphagia and drooling saliva. Gastric and oesophageal perforation may occur resulting in chemical peritonitis. Other effects include hoarseness, stridor, and respiratory distress secondary to laryngeal and epiglottic oedema, shock, metabolic acidosis, leucocytosis, acute tubular necrosis, renal failure, hypoxaemia, respiratory failure, intravascular coagulation, and haemolysis.

Hydrofluoric acid ingestion causes chelation of calcium, with resultant weakness, paraesthesiae, tetany, convulsions, cardiac arrhythmias, and disturbed coagulation.

Treatment

Acid burns to the skin should be irrigated liberally with water or saline. Dressings are applied as for a thermal burn. Skin grafting may be necessary.

After ocular exposure, the eye should be irrigated preferably with saline for 15 to 30 min. Topical local anaesthetic is usually required to relieve pain and to overcome blepharospasm. Ophthalmic advice should be sought.

After ingestion a clear airway should be established. Opioids are often necessary for analgesia. Dilution and/or neutralization is contraindicated. Urgent panendoscopy is needed and resection of necrotic tissue and surgical repair should be undertaken to ensure survival, particularly if inorganic acids have been ingested. Total parenteral nutrition is often required. Corticosteroids confer no benefit and may mask abdominal signs of perforation; antibiotics should be given for established infection only.

Acid ingestion may result in antral, pyloric, or jejunal strictures, achlorhydria, protein-losing enteropathy, and gastric carcinoma.

Alkalis

Those commonly encountered in cases of poisoning include drain, lavatory, and pipe cleaners (sodium hydroxide), dishwashing detergents (sodium carbonate, sodium silicate, sodium tripolyphosphate), denture cleaning tablets (sodium perborate, sodium phosphate, sodium carbonate), urinary glucose testing tablets (sodium hydroxide), water sterilizing tablets (sodium dichloroisocyanurate), alkaline batteries, and sodium hypochlorite (a bleaching agent).

Clinical features

The features of eye, skin, and laryngeal contamination with alkalis are similar to those produced by acids (above). When ingested, alkalis typically damage the oesophagus but usually spare the stomach. There is little immediate oral discomfort but subsequently a burning sensation develops in the mouth and pharynx, together with epigastric pain, vomiting, and diarrhoea. Oesophageal ulceration with or without perforation may occur with mediastinitis, pneumonitis, cardiac injury, and aorto-enteric fistula formation as secondary complications of perforation.

Treatment

The treatment of corrosive injuries caused by alkalis is largely the same as for those produced by acids.

Corticosteroids do not alter the incidence of stricture formation but may decrease the need for surgical repair of strictures if they are used in conjunction with either anterograde or retrograde oesophageal dilation. Methylprednisolone at a dose of 40 mg intravenously 8-hourly in adults or prednisolone at 2 mg/kg per day intravenously can be given, until oral intake is resumed, when an equivalent dosage of prednisolone is given orally and tapered off over a period of 3 to 6 weeks. A broad-spectrum antibiotic, such as amoxicillin, should be prescribed at the same time as the corticosteroid.

Alkali ingestion may result in stricture formation and there is a risk of malignancy. The mean latent period for development of carcinoma of the oesophagus following alkali ingestion is more than 40 years.

a-Chloralose

a-Chloralose is marketed as cereal baits containing 4 per cent rodenticide, while technical a-chloralose (about 90 per cent pure) is used against moles and is occasionally encountered in self-poisoning episodes. The toxic amount for an adult is approximately 1 g and for an infant, 20 mg/kg body weight.

Clinical features

Toxic amounts of a-chloralose cause severe CNS excitation with hypersalivation, increased muscle tone, hyperreflexia, opisthotonus, and convulsions. Rhabdomyolysis is a potential complication. Coma, generalized flaccidity, and respiratory depression may follow.

Treatment

No treatment is required for ingestion of a-chloralose baits. Supportive measures are necessary when large amounts of bait or the technical compound is involved. Gastric emptying should not be carried out since the stimulation may provoke seizures.

Further reading

Thomas HM, Simpson D, Prescott LF (1988). The toxic effects of a-chloralose. *Human Toxicology* **7,** 285–7.

Aluminium (aluminum)

Aluminium hydroxide is used as an antacid and as a phosphate binder in the management of chronic renal failure. Aluminium sulphate is employed in water purification and paper manufacture. Aluminium may be absorbed orally and by inhalation. More than 90 per cent of absorbed aluminium is bound to transferrin. Though some accumulates in brain tissue, most body aluminium is stored in bone and the liver. It is excreted mainly via the kidneys.

Clinical features

Acute poisoning

Ingestion of a significant quantity of soluble aluminium salts such as aluminium sulphate gives rise to burning in the mouth and throat, nausea, vomiting, diarrhoea, abdominal pain, hypotension, seizures, haemolysis, haematuria, and rarely, hepatorenal failure. Topical aluminium sulphate may be irritant to the skin and eyes. By contrast, insoluble aluminium salts, such as aluminium oxide, do not produce an acute toxic response.

Chronic poisoning

Inhalation of 'stamped aluminium powder' can cause a persistent cough and breathlessness due to lung fibrosis or occupational asthma. Workers involved in aluminium production may be at increased risk of developing lung cancer.

'Dialysis dementia' involves the accumulation of aluminium, mainly in the brain (‹Section 20).

Aluminium has also been implicated in Alzheimer's disease and may contribute to osteomalacia in renal osteodystrophy. It may cause contact allergy.

Treatment

Desferrioxamine (deferoxamine) forms a stable complex with aluminium and mobilizes aluminium primarily from bone with subsequent urinary elimination of the chelate. Theoretically 100 mg of desferrioxamine can bind 4.1 mg of aluminium. As desferrioxamine is absorbed poorly from the gastrointestinal tract, parenteral therapy is preferred.

The desferrioxamine chelate is dialysable and all published clinical studies of aluminium chelation using desferrioxamine have involved patients in renal failure undergoing either dialysis or haemofiltration. Haemofiltration is probably superior to haemodialysis in enhancing aluminium elimination using desferrioxamine. As the aluminium–desferrioxamine chelate concentration reaches a maximum 12 to 24 h postinfusion, desferrioxamine should be administered shortly before dialysis for maximum benefit.

There is clinical evidence that desferrioxamine can improve aluminium-induced encephalopathy, bone disease, and anaemia in patients on dialysis. Desferrioxamine should therefore be prescribed when features of dialysis encephalopathy are present, when there is an increased body aluminium load, and there is clinical evidence of aluminium-related bone disease. In addition, desferrioxamine should be considered in the presence of severe, transfusion-dependent anaemia even in the absence of characteristic clinical or analytical features of aluminium overload. It has also been proposed that desferrioxamine should be employed in the presence of an increased (greater than 60 µg/l) serum aluminium concentration.

Conventionally, desferrioxamine at 40 to 80 mg/kg has been administered once weekly as a subcutaneous or intravenous infusion, reduced to 20 to 60 mg/kg when treatment is required for several months. However, recent studies suggest that desferrioxamine 5 mg/kg once weekly is an adequate alternative regime.

Aluminium and zinc phosphides

Aluminium and zinc phosphides react with moisture in the air and the gastrointestinal tract to produce phosphine (see below), a gas with a garlic-like odour.

Clinical features

Exposure to phosphine causes lacrimation, rhinorrhoea, cough, breathlessness, chest tightness, dizziness, nausea, and drowsiness. Pulmonary oedema may develop later. Ingestion of aluminium phosphide causes vomiting, epigastric pain, peripheral circulatory failure, severe metabolic acidosis, and renal failure in addition to many of the features induced by inhalation of phosphine.

Treatment

Treatment is symptomatic and supportive. Gastric lavage should be considered if the poison has been ingested within 1 h.

Gupta S, Ahlawat SK (1995). Aluminium phosphide poisoning: a review. *Journal of Toxicology—Clinical Toxicology* **33**, 19–24.

Ammonia

Ammonia, a colourless gas with a strong irritating odour, is used in aqueous solution in industry and in the home.

Clinical features

Ammonia may be absorbed by inhalation, ingestion, or percutaneously. It irritates the eyes, upper respiratory tract, and pharynx. Exposed surfaces may develop chemical burns, blisters, thrombosis of surface vessels, and severe local oedema that may lead to respiratory obstruction and death, if the larynx and glottis are involved. Inhaled high concentrations may cause dyspnoea, pulmonary oedema, and persistent lung damage.

Treatment

The casualty should be removed from the contaminated area. The eyes should be irrigated with water or 0.9 per cent saline for 15 to 30 min and an ophthalmic opinion sought as permanent blindness may result. Pulmonary complications should be treated with humidified supplemental oxygen, bronchodilators, and if necessary, assisted ventilation with positive end-expiratory pressure. Although widely employed, there is no conclusive evidence that diuretics and corticosteroids alter the prognosis. Patients who survive for 24 h are likely to recover fully.

Amfetamines and ecstasy (MDMA)

Amfetamine, dexamfetamine, methamfetamine, and 'ecstasy' (3,4-methy-lenedioxymethamfetamine, MDMA) stimulate the central nervous system. Poisoning with them is usually the result of their use for pleasurable purposes rather than single massive doses.

Clinical features

These drugs cause increased alertness and self-confidence, euphoria, extrovert behaviour, increased talkativeness with rapid speech, lack of desire to eat or sleep, tremor, dilated pupils, tachycardia, and hypertension. More severe intoxication is associated with excitability, agitation, paranoid delusions, hallucinations with violent behaviour, hypertonia, and hyperreflexia. Convulsions, rhabdomyolysis, hyperthermia, and cardiac arrhythmias may also develop. In severe cases of MDMA poisoning, hyperthermia, disseminated intravascular coagulation, rhabdomyolysis, acute renal failure, and hyponatraemia are observed. Hepatic damage has also been reported. Rarely, poisoning due to amphetamines may result in intracerebral and subarachnoid haemorrhage and acute cardiomyopathy; these complications may be fatal. Hyperthyroxinaemia may be found in chronic amphetamine users.

Treatment

Gastric lavage should be considered if a substantial overdose has been ingested in the preceding 1 h. Sedation with diazepam, chlorpromazine, or droperidol may be required. b-Adrenoceptor blocking drugs will antagonize the peripheral sympathomimetic actions of amphetamines.

Angiotensin-converting enzyme (ACE) inhibitors

Clinical features

Anorexia, nausea, abdominal discomfort, headache, and paraesthesiae have been reported. In addition, hypotension (which may be mediated by the endogenous opioid system), sinus tachycardia, bronchospasm, and hyperkalaemia may develop. Fatalities have been reported.

Treatment

Gastric lavage or activated charcoal administration should be considered if the patient presents within 1 h of a substantial overdose. Supportive therapy should then be employed, including volume expansion with plasma expanders for hypotension. Naloxone in a dose of 0.8 to 1.2 mg may reverse ACE inhibitor-induced hypotension. Marked hyperkalaemia may require an intravenous infusion of glucose (50 g) and soluble insulin (15 units).

Antibacterial agents

Most patients develop no symptoms and require no treatment. Transient nausea, vomiting, and diarrhoea may occur. There have been rare reports of renal failure after overdosage with co-trimoxazole, pancreatitis with erythromycin, and haemorrhagic cystitis with amoxicillin.

Anticholinergic substances

Anticholinergic substances are occasionally abused. Plants have been used for this purpose for many years.

A large number of drugs currently used in medicine also have anticholinergic properties and have been misused. They include antihistamines, particularly cyclizine, antiparkinsonian drugs such as benzhexol (trihexyphenidyl), benzatropine, orphenadrine, biperiden, and tricyclic antidepressants (see below).

Anticoagulant rodenticides

Warfarin was widely used as a rodenticide until target species developed resistance to it. The newer anticoagulant rodenticides such as brodifacoum, bromodialone, chlorophacinone, coumatetralyl, difenacoum, diphacinone, and flocoumafen are more potent antagonists of vitamin K$_1$ than warfarin and reduce the synthesis of clotting factors II, VII, IX, and X. In the case of short-acting formulations, such as those containing warfarin, prolongation of the International Normalized**INR**) will be evident within 24 h and patients can remain anticoagulated for several days. In contrast, the ingestion of the more potent anticoagulant rodenticides may result in prolongation of the INR for weeks or months.

Clinical features

Gastrointestinal bleeding, haematuria, and bruising are the commonest features, though the most common site of fatal haemorrhage is intracranial.

Treatment

If the patient is not receiving an anticoagulant therapeutically, is not bleeding, and if the INR is more than 8, give vitamin K$_1$ (phytomenadione) in a dose of 5 mg slowly intravenously. If there is active bleeding give prothrombin complex concentrate at 50 units/kg (or fresh frozen plasma 15 ml/kg if the concentrate is not available) and vitamin K$_1$ 5 to 10 mg intravenously. Treatment may be required for several weeks in the case of the more potent anticoagulant rodenticides. The INR should be monitored for at least 2 weeks after stopping vitamin K$_1$ therapy. If the patient is receiving warfarin therapeutically see below under Warfarin for further discussion.

Antihistamines

First-generation antihistamines include brompheniramine, chlorpheniramine (chlorphenamine), cyclizine, diphenhydramine, mepyramine, methapyrilene, promethazine, and trimeprazine. Second-generation drugs include astemizole and terfenadine. The toxicity of the two groups varies.

Clinical features

The older antihistamines have anticholinergic actions and their effects are therefore similar to the tricyclic antidepressants (see below) although convulsions, coma, respiratory depression, arrhythmias (other than sinus tachycardia), and death are rare.

Astemizole and terfenadine lack anticholinergic actions but are cardiotoxic causing Q_c interval prolongation and ventricular tachycardia, including the *torsade de pointes* type. Associated giant U waves have been described. Terfenadine in overdose can cause convulsions.

Treatment

Gastric lavage may be undertaken or oral activated charcoal may be given if the patient presents less than 1 h after the ingestion of a substantial overdose of a first-generation antihistamine. The patient should be observed for about 12 h with cardiac monitoring if the Q–T interval is prolonged. Intravenous magnesium sulphate may abolish serious ventricular arrhythmias.

Antiparkinsonian drugs

Amantadine, benzhexol, and orphenadrine have anticholinergic effects in overdosage. Orphenadrine is probably the most toxic and has caused deaths.

Clinical features and treatment

The features of poisoning are similar to those of the tricyclic antidepressants and should be managed in the same way.

Further reading

Jones AL, Proudfoot AT (1997). The features and management of poisoning with drugs used to treat Parkinson's disease. *Quarterly Journal of Medicine* **91**, 613–16.

Antiseptics and disinfectants

Once these solutions commonly contained phenol but phenol has been replaced largely by small quantities of either chlorophenol or chloroxylenol which, although less toxic than phenol, can be hazardous if ingested in large quantities. More dangerous are isopropanol and ethanol (see below).

Clinical features

Ingestion of a substantial quantity results in a sensation of burning in the mouth and throat, followed by drowsiness, stupor, depression of respiration, and coma.

Treatment

Management is supportive. (See also ethanol and isopropanol.)

Further reading

Chan TYK (1994). Poisoning due to Savlon (cetrimide) liquid. *Human and Experimental Toxicology* **13**, 681–2.

Arsenic

Arsenic forms both trivalent and pentavalent derivatives. Inorganic arsenical compounds may generate arsine gas (see below) when in contact with acids, reducing metals, sodium hydroxide, and aluminium. Some 90 per cent of an ingested dose of most inorganic arsenicals is absorbed. The half-life is in the range of 1 to 3 days. Excretion is predominantly in the urine. Soluble arsenical compounds can also be absorbed by inhalation, but skin absorption is generally poor. In exposed individuals high concentrations of arsenic are present in bone, hair, and nails.

Clinical features

Acute poisoning

This can follow accidental, suicidal, or deliberate ingestion, the toxicity being largely dependent on the water solubility of the ingested compound. Within 2 h of substantial ingestion of a soluble arsenical compound, severe haemorrhagic gastritis or gastroenteritis may ensue with collapse and death usually within 4 days. A metallic taste, salivation, muscular cramps, facial oedema, difficulty in swallowing, hepatorenal dysfunction, convulsions, and encephalopathy are reported. A peripheral neuropathy (predominantly sensory), striate leuconychia (Mee's lines), and hyperkeratotic, hyperpigmented skin lesions are common in those surviving a near-fatal ingestion. In moderate or severe arsenic poisoning investigations may show anaemia, leucopenia, thrombocytopenia, and disseminated intravascular coagulation. ECG abnormalities have been reported and include Q–T prolongation and ventricular arrhythmias.

Chronic poisoning

The ingestion of arsenic in contaminated drinking water (recently in Bangladesh) or 'tonics' has led to progressive weakness, anorexia, nausea, vomiting, stomatitis, colitis, increased salivation, epistaxis, bleeding gums, conjunctivitis, weight loss, and low-grade fever. Characteristically there is hyperkeratosis of the palms and soles of the feet, 'raindrop' pigmentation of the skin, and 'Mee's lines' on the nails. There is an increased risk of skin cancer (usually squamous cell epithelioma) in affected individuals. A symmetrical peripheral neuropathy is typical. Hearing loss, psychological impairment, and electroencephalogram changes have been reported. Other chronic effects include disturbances of liver function and ulceration and perforation of the nasal septum. Chronic exposure to arsenic has been linked to lung cancer.

Treatment

Traditionally, dimercaprol (British Anti-Lewisite, BAL) has been the recommended chelator. However, DMPS (unithiol) and DMSA (succimer) are preferable, if available, as they are more effective in reducing the arsenic content of tissues and, unlike dimercaprol, they do not cause accumulation of arsenic in the brain. DMSA and DMPS may be given orally in a dose of 30 mg/kg body weight daily for 5 days, whereas dimercaprol must be given by a deep intramuscular injection in a dose of 2.5 to 5 mg/kg 4-hourly for 2 days followed by 2.5 mg/kg intramuscularly twice daily for 1 to 2 weeks.

Arsine

Arsine is a colourless, non-irritating gas which binds with oxidized haemoglobin causing marked intravascular haemolysis. Haemoglobinuria and acute renal tubular necrosis then develop.

Clinical features

There is usually a delay of some 2 to 24 h after exposure before the onset of eadache, malaise, weakness, dizziness, breathlessness, migratory abdominal pain, fever, tachycardia, tachypnoea, nausea, and vomiting. A bronze skin colour is noted in some patients but most have the typical appearance of a jaundiced patient. Acute renal failure is observed by the third day after substantial exposure and the urine is dark red then brown before anuria ensues. Investigations will show leucocytosis, reticulocytosis, elevated

plasma haemoglobin, and haemoglobinuria.

Treatment

If haemolysis is severe, plasmapheresis or exchange transfusion should be undertaken and, if renal failure ensues, haemodialysis/filtration. Dimercaprol and other chelating agents are of no value.

Further reading

Romeo L *et al.* (1997). Acute arsine intoxication as a consequence of metal burnishing operations. *American Journal of Industrial Medicine* **32**, 211–16.

Barbiturates

Amylobarbital, butobarbital, cyclobarbital, heptabarbital, hexabarbital, pentobarbital, and secobarbital are regarded as being short- or medium-acting. The more lipid soluble, shorter-acting preparations are associated commonly with more serious poisoning than phenobarbital and barbital, which are much more water-soluble.

Clinical features

Impairment of consciousness, respiratory depression, hypotension, and hypothermia are typical and potentiated by alcohol and benzodiazepines. There are no specific neurological signs. Hypotonia and hyporeflexia are the rule and the plantar responses are either flexor or absent. Hypotension, skin blisters, and rhabdomyolysis may develop. During recovery from coma, with or without hypothermia, it is common to observe a peak of temperature that cannot be explained by infection. Most deaths result from respiratory complications.

Treatment

Gastric lavage may be considered if it can be undertaken within 1 h of overdose; supportive measures should be used as appropriate. Although charcoal haemoperfusion is very effective for severely poisoned patients, phenobarbital can be removed efficiently by multiple-dose oral activated charcoal.

Hantson P *et al.* (1996). Severe hypoxia and hypothermia following barbiturate poisoning. *Intensive Care Medicine* **22**, 998–9.

Benzene

Benzene is a colourless, volatile liquid with a pleasant odour. It is an ingredient in many paints and varnish removers and some petrols (gasolines). About 10 per cent of inhaled benzene is excreted unchanged in the breath. The remainder is metabolized by mixed function oxidase enzymes predominantly in the liver, but also in the bone marrow, the target organ of benzene toxicity.

Clinical features

Acute exposure

Following inhalation or ingestion, euphoria, dizziness, weakness, headache, blurred vision, mucous membrane irritation, tremor, ataxia, chest tightness, respiratory depression, cardiac arrhythmias, coma, and convulsions have been reported. Direct skin contact with liquid benzene may produce marked irritation.

Chronic exposure

The toxic effects of chronic poisoning may not become apparent for months or years after initial contact and may develop after all exposure has ceased.

Anorexia, headache, drowsiness, nervousness, and irritability are well described. Anaemia (including aplastic anaemia), leucopenia, thrombocytopenia, pancytopenia, leukaemia, lymphomas, chromosomal abnormalities, and cerebral atrophy have been reported. Patients have recovered after as long as a year of almost complete absence of formation of new blood cells. A dry, scaly dermatitis may develop on prolonged or repeated skin exposure to liquid benzene.

Treatment

Following removal from the contaminated atmosphere, treatment should be directed towards symptomatic and supportive measures. Gastric lavage is hazardous as aspiration is likely to occur.

Benzodiazepines

These are widely used as tranquillizers, hypnotics, and sedatives.

Clinical features

Although many benzodiazepines have active metabolites that account for their sometimes prolonged sedative effects, they all share a remarkable safety when taken alone in overdose. However, there is individual variation in response; some otherwise healthy elderly people respond to an overdose with prolonged toxicity. Benzodiazepines potentiate the effects of other CNS depressants, particularly alcohol, tricyclic antidepressants, and barbiturates. Dizziness, drowsiness, ataxia, and slurred speech are the usual features while coma, respiratory depression, and hypotension are uncommon and usually mild. Flurazepam is most likely to cause significant CNS depression.

Treatment

Gastric lavage is unnecessary unless the overdose exceeds 30 therapeutic doses in an adult and the patient presents within 1 h. In severe poisoning, the specific benzodiazepine antagonist, flumazenil, may be indicated; 0.5 mg is given intravenously over 30 s and, if necessary, a further 0.5 mg over 30 s. Most patients will respond to a total dose of between 1 and 3 mg.

Benzyl alcohol

Benzyl alcohol has been used as a preservative in intravascular flush solutions and in drug formulations. Benzyl alcohol is metabolized to benzoic acid that is then conjugated with glycine in the liver and excreted as hippuric acid. The immature liver's capacity to metabolize benzoic acid is limited and when exceeded leads to accumulation of this metabolite and metabolic acidosis.

Clinical features

In 1982, a syndrome consisting of metabolic acidosis, convulsions, neurological deterioration (due to intraventricular haemorrhage), gasping respirations, hepatic and renal abnormalities, cardiovascular collapse, and death was described in small premature infants between 2 and 14 days of age. The removal of benzyl alcohol solutions from neonatal units led to a considerable reduction both in morbidity and mortality and in particular there was a reduction in cases of kernicterus and intraventricular haemorrhage.

Anderson CW *et al.* (1984). Benzyl alcohol poisoning in a premature newborn infant. *American Journal of Obstetrics and Gynecology* **130**, 344–6.

b-Adrenoceptor blocking drugs

b-Adrenoceptor blocking drugs antagonize the effects of endogenous catecholamines on the heart and other tissues by competitive inhibition at b-adrenoceptors. In overdose these drugs exhibit a marked negative inotropic action.

Clinical features

Sinus bradycardia may be the only feature following a small overdose, but if a substantial amount has been ingested, coma, convulsions (particularly with propranolol), profound bradycardia, and hypotension may occur. Other effects include drowsiness, delirium, hallucinations, low-output cardiac failure, and cardiorespiratory arrest (asystole or ventricular fibrillation). Bronchospasm and hypoglycaemia occur rarely.

First-degree heart block, intraventricular conduction defects, right and left bundle branch block, ST segment elevation, ventricular extrasystoles, and disappearance of the P wave may be noted on the electrocardiogram. Sotalol has been reported to cause Q–T interval prolongation and ventricular arrhythmias and asystole may follow severe overdose from any b-adrenoceptor blocking drug.

Treatment

A delay in treatment may be fatal in patients who are severely poisoned. The blood pressure and cardiac rhythm of the patient should be monitored immediately in an intensive care area and supportive measures implemented. Gastric lavage should be considered in adults who have ingested a substantial overdose less than 1 h previously; 0.6 to 1.2 mg of atropine intravenously may prevent vagal-induced cardiovascular collapse during this procedure.

Glucagon is the drug of choice for severe hypotension and should be given in a bolus dose of 50 to 150 µg/kg (typically 10 mg in an adult) over 1 min, followed by an infusion of 1 to 5 mg/h according to response.

Insertion of a temporary transvenous pacemaker wire, atropine, and isoprenaline 0.5 to 10 µg/min intravenously or other inotropic agents have been recommended but are probably less effective than glucagon. Occasionally, 5 to 10 mg of diazepam intravenously may be needed for convulsions. If bronchospasm supervenes, salbutamol (albuterol) by nebulizer, or aminophylline by intravenous infusion, should be employed. Hypoglycaemia should be corrected.

Taboulet P *et al.* (1993). Pathophysiology and management of self-poisoning with b-blockers. *Journal of Toxicology—Clinical Toxicology* **31,** 531–51.

b_2-Adrenoceptor stimulants

Poisoning with b_2-adrenoceptor stimulants, including fenoterol, pirbuterol, reprobuterol, rimiterol, salbutamol, and terbutaline, has followed deliberate and accidental ingestion of these drugs and may also result from confusion over the difference between oral and parenteral doses.

Clinical features

These include a feeling of excitement, hallucinations, and agitation, accompanied by palpitations, tachycardia, tremor, and peripheral vasodilation. More serious complications such as hypokalaemia, ventricular tachyarrhythmias, ECG changes of myocardial ischaemia, pulmonary oedema, convulsions, hyperglycaemia, and lactic acidosis are uncommon.

Treatment

Gastric lavage may be considered or activated charcoal administered if the patient presents within 1 h of a substantial overdose. Hypokalaemia should be corrected as soon as possible by the administration of an infusion of potassium at a rate of 40 to 60 mmol/h diluted in 1 litre 5 per cent dextrose. A non-selective b-blocker, such as propanolol 1 to 5 mg by slow intravenous injection will also reverse hypokalaemia induc$\bar{2}$-adrenoceptor stimulants. However, its use may exacerbate pre-existing chronic air flow obstruction. Methods to increase elimination have no role.

Further reading

Leikin JB *et al.* (1994). Hypokalemia after pediatric albuterol overdose: a case series. *American Journal of Emergency Medicine* **12**, 64–6.

Bismuth chelate (tripotassium dicitratobismuthate)

Although bismuth absorption from bismuth chelate is low after a therapeutic dose, a significant quantity may be absorbed after overdose. Renal toxicity is dose-dependent in animals and is directed primarily towards the tubular epithelial cells.

Clinical features

Self-poisoning with large doses of bismuth chelate has caused reversible renal failure up to 10 days after overdose and at least one death. During prolonged (and sometimes high-dose) therapy, bismuth-induced encephalopathy has been reported.

Treatment

If a patient presents within 1 h of a substantial overdose, gastric lavage should be considered. Dimercaprol can lower brain bismuth concentrations though there is no evidence that it can prevent nephrotoxicity. DMSA and DMPS may be effective oral alternatives.

Further reading

Akpolat I *et al.* (1996). Acute renal failure due to overdose of colloidal bismuth. *Nephrology, Dialysis, Transplantion* **11**, 1890–1.

Bleaches and lavatory leaners

Household bleach is normally a 3 to 6 per cent solution of sodium hypochlorite, whereas industrial bleaches contain more than 10 per cent. Some bleaches also contain sodium hydroxide. Household bleach may give rise to toxic gases such as chlorine if mixed with other cleaning agents in a lavatory bowl.

Clinical features

Ingestion may cause a burning sensation in the mouth, throat, and oesophagus, accompanied by a sensation of thirst, vomiting, and abdominal discomfort. Pharyngeal and laryngeal oedema and hypernatraemia may develop.

Treatment

When small quantities of household bleach have been ingested, liberal fluids by mouth are all that is required. Gastric lavage should only be considered if concentrated bleach has been swallowed less than 1 h previously. Endoscopy should be performed if industrial bleach has been ingested.

Inhalation of gases liberated by mixing bleach with other products may result in severe respiratory irritation and pulmonary oedema. Treat as for inhalation of chlorine.

Further reading

Hilbert G *et al.* (1997). Euro bleach: fatal hypernatremia due to 13.3 per cent sodium hypochlorite. *Journal of Toxicology—Clinical Toxicology* **35**, 635–6.

Kiristioglu I *et al.* (1999). Is it necessary to perform an endoscopy after the ingestion of liquid household bleach in children? *Acta Paediatrica* **88**, 233–4.

Butyrophenones

Benperidol, droperidol, haloperidol, and triperidol are used as antipsychotic and neuroleptic agents.

Clinical features

Overdosage may result in drowsiness and hypotension, but acute dystonic reactions are the most dramatic consequences. Neuroleptic malignant syndrome has also been reported.

Treatment

Treatment is supportive. Acute dystonic reactions should be treated with benztropine (benzatropine) 1 to 2 mg or procyclidine 5 to 10 mg intravenously for an adult.

Further reading

Yoshida I *et al.* (1993). Acute accidental overdosage of haloperidol in children. *Acta Paediatrica Scandinavica* **82**, 877–80.

Cadmium

Cadmium compounds are poorly absorbed orally but are well absorbed through the lungs. Cadmium is deposited in the liver and kidneys and very slowly excreted in the urine (half-life 10 to 30 years).

Clinical features

Acute poisoning

Inhalation of cadmium oxide fumes produced in welding or cutting has led to the development of severe lung damage and death. Often there are no initial symptoms but after some 4 to 10 h there is increasing respiratory distress. Chills and tremor accompany dyspnoea, cough, and chest pain. Severe pulmonary oedema may develop, or chemical pneumonitis in less severe cases. Recovery may be complicated by progressive pulmonary fibrosis.

The ingestion of cadmium salts (more than 3 mg/kg body weight) may lead to gastrointestinal disturbance which, in severe cases, may progress to circulatory ollapse, acute renal failure, pulmonary oedema, and death.

Chronic poisoning

Repeated exposure to cadmium leads to renal tubular dysfunction with glycosuria, aminoaciduria, and hypercalciuria, an increased incidence of renal stones and osteomalacia. Less common features include anosmia, anaemia, teeth discoloration, and neuropsychological impairment. Later, emphysema may develop.

Workers repeatedly exposed to high concentrations of cadmium have developed carcinoma of the prostate or lung.

Treatment

There is no clinical evidence that any currently available antidote chelates a substantial body burden of cadmium.

Further reading

Järup L *et al.* (1998). Health effects of cadmium exposure—a review of the literature and a risk estimate. *Scandinavian Journal of Work, Environment and Health*: **24**, 1–51.

Calcium-channel blockers

Calcium-channel blockers (amlodipine, diltiazem, felodipine, isradipine, nicardipine, nifedipine, nimodipine, verapamil) interfere with the inward transmembrane passage of calcium ions in myocardial cells, the cardiac conducting system, and vascular smooth muscle.

Clinical features

In overdose, calcium-channel blockers cause nausea, vomiting, dizziness, slurred speech, confusion, sinus bradycardia and tachycardia, prolonged atrioventricular conduction, atrioventricular dissociation, hypotension, pulmonary oedema, respiratory arrest, convulsions, coma, hyperglycaemia, and metabolic acidosis. Large overdoses carry a poor prognosis, particularly in patients with ischaemic heart disease and in those taking b-adrenoceptor blocking agents.

Treatment

Gastric lavage should be considered in all patients who present within 1 h of substantial overdose or, alternatively, 50 to 100 g of activated charcoal may be administered. Calcium gluconate in a dose of 10–20 ml of 10 per cent solution intravenously may reverse prolonged intracardiac conduction times but inotropic support with dobutamine at 2.5 to 10 µg/kg.min or isoprenaline at 0.5 to 10 µg/kg.min by intravenous infusion, will also be needed to maintain cardiac output in severe cases.

Cannabis

Cannabis is obtained from the plan*Cannabis sativa* that contains many active substances of which the most important are the tetrahydrocannabinols.

Smoking is the common route of use of cannabis. It is occasionally ingested and, rarely, made into a 'tea' and injected intravenously.

Clinical features

Euphoria with drowsiness and distorted and heightened images, colours, and sounds are the usual effects of this compound. Tactile sensations may also be altered. A tachycardia is often present and heavy use may lead to conjunctival suffusion, hypotension, and ataxia. Higher doses induce auditory hallucinations, confusion, depersonalization, and panic. Some people find the distortion of perception pleasurable but novice users may panic and seek medical help. Long-term use may predispose to psychosis.

Intravenous injection of cannabis infusions causes serious illness. Within a few minutes, there is nausea, vomiting, and chills followed after an interval of 1 h or so by profuse watery diarrhoea, tachycardia, hypotension, and arthralgia. A marked neutrophil leucocytosis is often present and hypoglycaemia has been reported in some cases. There may also be transient renal failure.

Treatment

Most patients respond to reassurance. Sedation with intravenous diazepam may be required for those whose behaviour is disruptive or who are clearly very distressed. Those who have injected cannabis infusions should be treated supportively.

Carbamate insecticides

Like many organophosphorus compounds, carbamate insecticides inhibit acetylcholinesterase. However, in comparison the duration of this effect is relatively short-lived since the carbamate–enzyme complex tends to dissociate spontaneously.

Clinical features

See organophosphorus insecticide poisoning (below).

Treatment

Symptomatic cases require atropine, but the use of oximes is usually unnecessary; rapid recovery within 24 h is the rule.

Further reading

Wagner SL (1997). Diagnosis and treatment of organophosphate and carbamate intoxication. *Occupational Medicine (Philadelphia)* **12,** 239–49.

Carbamazepine

Carbamazepine is structurally related to the tricyclic antidepressants and has similar anticholinergic actions. Overdosage may therefore result in a dry mouth, drowsiness, coma, and convulsions. Cardiotoxicity similar to that seen in tricyclic antidepressant poisoning also occurs but is uncommon. Relapse into coma has been described during the course of recovery, probably due to continuing drug absorption. Treatment should include administration of activated charcoal or gastric lavage, if appropriate, and supportive therapy. Diazepam may be required to treat convulsions. Carbamazepine elimination is hastened by giving multiple doses of activated charcoal.

Carbon dioxide

Carbon dioxide is a colourless gas that is also available commercially as a solid for refrigeration purposes ('dry ice'). High concentrations may accumulate in wells, silos, manholes, and mines.

Clinical features

Dyspnoea, cough, headache, dizziness, sweating, restlessness, paraesthesiae, and sinus tachycardia are features after modest carbon dioxide exposure. Higher concentrations produce psychomotor agitation, myoclonic twitches, eye flickering, coma, and convulsions. Death occurs from acute cardiorespiratory depression.

Skin contact with 'dry ice' may result in frostbite and local blistering.

Treatment

The casualty should be removed from the contaminated environment. Thereafter, supportive care should be employed.

Further reading

Guillemin MP, Horisberger B (1994). Fatal intoxication due to an unexpected presence of carbon dioxide. *Annals of Occupational Hygiene* **38**, 951–7.

Carbon disulphide

Carbon disulphide is used as a fumigant for grain and as a solvent, particularly in the rayon industry. It is a clear, colourless, volatile liquid with an odour like that of decaying cabbage.

Clinical features

Acute exposure

Acute poisoning is rare. Absorption occurs through the skin as well as by inhalation. Carbon disulphide, due to its potent defatting activity, causes reddening, cracking, and peeling of the skin and a burn may occur if contact continues for several minutes. Splashes in the eye cause immediate and severe irritation. Acute inhalation may result in irritation of the mucous membranes, blurred vision, nausea and vomiting, headache, delirium, hallucinations, coma, tremor, convulsions, and cardiac and respiratory arrest.

Chronic exposure

There is an increased incidence of cardiovascular disease among workers exposed to carbon disulphide. In addition, sleep disturbances, fatique, anorexia, and weight loss are common complaints. Intellectual decline, depression, stereotyped behaviour, ocular changes, cerebellar and extrapyramidal signs, hepatic damage, and permanent impairment of reproductive performance have been described.

Treatment

Treatment involves removal from exposure, washing contaminated skin, irrigation of the eyes with water, and supportive measures. In the majority of cases, however, preventive measures to keep carbon disulphide concentrations in the workplace as low as possible are more important.

Further reading

Spyker DA, Gallanosa AG, Suratt PM (1982). Health effects of acute carbon disulfide exposure. *Journal of Toxicology—Clinical Toxicology* **19**, 87–93.

Carbon monoxide

Carbon monoxide is a tasteless, odourless, colourless, non-irritating gas produced by incomplete combustion of organic materials. Normal endogenous carbon monoxide production is sufficient to maintain a resting carboxyhaemoglobin level of 1 to 3 per cent in urban non-smokers and 5 to 6 per cent in smokers.

Common sources of carbon monoxide are car exhaust fumes (in the absence of a catalytic converter), improperly maintained and vented heating systems, and smoke from all types of fire. Carbon monoxide derived from domestic heating systems is a major cause of accidental death in the developing world. Inhalation of methylene chloride (found in paint strippers) may also lead to carbon monoxide poisoning.

Mechanisms of toxicity

Symptoms and signs that follow inhalation of carbon monoxide are the result of tissue hypoxia. The affinity of haemoglobin for carbon monoxide is approximately 240 times greater than that for oxygen. Carbon monoxide combines with haemoglobin to form carboxyhaemoglobin, reducing the total oxygen-carrying capacity of the blood. In addition, the oxygen dissociation curve shifts to the left and modifies oxygen-binding sites. As a result, the affinity of the remaining haem groups for oxygen is increased, the oxygen dissociation curve is distorted as well as being shifted and the resulting tissue hypoxia is thus far greater than that which would result from simple loss of oxygen-carrying capacity.

Carbon monoxide may also inhibit cellular respiration as a result of reversible binding to cytochrome oxidase. Brain lipid peroxidation mediated by carbon monoxide may play a role in the development of delayed neuropsychiatric sequelae.

Clinical features

The clinical features of carbon monoxide poisoning are summarized Table 3.

Acute exposure

The symptoms of mild to moderate exposure to carbon monoxide are non-specific and may even be mistaken for a viral illness and for this reason it is important that the diagnosis is always borne in mind. Elderly patients and those with pre-existing cardiorespiratory disease are at greater risk. A carboxyhaemoglobin concentration of less than 10 per cent is not normally associated with symptoms and 10 to 30 per cent carboxyhaemoglobin may result only in headache and mild exertional dyspnoea. Even low concentrations of carbon monoxide produce significant effects on cardiac function during exercise in subjects with coronary artery disease. Coma, convulsions, and cardiorespiratory arrest may be expected with carboxyhaemoglobin concentrations in excess of 60 per cent.

Delayed effects

Neuropsychiatric problems after recovery from carbon monoxide intoxication may develop insidiously over a number of weeks. They include intellectual deterioration, memory impairment, features of cerebral, cerebellar, and midbrain damage, parkinsonism, akinetic mutism, irritability, verbal aggressiveness, violence, impulsiveness, and moodiness.

Treatment

The patient should be removed from exposure and 100 per cent oxygen administered using a tightly fitting facemask. Endotracheal intubation and mechanical ventilation may be required in those who are unconscious. The administration of oxygen should be continued until the carboxyhaemoglobin concentration is less than 10 per cent.

Controlled studies of hyperbaric oxygen have not shown greater benefit than 100 per cent normobaric oxygen with elective ventilation.

General symptomatic and supportive measures will be required. Diazepam (5 to 10 mg intravenously) repeated as necessary is the agent of choice for the management of convulsions. The benefit of corticosteroids for the treatment of cerebral oedema has not been proved but mannitol may be useful.

Carbon tetrachloride (tetrachloromethane)

Carbon tetrachloride was once widely used as a dry-cleaning chemical, degreasing agent, and fire extinguisher but international regulations have now restricted it to laboratory and industrial usage and it is no longer manufactured in most developed countries.

Clinical features

Acute exposure

The immediate effects include nausea, vomiting, abdominal pain, and diarrhoea. High concentrations cause dizziness, confusion, coma, respiratory depression, hypotension, and occasionally convulsions. Death may follow from respiratory failure or ventricular fibrillation due to cardiac sensitization to circulating catecholamines. Hepatorenal damage supervenes after a delay of up to 2 weeks. Hepatic enzyme activities increase before jaundice and a tender swollen liver develop. Maximal liver damage probably occurs within 48 h of an acute exposure and may progress to fulminant hepatic failure. Acute renal tubular necrosis is common and may develop in the absence of hepatic dysfunction 1 to 7 days after exposure. Rarely, cerebellar dysfunction, cerebral haemorrhage, optic atrophy, and parkinsonism may occur. Alcohol and previous liver damage render the individual more susceptible.

A plain film of the abdomen may confirm ingestion has occurred (Fig. 1).

Fig. 1 Plain abdominal radiograph in a patient who ingested carbon tetrachloride.

Chronic exposure

Repeated exposure to low concentrations of carbon tetrachloride may also cause hepatic and renal damage. Hepatic cirrhosis and hepatoma may develop. Prolonged carbon tetrachloride exposure is associated with polyneuropathy, various visual disturbances, and anaemia, including fatal aplastic anaemia.

Treatment

After ingestion, gastric emptying is probably best avoided because of the risk of aspiration. If the patient presents within 12 h of expo*N*-acetylcysteine should be given as for paracetamol overdose (see below). Renal and liver failure should be managed conventionally.

Further reading

International Programme on Chemical Safety (1999). *Environmental Health Criteria 208. Carbon tetrachloride.* World Health Organization, Geneva.

Chlorates

Clinical features

Sodium chlorate and potassium chlorate are powerful oxidizing agents and are highly toxic if ingested. The early features include nausea, vomiting, diarrhoea, abdominal pain, and cyanosis secondary to methaemoglobinaemia. Intravascular haemolysis occurs causing hyperkalaemia, jaundice, and oliguric renal failure.

Treatment

Gastric lavage should be considered if the patient presents within 1 h of ingestion. Methaemoglobinaemia can be corrected by slow intravenous injection of methylthioninium chloride (methylene blue) 2 mg/kg body weight, although antidotal efficacy is reduced in the presence of haemolysis. Blood transfusion may be required. Plasma potassium concentrations should be monitored and reduced if necessary. Haemodialysis will remove chlorate and may also be required for the management of renal failure and hyperkalaemia. Plasmapheresis has also been employed since it will remove chlorate, circulating free haemoglobin, and red cell stroma and thus help to prevent the development of renal failure.

Chlorine

Chlorine is a greenish-yellow gas normally transported as a pressurized liquid. Exposure after spillage may be prolonged because gaseous chlorine is heavier than air, causing it to remain near ground level. Chlorine has a pungent odour that can usually be detected by smell at concentrations of less than 0.5 ppm.

Molecular chlorine, a strong oxidizing agent, is known to react with many functional groups in cell components, forms chloramines, oxidizes thiol radicals, reacts with tissue water to form hypochlorite and hydrochloric acid, and it may generate oxygen free radicals.

Clinical features

Symptoms begin within minutes and include irritation of the mucous membranes of the eyes, nose, and throat, followed by cough, breathlessness, expectoration of white sputum (which may be bloodstained), chest pain and tightness, abdominal pain, nausea, headache, dizziness, and palpitation due to ventricular ectopic beats. Laryngeal oedema may cause hoarseness of the voice and stridor, and cardiac arrest may occur secondary to hypoxia.

Restrictive as well as obstructive ventilatory defects arise in those who have inhaled sublethal amounts. Diffusion is impaired, leading to arterial hypoxaemia. In very severe cases, non-cardiogenic pulmonary oedema and respiratory failure may develop. Survival is usually followed by complete resolution of the pulmonary defects.

Some workers chronically exposed to the gas become anosmic.

Treatment

The first priority is to remove the casualty from exposure. Conjunctival skin burns should be treated as for acids (see above).

Patients with respiratory symptoms persisting beyond the period of exposure should be admitted to hospital in case they require bronchodilators and humidified oxygen. Some will require mechanical ventilation, particularly if non-cardiogenic pulmonary oedema develops. Frusemide has been reported to be of value. Corticosteroids and prophylactic antibiotics have not been shown to be of value. Correction of serious metabolic acidosis with intravenous sodium bicarbonate may be necessary.

Chlorofluorocarbons (CFCs)

CFCs are derived by the partial or complete substitution of the hydrogen atoms in methane and ethane with chlorine and fluorine atoms. CFCs were developed as refrigerants some 60 years ago but have been used as propellants in aerosols, as blowing agents in foam insulation products, and as intermediates for plastics. The aerosol propellant market, which previously consumed half of the total production, is currently a minor application due to international restrictions imposed as a result of concerns that CFCs damage the ozone layer of the earth's atmosphere.

Clinical features

Acute exposure

Inhalation of CFCs may result in a tingling sensation, humming in the ears, apprehension, slurred speech, and decreased performance in psychological tests. Exposure to high concentrations may result in clinically significant arrhythmias, coma, and respiratory depression; fatalities have occurred particularly after CFC abuse (see volatile substance abuse).

Chronic exposure

A sensorimotor neuropathy developed in a laundry worker exposed for several years both to CFC 113 and tetrachloroethylene and in a refrigerator repair worker. However, epidemiological studies in exposed workers have not found evidence of a causal relationship.

International Programme on Chemical Safety (1991*Environmental Health Criteria 126. Partially halogenated chlorofluorocarbons (Methane derivativ* World Health Organization, Geneva.

International Programme on Chemical Safety (1992*Environmental Health Criteria 139. Partially halogenated chlorofluorocarbons (Ethane derivative* World Health Organization, Geneva.

Chlorophenoxy herbicides

The chlorophenoxy herbicides (Table 4) include the substances popularly referred to as 'hormone' weedkillers and are used widely in agriculture and by the public. Most instances of serious poisoning have been due to deliberate ingestion but few cases have been reported. These herbicides are often coformulated with the chemically related herbicide, dicamba, which is of low toxicity, and ioxynil

and bromoxynil, which uncouple oxidative phosphorylation.

Clinical features

Ingestion causes burning in the mouth and throat, nausea, vomiting, and abdominal pain. The face may be flushed and there is often profuse sweating and fever. CNS depression leading to deep, prolonged coma, hyperventilation, metabolic acidosis, and pulmonary oedema may develop. ECG abnormalities and skeletal muscle damage leading to proximal myopathy have been reported.

Treatment

Gastric lavage should be considered if the patient presents within 1 h of overdose. Supportive measures should be employed as necessary. Alkalinization of the urine (see above) is indicated for severe poisoning since it considerably enhances elimination of 2,4-dichlorophenoxy acetic acid (2,4-D) and, to a lesser extent, mecoprop, particularly if combined with a high urine flow (>600 ml/h). Alkalinization of the urine probably does not have a beneficial effect on the elimination of other phenoxyacetates and does not affect that of ioxynil.

Further reading

Bradberry SM *et al.* (2000). Mechanisms of toxicity, clinical features and management of acute chlorophenoxy herbicide poisoning: A rev *Journal of Toxicology—Clinical Toxicolog* **38**, 111–22.

Chloroquine

Chloroquine overdose is probably the most common form of self-poisoning with drugs in Africa, the Far East, and West Pacific and is a growing problem in Europe.

Clinical features

Toxicity can result from doses greater than 1 g (about six tablets) in adults. Cardiac arrest is commonly the first clinical manifestation of poisoning, but hypotension usually precedes it and may progress to cardiogenic shock and pulmonary oedema. Electrocardiographic abnormalities, bradyarrhythmias, and tachyarrhythmias are common and are similar to those of quinine (see below). Visual disturbance, agitation, drowsiness, acute psychosis, dystonic reactions, seizures, and coma may ensue. Hypokalaemia is common and is due to potassium channel blockade.

Treatment

Gastric lavage or activated charcoal (50 to 100 g) should be considered if the patient presents within 1 h. Supportive measures should be employed and hypokalaemia corrected. There is no specific antidote. There is evidence that mechanical ventilation, the administration of adrenaline (epinephrine) (0.25 µg/kg. min) and high-doses of diazepam (1 mg/kg as a loading dose and 0.25 to 0.4 mg/kg.h maintenance) may reduce the mortality to 10 per cent in severe poisoning. Multiple-dose activated charcoal may enhance chloroquine elimination.

Further reading

Clemessy JL *et al.* (1996). Treatment of acute chloroquine poisoning: a 5-year experien *Critical Care Medicin* **24**, 1189–95.

McKenzie AG (1996). Intensive therapy for chloroquine poisoning—a review of 29 cas *South African Medical Journa* **86**, 597–9.

Chromium

There is no good evidence that chromium(II), chromium(III) and chromium(IV) compounds are dangerous but chromium(III) compounds have produced skin sensitization. Chromium(VI) is the most important toxicologically because it can cross cell membranes readily. In contrast, chromium(III) compounds are confined to the extracellular space.

Chromium is absorbed mainly by inhalation and, to a lesser extent, via the skin or gastrointestinal tract. Hexavalent chromium compounds are generally better absorbed than trivalent chromium compounds and, understandably, soluble chromium compounds such as sodium (VI) chromate are absorbed more readily than insoluble compounds such as chromium(III) oxide. Chromium is excreted via the kidney.

Clinical features

Acute poisoning

Inhaled soluble chromium(VI) compounds, such as sodium and potassium chromate and dichromate, are highly irritant to mucous membranes and may lead to inflammation of the nasal mucosa. Inhalation of chromium(VI) trioxide (chromic acid) causes cough, headache, chest pain, dyspnoea, and cyanosis.

Ingestion of highly water-soluble chromium(VI) compounds leads within minutes to nausea, vomiting, abdominal pain, diarrhoea, and a burning sensation in the mouth, throat, and stomach; gastrointestinal haemorrhage is a frequent complication.

Methaemoglobinaemia, haemolysis, and disseminated intravascular coagulation, and renal and hepatic failure have been reported.

Chromic acid splashes produce severe burns. Percutaneous absorption may lead to kidney and liver failure; fatalities have occurred.

Chronic poisoning

'Chrome ulcers' may develop after repeated topical exposure to chromium(VI) compounds. They have a well-defined circular margin with raised edges and a central cavity that may penetrate to bone and is filled with exudate or a tenacious crust. Chromium(VI) compounds are also skin sensitizers and contribute to the development of cement dermatitis and contact dermatitis from paint primer, tanned leather, tattoo pigments, and matches.

Inhalation of chromium(VI) compounds has led to atrophy, ulceration, and perforation of the nasal septum. Pharyngeal and laryngeal ulcers may also occur. Asthma may be precipitated by exposure to fumes. Lung fibrosis, bronchitis, emphysema, and proximal tubular damage result from occupational exposure. There is an increased risk of lung cancer.

Treatment

Ascorbic acid reduces chromium(VI) to the less toxic chromium(III). Topical 10 per cent ascorbic acid, as an ointment or in solution, has led to dramatic resolution of occupational chromium dermatitis but there is no clinical evidence that the systemic administration of ascorbic acid, or any other reducing agent, lessens morbidity or mortality in severe chromium poisoning. Topical preparations containing sodium calcium edetate may also afford some protection to the skin but there is no evidence that systemic chelation treatment is beneficial in chromium poisoning. Haemodialysis effectively removes chromium from the blood but the high tissue uptake limits the value of this treatment when used alone.

Clomethiazole (chlormethiazole)

Clinical features

This hypnotic drug taken in overdose may cause coma, respiratory depression, reduced muscle tone, hypotension, and excessive salivation. The characteristic odour of clomethiazole is often detected on the breath.

Treatment

Treatment is supportive.

Clonidine

Clonidine exerts its hypotensive action by reduction of sympathetic tone mediated by a central effect on postsynaptic a_2-adrenoceptors in the medulla. Clonidine decreases heart rate, cardiac output, and total peripheral resistance. In the presence of high plasma clonidine concentrations, peripheral a_2-agonist activity predominates and accounts for those instances of vasoconstriction and hypertension reported following clonidine overdose.

Clinical features

Poisoning may be severe and life-threatening, particularly in children. Hypertension and severe vasoconstriction are unusual while bradycardia, hypotension, coma, and respiratory depression are common. Toxic effects last about 16 h, but may extend to several days in severe overdose.

Treatment

Gastric lavage should be considered or 50 to 100 g of activated charcoal administered if a patient presents within 1 h of a substantial overdose. Bradycardia is usually reversed by atropine in a dose of 0.6 to 2.4 mg intravenously. The use of a-adrenergic blocking drugs (tolazoline or phentolamine) has been advocated in severely poisoned patients but their action may be unpredictable. Severe hypotension should be treated with a plasma expander and then, if necessary, an inotropic agent such as, dobutamine 2.5 to 10 µg/kg.min may be given by intravenous infusion. The use of naloxone has been advocated but its benefit is inconsistent and it may produce hypertension. Sodium nitroprusside 0.5 to 8.0 µg/kg.min by intravenous infusion is the most effective agent for management of severe hypertension and peripheral vasoconstriction. Although forced diuresis has been employed in the treatment of clonidine poisoning, renal elimination is not increased.

Cobalt

Cobalt is a relatively rare element and usually exists in association with nickel, silver, lead, copper, and iron ores. It is used in steel alloys, in the manufacture of magnets, and in the hard metal industry as a binder for tungsten carbide. It is also an essential dietary trace element available as a component of vitamin B_{12} (cyanocobalamin).

Cobalt can be absorbed orally and by inhalation. Most absorbed cobalt is excreted within days but a small proportion is retained with a biological half-life of approximately 2 years. The normal body burden of cobalt is about 1.1 mg.

Clinical features

Acute poisoning

Cobalt salts are relatively non-toxic but their ingestion may lead to gastrointestinal disturbance.

Chronic poisoning

Occupational exposure to cobalt dust occurs mainly in the tungsten carbide industry and causes 'hard metal' pneumoconiosis with interstitial fibrosis. This usually develops after several years of exposure to high concentrations of cobalt and may prove fatal. There is also a higher incidence of bronchitis and emphysema amongst cobalt workers and occupational asthma has been reported.

Chronic occupational exposure also leads to anosmia, auditory nerve damage, visual disturbance, irritability, headache, memory deficit, weakness, peripheral neuropathy, gastrointestinal disturbance, and weight loss. There is no firm evidence that cobalt is carcinogenic and assessment of its cancer risk is often confounded by a simultaneous exposure to nickel and arsenic.

Chronic ingestion of cobalt causes polycythaemia, inhibits the iodination of tyrosine (and therefore can cause goitre), and leads to cardiomegaly, congestive cardiomyopathy, pericardial effusion, and hypertrichosis, most of which are reversible when exposure is discontinued.

Simultaneous allergies to nickel and to cobalt are frequent and there is some evidence for a mutual enhancing effect of contact sensitization to one metal in the presence of the other.

Treatment

If the patient presents early after ingestion of a cobalt salt, gastric lavage should be considered. In two studies, DMSA (succimer) significantly reduced mortality in mice poisoned with cobalt chloride but in another study, DTPA (calcium trisodium pentetate) was more effective than DMSA. No satisfactory human studies have yet been performed.

Cocaine

In recent years there has been a considerable increase in the recreational use of cocaine. Cocaine is a powerful local anaesthetic and vasoconstrictor and may be abused by smoking, ingestion, injection, or by 'snorting' it intranasally. Users, body packers, and those who swallow the drug to avoid being found in possession of it ('stuffers') are at risk of overdose. 'Street' cocaine (cocaine hydrochloride) is sometimes dissolved in an alkaline solution from which the cocaine is extracted into ether or other solvent that is then evaporated to leave crystals of relatively pure ('freebase') cocaine. 'Crack' is another type of freebase cocaine made by heating cocaine hydrochloride with baking soda. The hard paste which crackles when smoked is also used widely. Other drugs such as ethanol, cannabis, and conventional hypnotics and sedatives are frequently taken with cocaine to reduce the intensity of its less pleasant effects.

Clinical features

The features of cocaine overdosage are similar to those of amfetamine. In addition to euphoria, it also has sympathomimetic effects including agitation, tachycardia, hypertension, sweating, and hallucinations. Prolonged convulsions with metabolic acidosis, hyperthermia, rhabdomyolysis, ventricular arrhythmias, and cardiorespiratory arrest may follow in the most severe cases. Less common features include dissection of the aorta, myocarditis, myocardial infarction, dilated cardiomyopathy, subarachnoid haemorrhage, cerebral haemorrhage, and cerebral vasculitis.

A number of rare complications of the method of use of cocaine have been reported. These include pulmonary oedema after intravenous injection of freebase cocaine and pneumomediastinum and pneumothorax after sniffing it. In addition, chronic 'snorting' has caused perforation of the nasal septum, cerebrospinal fluid rhinorrhoea due to thinning of the cribriform plate, and pulmonary granulomatosis.

Treatment

Users who are intoxicated may require sedation with diazepam to control agitation or convulsions. Measures to prevent further absorption are usually irrelevant. Active external cooling is required when body temperature exceeds 41°C. Myocardial ischaemia is best treated with intravenous glyceryl nitrite or a calcium channel blocker. Hypertension and tachycardia usually respond to sedation and cooling. b-Adrenoceptor blocking drugs are absolutely contraindicated because of the risk of precipitating paradoxical hypertension. Phentolamine in a dose of 2 to 5 mg intravenously or other vasodilator can be employed, if necessary. Accelerated idioventricular rhythm should not normally require treatment but ventricular fibrillation and asystole should be managed conventionally.

Co-phenotrope (Lomotil)

Co-phenotrope is a mixture of an opioid, diphenoxylate hydrochloride, and atropine.

Mechanism of toxicity

Gastric emptying is delayed and intestinal motility reduced. The onset of toxicity following an overdose may be delayed for up to 12 h.

Clinical features

Respiratory depression is the major complication of diphenoxylate poisoning. Vomiting, abdominal pain, drowsiness, and coma also occur. Even though co-phenotrope tablets incorporate only a small amount of atropine this is often toxic to children under 5 years and several deaths have been reported. Anticholinergic features are to be expected (see tricyclic antidepressants below).

Treatment

Repeated doses of naloxone may be necessary to reverse respiratory depression because of the long duration of action of diphenoxylate (see opiates and opioids below). Lavage may be appropriate in an adult presenting within 1 h of a substantial overdose before toxicity develops; activated charcoal (50 to 100 g) may also reduce absorption significantly if administered within that period.

Further reading

McCarron MM, Challoner KR, Thompson GA (1991). Diphenoxylate-atropine (Lomotil) overdose in children: An update (report of eight cases and review of the literature). *Pediatrics* **87,** 694–700.

Copper

Copper is used for pipes and roofing material, in alloys, and as a pigment. It is a component of several enzymes, including tyrosinase and cytochrome oxidase, and is essential for the utilization of iron. Copper sulphate is used as a fungicide, an algicide, and in some fertilizers.

Approximately one-third of an ingested copper salt is absorbed and in the blood 80 per cent is bound to caeruloplasmin. Most absorbed copper is deposited in the liver and eliminated mainly in bile.

Clinical features

Acute poisoning

Acute copper poisoning usually results from the ingestion of contaminated foods or from accidental or deliberate ingestion of copper salts. Following a substantial ingestion of a copper salt there is profuse vomiting with abdominal pain, diarrhoea, headache, dizziness, and a metallic taste. Gastrointestinal haemorrhage, haemolysis, and hepatorenal failure may ensue and fatalities have occurred. Body secretions may have a green or blue discoloration.

Occupational exposure to copper fumes (during refining or welding) or to copper-containing dust causes 'metal-fume fever' with upper respiratory tract symptoms, headache, fever, and myalgia.

Chronic poisoning

Chronic occupational copper poisoning causes general malaise, anorexia, nausea, vomiting, and hepatomegaly. Contact dermatitis, pulmonary granulomas, and pulmonary fibrosis have also been described. There is no convincing evidence that copper is carcinogenic in humans.

Treatment

Although vomiting occurs invariably following the ingestion of many copper salts, gastric lavage may be of value in reducing copper absorption if presentation is early. Blood copper levels correlate well with severity of intoxication, a concentration of less than 3 mg/l indicating mild to moderate poisoning and a concentration in excess of 8 mg/l severe intoxication. D-Penicillamine 25 mg/kg body weight daily until recovery enhances copper chelation in both acute and chronic copper poisoning. There is now animal evidence to suggest that *N*-acetylcysteine and DMPS (unithiol) are of similar efficacy.

Cyanide

Hydrogen cyanide and its derivatives are used widely in industry and are released during the thermal decomposition of polyurethane foams. Cyanide poisoning may also result from the ingestion of the cyanogenic glycoside, amygdalin (vitamin B_{17}), which is found in the kernels of almonds, apples, apricots, cherries, peaches, plums, and other fruits.

Mechanisms of toxicity

Cyanide reversibly inhibits cellular enzymes which contain ferric iron, notably cytochrome oxidase a_3, so that electron transfer is blocked, the tricarboxylic acid cycle is paralysed, and cellular respiration ceases.

Clinical features

Acute exposure

The ingestion by an adult of 50 ml of (liquid) hydrogen cyanide or 200 to 300 mg of one of its salts is likely to prove fatal. Inhalation of hydrogen cyanide gas may produce symptoms within seconds and death within minutes.

Acute poisoning is characterized by dizziness, headache, palpitation, anxiety, a feeling of constriction in the chest, dyspnoea, pulmonary oedema, confusion, vertigo, ataxia, coma, and paralysis. Cardiovascular collapse, respiratory arrest, convulsions, and metabolic acidosis are seen in severe cases. Cyanosis may occur, and the

classic 'brick-red' colour of the skin is noted occasionally. There is sometimes an odour of bitter almonds on the breath, but the ability to detect it is genetically determined and some 40 per cent of the population are unable to do so.

Chronic exposure

Chronic exposure results predominantly in neurological damage that can include ataxia, peripheral neuropathies, amblyopia, optic atrophy, and nerve deafness.

Treatment

Cyanide poisoning is a medical emergency, although specific antidotal treatment may not always be necessary. Where appropriate, the patient should be removed from the source of exposure, contaminated clothing discarded, and the skin washed with soap and water. Gastric lavage should be considered if a cyanide salt has been ingested less than 1 h previously, but this procedure must not delay treatment if symptoms or signs of toxicity are present. It may be difficult to differentiate between the genuine fear and anxiety of a patient and the early symptoms of cyanide poisoning. However, a patient who has been exposed to hydrogen cyanide gas and who is conscious 30 min later is unlikely to require antidotal therapy.

Oxygen

The administration of oxygen is of paramount importance in the treatment of cyanide poisoning. It is believed to prevent inhibition of cytochrome oxidase a_3 and to accelerate its reactivation.

Dicobalt edetate

Cobalt compounds form stable inert complexes with cyanide. Dicobalt edetate (Kelocyanor), if available, is the treatment of choice for confirmed cyanide poisoning and should be given intravenously in a dose of 300 to 600 mg over 1 min, with a further 300 mg if recovery does not occur within 1 min. It should be administered only if the diagnosis is certain because, in the absence of cyanide, Kelocyanor may cause serious side-effects including vomiting, tachycardia, hypertension, chest pain, and facial and palpebral oedema as it contains free cobalt, which is responsible in part for its efficacy.

Sodium thiosulphate

Cyanide is detoxified by conversion to thiocyanate. Thiosulphate is required for this reaction. Sodium thiosulphate 12.5 g (25 ml of a 50 per cent solution) should be given by intravenous injection over 10 min. Experimental studies have shown that the coadministration of sodium nitrite enhances the antidotal benefit of sodium thiosulphate.

Sodium nitrite, 4-dimethylaminophenol (4-DMAP)

Another means of inactivating cyanide is to convert a portion of the body's haemoglobin to methaemoglobin, which binds cyanide. Although the affinity of cyanide for methaemoglobin is less than that of cytochrome oxidase, the presence of a large circulating methaemoglobin pool diminishes cyanide toxicity by binding cyanide ion before tissue penetration occurs. Methaemoglobinaemia may be induced by the administration of either sodium nitrite or 4-dimethylaminophenol (**4-DMAP**). 4-DMAP may produce unexpectedly high methaemoglobin concentrations and cause acute tubular necrosis and Heinz-body haemolytic anaemia. Nitrites may also mitigate cyanide toxicity by virtue of their vasodilator actions and improvement of tissue perfusion. Sodium nitrite 300 mg (10 ml of a 3 per cent solution) should be administered by intravenous injection over 3 min.

Inhalation of amyl nitrite was recommended in the past but it produces only low circulating concentrations of methaemoglobin.

Hydroxocobalamin

One mole of hydroxocobalamin inactives one mole of cyanide but, on a weight-for-weight basis, 50 times more hydroxocobalamin is needed than cyanide because hydroxocobalamin is a far larger molecule. Con-centrated formulations of hydoxocobalamin are not yet available in all countries. If available, give hydroxocobalamin in a dose of 5 g intravenously over 30 min. A second dose (5 g) may be required in severe cases of cyanide poisoning.

Conclusion

If dicobalt edetate or hydroxocobalamin are not available, a combination of sodium nitrite and sodium thiosulphate should be administered..

Dapsone

Dapsone is available formulated alone or in combination with pyrimethamine (as Maloprim).

Clinical features

Dapsone poisoning can be severe and result not only in methaemoglobinaemia but also in haemolysis, jaundice, drowsiness, coma, seizures, and metabolic acidosis.

Treatment

If presentation after overdose is within 1 h, gastric lavage should be considered or, alternatively, 50 to 100 g of activated charcoal may be administered. Administration of repeated doses of activated charcoal seems to have comparable efficacy to haemodialysis in increasing dapsone elimination. Methylthioninium chloride (methylene blue) at 1 to 2 mg/kg should be given intravenously over 5 min for severe methaemoglobinaemia.

Diethylene glycol

Diethylene glycol is used mainly in polyester resins and polyols, as a humectant in the tobacco industry, and as a solvent. It achieved notoriety in 1985 when it was discovered that for some years it had been added to some wines. Several pharmaceutical errors have also led to fatalities.

Mechanism of toxicity

Animal studies suggest that diethylene glycol is first oxidized by alcohol dehydrogenase to 2-hydroxyethoxyacetaldehyde and then to 2-hydroxyethoxyacetic acid.

Clinical features

Nausea, vomiting, and abdominal pain occur frequently and are followed by the development of jaundice and hepatomegaly, pulmonary oedema, metabolic acidosis, coma, and renal failure in most cases.

Treatment

Supportive measures to treat dehydration and to correct metabolic acidosis should be instituted promptly. Ethanol or fomepizole (4-methylpyrazole) should be administered to block diethylene glycol metabolism and dialysis should be employed if renal failure supervenes. A loading dose of 50 g of ethanol orally (conveniently given as 125 ml of gin, whisky, or vodka) should be administered followed by an intravenous infusion of 10 to 12 g ethanol/h to produce a blood ethanol concentration of 500 mg to 1 g/l. The infusion should be continued until diethylene glycol is no longer detectable in the blood. If dialysis is employed, the rate of ethanol administration will need to be increased to 17 to 22 g/h. The regimen for fomepizole is given in the section on ethylene glycol below.

Digoxin and digitoxin

Toxicity occurring during chronic administration of these cardiac glycosides is common. In contrast, acute poisoning from digoxin and digitoxin is infrequent, though the mortality may be as high as 20 per cent after a substantial overdose, particularly if digoxin-specific antibody fragments are not employed.

Clinical features

Nausea, vomiting, dizziness, anorexia, and drowsiness are common. Confusion, diarrhoea, visual disturbances, and hallucinations may also occur. Sinus bradycardia, often marked, is the earliest cardiotoxic effect and may be followed by supraventicular arrhythmias with or without heart block, ventricular premature beats, and ventricular tachycardia. Hyperkalaemia occurs due to inhibition of the Na^{+}-K^{+} ATPase pump. The diagnosis may be confirmed by measurement of the serum digoxin concentration.

Treatment

Gastric lavage should be considered in patients with a history of a substantial overdose less than 1 h previously. Alternatively, 50 to 100 g of activated charcoal may be administered to reduce absorption and repeated doses will also enhance elimination. Potassium supplements should not be given until the serum potassium concentration is known, as severe poisoning is commonly associated with hyperkalaemia that should be treated conventionally.

Sinus bradycardia, ventricular ectopics, atrioventricular block, and sinoatrial standstill or block are often reduced or abolished by atropine in a dose of 1.2 to 2.4 mg. Ventricular ectopics alone should not be treated unless cardiac output is impaired. Ventricular tachydysrhythmias may be treated with intravenous lignocaine, atenolol, phenytoin, or amiodarone; if clinically significant and persistent, digoxin-specific antibody fragments should be considered. Failure to achieve a satisfactory cardiac output by drug therapy in patients with bradycardia, atrioventricular block, or sinus arrest is an indication for insertion of a right ventricular pacing wire or, if available, the administration of digoxin-specific antibody fragments (6 to 8 mg/kg body weight is sufficient in most cases of poisoning. In very severe cases consult the product literature to calculate the optimal dose). An improvement in the patient's condition should occur within 20 to 40 min.

Forced diuresis, peritoneal dialysis, haemodialysis, and haemoperfusion do not significantly increase the elimination of the drug.

Dishwashing liquids, fabric conditioners, and household detergents

Most of these products including carpet shampoo, dishwashing rinse aid for dishwashing machines, fabric washing powder and flakes, scouring liquids, creams, and powders contain surfactants that have both hydrophilic and lipophilic groups to allow fat-soluble substances to be dispersed in aqueous media.

There are three types of surfactants of differing toxicity: anionic surfactants, which have a negative electrical charge on the lipophilic groups; cationic surfactants, which have a positive charge; and non-ionic surfactants that have no charge.

Clinical features

Anionic detergents irritate the skin by removing natural oils and cause redness, soreness, and even a papular dermatitis. Ingestion may cause mild gastrointestinal irritation, nausea, vomiting, and diarrhoea. Non-ionic surfactants irritate the skin only slightly and appear to be completely harmless when ingested. Cationic surfactants (e.g. quarternary ammonium compounds) are much more toxic than the others but are rarely found in household cleaning materials.

Treatment

After ingestion of products containing either a non-ionic or anionic surfactant, liberal amounts of water or milk should be administered.

Further reading

Cornish LS, Parsons BJ, Dobbin MD (1996). Automatic dishwasher detergent poisoning: opportunities for prevention. *Australian and New Zealand Journal of Public Health* **20**, 278–83.

Disulfiram (Antabuse)

Mechanism of toxicity

Disulfiram and its main metabolite diethyldithiocarbamate inhibit the activity of a wide range of enzymes, particularly aldehyde dehydrogenase. Carbon disulphide, another metabolite, may account for some of the side-effects observed during disulfiram therapy.

Clinical features

Adult cases are likely to be alcoholics who have been taking disulfiram before the overdose and to be malnourished, factors that may explain the frequency of neuropsychiatric features. Sensorimotor neuropathy, flaccid tetraparesis, and encephalopathy have been described after overdose though these features may have been exacerbated by pre-existing malnourishment. Vomiting for several days, abdominal pain, and diarrhoea were reported in a patient who ingested 18 g of disulfiram.

Several cases of paediatric poisoning have been reported. Drowsiness, pyrexia, hypotonia, ataxia, uncontrollable and inappropriate arm movements, irritability,

speech difficulties, hallucinations, coma, and hyperreflexia were the major features.

Disulfiram–ethanol reaction

Nausea, vertigo, anxiety, blurred vision, hypotension, chest pain, palpitation, tachycardia, facial flushing, and throbbing headache are the usual features. Symptoms usually last for 3 to 4 days but may persist for 1 week. Occasionally the reaction is very severe with respiratory depression, cardiovascular collapse, cardiac arrhythmias, coma, cerebral oedema, hemiplegia, and convulsions; fatalities have been reported.

Further reading

Zorzon M *et al.* (1995). Acute encephalopathy and polyneuropathy after disulfiram intoxication. *Alcohol and Alcoholism* **30,** 629–31.

Diuretics

Most overdoses involving diuretics are minor, although inevitably some disturbance of fluid and electrolyte balance will result. When combined diuretic and potassium formulations are ingested, the potassium content is likely to pose the greater risk. More serious consequences are likely if a potassium-sparing diuretic has been ingested.

Clinical features

Symptoms and signs of toxicity include anorexia, nausea, vomiting, diarrhoea, profound diuresis, dehydration, and hypotension. In addition, dizziness, weakness, muscle cramps, tetany, and occasionally gastrointestinal bleeding may be seen. The electrolytic and metabolic disturbances that may be observed include hyponatraemia, hypoglycaemia or hyperglycaemia, hyperuricaemia, hypokalaemia, and metabolic alkalosis. Hyperkalaemia may develop following the ingestion of combined diuretic and potassium preparations and potassium-sparing diuretics, such as amiloride, spironolactone, or triamterene and small-bowel ulceration and stricture formation has followed poisoning due to diuretics with an enteric-coated core of potassium chloride.

Treatment

Symptomatic and supportive therapy should be employed with correction of fluid and electrolyte imbalance. Patients with hyperkalaemia may need a glucose and insulin infusion followed by oral or rectal administration of an ion-exchange resin.

Further reading

Lip GYH, Ferner RE (1995). Poisoning with anti-hypertensive drugs: diuretics and potassium supplements. *Journal of Human Hypertension* **9**, 295–301.

Ethanol

Ethanol is commonly ingested in beverages before, or concomitant with, the deliberate ingestion of other substances in overdose. It is also used as a solvent and is found in many cosmetic and antiseptic preparations. It is rapidly absorbed through the gastric and intestinal mucosas and approximately 95 per cent is oxidized to acetaldehyde and then to acetate; the remainder is excreted unchanged in the urine and to a lesser extent in the breath and through the skin.

Ethanol is a central nervous depressant that exacerbates the effects of other central nervous system depressants, in particular, hypnotic agents. The fatal dose of ethanol alone is between 300 and 500 ml of absolute alcohol, if this is ingested in less than 1 h.

Clinical features

The clinical features of ethanol intoxication are well known and are generally related to blood concentrations (Table 5).

Severe hypoglycaemia may accompany alcohol intoxication due to inhibition of gluconeogenesis. This occurs more commonly in children than in adults and typically occurs within 6 to 36 h of ingestion of a moderate to large amount of alcohol by either a previously malnourished individual or one who has fasted for the previous 24 h. The patient is often in coma and hypothermic but flushing, sweating, and tachycardia are frequently absent. Rarely lactic acidosis, ketoacidosis, and acute renal failure have been described.

Treatment

Hypoglycaemia is usually unresponsive to glucagon and therefore intravenous glucose in a dose of 50 ml of 50 per cent solution should be given. Treatment is supportive. Gastric lavage has not been shown to be of benefit in ethanol poisoning. The use of haemodialysis should be considered if the blood ethanol concentration exceeds 5000 mg/l and/or if metabolic acidosis is present.

Further reading

Ernst AA *et al.* (1996). Ethanol ingestion and related hypoglycemia in a pediatric and adolescent emergency department population. *Academic Emergency Medicine* **3**, 46–9.

Ethylene glycol (1,2-ethanediol)

Ethylene glycol has a variety of commercial applications and is commonly used as an antifreeze fluid in car radiators. Its sweet taste and ready availability have contributed to its popularity as a suicide agent and as a poor man's substitute for alcohol.

It is thought that the minimum lethal dose of ethylene glycol is about 100 ml for an adult, although recovery after treatment has been reported following the ingestion of up to 1 litre.

Mechanism of toxicity

Ethylene glycol itself appears to be non-toxic. Metabolism takes place in the liver and kidneys. Accumulation of metabolites including aldehydes, glycolate, oxalate, and lactic acid may explain toxicity.

Clinical features

The clinical features of ethylene glycol poisoning may be divided into three stages depending on the time after ingestion (Table 6). In addition, hypocalcaemia, severe metabolic acidosis, and calcium oxalate crystalluria are observed in severe cases. The severity of each stage and the progression from one stage to the next depends on the amount of ethylene glycol ingested.

Death may occur during any of the three stages. A serum ethylene glycol concentration in excess of 500 mg/l indicates severe poisoning.

Treatment

Early diagnosis and appropriate therapy significantly reduce the mortality from ethylene glycol poisoning. Gastric lavage should be considered if presentation occurs less than 1 h after ingestion. Supportive measures to combat shock, respiratory distress, hypocalcaemia, and metabolic acidosis should be instituted. Thereafter, treatment has two main aims. First, the competitive inhibition of ethylene glycol metabolism, using ethanol or fomepizole (4-methylpyrozole), and, second, the

increased elimination of the glycol from the body using dialysis. A loading dose of 50 g of ethanol (conveniently given as approximately 125 ml of gin, whisky, or vodka) should be administered followed by an intravenous infusion of 10 to 12 g of ethanol to provide blood ethanol concentrations of 500 mg to 1 g/l. The infusion should be continued until ethylene glycol is no longer detectable in the blood. If dialysis is also employed, the rate of ethanol administration will need to be increased (17 to 22 g/h). Alternatively, fomepizole at 15 mg/kg body weight can be administered over 30 min, followed by four 12-hourly bolus doses of 10 mg/kg until ethylene glycol concentrations are less than 200 mg/l. If treatment is needed for more than 48 h, the bolus dose should be increased to 15 mg/kg to compensate for the induction of fomepizole metabolism. If dialysis is employed, the frequency of dosing should be increased to 4-hourly during dialysis because fomepizole is dialysable.

Ethylene glycol, its aldehyde metabolites, and glycolate may be removed by either peritoneal or haemodialysis, though the latter is two to three times more efficient. Oxalate, however, is poorly dialysable. In addition, it may be necessary to treat the uraemic complications of ethylene glycol poisoning with dialysis and to use haemodialysis/ultrafiltration to correct the sodium overload that can result from the necessary, but sometimes overjudicious, correction of the metabolic acidosis with sodium bicarbonate. Dialysis should be continued until ethylene glycol is no longer detectable in the blood.

Flecainide

Flecainide is a local anaesthetic-type antiarrhythmic drug that inhibits fast sodium channels of cardiac myocytes and markedly shortens action potential duration in the Purkinje system.

Clinical features

The features of overdose are predictable on the basis of the drug's known effects and include hypotension, bradycardia, intraventricular conduction abnormalities, atrioventricular block, and ventricular tachycardia. In severe cases convulsions and cardiorespiratory failure occur and fatalities have been reported.

Treatment

If the patient presents within 1 h of a substantial overdose, gastric lavage should be considered or, alternatively, activated charcoal (50 to 100 g) may be administered. Supportive measures should then be employed, as no specific antidote is available. Lignocaine has been found to be of value in controlling ventricular tachycardia after overdose. There is evidence from volunteer studies that acidification of the urine will increase flecainide elimination; haemodialysis and haemofiltration are of no benefit.

Folic acid

Overdosage with this vitamin does not cause toxic features. No treatment is necessary.

Formaldehyde

Formaldehyde is a flammable, colourless gas with a pungent odour. It is most commonly available commercially as a 30 to 50 per cent w/w aqueous solution and is an important raw material in the synthesis of organic compounds such as plastics and resins.

Metabolism

Formaldehyde is oxidized rapidly to formic acid then converted more slowly to carbon dioxide and water.

Clinical features

Acute exposure

Severe irritation of the mucous membranes of the eyes, nose, and upper airways occurs after minimal exposure to low (less than 5 ppm) formaldehyde concentrations, and tends to prevent higher exposure in even the most tolerant subjects. Substantial exposure may result in severe bronchospasm, pulmonary oedema, and death.

Formaldehyde solutions splashed into the eye have caused corneal damage and skin contamination has resulted in dermatitis. Spillage of phenol-formaldehyde resin on to the skin has produced extensive necrotic skin lesions, fever, hypertension, adult respiratory distress syndrome, proteinuria, and renal impairment. Ingestion of formaldehyde solution has resulted in severe corrosive damage to the buccal cavity and tonsils, oesophagus, and stomach with ulceration, necrosis, and subsequent fibrosis and contracture. Shock, metabolic acidosis (due in part to high formate concentrations), respiratory insufficiency, and renal impairment usually then ensue. Death may follow ingestion of less than 100 ml in an adult.

Treatment

Supportive measures, including the correction of acid–base disturbances, should be employed. Haemodialysis is only moderately effective in increasing formate elimination.

Glyphosate

Glyphosate-containing herbicides usually incorporate the isopropylamine salt together with a surfactant. The original surfactant was probably the main cause of toxicity but this is no longer present in currently marketed formulations.

Clinical features

The most prominent effects are on the alimentary tract with burning in the mouth and throat, nausea, vomiting, dysphagia, and diarrhoea being the main features. Upper gastrointestinal haemorrhage is a much less common complication. A polymorphic leucocytosis is usual. Hypotension, tachycardia, bradycardia, acute chemical pneumonitis, oliguria, haematuria, and metabolic acidosis may be seen in severe poisoning.

Treatment

Management is largely symptomatic and supportive. Intravenous fluids or blood transfusion may be required. Respiratory and renal failure should be managed

conventionally. The toxicokinetics of glyphosate in man are not known and rational use of elimination procedures is therefore not possible.

n-Hexane

n-Hexane is an extremely volatile liquid that is used as a solvent.

Clinical features

When ingested it causes nausea, dizziness, CNS excitation and then depression and, as a result, presents an acute aspiration hazard resulting in chemical pneumonitis and non-cardiogenic pulmonary oedema. Following inhalation, either inadvertently or deliberately, similar symptoms occur. The development of a progressive sensorimotor neuropathy is the principal hazard of chronic exposure.

Treatment

Treatment is supportive and symptomatic.

Household products

There is a commonly held belief that household products contain a wide range of highly toxic chemicals, and so the ingestion of these substances by children is a frequent cause for alarm in parents and doctors alike. So-called poisoning from household products is more often the result of accidental than deliberate ingestion, mostly involves young children, and is not usually serious. Even when the toxicity of a household product is high, the risk it poses is usually low, certainly when ingested accidentally. However, adults intent on suicide may, by deliberately swallowing massive quantities, succeed in killing themselves. Antiseptics and disinfectants, dishwashing liquids, fabric conditioners, detergents, bleaches and lavatory cleaners, lavatory sanitizers, and deodorants are dealt with elsewhere.

H_2-receptor antagonists

H_2-receptor antagonists such as cimetidine, famotidine, nizatidine, and ranitidine are very widely prescribed but few cases of overdose have been reported.

Clinical features

Most patients remain asymptomatic. In a few, drowsiness, dryness of the mouth, slurred speech, dizziness, confusion, vomiting, and abdominal discomfort have been reported. Rarely, bradycardia, respiratory depression, and coma may result.

Treatment

Gut decontamination is unnecessary and supportive and symptomatic measures should be employed if features develop. Although forced diuresis has been employed in one case, no supporting evidence of efficacy was given.

Hydrogen fluoride

Hydrogen fluoride is a corrosive, fuming, nearly colourless liquid (hydrofluoric acid) at atmospheric pressures and temperatures below 19°C; above 19°C it is gaseous. Hydrogen fluoride is very soluble in cold water and for this reason it fumes strongly in moist air. Aqueous solutions dissolve glass.

Mechanisms of toxicity

Fluoride directly inhibits many enzyme systems, including glycolytic enzymes, cholinesterases, and those in which magnesium and manganese are present. In addition, fluoride appears to have a direct toxic effect on nerve tissue and muscle; depression of vasomotor and smooth muscle tone may also occur.

Clinical features

Inhalation or ingestion of hydrogen fluoride causes severe corrosive damage similar to other acids (see above). Following absorption by whatever route, fluoride chelates calcium and lowers the serum ionized calcium concentration and causes weakness, paraesthesiae, tetany, and convulsions. Hypotension and cardiac arrhythmias, including ventricular fibrillation, may be observed. Central effects of fluoride include confusion and coma. Hepatic and renal failure may develop.

Skin contact with anhydrous hydrogen fluoride produces liquefactive necrosis and severe burns that are felt immediately. Concentrated aqueous solutions also cause an early sensation of pain, but more dilute solutions may give no warning of injury. If the solution is not removed promptly, penetration of the skin by fluoride ion may occur, leading to painful ulcers that heal only slowly.

Treatment

Following inhalation of hydrogen fluoride, the casualty should be removed immediately from the contaminated atmosphere. Further treatment is symptomatic and supportive. Mechanical ventilation with positive end-expiratory pressure may be needed to treat pulmonary oedema.

If hydrofluoric acid has been ingested, 10 to 20 g of soluble calcium tablets should be given by mouth, followed by an intravenous injection of 10 ml of 10 per cent calcium gluconate solution. Symptomatic and supportive measures should be employed thereafter.

Skin contact requires thorough washing of the affected area with copious quantities of water for 20 min, even if there is no apparent burn or pain. Skin burns should be coated repeatedly with 2.5 per cent calcium gluconate gel, but if the gel is unavailable, immersion of the skin in iced water until the pain subsides is often helpful. If the pain does not subside, 10 per cent calcium gluconate solution (up to 0.5 ml/cm^2) should be injected under the burn area, though calcium gluconate intra-arterially is more effective.

Hydrogen sulphide

Hydrogen sulphide is a colourless gas that smells of rotten eggs, although high concentrations cause olfactory nerve paralysis. The gas is also found in mines and sewers and is liberated from decomposing fish (a hazard in fishing boats if the hold is filled with 'trash' fish used for making fish meal) and liquid manure systems.

Mechanisms of toxicity

It is now thought that the serious sequelae following exposure to high concentrations of hydrogen sulphide are due principally to inhibition of cytochrome oxidase a $_3$, in which respect it may be more potent than cyanide.

Clinical features

Exposure to low concentrations leads to blepharospasm, pain and redness of the eyes, blurred vision, and coloured haloes round lights. Headache, nausea, dizziness, drowsiness, sore throat, and cough may also occur. With exposure to higher concentrations, cyanosis, confusion, pulmonary oedema, coma, and convulsions are common. Six per cent of casualties die.

Treatment

The casualty should be moved to fresh air from the contaminated atmosphere by a rescuer who has donned breathing apparatus beforehand.

It has been shown in mice that the administration of sodium nitrite is superior to oxygen alone in the treatment of acute hydrogen sulphide poisoning. However, the mechanism of this benefit is disputed and the value of this treatment in humans has not been established.

Hypoglycaemic agents

Intentional overdose with insulin and oral hypoglycaemic agents is uncommon. However, deaths from insulin and sulphonylurea overdosage have been reported. Chlorpropamide and glyburide (available only in the United States) are the oral agents most commonly ingested. Chlorpropamide, because of its long half-life, may, in overdose, induce hypoglycaemia for a considerable period of time. In all cases of poisoning with hypoglycaemic agents prompt diagnosis and treatment are essential if death or cerebral damage from neuroglycopenia are to be prevented.

Clinical features

Features of overdosage include drowsiness, coma, twitching, convulsions, depressed limb reflexes, extensor plantar responses, hyperpnoea, pulmonary oedema, tachycardia, and circulatory failure. Hypoglycaemia is to be expected and hypokalaemia, cerebral oedema, and metabolic acidosis might occur. Neurogenic diabetes insipidus and persistent vegetative states are possible long-term complications. Cholestatic jaundice has been described as a late complication of chlorpropamide poisoning.

Treatment

The blood or plasma glucose concentration should be measured urgently and intravenous glucose given. Glucagon may be ineffective. If the blood sugar is normal, gastric lavage should be considered if the patient has presented within 1 h of the ingestion of an oral preparation.

Recurring hypoglycaemia is highly likely. A continuous infusion of glucose together with carbohydrate-rich meals is required in cases of severe insulin overdosage, though there may be difficulty in maintaining normoglycaemia. In the case of sulphonylurea overdosage, however, further glucose (although its administration may be unavoidable) only serves to increase already high circulating insulin concentrations. Diazoxide has therefore been recommended since it increases blood glucose concentrations and raises circulating catecholamine concentrations while blocking insulin release. The dose is 1.25 mg/kg body weight intravenously over 1 h, repeated at 6-hourly intervals if necessary.

Iron

Most medicinal iron preparations are ferrous salts that must be oxidized to the ferric state before being absorbed and stored in the liver and reticuloendothelial system. Iron overdosage is much more common in preschool children than in adults. Toxic features are unlikely unless more than 60 mg of elemental iron/kg body weight has been ingested, probably because absorption is poor. Poisoning is therefore seldom severe and deaths are rare.

Mechanism of toxicity

Iron salts have complex actions, including direct corrosive effects on the upper gastrointestinal tract and potentially serious effects on the circulation; at a cellular level they tend to concentrate around mitochondrial cristae where they may act as an electron 'sink', thereby interfering with intermediary metabolism.

Clinical features

The course of iron poisoning is conventionally divided into four phases.

Phase 1

The first phase starts immediately after ingestion and lasts about 6 h. Nausea, vomiting, abdominal pain, and diarrhoea, all of which result from direct irritation of the gut, characterize it. The gastric and upper small bowel mucosas may be stained and impregnated with iron and become ulcerated, the severity of these changes decreasing with distance from the stomach. The disintegrating tablets may make the vomitus and stools grey or black in colour. Polymorphic leucocytosis and hyperglycaemia are common. Iron tablets in the upper gut may be visible in an abdominal radiograph, particularly if it is taken within 2 h of alleged ingestion.

A few patients develop haematemesis, hypotension, coma, and shock, which may be fatal.

Phase 2

This phase lasts from about 6 to 24 h after ingestion and is a period during which patients improve symptomatically. Indeed, most do not progress further.

Phase 3

During this phase, 12 to 48 h after ingestion, a small minority of patients deteriorate, often with profound shock, metabolic acidosis, and features which are due to acute renal tubular and hepatocellular necrosis. Liver failure and its complications develop and may be fatal. The extent of liver damage varies from almost complete necrosis in some areas to only periportal damage in others.

Phase 4

This is the period 2 to 6 weeks after ingestion. The features at this stage are those of high intestinal obstruction by a stricture formed at the site of corrosive damage to the mucosa, usually the pyloric antrum. Children are most likely to be affected.

Assessment of the severity of poisoning

The amount ingested is not reliable because of vomiting. Shock, coma, and acidosis indicate severe poisoning. Other clinical features are less useful. Emergency estimation of the serum iron concentration is essential. If the 4 to 6 h concentration exceeds the predicted normal iron-binding capacity (usually more than 90 µmol/l), free iron is circulating and treatment is needed. Measurement of the total iron-binding capacity in acute iron poisoning may give misleading results and is not recommended.

Treatment

Reducing absorption

Gastric lavage should be considered if more than 20 mg of elemental iron/kg body weight has been ingested in the previous 1 h. Addition of bicarbonate, phosphates, and desferrioxamine (deferoxamine) to lavage fluids does not reduce absorption further and may be dangerous. Whole bowel irrigation may have a role if a large amount (particularly of a slow release formulation) has been ingested and has already passed through the pylorus.

Severe poisoning with coma or shock

When coma or shock are present the specific iron-chelating agent desferrioxamine (deferoxamine) should be given without delay and without waiting for the result of the serum iron concentration. The dose is 15 mg/kg body weight/h intravenously and the total amount infused should not exceed 80 mg/kg in 24 h. Clinical improvement can be expected within 1 to 2 h, after which the rate of infusion may be reduced. There is no simple or readily available method of deciding when to stop desferrioxamine administration; the clinical state of the patient is probably the most appropriate guide. Desferrioxamine may also be given intramuscularly in a dose of 2 g for an adult and 1 g for a child.

Hypotension due to desferrioxamine-induced histamine release may develop if the recommended rate of administration is exceeded. Other adverse effects include hypersensitivity reactions and, rarely, anaphylaxis. Pulmonary oedema and adult respiratory distress syndrome attributed to desferrioxamine have been reported in patients given 15 mg/kg for 65 h and longer.

Poisoning without coma or shock

Routine administration of desferrioxamine cannot be recommended. Patients who are not in coma or shock but who have a serum iron concentration greater than 90 µmol/l should be given desferrioxamine.

Overdose without features

Patients who have not developed features of poisoning within 6 h have probably not ingested toxic amounts and therefore they do not require treatment. Those who present earlier than 6 h should be assessed as described above and treated accordingly.

Supportive measures

Only a small minority of patients will require supportive measures in addition to those described above. Attention to the airway and ventilation is obviously important if consciousness is impaired and fluid and electrolytes should be replaced as necessary. Blood transfusion may be required if there has been significant haemorrhage. Liver and renal function should be monitored and failure managed conventionally.

Overdosage in pregnancy

Overdosage with iron salts during pregnancy should be treated as under other circumstances. Limited evidence indicates that desferrioxamine is not fetotoxic or teratogenic and to withhold it when it is indicated may be fatal.

Isoniazid

Poisoning with isoniazid is potentially very serious, but uncommon.

Mechanisms of toxicity

Isoniazid depresses brain concentrations of g-aminobutyric acid (GABA), thus leading to seizures.

Clinical features

The ingestion of 80 to 150 mg of isoniazid/kg body weight is likely to cause severe poisoning. Nausea, vomiting, slurred speech, dizziness, and visual hallucinations may develop. Stupor, coma, and convulsions follow rapidly and may be associated with hyperthermia, hyperreflexia, extensor plantar responses, and later, rhabdomyolysis. In addition, dilated pupils, sinus tachycardia, and urinary retention may be observed. In severe cases, hypotension, acute renal failure, and respiratory failure may ensure. Marked metabolic (lactic) acidosis is common. Less commonly, hyperglycaemia, ketoacidosis, glycosuria, and ketonuria are found.

Treatment

Supportive measures including the correction of metabolic acidosis should be instituted immediately if the patient is unconscious. If the airway can be protected, gastric lavage or the administration of 50 g of activated charcoal should be considered if presentation is less than 1 h after overdose. Pyridoxine (1 g for 1 g of isoniazid ingested) should be given intravenously to control convulsions. When the ingested dose of isoniazid is unknown, an initial intravenous dose of 5 g of pyridoxine should be given. Diazepam alone may be ineffective but the use of diazepam and pyridoxine is synergistic and both should be used in those with convulsions. Pyridoxine in a dose of 5 g may be repeated if convulsions persist (in one case 52 g of pyridoxine was given intravenously without ill effects).

Charcoal haemoperfusion is the most effective technique for elimination of isoniazid from the circulation but its use should rarely be necessary provided appropriate supportive measures and adequate and repeated doses of pyridoxine and diazepam are given.

Isopropanol (isopropyl alcohol; 2-propanol)

Isopropanol is used as a sterilizing agent and as rubbing alcohol. It is also found in aftershave lotions, disinfectants, and window-cleaning solutions. Intoxication can result both from ingestion and skin absorption. Isopropanol is oxidized in the liver to acetone.

Clinical features

Features of toxicity include coma and respiratory depression, the odour of acetone on the breath, gastritis, haematemesis, hypotension, hypothermia, renal tubular necrosis, acute myopathy, and haemolytic anaemia; cardiac arrest has occurred. The development of hypotension is a poor prognostic feature.

Treatment

Gastric lavage should be considered if the patient presents less than 1 h after ingestion. In addition to supportive measures, haemodialysis should be employed in severely poisoned patients as it not only removes isopropanol but also shortens the duration of coma.

Further reading

Pappas AA *et al.* (1991). Isopropanol ingestion: report of six episodes with isopropanol and acetone serum concentration time data. *Journal of Toxicology—Clinical Toxicology* **29**, 11–21.

Lavatory sanitizers and deodorants

Solid lavatory sanitizer or deodorant blocks normally contain paradichlorobenzene. Ingestion may cause nausea, vomiting, diarrhoea, and abdominal pain. Symptomatic and supportive treatment is all that is required unless many grams have been ingested in which case gastric lavage should be considered if the patient presents within 1 h of ingestion.

Lead

Exposure to lead occurs in the reclamation of lead from scrap metal, in the demolition and flame-cutting of old railway bridges previously painted with lead paint, and in the manufacture of storage batteries and ceramics. Children with pica who chew on lead-painted railings in homes, or who eat contaminated soil, have developed lead poisoning. As a consequence of lead leaching out of the glazing material, poisoning has also been described in individuals who have consumed drinks from lead-glazed mugs. Ingestion of lead-based powders in paints and imported baby tonics and application of lead-containing cosmetics such as 'surma' to the face in Asian communities has resulted in lead intoxication. Rarely, lead acetate has been injected intravenously with suicidal intent. Tetraethyl lead, which is used as an anti-knock agent in leaded petrol, can be absorbed systemically by inhalation, ingestion, and through the skin. Transplacental transfer of lead from mother to fetus results in reduced viability of the fetus, reduced birth weight, and premature birth.

The Centers for Disease Control and Prevention in Atlanta have reduced the concentration of lead at which intervention is indicated from 150 µg/l as some adverse health effects have been observed in young children at a blood lead concentration of 100 µg/l.

Lead absorbed into the body is mainly (95 per cent) deposited in the bones and teeth. Of the lead in the blood, 99 per cent is associated with erythrocytes. As the body accumulates lead over many years and releases it into the urine only slowly, even small doses can in time lead to intoxication.

Clinical features

Mild intoxication may result in no more than lethargy and occasional abdominal discomfort, whereas abdominal pain (which is usually diffuse but may be colicky), vomiting, constipation, and encephalopathy develop in more severe cases. Lead colic was first described by Hippocrates and, on occasions, has been incorrectly managed surgically as a case of an acute abdomen. Encephalopathy (seizures, mania, delirium, coma) is more common in children than in adults. Classically, lead poisoning results in foot drop attributable to primary motor peripheral neuropathy; wrist drop occurs only as a late sign.

Renal effects include reversible renal tubular dysfunction causing glycosuria, aminoaciduria, and phosphaturia and irreversible interstitial fibrosis with progressive renal insufficiency leading to hypertension.

A bluish discoloration of the gum margins due to deposition of lead sulphide is observed occasionally.

Lead depresses the enzymes responsible for haem synthesis and shortens erythrocyte lifespan leading to microcytic or normocytic hypochromic anaemia. In severe intoxication haemolytic anaemia may occur. Basophilic stippling of erythrocytes is due to nuclear remnants. Lead blocks the conversion of †-aminolaevulinic acid to porphobilinogen leading to an increase in †-aminolaevulinic acid in blood and urine. Lead also inhibits ferrochelatase that results in elevated free erythrocyte protoporphyrin (**FEP**) concentrations. There is a concomitant increase in urinary coproporphyrins and FEP, commonly assayed as zinc protoporphyrin.

An elevated zinc protoporphyrin concentration (more than 350 µg/l) reaches a steady state in the blood only after the entire population of circulating erythrocytes has turned over (approximately 120 days). Consequently, it lags behind blood lead concentrations and is an indirect measure of long-term lead exposure. Moreover, zinc protoporphyrin is not a good screening test, as it is not sensitive at the lower levels of lead poisoning.

Medical surveillance

The current practice in the United Kingdom and some other European countries is to recommend stopping work with lead where a worker's blood lead concentration is shown to be above 700 µg/l although workers may be symptomatic below this concentration. In workers exposed to organic lead compounds, the urinary lead concentration (more than 150 µg/l) is a good indicator of exposure.

Treatment

Primary prevention aimed at eliminating lead hazards for children and workers must receive due public-health attention. The social dimension of the problem must also be recognized: simply giving children chelation therapy and then returning them to a contaminated home environment is of no value. Similarly, if an occupational source of lead exposure is implicated, a thorough evaluation of the workplace, other exposed workers, and the systems for handling lead at work is appropriate.

The decision to use chelation therapy is based not only on the blood lead concentration but also on the symptoms present and, if available, an estimate of the total body burden of lead using X-ray fluorescence. Sodium calcium edetate and DMSA (succimer) both increase lead excretion, though the former must be given intravenously and may result in increased uptake of lead into the brain. In severe acute lead poisoning, particularly of occupational origin, sodium calcium edetate 75 mg/kg body weight daily for 5 days provides rapid relief of symptoms with minimal risk of adverse effect; a second course may be given a week after the first. If hydration is maintained during chelation, proximal tubular damage is not usually observed. DMSA 30 mg/kg body weight orally for 5 days is an alternative though less efficient chelator than sodium calcium edetate.

Lignocaine and related drugs

Lignocaine, mexiletine, and tocainide are sodium channel blockers. Intoxication with these agents, particularly lignocaine, occurs most often as a result of therapeutic overdose in intensive care areas or inadvertent intravenous administration during local anaesthesia. Topical absorption of lignocaine may result in systemic toxicity, particularly in children.

Clinical features

Poisoning induces nausea, vomiting, paraesthesias, tremor, drowsiness, dizziness, dysarthria, diplopia, nystagmus, ataxia, confusion, convulsions, and coma. Sinus bradycardia, heart block, and hypotension may develop in severe poisoning and cardiac arrest may ensue; mexiletine may also cause atrial fibrillation.

Treatment

Gastric lavage should be considered or 50 to 100 g of activated charcoal administered if an overdose has been ingested less than 1 h previously. Diazepam in a dose of 5 to 10 mg intravenously should be given for convulsions, if they are not short-lived, and atropine in a dose of 1 to 2 mg intravenously should be administered for sinus bradycardia. Inotropic support may become necessary if heart block or severe hypotension supervene. Pacing may be attempted but the ventricular response is usually poor. Tocainide elimination is increased significantly with haemodialysis.

Denaro CP, Benowitz NL (1989). Poisoning due to class 1B antiarrhythmic drugs: Lignocaine, mexilitine and tocainide. *Medical Toxicology* **4**, 412–28.

Lindane

Lindane is an organchlorine pesticide.

Clinical features

The main toxic effects following ingestion are on the central nervous system with rapid loss of consciousness and the development of myoclonus, hypertonia, hyperreflexia, convulsions, and rhabdomyolysis. Metabolic acidosis, disseminated intravascular coagulation, renal tubular and hepatocellular necrosis, pancreatitis, and proximal myopathy have been reported.

Treatment

Treatment is symptomatic and supportive. Gastric lavage should be considered if lindane has been ingested less than 1 h previously. Metabolic acidosis and convulsions should be treated conventionally.

Liquefied petroleum gas (LPG 'bottled gas')

Liquefied petroleum gas (LPG 'bottled gas') contains propane and butane (and sometimes propylene and butylene). Propane and butane may cause vertigo and drowsiness and, at high concentrations, may act as asphyxiants.

Further reading

Gray MY, Lazarus JH (1993). Butane inhalation and hemiparesis. *Journal of Toxicology—Clinical Toxicology* **31**, 483–5.

Lithium carbonate

The therapeutic index of lithium is low and toxicity is usually the result of therapeutic overdose rather than deliberate self-poisoning. However, individuals on or not on long-term treatment with the drug occasionally ingest single large doses.

Clinical features

Features of intoxication include thirst, polyuria, diarrhoea, and vomiting, and in more serious cases, impairment of consciousness, hypertonia, tremor, and convulsions; irreversible neurological damage may occur. Measurement of the serum lithium concentration confirms the diagnosis, therapeutic toxicity usually being associated with concentrations above 1.5 mmol/l. However, acute massive overdosage may produce much higher concentrations without causing toxic features, at least initially.

Treatment

Gastric lavage may be considered if the patient presents less than 1 h after a substantial overdose. Thereafter, treatment is supportive together with measures to enhance the rate of lithium elimination. The decision to enhance elimination is based on the severity of features and a serum lithium concentration greater than 3 mmol/l, particularly in patients receiving lithium chronically. Forced diuresis with 0.9 per cent sodium chloride is effective but its use is commonly complicated by hypernatraemia and increased plasma osmolality; the infusion of low-dose dopamine at 2.5 µg/kg.min may be an effective alternative. Peritoneal dialysis or haemodialysis may be needed if renal function is impaired and in severe poisoning; peritoneal dialysis is much less effective. However, the relatively slow movement of lithium ions across cell membranes limits the efficacy of all these techniques. It is easy to reduce serum lithium concentrations but they frequently rebound when

treatment is stopped and clinical improvement is much slower.

Further reading

Lysergic acid diethylamide (LSD)

As with cannabis, individuals intoxicated with LSD rarely present to medical services.

Clinical features

The ability of LSD to distort reality is well known. Visual hallucinations, distortion of images, agitation, excitement, dilated pupils, tachycardia, hypertension, hyperreflexia, tremor, and hyperthermia are common; auditory hallucinations are rare. Time seems to pass very slowly and behaviour may become disturbed with paranoid delusions. Flashbacks in which the effects of LSD may be re-experienced without further exposure to the drug occur in about 15 per cent of users for several years and are not explained.

Treatment

Most individuals will require little more than reassurance and sedation. Supportive measures are all that can be offered to those who are seriously ill.

Mefenamic acid

Clinical features

Overdose of mefenamic acid produces nausea, vomiting, and occasionally, bloody diarrhoea. Drowsiness, dizziness, and headaches are common and hyperreflexia, muscle twitching, convulsions, cardiorespiratory arrest, hypoprothombinaemia, and acute renal failure have been reported. In a study of 29 cases of mefenamic acid poisoning, convulsions were noted in 38 per cent of patients, although only rarely were they persistent.

Treatment

Gastric lavage or activated charcoal may be considered if the patient presents less than 1 h after overdose. Symptomatic and supportive measures should be employed and haemodialysis/filtration undertaken for renal failure.

Further reading

Turnbull AJ, Campbell P, Hughes JA (1988). Mefenamic acid nephropathy—acute renal failure in overdose. *British Medical Journal* **296**, 46.

Mercury

Mercury is the only metal which is liquid at room temperature. It exists in three forms, metallic (Hg°), mercurous (Hg_2^{2+}), and mercuric (Hg^{2+}). Metallic mercury is very volatile and when spilt has a large surface area so that high atmospheric concentrations may be produced in enclosed spaces, particularly when environmental temperatures are high. In addition to simple salts, such as chloride, nitrate, and sulphate, mercuric mercury forms organometallic compounds where mercury is covalently bound to carbon, such as methyl-, ethyl-, phenyl-, and methoxyethyl mercury.

Non-occupational mercury exposure occurs principally from dietary intake and to a minor extent from dental amalgam. Many foodstuffs contain small amounts of mercury.

The absorption of mercury depends on its chemical form. Inhaled mercury vapour is absorbed rapidly and oxidized to Hg^{2+} in erythrocytes and other tissues. Prior to oxidation, absorbed mercury vapour can cross the blood–brain barrier, but the divalent ion oxidation product serves to trap mercury in the brain. Mercury vapour is also absorbed via the skin, at an average rate of 0.24 ng/cm^2.min. Less than 1 per cent of an ingested dose of metallic mercury reaches the systemic circulation. Organic mercuric salts are better absorbed following ingestion than are inorganic mercuric salts. Organic mercury compounds cross the blood–brain barrier readily to accumulate in the brain. In contrast the kidney is the main storage organ for inorganic mercury compounds. *In vivo* mercury is bound to metallothionein, which serves a protective role since renal damage is caused only by the unbound metal. Mercury is excreted mainly in urine and faeces although a small amount of absorbed inorganic mercury is exhaled as mercury vapour. The half-life of most body mercury is 1 to 2 months but a small fraction has a half-life of several years.

Clinical features

Acute poisoning

Acute mercury vapour inhalation causes headache, nausea, cough, chest pain, bronchitis, and pneumonia. In a few individuals renal damage from such acute exposure may produce gross proteinuria or nephrotic syndrome. In addition, a fine tremor and neurobehavioural impairment occurs and peripheral nerve involvement has also been observed.

Ingestion of metallic mercury is usually without systemic effects as metallic mercury is poorly absorbed from the gastrointestinal tract. However, mercuric chloride or other inorganic mercuric salts cause an irritant gastroenteritis with corrosive ulceration, bloody diarrhoea, and abdominal cramps and may lead to circulatory collapse and shock. The ingestion of disc batteries containing mercuric oxide usually results in uneventful spontaneous passage through the gastrointestinal tract, but potentially toxic mercury levels may result if the battery opens in transit. Mercury-containing batteries have been withdrawn from the European Union. Mercurous compounds are less soluble, less corrosive, and less toxic than mercuric salts. Ingestion of mercurous chloride in teething powder has led to 'pink disease' or acrodynia in infants.

There are reports of deliberate intravenous or subcutaneous metallic mercury injection. Accidental injection also has occurred after injury from broken thermometers and, in the past, following gas analysis procedures using mercury as a syringe sealant. Intravascular mercury may result in pulmonary venous or peripheral arterial embolism. Subcutaneous mercury initiates a soft-tissue inflammatory reaction with granuloma formation. Signs of systemic mercury toxicity are rare following metallic mercury injection.

Chronic poisoning

Chronic poisoning from inorganic mercury compounds or mercury vapour is characterized by non-specific early symptoms such as anorexia, insomnia, abnormal sweating, headache, lassitude, increased excitability, tremor, gingivitis, hypersalivation, personality changes, and memory and intellectual deterioration. Glomerular and tubular damage may follow chronic exposure to mercury and renal tubular acidosis has been described in children.

Exposure to organic mercury compounds usually involves aromatic derivatives such as phenyl mercuric acetate and phenyl mercuric benzoate, or aliphatic compounds such as methylmercury and ethylmercury chloride. The main features of poisoning are paraesthesias of the lips, hands, and feet, ataxia, tremor, dysarthria, constriction of visual fields, deafness, and emotional and intellectual changes. There is often a latent period of several weeks between the last exposure and the development of symptoms.

Treatment

Even prompt removal from exposure to mercury vapour may not prevent the development of serious sequelae. Early intensive supportive measures are of paramount importance in the management of the severe gastrointestinal complications caused by the ingestion of mercuric salts, such as mercuric chloride. In these circumstances gastric lavage is best avoided as significant oesophageal erosions may be present.

Traditionally, dimercaprol (British Anti-Lewisite, BAL) has been used in the treatment of inorganic mercury poisoning, but it has to be administered intramuscularly and has adverse effects. Oral DMPS (unithiol) and DMSA (Succimer) in a dose of 30 mg/kg body weight daily have been shown to enhance mercury elimination significantly, protect against renal damage, and increase survival, at least in animal studies. In some of these experimental studies DMPS appears to be significantly better than DMSA in reducing the total body mercury burden, renal deposition of mercury, and mortality.

DMPS also appears to be of value in the treatment of acute methylmercury poisoning. Limited data suggest DMPS may improve the neurological features of chronic mercury poisoning.

Metaldehyde

Metaldehyde in the form of pellets is used widely for killing slugs and in some countries as a solid fuel.

Clinical features

Nausea, vomiting, abdominal pain, and diarrhoea often occur 1 to 3 h after ingestion of any amount, while more than 100 mg/kg body weight may cause hypertonia, convulsions, impairment of consciousness, and metabolic acidosis. Hepatic and renal tubular necrosis may become apparent after 2 to 3 days.

Treatment

Gastric lavage should be considered if more than 50 mg/kg has been ingested within 1 h. Treatment thereafter is supportive.

Methanol (methyl alcohol)

Methanol is used widely as a solvent. It is also found in antifreeze solutions, paints, duplicating fluids, paint removers and varnishes, and shoe polishes. The ingestion of as little as 10 ml of pure methanol has caused permanent blindness and 30 ml is potentially fatal although individual susceptibility varies widely. Toxicity may also occur as a result of inhalation or percutaneous absorption.

Mechanisms of toxicity

In humans, methanol is metabolized by alcohol dehydrogenase and catalase enzyme systems to formaldehyde and formic acid (formate). The concentration of formate increases greatly and is accompanied by accumulation of hydrogen ions causing metabolic acidosis.

Clinical features

Ingested alone, methanol causes mild and transient inebriation and drowsiness. After a latent period of 8 to 36 h, nausea, vomiting, abdominal pain, headache, dizziness, and coma supervene. Blurred vision and diminished visual acuity may occur and the presence of dilated pupils, unreactive to light, suggests that permanent blindness is likely to ensue. A severe metabolic acidosis may develop and this may be accompanied by hyperglycaemia and raised serum amylase activity. A blood methanol concentration greater than 500 mg/l confirms serious poisoning. Mortality increases with the severity and duration of the metabolic acidosis. Survivors may show permanent neurological sequelae including blindness, rigidity, hypokinesis, and other parkinsonian-like signs; these features follow the development of optic neuropathy and necrosis of the putamen.

Treatment

Gastric lavage may be considered in patients who present less than 1 h after ingestion. Thereafter, the treatment of methanol poisoning is directed towards: first, the correction of metabolic acidosis; second, the inhibition of methanol oxidation; and third, the removal of circulating methanol and its toxic metabolites. Substantial quantities of bicarbonate (often as much as 2 mol) may be required and since this must be accompanied by sodium, hypernatraemia and hypervolaemia may result.

Ethanol and fomepizole (4-methylpyrazole) inhibit methanol oxidation. These antidotes should be given and monitored as for ethylene glycol. If admission plasma concentrations show that most of the methanol ingested has already been metabolized, ethanol or fomepizole administration will not be of benefit and ethanol might exacerbate the acidosis.

Dialysis is indicated when a patient has ingested more than 30 g of methanol, or develops metabolic acidosis, mental, visual, or fundoscopic abnormalities attributable to methanol, or a blood methanol concentration in excess of 500 mg/l. Folinic acid (30 mg intravenously 6-hourly) may protect against ocular toxicity by accelerating formate metabolism.

Methyl bromide (bromomethane)

Methyl bromide is a colourless, odourless gas at ordinary temperatures and, therefore, dangerous concentrations may accumulate without warning. Methyl bromide has high penetrating power and is non-flammable and explosive; these features explain its increasing use as a disinfectant to fumigate soil, a wide range of commodities, grain, warehouses, and mills. Its high density causes it to settle at floor level.

Mechanism of toxicity

Methyl bromide is absorbed readily through the lungs and is excreted largely unchanged by the same route. The remainder is metabolized and inorganic bromide is excreted in the urine. The mechanism of toxicity is uncertain but methyl bromide appears to have an affinity for intracellular proteins, particularly those with sulphydryl

groups.

Clinical features

There is a latent period of up to 12 h before toxic symptoms occur. Symptoms include dizziness, headache, nausea, vomiting, abdominal pain, malaise, transient blurring of vision, diplopia, and breathlessness. In severe cases, coma, status epilepticus, tremor, ataxia, hyporeflexia, paraesthesiae, hallucinations, acute psychosis, and polyneuropathy may be found. Proteinuria, oliguria (due to renal tubular and cortical necrosis), and jaundice have been described.

Long-term exposure to methyl bromide may lead to a chronic polyneuropathy, lethargy, personality changes, intolerance of alcohol, dysarthria, and epilepsy.

Treatment

The casualty should be removed promptly from the contaminated atmosphere and undressed, as methyl bromide can penetrate clothing and rubber gloves. Contaminated skin should be washed with water. Treatment is supportive.

Methylene chloride (dichloromethane)

Methylene chloride is a common ingredient in paint removers and is used as a solvent for plastic films and cements and also as a degreaser and aerosol propellant.

Mechanism of toxicity

Methylene chloride is metabolized to carbon dioxide and carbon monoxide. Carboxyhaemoglobin concentrations of 3 to 10 per cent (exceptionally 40 per cent) are attained.

Clinical features

Skin contact with liquid methylene chloride can be painful. Following inhalation, dizziness, tingling and numbness of the extremities, throbbing headache, nausea, irritability, fatigue, and stupor have been reported. Severe and prolonged exposure may lead to irritative conjunctivitis, lacrimation, respiratory depression, and death. Hepatorenal dysfunction and pulmonary oedema have also been described. In addition, if high concentrations of carboxyhaemoglobin are present, the features of acute carbon monoxide poisoning may occur, although these tend to be mild even in the presence of very high carboxyhaemoglobin concentrations.

Treatment

Prompt removal from exposure prior to death usually results in complete recovery. Thereafter, treatment is supportive and should include the use of supplemental oxygen.

Metoclopramide

Overdose causes acute dystonic reactions affecting the eyes, tongue, and neck.

Treatment

Gastric lavage and activated charcoal may be considered if the patient presents less than 1 h after a substantial overdose. Benztropine in a dose of 1 to 2 mg for an adult should be given intravenously if extrapyramidal features are present. Alternatively, 5 to 10 mg of diazepam intravenously is effective and has the additional advantage of alleviating anxiety and agitation.

Monoamine-oxidase inhibitors (MAOIs)

Phenelzine and tranylcypromine are now used less frequently in the treatment of depression, and poisoning with them is correspondingly uncommon. A new type A MAOI, moclobemide, is now marketed.

Clinical features

The onset of features may be delayed for 12 to 24 h after acute overdose and are due principally to increased sympathetic activity. They include excitement, restlessness (which may be extreme), hyperpyrexia, hyperreflexia, convulsions, opisthotonos, rhabdomyolysis, and coma. Cardiovascular effects include sinus tachycardia and either hypotension or hypertension.

Treatment

Gastric lavage and activated charcoal may be considered if the patient presents less than 1 h after a substantial overdose. Treatment of overdose is essentially supportive and includes control of convulsions and marked excitement with drugs such as diazepam. Dantrolene may be used to treat hyperpyrexia and extreme restlessness. Hypotension should, in the first instance, be treated by fluid replacement to restore a normal circulating blood volume. The use of sympathomimetic drugs should clearly be avoided. Hypertension, which persists despite diazepam administration, should be treated by the administration of an a-adrenoceptor blocker, such as chlorpromazine.

Natural gas (methane, ethane)

Natural gas contains methane and ethane. Methane and ethane are pharmacologically inert and can be tolerated in high concentrations without producing any toxic effects. Both gases, however, if present in very high concentration (greater than 80 per cent), may produce asphyxia in poorly ventilated areas, as a result of oxygen

deprivation. After removal from the asphyxia-inducing atmosphere, supplemental oxygen should be administered.

Nickel

Nickel is a ubiquitous trace metal and is mined in the form of sulphide ore. It is used primarily for producing stainless steel and other alloys. Nickel carbonyl, an intermediate compound in nickel purification, is used as a catalyst in the petroleum, plastic, and rubber industries. Nickel compounds have been divided into nickel carbonyl, soluble nickel salts (e.g. acetate, bromide, chloride, chloride hexahydrate, nitrate, sub-sulphide, sulphate), insoluble nickel compounds (e.g. arsenate, carbonate, hydroxide, oxide, phosphate) and metallic nickel. Nickel sulphate is used for electroplating and nickel hydroxide is a component of nickel–cadmium batteries.

Nickel can be absorbed both orally and by inhalation, and in the blood is transported bound principally to albumin. Nickel is concentrated in the kidneys, liver, and lungs and is excreted primarily in the urine.

Clinical features

Acute poisoning

Nickel carbonyl is a colourless, volatile liquid which when inhaled leads, within a few minutes, to dizziness, headache, vertigo, nausea, vomiting, cough, and dyspnoea. In many cases these symptoms disappear and there follows a symptom-free period lasting several days before the start of tachypnoea, dyspnoea, haemoptysis, cyanosis, chest pain, vomiting, tachycardia, weakness, and muscle fatigue. Paraesthesiae, diarrhoea, abdominal distension, delirium, and convulsions have also been reported. Death may occur 4 to 11 days after exposure from cardiorespiratory failure.

Urine nickel concentrations immediately following exposure to nickel carbonyl provide a guide as to the severity of exposure.

At high concentrations soluble nickel salts are primarily skin, gut, and eye irritants. Workers at an electroplating plant who drank water accidentally contaminated with nickel sulphate experienced nausea, vomiting, diarrhoea, abdominal pain, headache, cough, and breathlessness which persisted for up to 2 days. A 2-year-old child died 4 h after ingesting 15 g of nickel sulphate crystals.

Chronic poisoning

Chronic exposure to aerosols of nickel salts may lead to chronic rhinitis and sinusitis and, in rare cases, anosmia and perforation of the nasal septum. Inhaled nickel can produce a type I hypersensitivity respiratory reaction manifest as bronchial asthma with circulating IgE antibodies to nickel. Pulmonary eosinophilia (Loeffler's syndrome) due to a type III hypersensitivity reaction to nickel has also been described.

A significant increase in deaths from non-malignant respiratory disease or pneumoconiosis has also been observed in nickel refinery workers. There is evidence that occupational exposure to nickel may cause cancer of the lung and nasal sinuses.

Metallic nickel and nickel salts cause allergic contact dermatitis in up to 10 per cent of females and 1 per cent of males that is due to type IV delayed hypersensitivity.

Treatment

Severe acute nickel carbonyl poisoning requires intensive supportive care. Although chelation therapy with oral or parenteral diethyldithiocarbamate has been employed, its benefit remains uncertain. Ingestion of a substantial quantity of a nickel salt is likely to produce vomiting but if this does not occur, gastric lavage or activated charcoal may be considered if presentation is within 1 h.

Avoidance of exposure and symptomatic treatment of exacerbations with topical or systemic steroids, remain the mainstay of treatment of nickel allergy.

Nitrates

Organic nitrates such as isosorbide mononitrate and isosorbide dinitrate relax smooth muscle cells and undergo extensive first-pass metabolism in the liver.

Clinical features

The symptoms and signs caused by nitrates in overdose are due primarily to *in vivo* conversion to nitrites causing excessive arteriolar and venous dilation. Headache and vomiting are common, accompanied by flushing of the skin and dizziness. Sinus tachycardia, severe orthostatic hypotension, and syncope may develop. Convulsions and coma may be seen in severely poisoned patients. Methaemoglobinaemia is seen very rarely with organic nitrates.

Treatment

Mild hypotension may be treated by placing the patient in a head-down position, but more severe hypotension will require plasma expanders or a vasopressor agent.

Nitrogen dioxide

Combustion of fossil fuels yields nitric oxide and nitrogen dioxide (a largely insoluble, brown, mildly irritating gas). Fermentation of silage produces high concentrations of this gas within 2 days of filling the silo. It is also a by-product of many industrial processes.

Clinical features

The clinical features following acute exposure to high concentrations of nitrogen dioxide depend on the concentration and duration of exposure to the gas. Since nitrogen dioxide is only a mild upper respiratory tract irritant, modest acute exposure (less than 50 ppm) for a short time often produces no immediate symptoms, although throat irritation, cough, transient choking, tightness in the chest, and sweating have been observed. By contrast, exposure to a massive concentration of nitrogen dioxide such as that found in a silo can produce severe and immediate hypoxaemia, which may be fatal. In less severe cases, the onset of symptoms may be delayed for a few hours (typically 3 to 36 h) and the patient then develops dyspnoea, chest pain (which may be pleuritic), haemoptysis, tachycardia, headache, conjunctivitis, generalized weakness, and dizziness (which may be due to hypotension). Bronchiolitis obliterans may develop within 2 to 6 weeks.

Treatment

Bronchodilator and corticosteroid therapy is sufficient in most cases. Pulmonary oedema responds poorly to diuretics; corticosteroids and mechanical ventilation with

positive end-expiratory pressure offer the best hope of reducing the mortality.

Opiates and opioids

Acute opioid overdose occurs commonly in 'addicts' in whom the presence of venepuncture marks and thrombosed veins in the arms and legs should prompt the diagnosis.

Clinical features

The cardinal signs of opioid overdose are pinpoint pupils, reduced respiratory rate (often accompanied by cyanosis), and coma. These depressant effects are increased by alcohol. Hypotension, due to peripheral vasodilation, occurs in less than 10 per cent of cases. Hypothermia and hypoglycaemia may also complicate the clinical picture of opioid poisoning. As many as 50 per cent of heroin overdose victims develop non-cardiogenic pulmonary oedema, the majority of whom, in turn, develop bacterial pneumonia.

Methadone poses particular problems because of its long half-life (up to 50 h).

Codeine, dextropropoxyphene, and pethidine cause increased muscle tone, twitching, and convulsions. Rhabdomyolysis and its complications have been reported in association with poisoning due to diamorphine, dihydrocodeine, dipipanone, methadone, and morphine poisoning.

Diphenoxylate is used as an antidiarrhoeal agent in conjunction with atropine, and paediatric poisoning due to the ingestion of this antidiarrhoeal preparation is not uncommon (see Co-phenotrope).

Management

Naloxone is used to reverse severe respiratory depression and coma due to opioid poisoning. The adult dose is 0.8 to 1.2 mg given intravenously or, less satisfactorily, intramuscularly; the dose in children is 5 to 10 µg/kg body weight. If the diagnosis of opioid poisoning is correct, the patient should improve within 1 min with an increase in respiratory rate, an improvement in the level of consciousness, and dilation of the pupils. In severe opioid poisoning, larger initial doses of naloxone (e.g. 2.4 mg) may be required to obtain the desired response. The duration of action of naloxone (1 to 4 h) is often less than that of the drug taken in overdose and, for this reason, careful observation of the patient is necessary. Repeated doses of naloxone should be given as required.

The respiratory depressant effects of pentazocine and buprenorphine are only partially reversed by naloxone. Assisted ventilation may be necessary.

Gastric lavage and the administration of activated charcoal may be of value if an opioid had been ingested in overdose less than 1 h previously.

The development of non-cardiogenic pulmonary oedema may necessitate the use of assisted ventilation. Antibiotics will be required to treat secondary bacterial infection. Hyperkalaemia and renal failure, as a result of rhabdomyolysis, should be treated conventionally.

Organophosphorus insecticides

Organophosphorus insecticides are among the most extensively used pesticides throughout the world. They vary widely in their toxicity and while some (the phosphates) are directly toxic, others (the phosphorothioates) need biotransformation to become active.

Mechanisms of toxicity

Organophosphorus insecticides inhibit acetylcholinesterase causing accumulation of acetylcholine at central and peripheral cholinergic nerve endings, including neuromuscular junctions.

Clinical features

The features of organophosphorus insecticide poisoning are dose related. Minor exposure may produce subclinical poisoning in which there is reduction of cholinesterase activity but no symptoms or signs. Poisoning is characterized by anxiety, restlessness, insomnia, nightmares, tiredness, dizziness, headache, and muscarinic features such as nausea, vomiting, abdominal colic, diarrhoea, tenesmus, sweating, hypersalivation, and chest tightness. Miosis may be present. Nicotinic effects follow with muscle fasciculation and flaccid paresis of limb muscles, respiratory muscles, and occasionally, various combinations of extraocular muscles. Respiratory failure ensues and is exacerbated by the development of pulmonary oedema and by the retention in the bronchi of large amounts of respiratory secretions. Consciousness is impaired in severe poisoning and convulsions may occur. Hyperglycaemia and glycosuria have been reported though ketonuria is absent. Though bradycardia would be expected from the mode of action of organophosphates, it is present in only about 20 per cent of cases. Rarely, complete heart block and arrhythmias occur.

Diagnosis

Diagnosis of organophosphorus insecticide poisoning is difficult in the absence of a history of exposure and requires a high index of suspicion. Gastroenteritis is a common erroneous diagnosis and the findings of glycosuria and hyperglycaemia may prompt consideration of diabetes mellitus and its complications. Miosis is an important diagnostic sign but is not invariable. Once raised, the diagnosis can be confirmed by demonstrating reduced plasma, but preferably erythrocyte, cholinesterase activity. However, the extent of reduction correlates only crudely with the severity of poisoning. In subclinical poisoning cholinesterase activity may be reduced by up to 50 per cent while mild, moderate, and severe poisoning are associated with reduction of cholinesterase activity to approximately 20 to 50 per cent, 10 to 20 per cent, and less than 10 per cent of normal, respectively.

Treatment

Subclinical poisoning does not require treatment other than appropriate measures to prevent further absorption of the poison. The patient should be kept under observation for about 24 h to ensure that delayed toxicity does not develop. The management of symptomatic organophosphorus insecticide poisoning involves supportive measures and judicious administration of antidotes. Soiled clothing should be removed and contaminated skin washed with soap and water to prevent further absorption. Gastric lavage should be considered if the insecticide has been ingested less than 1 h previously. A clear airway, effective removal of respiratory secretions, and correction of hypoxia are essential using endotracheal intubation and assisted ventilation if necessary. The early use of diazepam may reduce morbidity and mortality; 5 to 10 mg intravenously for an adult reduces anxiety and restlessness but larger doses may be required to control convulsions.

Atropine in a dose of 2 mg intravenously every 10 to 30 min for an adult, depending on the severity of poisoning, should be given to reduce bronchorrhoea and bronchospasm or until signs of atropinization (flushed dry skin, tachycardia, and dry mouth) develop. As much as 30 mg and occasionally much more may be required in the first 24 h in severe cases. Children should be given atropine at 0.02 mg/kg body weight but may require up to 0.05 mg/kg.

Pralidoxime reactivates phosphorylated acetylcholinesterase and should be given together with atropine to every symptomatic patient. The dose (of the mesylate and chloride salts) is 30 mg/kg body weight by slow intravenous injection. Improvement will usually be apparent within 30 min. Further bolus doses of pralidoxime may be required every 4 to 6 h. Alternatively, an infusion of pralidoxime at 8 to 10 mg/kg body weight per h may be administered. Monitoring of erythrocyte (not plasma) cholinesterase activity may be used together with clinical signs to guide the duration of therapy.

Complications

A small number of patients develop what has been called the intermediate syndrome that comprises cranial nerve and brainstem lesions and a proximal neuropathy starting 1 to 4 days after acute intoxication and persisting for 2 to 3 weeks. Respiratory failure secondary to muscle weakness is observed. The aetiology of this syndrome is uncertain but is probably due to inadequate oxime therapy.

A variety of longer-term complications may develop including tiredness, insomnia, inability to concentrate, depression, and irritability. A peripheral neuropathy starting 2 weeks after exposure and mainly affecting the lower limbs is also well recognized. Axonal degeneration of large myelinated motor and sensory fibres has been demonstrated and is thought to be caused by inhibition of neuropathy target esterase.

Oxicams

These include meloxicam, piroxicam, and tenoxicam.

Clinical features

The clinical features of oxicam overdose are summarized in Table 7.

Treatment

Treatment is symptomatic and supportive. Gastric lavage or activated charcoal may be considered if the patient presents within 1 h of a substantial overdose.

Paracetamol (acetaminophen)

Mechanism of toxicity

The toxicity of paracetamol is related to its metabolism. In therapeutic doses, 60 to 90 per cent is metabolized by conjugation to form paracetamol glucuronide and sulphate (Fig. 2). A much smaller amount (5 to 10 per cent) is oxidized by mixed function oxidase enzymes to form a highly reactive compound (*N*-acetyl-*p*-benzoquinoneimine, **NAPQI**) that is then immediately conjugated with glutathione and subsequently excreted as cysteine and mercapturate conjugates. Only 1 to 4 per cent of a therapeutic dose of the drug is excreted unchanged in urine.

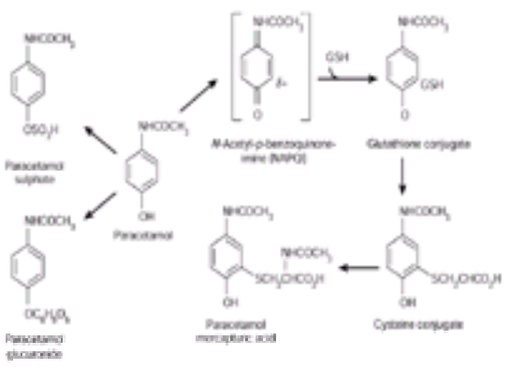

Fig. 2 Paracetamol metabolism in therapeutic dose and overdose.

In overdose, larger amounts of paracetamol are metabolized by oxidation because of saturation of the sulphate conjugation pathway. As a result, liver glutathione stores become depleted so that the liver is unable to 'deactivate' the toxic metabolite. The reactive metabolite has a high affinity for cell protein and binds to liver cell macromolecules. However, covalent binding of NAPQI to cell structure nucleophiles is not thought to be directly responsible for paracetamol-induced hepatic necrosis. NAPQI is believed to have two separate but complementary effects. First, it reacts with glutathione, thereby depleting the cell of its normal defence against oxidizing damage. Second, it is a potent oxidizing as well as arylating agent; it inactivates key sulphydryl groups in certain enzymes, particularly those controlling calcium homeostasis. Inhibition of membrane calcium translocase activity and impairment of microsomal calcium uptake leads to a marked increase in cytosolic calcium concentration, which causes depolymerization of microtubules and contraction of microfilaments, with consequent disruption of cellular architecture and function. The activity of the mixed function oxidase enzyme system and the size of liver glutathione stores may be modified by pharmacological means.

Paracetamol-induced renal damage probably results from a mechanism similar to that which is responsible for hepatotoxicity, that is by formation of NAPQI, although in the kidney this is generated by prostaglandin endoperoxide synthetase rather than by cytochrome P450-dependent mixed function oxidases.

Prediction of liver damage

In the early stages following ingestion of a paracetamol overdose, most patients have few symptoms and no physical signs. There is thus a need for some form of assessment that estimates the risk of liver damage at a time when the liver function tests are still normal. Details of the dose ingested may be used but, in many cases, the history is unreliable and, even when the dose is known for certain, it does not take account of early vomiting and individual variation in response to the drug. However, a single measurement of the plasma paracetamol concentration is an accurate predictor of liver damage provided that it is taken not earlier than 4 h after the overdose. Information gained from several studies has enabled the production of a graph which may be used for prediction of liver damage and which serves as a guide to the need for specific treatment (Fig. 3). Sixty per cent of patients whose plasma paracetamol concentration falls above a line drawn between 200 mg/l (1.32 mmol/l) at 4 h and 50 mg/l (0.33 mmol/l) at 12 h after the ingestion of the overdose are likely to sustain liver damage (serum alanine or aspartate aminotransferase, **ALT** or **AST**, greater than 1000 iu/l) unless specific protective treatment is given. When more than 12 h have lapsed after ingestion, the plasma paracetamol concentration is still of value and should be considered in conjunction with changes in the prothrombin time (see below) when assessing the prognosis of an individual patient.

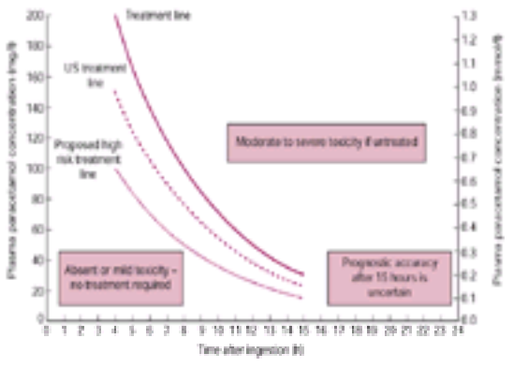

Fig. 3 Prediction of liver damage after paracetamol overdose.

There is, however, some variation in individual susceptibility to paracetamol-induced hepatotoxicity and patients with pre-existing liver disease, those with a high alcohol intake particularly if malnourished, and those receiving enzyme-inducing drugs should be considered to be at greater risk ('High risk group'; Fig. 3). Individuals with HIV-related disease also appear to be more susceptible to paracetamol-induced hepatic damage. It is uncommon for young children to develop paracetamol-induced liver or renal damage, probably because they ingest relatively small amounts in overdose.

Clinical features

As would be expected from the mechanism of toxicity, the severity of paracetamol poisoning is dose-related. An absorbed dose of 15 g (approximately 200 mg/kg) or more is potentially serious in most patients.

Following the ingestion of an overdose of paracetamol, patients usually remain asymptomatic for the first 24 h or, at most, develop anorexia, nausea, and vomiting. Liver damage is not usually detectable by routine liver function tests until at least 18 h after ingestion of the drug, and hepatic tenderness and abdominal pain are seldom exhibited before the second day. Maximum liver damage, as assessed by plasma ALT or AST activity or prothrombin time, occurs 72 to 96 h after ingestion. Hepatic failure, manifest by jaundice and encephalopathy, may then develop between the third and fifth day (Table 8) with the rate of clinical deterioration reflecting the severity of the overdose. More usually there is prolongation of the prothrombin time and a marked rise in aminotransferase activity without the development of fulminant hepatic failure. Renal failure due to acute tubular necrosis develops in about 25 per cent of patients with severe hepatic damage and in a few without evidence of serious disturbance of liver function.

Other features, including hypoglycaemia and hyperglycaemia, cardiac arrhythmias, pancreatitis, gastrointestinal haemorrhage, and cerebral oedema, may all occur with hepatic failure due to any cause and are not direct consequences of paracetamol toxicity.

There are two additional metabolic complications of paracetamol overdosage: metabolic acidosis and hypophosphataemia. Paracetamol can cause metabolic acidosis at two distinct periods after overdosage. Transient hyperlactataemia is frequently found within the first 15 h of ingestion of paracetamol in all but minor overdoses. This appears to be due to inhibition of mitochondrial respiration at the level of ubiquinone and increased lactate production, and may be associated with a metabolic acidosis. It is rarely of clinical consequence, although in very severe paracetamol poisoning (plasma paracetamol concentration more than 500 mg/l at 4 h after ingestion) the acidosis may be associated with coma. The second phase of hyperlactataemia and acidosis occurs in those patients who present late and go on to develop hepatic damage. In this instance decreased hepatic lactate clearance appears to be the major cause, compounded by poor peripheral perfusion and increased lactate production. The development of lactic acidosis consequent upon paracetamol-induced liver damage is associated with a poor prognosis.

Hypophosphataemia is a recognized complication of acute liver failure, including that due to paracetamol, and may contribute to morbidity and mortality by inducing mental confusion, irritability, coma, and abnormalities of platelet, white cell, and erythrocyte function. Phosphaturia appears to be the principal cause of hypophosphataemia in paracetamol poisoning; it may occur in the absence of fulminant hepatic failure and indicates paracetamol-induced renal tubular damage.

Prognostic factors

The overall mortality of paracetamol poisoning in untreated patients is only of the order of 5 per cent. The prothrombin time is usually the first liver function test to become abnormal and, for this reason, it is of particular value in assessing the prognosis of an individual patient. The more rapid the increase in prothrombin time, the worse the prognosis of the patient. A prothrombin time of more than 20 s at 24 h after ingestion indicates that significant hepatic damage has been sustained, and a peak prothrombin time of more than 180 s is associated with a chance of survival of less than 8 per cent.

Acid–base disturbances are also a good guide to prognosis. Systemic acidosis developing more than 24 h after overdose indicates a poor prognosis; patients with a blood pH below 7.30 at this time have only a 15 per cent chance of survival. In addition, a rise in the serum creatinine concentration is associated with poor survival; patients with a serum creatinine concentration above 300 µmol/l have only a 23 per cent chance of survival.

A study of prognostic indicators in paracetamol-induced fulminant hepatic failure treated conventionally compared the sensitivity (percentage of patients who died with a positive test), predictive accuracy (percentage of patients whose outcome was predicted accurately), positive predictive value (percentage of patients with a positive test who died), and specificity (percentage of survivors with a negative test) of measurement of factors V and VIII with conventional tests. (Factor V is vitamin K dependent and concentrations fall in liver failure; levels of factor VIII rise in patients with liver failure.) An admission pH below 7.30 with a serum creatinine concentration above 300 µmol/l and a prothrombin time above 100 s in grade III to IV encephalopathy has a sensitivity, predictive accuracy, positive prediction value, and specificity of 91, 86, 83, and 91, respectively. However, a factor VIII/V ratio above 30 had comparable values of 91, 95, 100, and 100.

Treatment

Gastric lavage and activated charcoal may be of value within 1 h of overdose. Parenteral fluid replacement should be given if nausea persists or vomiting occurs.

From knowledge of the mechanism of toxicity, it may be predicted that replenishment of glutathione stores would be of value. Two substances, methionine and *N*-acetylcysteine have emerged as effective protection agents, provided that they are administered within 8 to 10 h of ingestion of the overdose; thereafter, the protective effects decline rapidly (Table 9). Both substances act by replenishing cellular glutathione stores, though *N*-acetylcysteine may also repair oxidation damage caused by NAPQI either directly or, more probably, through the generation of cysteine and/or glutathione. It may also act as a source of sulphate and so 'unsaturate' sulphate conjugation. Methionine appears more effective when given orally than when administered intravenously. As oral *N*-acetylcysteine induces vomiting in most patients, the intravenous route is preferred. Some 6 per cent of patients treated with intravenous *N*-acetylcysteine develop rash, angio-oedema, and bronchospasm. These reactions are seldom serious and no fatalities have so far been reported in those receiving the regimen outlined in Table 9. An antihistamine such as chlorpheniramine or terfenadine should be given if such anaphylactoid reactions do not settle after discontinuing the infusion of *N*-acetylcysteine for 30 to 45 min.

Forced diuresis, dialysis, or haemoperfusion have no role to play in the management of paracetamol poisoning, though dialysis or haemofiltration will be required if acute renal failure supervenes.

Fortunately, only a minority of patients present more than 12 to 24 h after an overdose of paracetamol but, in these cases, the morbidity and mortality is greater and the correct treatment is that intended to prevent or support hepatic failure, though the use of *N*-acetylcysteine has been advocated. Ten per cent glucose solution should be administered to prevent the onset of hypoglycaemia. Although there is no evidence that correction of severe coagulation abnormalities (prothrombin time greater than 100 s) with fresh frozen plasma improves the prognosis, bleeding can be catastrophic if it does occur. Fresh frozen plasma will be required to cover the insertion of intracranial pressure monitoring apparatus, if employed. An H_2-receptor antagonist or proton pump inhibitor may reduce the risk of gastrointestinal bleeding from 'stress' ulceration/erosion. If acute renal failure supervenes, this should be managed conventionally.

Current evidence suggests that if fulminant hepatic failure does supervene, the use of intravenous *N*-acetylcysteine (see Table 9 for 20.25 h regimen; the 16 h

infusion is continued until recovery or death) will reduce morbidity and mortality. This beneficial effect is observed even after the onset of encephalopathy. In one study the survival rate in 25 patients with paracetamol-induced fulminant hepatic failure was 20 per cent, with an incidence of cerebral oedema and hypotension requiring inotropic support of 68 and 80 per cent, respectively. With *N*-acetylcysteine, the comparable figures in 25 matched patients were 48 per cent (survival rate), 40 per cent (cerebral oedema), and 48 per cent (hypotension), respectively.

Liver transplantation has been performed successfully in patients with paracetamol-induced fulminant hepatic failure, using criteria outlined above (see Prognostic factors) to identify those individuals who would otherwise be likely to die. However, there has been no formal study to compare the value of transplantation with *N*-acetylcysteine in fulminant hepatic failure.

Paraffin oil (kerosene)

Paraffin oil has three physical properties accounting for its toxicity. Its low viscosity and surface tension allow it to spread rapidly throughout the lungs when aspirated after ingestion. Its low vapour pressure makes it unlikely to cause poisoning by inhalation.

Clinical features

Repeated local application to the skin results in dryness, dermatitis, and rarely, epidermal necrolysis. Pulmonary toxicity may occur within 1 h of ingestion and is characterized by pyrexia, cough, tachypnoea, tachycardia, basal crackles, and cyanosis. Non-segmental consolidation or collapse is seen radiologically. Pneumatocele formation, pneumothorax, pleural effusion, or pulmonary oedema may occur.

Paraffin ingestion causes respiratory symptoms, a burning sensation in the mouth and throat, vomiting, diarrhoea, abdominal pain, mild hepatomegaly with hepatic dysfunction, and in severe cases, atrial fibrillation and ventricular fibrillation.

Treatment

Gastric lavage and emesis should be avoided because of the increased risk of chemical pneumonitis, but lavage may be considered in those adults who ingest very large quantities of paraffin oil, if the airway can be protected and the procedure can be carried out within 1 h. There is no evidence that corticosteroids and antibiotics reduce morbidity or mortality; mechanical ventilation with positive end-expiratory pressure may be necessary in severe cases of aspiration.

Paraquat and other bipyridyl herbicides

The bipyridilium herbicides include diquat, morfamquat, and paraquat, the last being the one most commonly encountered in clinical toxicology.

Clinical features

Occupational carelessness in handling paraquat has led to reversible changes in the fingernails and inhalation of spray may cause pain in the throat and epistaxis. Skin splashes that are promptly and thoroughly washed should not cause problems, but prolonged dermal exposure may cause burns and, very rarely, may enable enough paraquat to be absorbed to cause serious and fatal systemic poisoning. Splashes in the eye cause blepharospasm, lacrimation, and corneal ulceration.

Potentially lethal poisoning is most common after paraquat ingestion. Probably no more than 5 per cent of the ingested amount is absorbed but absorption is rapid, the volume of distribution is high, and there is energy-dependent accumulation in some organs (particularly the lungs). Elimination is mainly through the kidneys.

The features of toxicity are largely dependent on the amount of paraquat swallowed. Ingestion of 6 g or more of paraquat ion is likely to be fatal within 24 to 48 h, while 3 to 6 g is likely to lead to a more protracted, but still fatal, outcome. Nausea, vomiting, abdominal pain, and diarrhoea, rapidly followed by peripheral circulatory failure, metabolic acidosis, impaired consciousness, convulsions, and increasing breathlessness and cyanosis secondary to acute pneumonitis are the features of ingestion of large amounts of paraquat. With smaller amounts, the cardiovascular and CNS complications are not seen and alimentary features dominate the course of poisoning, particularly painful ulceration of the mouth, tongue, and throat, which makes it difficult to swallow, speak, and cough. Perforation of the oesophagus with subsequent mediastinitis has been reported. Mild jaundice may be seen and renal failure is usually severe. Breathlessness, tachypnoea, widespread crepitations, and central cyanosis may be present by 5 to 7 days after ingestion and progress relentlessly until the patient dies from hypoxia a few days later.

Ingestion of 1.5 to 2.0 g of paraquat causes nausea, vomiting and diarrhoea, mild renal tubular necrosis, and pain in the throat. Respiratory involvement may not be apparent until 10 to 21 days after ingestion, but may progress till the patient dies of respiratory failure as late as 5 or 6 weeks after taking the paraquat.

Diagnosis

The diagnosis of poisoning is usually made on the basis of the history and can be readily confirmed by a simple qualitative test on urine. This test is of particular value in accidental inhalation or ingestion of very small quantities and if performed on urine passed within 4 h of alleged ingestion; a negative test indicates that not enough has been taken to cause problems.

Treatment

There is no evidence that any form of intervention can alter the outcome of paraquat poisoning. It is traditional to empty the stomach despite the corrosive effects of the toxin, but administration of activated charcoal is probably more effective in reducing absorption.

Symptomatic measures including antiemetics, mouth washes, and analgesics are indicated and intravenous fluids may be necessary to replace gastrointestinal losses. Skin ulcers should be treated as burns. Unfortunately, currently available techniques for enhancing the elimination of poisons appear incapable of rapidly removing toxicologically significant quantities of paraquat. Equally there is no evidence that corticosteroids, drugs to prevent free radical formation, free radical scavengers, immunosuppressive agents, radiotherapy to the lungs, or lung transplantation reduce mortality. The prognosis in individual cases can be predicted from the plasma paraquat concentration related to the time from ingestion.

Petrol (gasoline)

Petrol is a complex mixture of hydrocarbons containing a small proportion of non-hydrocarbon additives.

Clinical features

Acute exposure

Following the inhalation of petrol, dizziness and irritation of the eyes, nose, and throat may occur within 5 min followed by euphoria, headache, and blurred vision. If inhalation continues, or if significant quantities of petrol are ingested, then excitement and depression of the nervous system occurs; incoordination, restlessness, excitement, confusion, disorientation, hallucinations, ataxia, nystagmus, tremor, delirium, coma, and convulsions may be seen. The inhalation of high concentrations of petrol may cause immediate death, probably from ventricular fibrillation or respiratory failure. Chemical pneumonitis may occur as in paraffin oil ingestion (see above) and the clinical features and management are then identical. In addition, intravascular haemolysis, hypofibrinogenaemia, and cardiorespiratory arrest have been reported together with, in one patient, epiglottitis so severe that near total airway obstruction resulted.

Chronic exposure

Men engaged in cleaning storage tanks and those who habitually sniff may develop both hydrocarbon and lead poisoning.

Treatment

Following removal from exposure, supportive measures provide the basis of treatment. Gastric lavage and emesis will increase the risk of aspiration and chemical pneumonitis. Lavage could be considered, with protection of the airway, if an adult ingested a large amount of petrol and the procedure could be performed within 1 h of ingestion.

Phenol

Phenol (carbolic acid) is recognizable by its odour and, distinctively, the pain to which it gives rise is much less than might be expected. This is due to its ability to damage afferent nerve endings.

Clinical features

If phenol is spilt on the skin, pain is followed promptly by numbness. The skin becomes blanched, and a dry opaque eschar forms over the burn. When the eschar sloughs off, a brown stain remains. Phenol penetrates intact skin rapidly and is well absorbed through the lungs. After ingestion, vomiting and abdominal pain occur. Systemic toxicity may follow exposure by any route. Features include coma, loss of vasoconstrictor tone, and hypothermia together with cardiac and respiratory depression. An initial phase of CNS stimulation, and rarely convulsions, has sometimes been observed in children. Phenol poisoning is associated with grey or black urine and although this is due in part to metabolites of phenol, Heinz body haemolytic anaemia as well as methaemoglobinaemia and hyperbilirubinaemia are recognized features. Renal complications are seen frequently.

Treatment

Gastric lavage may be considered if the patient presents less than 1 h after ingestion and severe oropharyngeal burns are not suspected. Skin and eye contamination, renal failure, and methaemoglobinaemia are managed appropriately.

Christiansen RG, Klaman JS (1996). Successful treatment of phenol poisoning with charcoal hemoperfusion. *Veterinary and Human Toxicology* **38,** 27–8.

Phenothiazines

The phenothiazines block peripheral cholinergic and a-adrenergic receptors, reuptake of amines, and the effects of histamine and serotonin.

Clinical features

The features of overdose include impairment of consciousness, hypotension, and respiratory depression. Chlorpromazine, perphenazine, and promazine seem more prone to cause hypothermia and hypotension, while anticholinergic effects with tachycardia, ECG abnormalities, and arrhythmias are most common with overdosage of thioridazine and mesoridazine, and acute spasmodic torticollis, oculogyric crises, and orolingual dyskinesias with trifluperazine and prochlorperazine.

Treatment

Treatment is supportive and symptomatic. Benztropine in a dose of 2 mg intravenously in an adult is required occasionally to reverse spasmodic torticollis and oculogyric crises.

Phenylpropionic (arylpropionic) acid derivatives

These include fenbufen, fenoprofen, flurbiprofen, ibuprofen, cetoprofen, naproxen, and tiaprofenic acid.

Clinical features

Propionic acid derivative poisoning causes nausea, vomiting, abdominal pain, drowsiness, headache, tinnitus, ataxia, stupor, and rarely, coma and convulsions. Hyperventilation, bronchospasm, and hypotension occur but gastrointestinal haemorrhage and renal failure are rare. These and additional clinical features are summarized in Table 10.

Treatment

Management is supportive.

Phenytoin

Clinical features

Acute overdose of phenytoin results in nausea, vomiting, headache, tremor, cerebellar ataxia, nystagmus, and rarely, loss of consciousness.

Treatment

Gastric lavage may be considered if the patient presents within 1 h after a substantial overdose. Multiple-dose activated charcoal may increase elimination although this has not been confirmed.

Phosgene

Phosgene is a colourless gas, which is now used in the synthesis of isocyanates, polyurethane and polycarbonate resins, dyes, and is produced in fires.

Mechanism of toxicity

Phosgene reacts with glutathione. When glutathione stores become depleted beyond a critical level covalent binding occurs between phosgene and cell macromolecules with resultant hepatic and renal necrosis.

Clinical features

Exposure to phosgene causes irritation of the eyes, dryness or burning sensation in the throat, cough, chest pain, and nausea and vomiting. There is usually a latent period lasting between 30 min and 24 h (rarely, 72 h) during which the casualty suffers little discomfort and has no abnormal chest signs. Subsequently, pulmonary oedema develops due to increased capillary permeability; circulatory collapse may follow.

Treatment

Administration of *N*-acetylcysteine may confer some protection. Oxygen should be administered. Mechanical ventilation may be life-saving in severe cases.

Wyatt JP, Allister CA (1995). Occupational phosgene poisoning: a case report and review. *Journal of Accident and Emergency Medicine* **12**, 212–13.

Phosphine

Phosphine is a colourless gas with a fish-like odour and is used as a fumigant against insects and rodents in stored grain, particularly in grain elevators and, increasingly, aboard ships. It is also used to treat silicon crystals in the semiconductor industry.

Clinical features

Fatigue, nausea, vomiting, diarrhoea, chest tightness, breathlessness, productive cough, dizziness, and headache are common features of acute phosphine exposure. Acute pulmonary oedema, hypertension, cardiac arrhy-thmias, and convulsions have been described in severe cases. Ataxia, intention tremor, and diplopia may be found on examination. Focal myocardial infiltration with necrosis, pulmonary oedema, and widespread small-vessel injury were found at autopsy in a child who died.

Treatment

The casualty should be removed from exposure as soon as possible. Thereafter, treatment is supportive and symptomatic. The value of steroids in preventing pulmonary damage (which may be delayed) has not been established.

Schoonbroodt D *et al.* (1992). Acute phosphine poisoning? A case report and review. *Acta Clinica Belgica* **47**, 280–4.

Primaquine

Clinical features

Primaquine poisoning is rare, though toxicity is frequent if more than 60 mg is ingested in 1 day. Headache, nausea, abdominal pain, and methaemoglobinaemia may occur and haemolytic anaemia and leucopenia have been observed, especially in patients with glucose-6-phosphate dehydrogenase deficiency.

Treatment

Gut decontamination should be considered if presentation is within 1 h of exposure. If methaemoglobinaemia exceeds 40 per cent, methylthioninium (methylene blue) at 1 to 2 mg/kg body weight should be administered intravenously over 5 min. Antidotal efficacy is NADPH dependent and therefore reduced in the presence of G6PD deficiency

Jaeger A *et al.* (1987). Clinical features and management of poisoning due to antimalaria drugs. *Medical Toxicology* **2,** 242–73.

Propylene glycol (1,2-propanediol)

Propylene glycol is used widely as a preservative as a vehicle for both oral and intravenous medications and in preparations used for treating burns.

Mechanism of toxicity

Propylene glycol is oxidized to lactic acid and pyruvate.

Clinical features

The ingestion of substantial quantities of propylene glycol or its administration to neonates or those in renal failure may cause convulsions, coma, cardiac arrhythmias, hepatorenal damage, intravascular haemolysis, metabolic acidosis, and increased serum osmolality.

Treatment

Gastric lavage should be considered if the patient presents within 1 h after ingestion. Metabolic acidosis, renal failure, and respiratory depression should be treated

conventionally. Haemodialysis removes propylene glycol efficiently.

Levy ML *et al.* (1995). Propylene glycol toxicity following continuous etomidate infusion for the control of refractory cerebral edema. *Neurosurgery* **37**, 363–71.

Pyrethroids

Clinical features

Pyrethroids are best known for their ability to cause facial paraesthesiae following occupational exposure; these symptoms last only a few hours at most. Coma, convulsions, and pulmonary oedema may occur after substantial ingestion, percutaneous absorption, or inhalational exposure.

Treatment

Symptomatic and supportive measures should be employed and reassurance given that facial paraesthesiae will not be a long-term problem.

Pyridoxine

High doses (more than 2 to 3 g/day) have been used for the treatment of a variety of conditions including the premenstrual syndrome, carpal tunnel syndrome, schizophrenia, and hyperactivity in childhood.

Clinical features

Prolonged daily intake of 50 to 300 mg in women has been reported to cause headaches, irritability, tiredness, shooting pains, circumoral and limb paraesthesiae, numb extremities, clumsiness, and ataxia, indicating a sensory neuropathy.

Treatment

Improvement occurs within 2 months of stopping the drug. There is no specific treatment.

Quinidine and quinine

Though quinidine and quinine are optical isomers, quinine is more oculotoxic and quinidine more cardiotoxic in overdose. Poisoning with quinine is much more common than with quinidine and may be iatrogenic, suicidal, or from attempted abortion or adulterated heroin.

Clinical features

Doses as low as 2 g can be toxic in adults. Cinchonism (tinnitus, deafness, vertigo, nausea, headache, and diarrhoea) is common at plasma concentrations greater than 10 mg/l. In more serious poisoning, collapse with impairment of consciousness (due to ventricular arrhythmias), convulsions, rapid shallow breathing, hypotension, pulmonary oedema, and cardiorespiratory arrest may be observed. Ventricular tachycardia and fibrillation and depression of automaticity and intracardiac conduction are potentially lethal. Pulmonary oedema and acute renal failure have been described. About 40 per cent of patients develop ocular features, which may be unilateral, including blindness, contracted visual fields, scotomas, dilated pupils, blurred disc margins, macular oedema, arteriolar spasm, and late optic atrophy. Oculotoxicity is likely when plasma concentrations exceed 10 mg/l. Visual loss is permanent in about 50 per cent of cases. Hypoglycaemia resulting from insulin release is a common side-effect of quinine and quinidine, even when used in therapeutic doses.

Treatment

Gastric lavage may be indicated if the patient presents within 1 h of ingestion or, alternatively, 50 to 100 g of activated charcoal may be administered. Multiple doses of activated charcoal increase quinine clearance. Forced diuresis, charcoal haemoperfusion, haemodialysis, and stellate ganglion block are of no value. Electrolyte and acid–base disturbances and hypoglycaemia should be corrected. Bradyarrhythmias may respond to isoprenaline; overdrive pacing may be required if *torsade de pointes* occurs. Plasma expanders should be given for hypotension, but if the response is poor, an inotrope should be administered.

Rifampicin

Clinical features

Poisoning with rifampicin results in the so-called 'red man syndrome' that can be fatal. The skin, and subsequently the sclerae, become yellow-orange in colour (the colour of a boiled lobster) and the skin discoloration may be removed by washing. These appearances are due to the intense colour of rifampicin and its metabolites that are distributed throughout the body. In addition, nausea, vomiting, abdominal pain, pruritis, a sensation of the skin burning, and convulsions have been observed. Less commonly, marked oedema of the forehead, cheeks, chin, and lips with associated eosinophilia has occurred. Elevations in serum activities of hepatic enzymes and bilirubin concentration have been noted. Sudden death has also been recorded in two patients, due probably to cardiorespiratory arrest.

Treatment

Treatment is supportive and symptomatic. Gastric lavage may be considered if the patient presents within 1 h of a substantial overdose.

Further reading

Holdiness MR (1989). A review of the red man syndrome and rifampicin overdose. *Medical Toxicology and Adverse Drug Experience* **4,** 444–51.

Salicylates

Despite the introduction of child-resistant packaging, the ingestion of aspirin by children still occurs, iatrogenic overdose is not uncommon, and moreover, aspirin remains the drug of choice for many adults who choose deliberately to poison themselves. Salicylate poisoning may also result from percutaneous absorption of

salicylic acid (used in keratolytic agents), and ingestion of methyl salicylate (oil of wintergreen).

Mechanisms of toxicity

In therapeutic doses, aspirin is absorbed rapidly from the stomach and small intestine, but in overdose, absorption may occur more slowly and the plasma salicylate concentration may continue to rise for up to 6 to 12 h.

The pharmacokinetics of elimination of aspirin are an important determinant in the development of salicylate toxicity. The biotransformation pathways concerned with the formation of salicyluric acid and salicyl-phenolic glucuronide (Fig. 4) are saturable, a fact which has the following clinical consequences: (i) the time needed to eliminate a given fraction of a dose increases with increasing dose; (ii) the steady-state plasma concentration of salicylate, particularly that of the pharmacologically active non-protein-bound fraction, increases more than proportionately with increasing dose; and (iii) as the metabolic pathways of elimination become saturated, renal excretion of salicylic acid becomes increasingly important, a pathway which is extremely sensitive to changes in urinary pH.

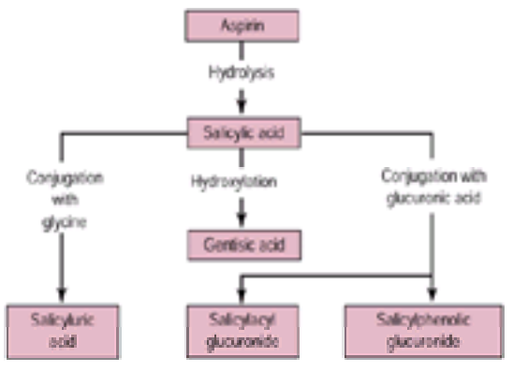

Fig. 4 The principal biotransformation pathways of aspirin.

When ingested in overdose, salicylates directly stimulate the respiratory centre to produce both increased depth and rate of respiration, thereby causing a respiratory alkalosis (Fig. 5). At least part of this effect on the respiratory centre has been shown to be due to local uncoupling of oxidative phosphorylation within the brainstem. In an attempt to compensate, bicarbonate, accompanied by sodium, potassium, and water, is excreted in the urine. Dehydration and hypokalaemia result, but more importantly, the loss of bicarbonate diminishes the buffering capacity of the body and allows an acidosis to develop more easily. A very high salicylate concentration in the brain depresses the respiratory centre and may further contribute to the development of acidaemia.

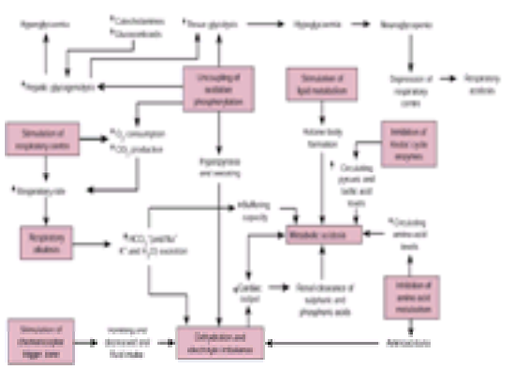

Fig. 5 The pathophysiology of salicylate poisoning.

Simultaneously, a variable degree of metabolic acidosis develops, not only because of the presence of salicylic acid itself, but also because of interference with carbohydrate, lipid, protein, and amino acid metabolism by salicylate ions (Fig. 5). Inhibition of citric acid cycle enzymes causes an increase in circulating lactic and pyruvic acids. Salicylates stimulate fat metabolism and cause increased production of the ketone bodies, b-hydroxybutyric acid, acetoacetic acid, and acetone. Dehydration and lack of food intake because of vomiting further contribute to the development of ketosis. Protein catabolism is accelerated, protein synthesis diminished, and aminotransferases (responsible for the interconversion of amino acids) inhibited. Increased circulating blood concentrations of amino acids result, together with aminoaciduria; this latter feature is further enhanced by inhibition of active tubular reabsorption of amino acids. The aminoaciduria increases the solute load on the kidneys and, thereby, increases water loss from the body.

A primary toxic effect of salicylates in overdose is uncoupling of oxidative phosphorylation (Fig. 5). ATP-dependent reactions are inhibited and oxygen utilization and carbon dioxide production increased. Energy normally used for the conversion of inorganic phosphate to ATP is dissipated as heat. Hyperpyrexia and sweating result causing further dehydration. Fluid loss is enhanced because salicylates stimulate the chemoreceptor trigger zone and induce nausea and vomiting and, thereby, diminish oral fluid intake. If dehydration is sufficiently marked, low cardiac output and oliguria will aggravate the metabolic acidosis already present which, if severe, can itself diminish cardiac output.

Glucose metabolism also suffers as a result of uncoupled oxidative phosphorylation because of increased tissue glycolysis and peripheral demand for glucose (Fig. 5). This is seen principally in skeletal muscle and may cause hypoglycaemia. The brain appears to be particularly sensitive to this effect and neuroglycopenia can occur in the presence of a normal blood sugar level when the rate of utilization exceeds the rate at which glucose can be supplied from the blood. Increased metabolism and peripheral demand for glucose activates hypothalmic centres resulting in increased adrenocortical stimulation and release of adrenaline. Increased glucose-6-phosphatase activity and hepatic glycogenolysis contribute to the hyperglycaemia that is sometimes seen following ingestion of large amounts of salicylate. Increased circulating adrenocorticosteroids exacerbate fluid and electrolyte imbalance.

Although rarely a practical problem, salicylate intoxication may be accompanied by hypoprothrombinaemia due to a warfarin-like action of salicylates on the physiologically important vitamin K_1 epoxide cycle. Vitamin K is converted to vitamin K 2,3-epoxide and then reconverted to vitamin K by a liver membrane reductase enzyme which is competitively inhibited by salicylates (and warfarin).

Clinical features and assessment of severity of salicylate intoxication

The dose of salicylate ingested and the age of the patient (see below) are the principal determinants of the severity of an overdose. The plasma salicylate concentration should be determined on admission, but it is important to repeat it 2 h later to ensure that the concentration is not rising. If the concentration has risen, the level should be repeated after a further 2 h. Generally speaking, plasma salicylate concentrations that lie between 300 and 500 mg/l some 6 h after ingestion of an overdose are associated with only mild toxicity, concentrations between 500 and 700 mg/l are associated with moderate toxicity, and concentrations in excess of 700 mg/l confirm severe poisoning.

Salicylate poisoning of any severity is associated with sweating, vomiting, epigastric pain, tinnitus, and deafness (Table 11).

Young children quickly develop metabolic acidosis following the ingestion of aspirin in overdose, but by the age of 12 years, the usual adult picture of a combined dominant respiratory alkalosis and mild metabolic acidosis is seen. Dehydration and electrolyte imbalance occur early. To some extent, the presence of an alkalaemia protects against serious salicylate toxicity because salicylate remains ionized and unable to penetrate cell membranes easily. Development of acidaemia allows

salicylates to penetrate tissues more readily and leads, in particular, to CNS toxicity characterized by excitement, tremor, delirium, convulsions, stupor, and coma. Very high plasma salicylate concentrations cause paralysis of the respiratory centre and cardiovascular collapse due to vasomotor depression.

Pulmonary oedema is seen occasionally in salicylate poisoning, and although this is often due to fluid overload as a result of treatment, it may be non-cardiac and occur in the presence of hypovolaemia. In these circumstances, the pulmonary oedema fluid has the same protein and electrolyte composition as plasma, suggesting increased pulmonary vascular permeability.

Although aspirin overdose may be complicated by inhibition of platelet aggregation and hypoprothrombinaemia, gastric erosions and gastrointestinal bleeding are rare following acute salicylate overdose.

Oliguria is sometimes seen in patients following the ingestion of salicylates in overdose. The most common cause is dehydration, but rarely, acute renal failure or inappropriate secretion of antidiuretic hormone may occur.

Whilst the urinary pH may be alkaline in the early stages of salicylate overdose, it soon becomes acid. Measurement of arterial blood gases, pH, and standard bicarbonate may show a respiratory alkalosis in the early stages of salicylate intoxication accompanied by the development of a metabolic acidosis. The plasma potassium concentration is often low; rarely, the blood sugar may be high.

Treatment

Gastric lavage and activated charcoal may be considered if the patient presents within 1 h of ingestion. Fluid and electrolyte replacement is particularly important and special attention should be paid to potassium supplementation. Severe metabolic acidosis requires at least partial correction with bicarbonate. Sedatives and respiratory depressant drugs should be avoided because they may hasten the development of acidaemia and CNS toxicity. Mild cases of salicylate poisoning may be managed with either oral or parenteral fluid and electrolyte replacement only.

Patients who exhibit marked symptoms or signs of salicylism and whose plasma salicylate concentration is in excess of 700 mg/l (or lower if acidaemia is present) should receive specific elimination therapy. Urine alkalinization is most often used for this purpose. The pH of the urine during this procedure is of far greater importance than the volume of urine excreted. The urinary pH should be in excess of 7.5 and should ideally lie between 8.0 and 8.5. Rarely, patients prove refractory to urine alkalinization, or this therapy may be contraindicated. Haemodialysis may then prove necessary to remove salicylate from the body. Haemodialysis is the treatment of choice for severely poisoned patients, particularly those with features of CNS toxicity and metabolic acidosis, and has the advantage that it enables simultaneous correction of the acid–base and fluid and electrolyte imbalances.

Pulmonary oedema occasionally complicates salicylate toxicity. Fluid overload should be excluded as far as possible, but if increased pulmonary vascular permeability is suspected, measurement of the pulmonary artery wedge pressure may be needed both for confirmation of the diagnosis and to monitor subsequent fluid administration. Positive and expiratory pressure ventilation appears to be beneficial in this form of pulmonary oedema.

Selective serotonin reuptake inhibitors (SSRIs)

Citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline are new antidepressants that inhibit serotonin reuptake (SSRIs). They lack the anticholinergic actions of tricyclic antidepressants.

Clinical features

Doses of up to 3.6 mg/kg body weight of fluoxetine and fluvoxamine do not appear to cause toxicity and even larger amounts are relatively safe unless potentiated by ethanol. Most patients will show no signs of toxicity but drowsiness, nausea, diarrhoea, and sinus tachycardia have been reported. Rarely, junctional bradycardia, seizures, and hypertension have been encountered and influenza-like symptoms may develop after a day or two.

Treatment

Supportive measures are all that are required. Activated charcoal may reduce absorption if administered within 1 h of overdose, but should only be considered if a substantial overdose has been ingested.

Smoke

Smoke consists of a suspension of small particles in hot air and gases that are generated by thermal decomposition and combustion. The particles consist of carbon and are coated with combustion products such as organic acids and aldehydes. The gaseous phase of smoke has an extremely variable composition, depending on the materials involved in the fire. Carbon dioxide and carbon monoxide are always present and usually constitute major components.

Other toxic gases commonly contained in the gaseous phase, though not necessarily in high concentration, include acrolein, ammonia, chlorine, hydrogen bromide, hydrogen chloride, hydrogen cyanide, oxides of nitrogen, phosgene, phosphorus pentoxide, and sulphur dioxide.

Clinical features

The main effects are asphyxia and severe pulmonary irritation and oedema. Smaller particles, acids, and aldehydes cause lacrimation, burning of the throat, and nausea and vomiting when swallowed. Highly water-soluble gases (e.g. hydrogen chloride, sulphur dioxide) cause immediate irritation to the upper respiratory tract, whereas gases with low solubility (e.g. chlorine, nitrogen dioxide, phosgene) penetrate further into the lung and cause injury to the distal airways and alveoli.

Thus, features range from mild irritation of the eyes and upper airways to severe tracheobronchitis, bronchospasm, pulmonary oedema, and bronchopneumonia, which may result in pulmonary insufficiency and death. Laryngitis and laryngeal oedema can also occur and may progress to complete laryngeal obstruction over a period of several hours. Acute hypoxaemia may be associated with the occurrence of frequent ventricular premature beats; tissue hypoxia due to an elevated carboxyhaemoglobin concentration may lead to chest pain and cardiac arrhythmias in subjects with pre-existing ischaemic heart disease.

Treatment

Casualties should be removed from the smoke and resuscitated. Humidified oxygen should be administered, together with a nebulized bronchodilator such as salbutamol if bronchospasm is present. A carboxyhaemo-globin concentration should be obtained and arterial blood gases should be measured.

In the case of burning plastics, the possibility of cyanide poisoning should be considered. Early fibreoptic laryngoscopy or bronchoscopy may assist the diagnosis and

enable the severity of any subglottal injury to be determined. Evidence that corticosteroids protect against pulmonary injury is lacking.

Sodium chloride

Poisoning with sodium chloride is uncommon but has occurred accidentally (e.g. addition of salt instead of sugar to infant feeds), as a result of deliberate intent (e.g. as a form of child abuse), or iatrogenically (e.g. use of hypertonic saline in gastric lavage or too rapid administration of saline during treatment of hyponatraemia).

Mechanism of toxicity

An increase in plasma sodium will increase plasma osmolality causing a shift of water from the intracellular to the extracellular space. CNS cell dehydration results in distended cerebral vessels. Subarachnoid, subdural, and intravascular haemorrhages may follow; these changes may be aggravated by overzealous rehydration.

Clinical features

Poisoning with sodium chloride can induce vomiting, increased thirst, anorexia, fever, hypotonia, lethargy, dehydration, peripheral vasoconstriction, irritability, muscular rigidity, convulsions, and coma. Hypernatraemia, increased plasma and urine osmolality, hyperglycaemia, metabolic acidosis, and hypocalcaemia may ensue. In severe cases pulmonary oedema and congestive heart failure may develop.

Treatment

The aim is to lower the serum sodium concentration slowly so that cerebral oedema, pulmonary oedema, convulsions, and coma are not provoked. Five per cent dextrose followed by hypotonic saline solutions should be given intravenously, but in severe cases complicated by renal insufficiency, haemodialysis (peritoneal dialysis is less efficient) should be considered. Hyperglycaemia should not be corrected by insulin as this may induce cerebral oedema.

Sodium nitroprusside

This vasodilator is converted *in vivo* to nitric oxide and cyanide. Accumulation of cyanide occurs if too high an infusion rate of nitroprusside is used.

Clinical features

Hypotension is the major side-effect of treatment and may be corrected by a change in infusion rate. Metabolic (lactic) acidosis is usually the first indication of cyanide toxicity. Thiocyanate accumulation may lead to anorexia, nausea, lethargy, fatigue, and psychosis.

Treatment

During prolonged infusions the blood cyanide and thiocyanate concentrations should be measured and should not exceed 1 mg/l and 100 mg/l, respectively. The risk of toxicity can be avoided by not exceeding the recommended infusion rates and/or by giving sodium thiosulphate or hydroxocobalamin intravenously. Cyanide toxicity should be treated conventionally (see above).

Johanning RJ *et al.* (1995). A retrospective study of sodium nitroprusside use and assessment of the potential risk of cyanide poisoning. *Pharmacotherapy* **15**, 773–7.

Sodium valproate

Clinical features

Sodium valproate in overdose causes impairment of consciousness and respiration. In severe cases, abnormal liver function tests, hyperammonaemia, increased anion gap acidosis, hypocalcaemia, and hypernatraemia have been reported. In addition, optic nerve atrophy, cerebral oedema, non-cardiogenic pulmonary oedema, renal failure, and pancreatitis have been observed.

Treatment

Gastric lavage may be considered if the patient presents less than 1 h after the ingestion of a substantial overdose. Treatment is symptomatic and supportive.

Andersen GA, Ritland S (1995). Life threatening intoxication with sodium valproate. *Journal of Toxicology—Clinical Toxicology* **33**, 279–84.

Strychnine

Poisoning with strychnine, an alkaloid from *Strychnos* species (*Loganiaceae*), is now rare. It is no longer used as a medicine but has a continuing role for killing rodents, moles, and other vermin, and and has been used to 'cut' illicit drugs, especially cocaine and heroin. Strychnine is readily absorbed from the gastrointestinal tract and nasal mucosa and is highly toxic.

Clinical features

Systemic effects occur within 30 min of ingestion or inhalation. The threshold for CNS stimulation is lowered with the result that any sensory stimulus may produce violent muscular spasms reminiscent of tetanus. Features include stiffness of the neck and facial muscles, producing trismus and risus sardonicus. Increased muscle tone, hyperreflexia, agitation, restlessness, and convulsions lead to profound lactic acidosis, rhabdomyolysis, and hyperthermia. Painful muscle spasms and convulsions may be provoked by touch, pain, and noise. Opisthotonos may develop. Death usually results from contracture of respiratory muscles. Strychnine blocks glycine-mediated activation of chloride channels, especially in Renshaw cells of the spinal cord, disinhibiting reflex activity and leading to tetanus-like spasms and muscular rigidity.

Treatment

The patient should be kept at rest. Any type of stimulation must be reduced to a minimum and gastric lavage avoided. Oral activated charcoal, in a dose of 50 to 100 g for an adult, adsorbs strychnine and may reduce its absorption if given within 1 h of ingestion.

In severe poisoning, supportive measures to establish and maintain a clear airway and adequate ventilation are of prime importance. Convulsions should be controlled with intravenous diazepam and muscular spasms with neuromuscular blockade (e.g. with pancuronium) and mechanical ventilation. This, together with supplemental oxygen, will help correct metabolic acidosis. Hyperthermia, rhabdomyolysis, and renal failure should be managed conventionally. Patients may recover without apparent sequelae.

Styrene (vinyl benzene)

Styrene is a colourless to yellow liquid with a pleasant, sweet odour at low concentrations. Styrene monomer is an important agent in the production of plastic and a stabilizing agent in a variety of products.

Mechanism of toxicity

Styrene is oxidized to styrene oxide that binds covalently to cellular macromolecules, probably due to depletion of glutathione.

Clinical features

Although inhalation is the most common route of exposure, absorption of styrene may also occur through the skin and gut. It is irritant to the eyes, skin, mucous membranes, and respiratory system accompanied by mucous secretion, a metallic taste, drowsiness, and vertigo. Higher concentrations may cause CNS depression.

Treatment

If acute exposure has occurred, the subject should be removed from further exposure, the skin washed, and the eyes irrigated. CNS effects should be treated symptomatically and supportively. Potentially, *N*-acetylcysteine could be of value in preventing hepatic damage.

Further reading

Pahwa R, Kalra J (1993). A critical review of the neurotoxicity of styrene in humans. *Veterinary and Human Toxicology* **35**, 516–20.

Sulphur dioxide

Sulphur dioxide is a colourless gas which has a pungent irritating odour. The combustion of fuels for heating and power generation results in environmental pollution from this cause. Sulphur dioxide is also employed in the manufacture of sulphuric acid and is a potential occupational problem in paper mills, steel works, and oil refineries.

Mechanism of toxicity

The irritant effects of sulphur dioxide are thought to be caused by the rapidity with which it forms sulphurous acid on contact with moist membranes.

Clinical features

Following exposure to sulphur dioxide, lacrimation, rhinorrhoea, cough, increased bronchial secretions, bronchoconstriction, and in severe cases, pulmonary oedema and respiratory arrest occur. Corneal burns can follow eye exposure and liquified sulphur dioxide can cause skin burns. Survivors of massive sulphur dioxide exposure have shown a chronic obstructive defect in serial pulmonary studies along with bronchial hyperactivity.

Treatment

After removal from exposure, admission to hospital for observation is mandatory in severe cases to ensure that delayed pulmonary oedema is treated effectively. Symptomatic and supportive measures should be given and, if necessary, mechanical ventilation with positive end-expiratory pressure should be undertaken if diuretics alone do not control pulmonary oedema; the role of corticosteroids is uncertain. The eyes and skin should be irrigated with water if exposure has occurred.

Tetrachloroethylene (perchloroethylene)

Tetrachloroethylene is a colourless, non-flammable liquid with a chloroform-like odour. It is used widely as an industrial solvent, particularly for dry cleaning and degreasing. Poisoning may occur by inhalation or ingestion.

Mechanisms of toxicity

A considerable proportion of an inspired dose is exhaled unchanged and that retained is excreted only slowly (half-life approximately 144 h), mainly by metabolism to trichloroacetic acid, the major urinary metabolite.

Clinical features

Following inhalation or ingestion, there is depression of the central nervous system; nausea and vomiting may occur and persist for several hours. Irritation of the eyes, nose, and throat may occur. Hepatic and renal dysfunction may also develop and ventricular arrhythmias and non-cardiogenic pulmonary oedema have been reported.

Treatment

After removal from exposure, treatment is supportive and symptomatic.

Theophylline

Poisoning may complicate therapeutic use as well as being the result of deliberate self-poisoning. It is important to establish at an early stage the precise theophylline product involved in a poisoning incident since many of them are sustained-released formulations. As a consequence, peak plasma concentrations of the drug are frequently not attained until 6 to 12 h after overdosage and the onset of toxic features is correspondingly delayed.

Clinical features

Most symptomatic patients have concentrations in excess of 25 mg/l. Convulsions are seen more commonly when concentrations are greater than 50 mg/l.

Symptoms include nausea, vomiting, hyperventilation, haematemesis, abdominal pain, diarrhoea, sinus tachycardia, supraventricular and ventricular arrhythmias, hypotension, restlessness, irritability, headache, hyperreflexia, tremor, and convulsions. Hypokalaemia results predominantly from Na^{+}/K^{+} ATPase activation. A mixed respiratory alkalosis and metabolic acidosis is common.

Assessment of the severity of poisoning

The severity of theophylline intoxication is important in deciding management. Plasma potassium concentrations of less than 2.6 mmol/l, acidaemia, hypotension, seizures, and arrhythmias are indications for urgent measurement of plasma theophylline concentrations. Patients require close observation to detect the onset of delayed toxicity and it may be necessary to repeat measurement of the plasma theophylline concentration a few hours after admission.

Treatment

Gastric lavage may be considered in patients who have ingested a significant overdose of theophylline and who present within 1 h; administration of 50 to 100 g of activated charcoal (by nasogastric tube if necessary) is an alternative. Multiple doses of charcoal (e.g. 50 g 4-hourly) will enhance the systemic elimination of theophylline. Intractable vomiting may be alleviated by ondansetron in a dose of 8 mg intravenously in an adult. Gastrointestinal haemorrhage may require blood transfusion and a proton pump inhibitor should be given intravenously. Tachyarrhythmias may be induced by the rapid flux of potassium across cell membranes and early correction of hypokalaemia may prevent their development. The plasma potassium concentration should therefore be measured on admission and at houry intervals thereafter while the patient is symptomatic. Potassium supplements will be needed in almost all cases and doses of up to 60 mmol/h may be required at the outset. Non-selective b-adrenoceptor blocking drugs, such as propranolol, may also be useful to treat tachyarrhythmias and reverse hypokalaemia. Convulsions should be managed conventionally.

Although charcoal haemoperfusion increases theophylline clearance, it should be reserved for those in whom intractable vomiting or recurrent seizures make oral charcoal impracticable or hazardous.

Thyroxine

Acute overdosage with thyroid hormones is uncommon. Not surprisingly, thyroxine is the agent most commonly involved.

Clinical features

Probably only a small percentage of patients who ingest large amounts of thyroid hormones develop features of toxicity. Symptoms develop within a few hours with tri-iodothyronine (T_3) and after 3 to 6 days with thyroxine (T_4). They tend to resolve in about the same time as they take to develop. Mental confusion, agitation, irritability, and hyperactivity with sinus tachycardia, tachypnoea, pyrexia, and dilated pupils are common while atrial fibrillation, sweating, loose stools, and the ocular features of hyperthyroidism are rare. Convulsions developed in one child.

Treatment

Gastric lavage may be considered if more than 2 mg of thyroxine has been ingested within the preceding 1 h; activated charcoal is an alternative. Serum T_4 and T_3 concentrations should be measured in blood taken 6 to 12 h after ingestion since a normal result precludes the possibility of delayed toxicity and allows the patient to be discharged. Those with high T_4 concentrations should be reviewed for evidence of toxicity on the fourth or fifth day after ingestion. Patients who develop toxicity should be given propranolol for 5 days.

Hack JB *et al.* (1999). Severe symptoms following massive intentional L-thyroxine ingestion. *Veterinary and Human Toxicology* **41**, 323–6.

Toluene

Toluene has much lower volatility and toxicity than benzene. It is used extensively as a solvent in the chemical, rubber, paint, glue, and pharmaceutical industries and as a thinner for inks, perfumes, and dyes.

Metabolism

Following inhalation or ingestion, toluene is oxidized to benzoic acid then to hippuric acid benzoylglucuronates that are excreted in the urine.

Clinical features

Acute poisoning results in euphoria, excitement, dizziness, confusion, increased lacrimation, headache, nervousness, nausea, tinnitus, ataxia, tremor, and coma.

Chronic exposure

Chronic poisoning may give rise to muscle weakness, abdominal pain and haematemesis, cerebellar abnormalities, optic neuropathy, peripheral neuropathy, altered mental state, dementia, hearing loss, hypokalaemia, and hepatorenal disease, including distal renal tubular acidosis and urinary calculi.

Treatment

If poisoning results from inhalation, whether accidental or intentional as in volatile substance abuse (see below), the patient should be removed from the ontaminated environment. Thereafter, treatment consists of symptomatic and supportive measures.

1,1,1-Trichloroethane (methyl chloroform)

1,1,1-Trichloroethane is a colourless, non-flammable liquid of high volatility widely used as a solvent in industry, in the office (e.g. typewriter correction fluid), and at home (e.g. waterproofing aerosol products).

Mechanism of toxicity

1,1,1-Trichloroethane has low systemic toxicity because only small amounts of trichloroacetic acid and trichloroethanol are formed. Most of an inhaled dose is expired unchanged. Concomitant ingestion of ethanol is known to enhance toxicity.

Clinical features

Following inhalation of a sufficiently large dose, CNS depression occurs in proportion to the amount inhaled; hepatic and renal dysfunction may also result. Deaths have followed exposure to very high concentrations in unventilated tanks. In such cases death may either be due to CNS depression, culminating in respiratory arrest, or to fatal arrhythmias as a result of myocardial sensitization to circulating catecholamines in the presence of hypoxia. Inhalation of a weather-proofing aerosol containing 96.6 per cent 1,1,1-trichloroethane has been reported to give rise to transient shortness of breath, constricting chest pain, cough, and myalgia.

Treatment

The casualty should be removed from the contaminated environment. Thereafter treatment is symptomatic and supportive.

Trichloroethylene

Trichloroethylene is a colourless, volatile liquid used widely as an industrial solvent, particularly in metal degreasing and extraction processes.

Mechanisms of toxicity

Trichloroethylene is absorbed readily from the gut and through the skin and lungs. Following inhalation, it is excreted unchanged in the breath and metabolized via chloral hydrate to trichloroethanol (by alcohol dehydrogenase) and trichloroacetic acid, which are excreted in the urine.

Clinical features

Following inhalation, ingestion, or dermal absorption, CNS depression occurs with nausea and vomiting, hepatic and renal dysfunction, and death. 'Degreaser's flush' (in which the skin on the face and arms becomes markedly reddened) may occur if ethanol is consumed shortly before or after exposure to trichloroethylene, as the metabolism of trichloroethylene is inhibited. Cranial nerve damage, cerebellar dysfunction, and convulsions have been described.

Treatment

Removal from exposure will reduce CNS depression, and thereafter, whether trichloroethylene has been inhaled, ingested, or absorbed through the skin, treatment is supportive and symptomatic.

Tricyclic antidepressants

Tricyclic antidepressants have complex actions that account for the diverse nature of the features seen after overdosage. They block the reuptake of noradrenaline into peripheral and intracerebral neurones, thereby increasing the concentration of monoamines in these areas. They also have anticholinergic actions and class 1 antiarrhythmic (quinidine-like) activity.

Clinical features

Features of poisoning typically appear within 30 to 60 min after ingestion of an overdose and usually reach maximum intensity in 4 to 12 h. Drowsiness, sinus tachycardia, dry mouth, dilated pupils, urinary retention, increased reflexes, and extensor plantar responses are the most common features of mild poisoning. Severe intoxication leads to coma, often with divergent strabismus and convulsions. Plantar, oculocephalic ('doll's head'), and vestibulo-ocular reflexes may be temporarily abolished. Skin blisters and rhabdomyolysis may be present.

Sinus tachycardia is very common and the dose-related quinidine-like action decreases myocardial contractility and delays conduction producing a bizarre ECG; P–R and QRS intervals increase and the P waves diminish in amplitude and may be completely obscured by the preceding T wave. These changes, in conjunction with the increased heart rate, not infrequently make differentiation between ventricular tachycardia and supraventricular tachycardia with aberrant conduction difficult, if not impossible. Serious arrhythmias, particularly ventricular tachycardia, occur in only 4 per cent of cases. In severe cases the blood pressure and cardiac output fall; metabolic acidosis and cardiorespiratory depression are the major contributing factors to death.

Treatment

The great majority of patients poisoned with tricyclic antidepressants recover with supportive therapy alone. Potentially lethal complications such as convulsions and arrhythmias are most common within 6 h of overdosage. It is uncommon for coma to last for more than 24 h and most severely poisoned patients recover consciousness within 48 h.

Gastric lavage may be considered in adults when more than 250 mg of the drug has been ingested less than 1 h previously. Alternatively, 50 to 100 g of activated charcoal can be administered orally.

Management of tricyclic antidepressant-induced cardiotoxicity poses serious difficulties. In general, the natural inclination to use antiarrhythmic drugs to treat tachycardia and arrhythmias should be resisted. Attention to supportive measures, particularly adequate oxygenation, control of convulsions, and correction of acidosis will generally be more rewarding; 50 mmol of sodium bicarbonate intravenously over 20 min should be given even if there is no acidosis. Lignocaine in a dose of 50 to 100 mg intravenously may be tried cautiously if ventricular tachycardia is compromising cardiac output.

Physostigmine salicylate, a cholinesterase inhibitor, has no role. When benzodiazepines have been taken in overdose together with tricyclic antidepressants,

flumazenil may unmask the tricyclic antidepressant-induced seizure potential and should therefore be used with caution.

Forced diuresis and haemodialysis are of no value. Nor is there convincing evidence that charcoal haemoperfusion is effective.

Delirium with auditory and visual hallucinations is a frequent and troublesome complication during the recovery phase. Sedation with oral or intravenous diazepam may be required.

Vinyl chloride (monochloroethylene, chloroethene)

Vinyl chloride is a colourless, highly flammable, and explosive gas. It is usually handled as a liquid under pressure and in this form it polymerizes readily, at temperatures in the range of 40 to 70°C, to form polyvinyl chloride (PVC).

Mechanisms of toxicity

The main route of absorption of vinyl chloride is through the lungs, although some skin penetration does occur. Metabolism to a reactive metabolite appears to be necessary before toxic effects are seen. It has also been postulated that the various features of vinyl chloride disease may have an immunological basis.

Clinical features

Acute exposure

Acute exposure to vinyl chloride results in CNS depression, but concentrations need to be in excess of 10 000 ppm before this effect becomes noticeable. Exposure of volunteers to 20 000 ppm for 5 min caused dizziness, light-headedness, nausea, and dulling of vision.

Chronic exposure

Acro-osteolysis has been described in workers engaged in cleaning autoclaves by hand. The syndrome has three main components: (i) Raynaud's phenomenon, (ii) skin changes resembling scleroderma, and (iii) bony changes of the terminal phalanges of the fingers and sometimes the toes, radial and ulnar styloid processes, sacroiliac joints, and lower poles of patellas.

Angiosarcoma of the liver and hepatic fibrosis, often associated with splenomegaly and portal hypertension, have been reported in vinyl chloride workers.

Exposure to vinyl chloride may also be associated with the development of cancer of the liver and biliary tract and cancer of the brain, though the latter association has not been confirmed in some studies.

Treatment

Preventive measures, adopted worldwide, and designed to protect against angiosarcoma of the liver, should also prevent other adverse effects. Symptoms due to osteo-acrolysis do not improve significantly after removal from exposure, but radiographic improvement of the phalangeal lesions, with recalcification, has been demonstrated.

Volatile substance abuse

Solvent abuse may be defined as the intentional inhalation of volatile organic chemicals other than conventional anaesthetic gases. These include organic solvents and vapours, hydrocarbon mixtures such as petrol (gasoline), and aerosol propellants.

Volatile substances are either 'bagged' (sprayed into a plastic bag and then inhaled until the subject passes out) or 'huffed' (sprayed on to a cloth held to the mouth). Glue is most often sniffed from a potato crisp bag and repeated abuse in this manner leads to the development of erythematous spots around the mouth and nose ('glue-sniffer's rash').

Clinical features

The clinical features of intoxication with volatile substances are similar to those of alcohol intoxication with initial CNS stimulation followed by depression. Other symptoms may include euphoria, blurring of vision, tinnitus, slurring of speech, ataxia, feelings of omnipotence, headache, abdominal pain, anorexia, nausea, vomiting, jaundice, chest pain, bronchospasm, impaired judgement, irritability, and excitement. Less often a delirious state is seen, with clouding of consciousness and hallucinations. Many chronic users report transient psychotic symptoms that often have an affective component. Convulsions, status epilepticus, and coma may occur. Those under the influence of volatile substances may carry out self-destructive and antisocial acts. Psychological dependence and tolerance may develop, but physical dependence is rare.

Unexplained listlessness, anorexia, and marked moodiness are suggestive of chronic abuse. Poor school adjustment and scholastic performance have been noted in chronic glue sniffers apparently due to lack of motivation.

'Glue sniffing'

Glues are volatile, semiliquid preparations that usually contain an aromatic hydrocarbon as the vehicle. The physical sequelae of prolonged glue sniffing include aplastic anaemia and acute hepatic and renal damage. Features of renal toxicity include proteinuria, haematuria, distal renal tubular acidosis, and recurrent urinary calculi. Irreversible neurological sequelae such as optic atrophy, encephalopathy, cerebellar degeneration, and equilibrium disorders have been reported in adults who are chronic abusers. Toluene inhalation may cause encephalopathy in children. Neurological damage may occur after 'sniffing' of less than 1 year's duration and symptoms may progress for up to 3 months after the habit has been abandoned. Glues containing *n*-hexane and toluene have been associated with the development of muscle weakness and atrophy and sensory impairment of either the 'glove and stocking' or sensorimotor type, with or without muscle atrophy.

A review of adults who had sniffed toluene indicated three major patterns of presentation: (i) muscle weakness, (ii) gastrointestinal complaints (abdominal pain, haematemesis), and (iii) neuropsychiatric disorders (altered mental status, cerebellar abnormalities, and peripheral neuropathy). In addition, hypokalaemia, hypophosphataemia, and hyperchloraemia were common. Rhabdomyolysis occurred in 40 per cent of cases. Cardiac and haematological toxicity due to toluene appears to be uncommon.

Petrol (gasoline) sniffing

Abusers of petrol have reported that 15 to 20 breaths of the vapour are sufficient to produce intoxication for 3 to 6 h.

The euphoria of mild intoxication may be accompanied by nausea and vomiting. After prolonged inhalation, or rapid inhalation of highly concentrated vapour, the 'sniffer' may experience a phase of violent excitement followed by loss of consciousness and coma. While unconscious, the subject may suffer convulsions and the pupils may become fixed and dilated or unequal. Nystagmus and conjugate deviation of the eyes may be observed. Cerebral and pulmonary oedema and renal and hepatic damage have been noted at autopsy. The greater danger from petrol 'sniffing' is related to the long-term effects of chronic exposure that include loss of appetite and loss of weight, neurasthenia, muscle weakness and cramps, and neuropsychological damage. Encephalopathy in petrol sniffers may also be due to tetraethyl lead.

Chlorinated hydrocarbon abuse

Inhalation of chlorinated hydrocarbons causes a sense of euphoria, and sometimes excitement, associated with headache, dizziness, nausea, vomiting, stupor, coma, and convulsions.

Aerosol inhalation

The most commonly abused aerosol propellants are the chlorofluorocarbons (CFCs). Several hundred teenagers have died from this cause. It is likely that the fatalities were due to cardiac arrhythmias.

Diagnosis and treatment

The clinical features described above and the circumstances in which patients are found usually point to the diagnosis, but confirmation may be obtained by detection of solvents in blood or metabolites in the urine.

Acute intoxication from volatile substance abuse is usually brief and self-limiting. If respiratory depression and cardiac arrhythmias supervene, they should be treated conventionally and renal and hepatic failure may require further supportive measures and dialysis.

Warfarin

Warfarin toxicity is more likely to occur in the setting of therapeutic anticoagulation (as a result of a drug interaction) than as a consequence of acute overdose.

Clinical features

Epistaxis, gingival bleeding, spontaneous bruising, haematomas, haematuria, bilateral flank pain, rectal bleeding, and haemorrhage into any organ may occur. Spontaneous haemoperitoneum has been reported. Severe blood loss may result in hypovolaemic shock, coma, and death.

Treatment

If the intention is to continue anticoagulation

If the INR is less than 6.0 but more than 0.5 units above the target value, reduce the dose or stop warfarin; restart when the INR is less than 5.0. If the INR is 6.0 to 8.0 and the patient is not bleeding (or only minor bleeding is present), stop warfarin and restart when the INR is less than 5.0. If the INR is greater than 8.0 and the patient is not bleeding (or the bleeding is minor), stop warfarin and restart when the INR is less than 5.0. If there are other risk factors for bleeding, give 0.5 mg of vitamin K_1 intravenously slowly. If major bleeding occurs, give 5 mg of vitamin K_1 by slow intravenous injection together with prothrombin complex concentrate at 50 units/kg or, if the complex is not available, give fresh frozen plasma at 15 ml/kg.

If continued anticoagulation is unnecessary

If the INR is greater than 6.0, give 5 mg of vitamin K_1 and repeat if necessary. If active bleeding occurs, give prothrombin complex concentrate at 50 units/kg in addition or, if the complex is not available, give fresh frozen plasma at 15 ml/kg.

Xylenes

The three isomers of xylene, which possess similar properties, are used widely as solvents in paints, lacquers, pesticides, gums, resins, adhesives, and the paper-coating industry.

Metabolism

Xylene is oxidized and excreted in the urine either free or conjugated with glycine as methylhippuric acid. Ethanol inhibits xylene metabolism.

Clinical features

Following inhalation, dizziness, excitement, flushing of the face, eye irritation, drowsiness, incoordination, ataxia, tremor, confusion, coma, respiratory depression, and catecholamine-induced ventricular arrhythmias may occur. Hepatorenal damage also has been described. Immersion in liquid xylene may result in a burning feeling, erythema, and some scaling of the skin.

Treatment

Treatment is supportive.

Zinc

Zinc oxide fumes are emitted in any process involving molten zinc and are the most common cause of metal fume fever. Exposure to zinc chloride occurs in soldering, in the manufacture of dyes, paper, and deodorants, and on military exercises when it is used as a smoke screen.

Poisoning has followed the accidental or deliberate ingestion of elemental zinc and zinc chloride and fatal intoxication has followed inadvertent intravenous administration. Inhalation of zinc chloride and oxide may lead to nasopharyngeal and respiratory toxicity.

Zinc may be absorbed through broken skin when zinc oxide paste is used to treat wounds and burns.

Clinical features

Acute poisoning

Zinc sulphate ingestion causes gastrointestinal irritation, sometimes in association with headache and dizziness. Zinc chloride is highly corrosive and ingestion has led to erosive pharyngitis, oesophagitis, and haematemesis. Acute renal failure and pancreatitis have also been recorded after ingestion of zinc salts. Topical exposure to zinc chloride causes ulceration and dermatitis of the exposed skin. Zinc chloride is highly irritant to the eye.

Metal fume fever starts up to 24 h after exposure to zinc oxide fumes. It presents as an influenza-like illness with headache, fever, sweating, chest tightness and discomfort, and joint pains. Typically symptoms appear after the weekend. The illness usually has an excellent prognosis and the symptoms often improve towards the end of the working week as some short-term immunity from further symptoms develops.

In contrast to the relatively mild clinical course after zinc oxide inhalation, exposure to zinc chloride ammunition bombs (hexite) produces a chemical pneumonitis with marked dyspnoea, a productive cough, fever, chest pain, and cyanosis. The adult respiratory distress syndrome may ensue in the most severe cases; fatalities have been reported.

Chronic poisoning

Repeated topical exposure to zinc oxide may cause a papular folliculitis. Chronic excessive ingestion of zinc supplements (zinc sulphate) may induce reversible anaemia and leucopenia secondary to a relative copper deficiency.

Treatment

Symptomatic and supportive measures should be employed with treatment as for acids as appropriate (see above).

8.2 Injuries, envenoming, poisoning, and allergic reactions caused by animals

D. A. Warrell

Mechanical injuries caused by animals

Lions, tigers, leopards, jaguars, hyenas, wolves, dingoes, bears, elephants, hippopotamuses, buffaloes, rhinoceroses, musk oxen, wild pigs, and ostriches have mauled and killed humans. About 100 shark attacks are reported each year between latitudes 46 °N and 47 °S, half of which are fatal (Plate 1). Other fish capable of causing life-threatening mechanical trauma are barracuda, moray and conger eels, garfish, groupers, stingrays, and piranãs. Tiny Amazonian catfish (genus *Vandelia*; Spanish—'canero'; Portuguese—'candirú') are the only vertebrate parasites of humans. Attracted by urine, these 5-cm long fish may enter the urethra, vulva, or anus of swimmers causing pain, bleeding, and obstruction. Their spines make them difficult to remove. The 'electric eel' (*Electrophorus electricus*) of South American rivers can discharge up to 650 volts, 1 amp, 400 times per second, a shock capable of killing an adult. Marine torpedo rays can produce a dangerous 80-volt, high-amperage shock. Crocodiles (*Crocodilus niloticus*) kill about 1000 people each year in Africa, while in northern Australia 27 deaths from 60 attacks by the salt-water crocodile (*C. porosus*) have been reported since 1876. Giant pythons have attacked, killed, and even swallowed people in Indonesia (*Python reticulatus*) (Plate 2), Africa (*P. sebae*), and South America (*Eunectes murinus*). Collisions between vehicles and deer cause more than a 100 injuries each year in Kentucky and are also common in other areas. In the United States, injuries to horseback riders result in more than 46 000 visits to casualty departments each year and at least 20 deaths.

Bites by domestic dogs are common. An estimated 6 million dogs live in England and Wales. More than 200 000 patients bitten by dogs attend hospital each year. About 600 000 people are bitten by dogs each year in the United States. Other domestic animals which have caused severe injuries or deaths include camels, cattle, water buffalo, sheep, pigs, cats, and ferrets.

Treatment

First aid of severe injuries involves controlling bleeding, closing perforating injuries with pressure dressings, and rapid evacuation to hospital. All injuries inflicted by animals must be assumed to be infected by a range of organisms. Wounds may contain teeth and other foreign bodies and necrotic tissue, especially if treatment is delayed.

Wounds should be thoroughly cleaned with soap and water as soon as possible; suitable antiseptics include iodine and alcohol solutions. Prophylactic antimicrobials such as amoxicillin/clavulanic acid, doxycycline, or erythromycin have proved effective in dog- and cat-bite wounds and are indicated for multiple or severe wounds and bites on the face and hands.

Specific infections, such as tetanus, rabies, and herpes simiae virus must be considered and treated/prevented appropriately. Emergency surgery may be required, with: replacement of blood loss; attention to local mechanical complications such as fractures, tension pneumothorax, damage to large blood vessels, perforation of the bowel, and lacerations of other abdominal viscera; and thorough débridement or amputation of dead tissue with removal of foreign material, teeth, etc.; irrigation and drainage. Except for wounds on the head and neck, which can be sutured immediately, primary suturing should be delayed for 48 to 72 h, after which further débridement, suturing, or covering with split skin grafts should be considered. In these cases infection must be prevented by using a combination of penicillin, an aminoglycoside (such as gentamicin for 48 h), and metronidazole.

Venomous animals

For predation or defence, some animals inject venoms through fangs, chelicerae (venom jaws), stings, spines, hairs, nematocysts, and other specialized venom organs. 'Spitting' snakes, scorpions, and millipedes squirt venom on to absorbent mucous membranes. The flesh or skin of some animals contain poisons acquired through the food chain. Allergic reactions to injected venoms (for example, of *Hymenoptera* and cnidarians) and ingested poisons (for example, ciguatera) may create medical problems more commonly than their direct toxic effects.

Venomous mammals

Male duck-billed platypuses (*Ornithorhynchus anatinus*) have erectile venomous spurs on their hind limbs. These aquatic, egg-laying mammals of eastern Australia sting at least one person each year in Victoria, but only 17 cases have been reported since 1817. There is immediate, agonizing, persistent local pain, as well as prolonged local swelling, chronic pain on movement, hyperaesthesia, wasting, inflammation, and regional lymphadenopathy. These effects are not life-threatening in humans, but dogs have died of envenoming. In the absence of specific treatment, non-steroidal anti-inflammatory agents or corticosteroids have proved effective. The venom contains a C-type natriuretic peptide (which causes mast-cell degranulation), nerve growth factor, four defensin-like peptides, enzymes, and other peptides and proteins. Males of the echidna, the other egg-laying mammal, possess a similar but smaller venom apparatus. Several species of Insectivora produce venomous saliva conducted into bite wounds by curved and sometimes grooved lower incisors. Venomous species include the Hispaniolan and Cuban solenodons (*Solenodon paradoxus, S. (Apotogale) cubanus*), northern water shrew (*Neomys fodiens*), southern water shrew (*N. anomalus*), and the North American short-tailed shrew (*Blarina brevicauda*). Their bites can kill rodents and lagomorphs, but in humans the effect is local pain, swelling, and inflammation. The saliva of vampire bats (Desmodontinae) contains permeability increasing factors, a platelet inhibitor, draculin—an inhibitor of activated factors X and IX, and a plasminogen activator which is being developed as a thrombolytic drug.

Venomous snakes

Fewer than 200 species of venomous snake (families Colubridae, Atractaspididae, Elapidae, and Viperidae) have been responsible for severely envenoming humans resulting in death or permanent disability. Since it may be difficult to distinguish venomous from non-venomous species, unnecessary contact with snakes should be avoided and patients bitten by any species should be assessed carefully.

Distribution of venomous snakes

Free from venomous snakes are the Antarctic, most islands of the western Mediterranean, Atlantic, Caribbean, and Eastern Pacific (including Hawaii), Madagascar, New Caledonia, New Zealand, Ireland, Iceland, and the Atlantic Ocean, and Chile. Elsewhere, venomous snakes are widely distributed up to altitudes of more than 4000 m in the Himalayas (*Gloydius himalayanus*), within the Arctic Circle (*Vipera berus*), in the Indian and Pacific Oceans as far north as Siberia (*Pelamis platurus*), and in some freshwater lakes (*Hydrophis semperi*).

Classification

Medically important species have in their upper jaws one or more pairs of enlarged teeth (fangs) that inject venom into their victims through a groove or closed channel.

Colubridae

The short, immobile fangs are at the back of the maxilla (Fig. 1). Most familiar non-venomous snakes, such as the British grass snake and smooth snake, belong to this large family. However, some species have caused severe envenoming or death, including: three African species—the boomslang (*Dispholidus typus*) and the vine, twig, bird, or tree snake or Voëlslang (*Thelotornis kirtlandii* and *T. capensis*); the Japanese yamakagashi (*Rhabdophis tigrinus*); the Southeast Asian red-necked keelback (*R. subminiatus*); the Australasian brown tree snake (*Boiga irregularis*) introduced to Guam; and the South American green racer (*Philodryas olfersii*) (Fig. 1).

Fig. 1 Back fangs of the green racer (*Philodryas olfersii*), a South American colubrid snake. A case of fatal envenoming has been reported from Brazil. (Copyright D.A. Warrell.)

Atractaspididae

The African and Middle Eastern burrowing asps, stiletto snakes, burrowing or mole vipers or adders, strike sideways, impaling their victims on a long front fang

protruding through the partially closed mouth (Fig. 2). Several species, including *Atractaspis microlepidota, A. engaddensis,* and *A. irregularis* have killed humans.

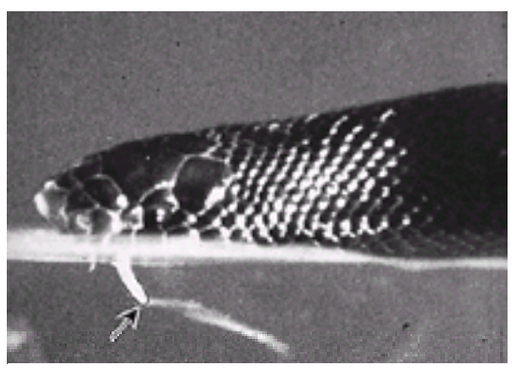

Fig. 2 Burrowing asp (*Atractaspis engaddensis*) showing side-stabbing action with one of the long fangs (arrow) (in this case through a membrane). (Photograph by courtesy of Dr I. Golani and Professor E. Kochva, Tel Aviv.)

Elapidae

This family includes cobras (Fig. 3), kraits, mambas, shield-nose snakes, coral snakes, garter snakes, venomous Australasian snakes (Fig. 4), and sea snakes (Fig. 5). The short, front fangs are immobile (Fig. 3(a) and Fig. 5). Several African and Asian species (rinkhals and spitting cobras) can eject their venom from the tips of the fangs as a fine spray for a distance of a few metres into the eyes of an enemy.

Fig. 5 Short front fangs of the laticaudine sea snake (sea krait) *Laticauda colubrina*. (Copyright DA Warrell.)

Viperidae

The front fangs are long, curved, and capable of a wide range of movement (Fig. 6). The subfamily Crotalinae comprises the American rattlesnakes (Fig. 7), moccasins, lance-headed vipers, and Asian pit vipers which possess a heat-sensitive pit organ behind the nostril (Plate 3). The Old World vipers and adders (subfamily *Viperinae*) have no pit organ.

Incidence and importance of snake bites

Snake bite is an important medical emergency in some parts of the rural tropics; its incidence is usually underestimated because most victims seek the help of traditional healers rather than practitioners of western-style medicine. In a rural population in Kenya, snake bites cause 6.7 deaths per 100 000 per year, 0.7 per cent of all deaths; it was found that 68 per cent of bitten people had sought treatment from traditional healers. In Africa, the saw-scaled or carpet viper (*Echis* spp.), puff adder (*Bitis arietans*), and spitting cobra (*Naja nigricollis, N. mossambica*, etc.) are the species of greatest medical importance. In the Benue Valley of NE Nigeria, *E. ocellatus* (Fig. 8) causes some 500 bites per 100 000 population per year, with a 12 per cent mortality. Vipers of the genus *Echis*, whose geographical range extends through the northern third of Africa, the Middle East, and Eastern Asia to India, are responsible for many bites and deaths. In India, the most important species are cobras (*Naja naja, N. oxiana, N. kaouthia*) (Fig. 3), common krait (*Bungarus caeruleus*), Russell's viper (*Daboia russelii*) (Fig. 6), and *E. carinatus*. An annual snake-bite mortality of 30 000 has been suggested. In Burdwan District, West Bengal, 8000 people are bitten and 800 die each year. In Southeast Asia, the Malayan pit viper (*Calloselasma rhodostoma*), *D. russelii*, green pit vipers (e.g. *Trimeresurus albolabris*) (Plate 3), and cobras (*N. kaouthia* and *N. siamensis*) cause most bites and deaths. In Burma, Russell's viper bite is the leading cause of acute renal failure and is responsible for most of the estimated 1000 snake-bite deaths each year. In Central and South America, medically important species include rattlesnakes (e.g. *C. durissus terrificus*) (Fig. 7) and the lance-headed vipers, *Bothrops atrox* ('barba amarilla' or 'fer de lance'), *B. asper* ('terciopelo'), and *B. jararaca* ('jararaca'). In the United States, 1370 bites were reported to Poisons Centers during 1995, but with only one death. Deaths are caused by rattlesnakes, especially eastern and western diamond-backs (*C. adamanteus* and *C. atrox*). In the Amami and Ryukyu islands of Japan, the habu (*T. flavoviridis*) inflicted an average of 610 bites with 5.6 deaths per year during the 1960s. In Britain, the adder or viper (*Vipera berus*) is the only venomous species (Fig. 9). More than 200 people are bitten each year but only 14 deaths have been reported since 1876, the last in 1975. In Sweden, this species causes between 150 and 200 hospital admissions each year: 44 deaths occurred between 1911 and 1978; and in Finland, 21 deaths in 25 years with an annual incidence of almost 200 bites. *V. aspis* causes most bites in France, while *V. ammodytes* is important in eastern Europe.

Fig. 9 European adder or viper (*Vipera berus*), Britain's only venomous snake. This specimen is 50 cm long. (Copyright D.A. Warrell.)

Australia harbours the deadliest snakes in the world, judging by the lethal potency of their venoms. However, only 3 or 4 people die each year from a snake bite. The most important species are the eastern brown snake (*Pseudonaja textilis*), tiger snake (*Notechis scutatus*), taipan (*Oxyuranus scutellatus*) (Fig. 4), and death adder (*Acanthophis* spp.). The highest snake-bite mortalities, up to 24 per cent of all adult deaths, are recorded among the hunter–gatherer tribes of Brazil (Kashinawa), Venezuela (Yanomamo), Ecuador (Waorani), Tanzania (Hadza), and Papua New Guinea.

Epidemiology

Most snake bites are inflicted on the lower limbs of farmers, plantation workers, herdsmen, and hunters in rural areas. The snake is usually trodden on at night or in undergrowth. Some species such as the Asiatic kraits (*Bungarus* spp.) and African spitting cobras (*N. nigricollis*) enter human dwellings at night and may bite people who roll over on to them while sleeping on the floor. Snakes do not bite without provocation, but may strike if inadvertently trodden upon or touched. In Europe, North America, and Australia, snakes are increasingly popular 'macho' pets: in these countries many bites are inflicted on the hands of males who are picking up the snake. In the United States, 25 per cent of bites result from snakes being attacked or handled. Serious bites by back-fanged (colubrid) snakes usually occur only under these conditions. Seasonal peaks in the incidence of snake bite are associated with agricultural activities, such as ploughing before the annual rains in the West African Sahel and the rice harvest in Southeast Asia, or to fluctuations in the activity or population of venomous snakes. Severe flooding, by concentrating the human and snake populations, has given rise to epidemics of snake bite in Colombia, Pakistan, India, Bangladesh, Nepal, Burma, and Vietnam. Invasion of virgin jungle during construction of new highways and irrigation and hydroelectric schemes has led to an increased incidence of snake bite in Brazil and Sri Lanka. Snake bite or injection of snake venom has long been used for murder and suicide. Snake venoms or purified toxins have been used therapeutically.

Venom apparatus

The venom glands of Elapidae and Viperidae are situated behind the eye, surrounded by compressor muscles (Fig. 10). A venom duct opens within the sheath at the base of the fang and venom is conducted to its tip through a canal. In Colubridae, venom secreted by Duvernoy's gland tracks down grooves in the anterior surfaces of fangs at the posterior end of the maxilla (Fig. 1). The average dry weight of venom injected at a strike is approximately 60 mg in *N. naja*, 13 mg in *E. carinatus*, 63 mg in *D. russelii*, and 32 mg in *V. palaestinae*. The amount injected when a snake bites humans is very variable. A proportion of bites are 'dry bites', associated with negligible envenoming: more than 50 per cent of those bitten by Malayan pit vipers (*C. rhodostoma*) or Russell's vipers; less than 10 per cent bitten by *Echis* spp.; but more than 75 per cent bitten by common brown snakes in Australia (*Pseudonaja textilis*). The Palestine viper (*V. palaestinae*) expends only about one-tenth of the capacity of its venom gland at each consecutive strike, whereas *D. russelii* exhausts more than three-quarters of its supply at the first strike. There is no support for the popular belief that snakes are less dangerous after they have eaten.

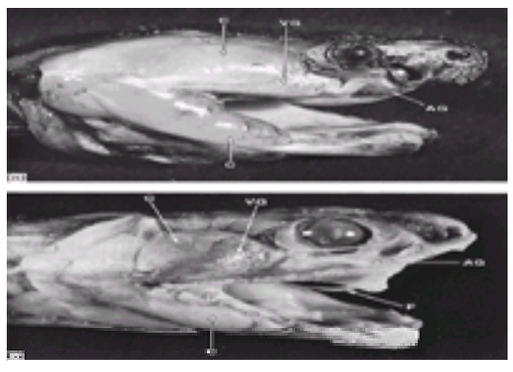

Fig. 10 Venom apparatus of viperine and crotaline snakes. (a) Venom gland of Palestine viper (*Vipera palaestinae*). (b) Venom gland of Western rattlesnake (*Crotalus viridis*). C, compressor glandulae muscle; VG, venom gland; AG, accessory gland; F, fang. (Dissection by Professor E. Kochva, reproduced from Gans, C. and Gans, K.A. (eds), 1978, *Biology of the reptilia*, vol 8. Academic Press, London, by permission.)

Venom properties

Snake venoms may contain 20 or more components. More than 90 per cent of the dry weight of venom is protein, in the form of enzymes, non-enzymatic polypeptide toxins, and non-toxic proteins such as nerve growth factor. Between 80 and 90 per cent of viperid and 25 to 70 per cent of elapid venom consists of enzymes, including digestive hydrolases, hyaluronidase, and activators or inactivators of physiological processes. Most venoms contain L-amino acid oxidase, phosphomono- and diesterases, 5'-nucleotidase, DNAase, NAD-nucleosidase, phospholipase A_2, and peptidases. Elapid venoms, in addition, contain acetylcholine esterase, phospholipase B, and glycerophosphatase, while viperid venoms have endopeptidase, arginine ester hydrolase, kininogenase, as well as thrombin-like, factor X, and prothrombin-activating enzymes. Phospholipase A_2 (lecithinase) is the most widespread and extensively studied of all venom enzymes. It damages mitochondria, red blood cells, leucocytes, platelets, peripheral nerve endings, skeletal muscle, vascular endothelium, and other membranes, produces presynaptic neurotoxic activity, opiate-like sedative effects, and the autopharmacological release of histamine. The acetylcholinesterase found in most elapid venoms does not contribute to their neurotoxicity. Hyaluronidase promotes the spread of venom through tissues. Proteolytic enzymes (endopeptidases or hydrolases) are responsible for local changes in vascular permeability leading to oedema, blistering, and bruising, and to necrosis. L-amino acid oxidase, which gives yellow snake venoms their colour, is a digestive enzyme.

Polypeptide toxins (neurotoxins)

Postsynaptic (a) neurotoxins such as a-bungarotoxin and cobrotoxin, contain about 60 to 62 or 66 to 74 amino acids. They bind to acetylcholine receptors at the motor endplate. Presynaptic (b) neurotoxins such as b-bungarotoxin, crotoxin, and taipoxin, contain about 120 to 140 amino-acid residues and a phospholipase A subunit. These release acetylcholine at the nerve endings at neuromuscular junctions and then damage the endings, preventing further release of transmitter.

Pharmacology

The neurotoxins of the Elapidae are rapidly absorbed into the bloodstream, whereas the much larger molecules of Viperidae venoms are taken up more slowly through the lymphatics. Venoms of the spitting cobras and rinkhals can be absorbed through the intact cornea, causing systemic envenoming and even death in animals. Envenoming after ingestion of snake venom has not been reported in humans. Most venoms are concentrated and bound in the kidney and some components are eliminated in the urine. Crotaline venoms are selectively bound in the lungs, concentrated in the liver, and excreted in bile, while polypeptide neurotoxins, such as a-bungarotoxin, are tightly bound at neuromuscular junctions. Most venom components do not cross the blood–brain barrier.

Pathophysiology

Swelling and bruising of the bitten limb result from increased vascular permeability induced by proteases, phospholipases, membrane-damaging polypeptide toxins, and endogenous autacoids released by the venom, such as histamine, 5-hydroxytryptamine, and kinins. Venoms of some of the North American rattlesnakes and viperine species cause a generalized increase in vascular permeability resulting in hypovolaemia, haemoconcentration, hypoalbuminaemia, albuminuria, serous effusions, pulmonary oedema, and, in the case of Burmese *D. russelii*, conjunctival and facial oedema (Fig. 11). Tissue necrosis near the site of the bite is caused by myotoxic and cytolytic factors: in some cases, ischaemia resulting from thrombosis, intracompartmental syndrome, or a tight tourniquet may contribute. Causes of hypotension and shock include hypovolaemia, vasodilatation, and myocardial dysfunction. Some venoms release vasodilating autacoids such as histamine and kinins. Venom of the Brazilian jararaca (*B. jararaca*) was found to activate bradykinin and, through a bradykinin-potentiating peptide, to prolong its hypotensive effect by inactivating the peptidyl dipeptidase responsible both for destroying bradykinin and for converting angiotensin I to angiotensin II. This observation led to the synthesis of angiotensin-converting enzyme (**ACE**) inhibitors. Bradykinin-potentiating and ACE-inhibiting peptides have also been found in a number of other crotaline venoms (genera *Bothrops* and *Agkistrodon*). To date, four sarafotoxins have been isolated from the venom of the Israeli burrowing asp (*Atractaspis engaddensis*) (Fig. 2). They show 60 per cent sequence homology with the endothelins, which are also 21-amino acid polypeptides. Sarafotoxins and endothelins are potent vasoconstrictors (including coronary arteries), delay atrioventricular conduction, and are positively inotropic.

Fig. 11 Gross bilateral conjunctival oedema (chemosis) in a Burmese rice farmer 48 h after being bitten by a Russell's viper. (Copyright D.A. Warrell.)

Snake venoms can cause haemostatic defects in a number of different ways: venom procoagulant enzymes, many of them serine proteases, activate the blood clotting cascade at various sites. Some Viperidae venoms contain thrombin-like fibrinogenases which remove fibrinopeptides from fibrinogen directly. Others activate endogenous plasminogen. Venoms may induce or inhibit platelet aggregation. Spontaneous systemic bleeding is caused by haemorrhagins, metalloendopeptidases, some with disintegrin-like and other domains, which damage vascular endothelium (Fig. 12). The combination of consumption coagulopathy, thrombocytopenia, and vessel wall damage can result in massively incontinent bleeding, a common cause of death after bites by Viperidae, Australasian Elapidae, and the few medically important Colubridae. Many venoms are haemolytic *in vitro*, but clinically significant intravascular haemolysis, apart from the microang-iopathic haemolysis associated with disseminated intravascular coagulation, is seen only after bites by *D. russelii* (Sri Lanka and India), and some *Bothrops* and colubrid species. Acute renal tubular necrosis may be caused by severe hypotension, disseminated intravascular coagulation (*D. russelii*), a direct nephrotoxic effect of the venom (*D. russelii*), and myoglobinuria secondary to generalized rhabdomyolysis (sea snakes, *D. russelii* in Sri Lanka and India, and tropical rattlesnakes). Neurotoxic polypeptides and phospholipases block neuromuscular transmission causing death through bulbar or respiratory paralysis.

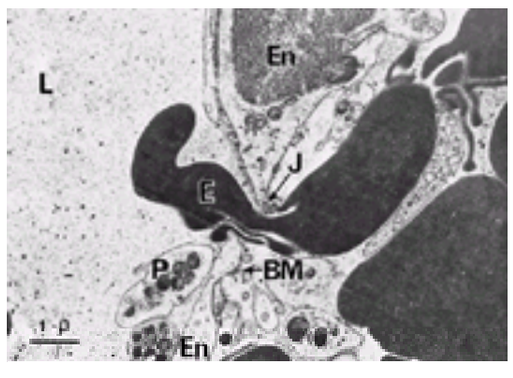

Fig. 12 Haemorrhagin activity. An erythrocyte (E) spurting through an open endothelial junction (J) between endothelial cells (En) from the lumen (L) of a rat mesenteric blood vessel, 5 min after exposure to habu (*Trimeresurus flavoviridis*) venom. Note extensive destruction of the basement membrane (Bm), and failure of the platelet (P) to undergo viscous metamorphosis. (By courtesy of Dr A. Ohsaka and Academic Press, reproduced from Ohsaka A, Suzuki K, Ohashi M (1975). *Microvascular Research* **10**, 208).

Clinical features

Fear and treatment effects as well as the venom contribute to the symptoms and signs of snake bite. Even patients who are not envenomed may feel flushed, dizzy, and breathless and may notice constriction of the chest, palpitations, sweating, and acroparaesthesiae. Tight tourniquets may produce congested and ischaemic limbs; local incisions at the site of the bite may cause bleeding, and sensory loss and herbal medicines often induce vomiting. The earliest symptoms directly attributable to the bite are local pain and bleeding from the fang punctures, followed by pain, tenderness, swelling and bruising extending up the limb, lymphangitis, and tender enlargement of regional lymph nodes. Early syncope, vomiting, colic, diarrhoea, angio-oedema, and wheezing may follow bites by some snakes (e.g. European Vipera, *D. russelii*, *Bothrops* spp., Australian elapids, and *Atractaspis engaddensis*). Nausea and vomiting is a common early symptom of systemic envenoming.

Bites by Colubridae (back-fanged snakes)

Severe envenoming causes repeated vomiting, colicky abdominal pain, headache, widespread systemic bleeding with extensive ecchymoses, incoagulable blood, intravascular haemolysis, and renal failure. Local swelling and bruising may be the only results of envenoming. The first symptoms of envenoming may be delayed for 24 to 72 h after the bite.

Bites by Atractaspididae (burrowing asps or stiletto snakes)

Local effects are pain, swelling, blistering, necrosis, and tender enlargement of local lymph nodes. Violent gastrointestinal symptoms (nausea, vomiting, and diarrhoea), anaphylaxis (dyspnoea, respiratory failure), and electrocardiogram (**ECG**) changes (atrioventricular block, ST, T-wave changes) have been described in patients envenomed by *A. engaddensis*.

Bites by Elapidae (cobras, kraits, mambas, African garter snakes, coral snakes, and Australasian snakes)

Bites by kraits, mambas, coral snakes, and some cobras (e.g. *N. haje*, *N. nivea* and *N. philippinensis*) produce minimal local effects, but the venoms of African spitting cobras (*N. nigricollis*, *N. mossambica*, etc.) and Asian cobras (*N. naja, N. kaouthia, N. sumatrana*, etc.) cause tender local swelling, blistering, and superficial necrosis which may be extensive (Fig. 13). 'Skip' lesions, separated by apparently normal areas of skin, are a typical finding (Fig. 14). However, elapid venoms are best known for their neurotoxic effects. Early symptoms, before there are objective neurological signs, include vomiting, 'heaviness' of the eyelids, blurred vision, paraesthesias around the mouth, hyperacusis, headache, dizziness, vertigo, hypersalivation, congested conjunctivas, and 'gooseflesh'. Paralysis is first detectable as ptosis and external ophthalmoplegia appearing as early as 15 min after the bite, but sometimes it is delayed for 10 h or even more than 24 h following death-adder (Acanthophis) bites. Later the face, palate, jaws, tongue, vocal cords, neck muscles, and muscles of deglutition may become paralysed (Fig. 15). The pupils are dilated. Respiratory failure may be precipitated by airway obstruction at this stage, or later after paralysis of intercostal muscles and the diaphragm. Neurotoxic effects are completely reversible, either acutely in response to antivenom or anticholinesterases (for example, following bites by Asian cobras, some Latin American coral snakes— *Micrurus* spp., and Australasian death adders—Acanthophis) or they may wear off spontaneously in 1 to 7 days.

Fig. 13 Extensive necrosis of skin and subcutaneous tissues in a Nigerian girl bitten 9 days previously on the elbow by a black-necked or spitting cobra (*Naja nigricollis*). (Copyright D.A. Warrell.)

Fig. 14 Sierra Leonian woman showing 'skip lesion' separated by an area of unaffected skin after envenoming by a black-necked spitting cobra. (Copyright D.A. Warrell.)

Fig. 15 Neurotoxic envenoming. Ptosis, ophthalmoplegia, and inability to open the mouth and protrude the tongue in a Sri Lankan patient envenomed by the common krait (*Bungarus caeruleus*). (Copyright D.A. Warrell.)

Envenoming by terrestrial Australasian elapids produces four main groups of symptoms: neurotoxicity (Fig. 16), haemostatic disturbances and, rarely, generalized rhabdomyolysis and renal failure. Painful regional lymph nodes are a useful sign of impending systemic envenoming, but local signs are usually mild, except after bites by the king brown or Mulga snake (*Pseudechis australis*). Early symptoms include vomiting, headache and syncopal attacks.

Fig. 16 Generalized paralysis, including ptosis, external ophthalmoplegia, inability to open the mouth, protrude the tongue, swallow or speak, and respiratory paralysis requiring mechanical ventilation in a Papua New Guinean man bitten 24 h previously by a taipan (*Oxyuranus scutellatus canni*). (Copyright D.A. Warrell.)

Patients 'spat' at by spitting elapids may develop venom ophthalmia. There is intense pain in the eye, blepharospasm, palpebral oedema, and leucorrhoea (Fig. 17(a)). Corneal erosions can be seen by slit-lamp or fluorescein examination in more than half of patients spat at by *N. nigricollis*. Rarely, venom is absorbed into the anterior chamber causing hypopyon and anterior uveitis. Secondary infection of corneal abrasions may lead to permanent blinding opacities or panophthalmitis (Fig. 17(b)).

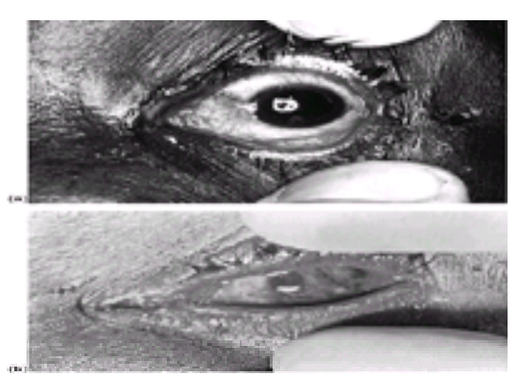

Fig. 17 Venom ophthalmia caused by the black-necked spitting cobra (*Naja nigricollis*). (a) Acute venom ophthalmia showing intense painful inflammation and

discharge. (b) In this case, the corneal injury was neglected and so secondary infection developed, necessitating enucleation of the eye. (Copyright D.A. Warrell.)

Bites by sea snakes and sea kraits

Patients envenomed by sea snakes notice headache, a thick feeling of the tongue, thirst, sweating, and vomiting. Between 30 min and 3.5 h after the bite there is generalized aching, stiffness, and tenderness of the muscles. Trismus is common. Later there is generalized flaccid paralysis. Myoglobinuria appears 3 to 8 h after the bite. Myoglobin and potassium released from damaged skeletal muscles can cause renal failure, while hyperkalaemia may precipitate cardiac arrest.

Bites by Viperidae (vipers, adders, rattlesnakes, lance-headed vipers, moccasins, and pit vipers)

Viper venoms usually produce more severe local effects than do those of other snakes. Swelling may become detectable within 15 min but is sometimes delayed for several hours. It spreads rapidly, sometimes involving the whole limb and adjacent trunk. There is associated pain and tenderness in regional lymph nodes, with bruising of overlying tissues and lymphangitic lines. Bruising, blistering, and necrosis may appear during the next few days (Fig. 18). Necrosis can be severe following bites by some rattlesnakes, lance-headed vipers (genus *Bothrops*), Asian pit vipers, and the large African *Bitis* species (puff adder, Gabon, and rhinoceros-horned vipers, etc.). When the envenomed tissue is contained in a tight fascial compartment such as the pulp space of digits or the anterior tibial compartment, ischaemia may result (Fig. 19). Absence of swelling 2 h after a viper bite suggests that there has been no envenoming. However, fatal envenoming by a few species can occur in the absence of local signs (for example, *C. d. terrificus, C. scutulatus*, and Burmese Russell's viper). Haemostatic abnormalities are characteristic of envenoming by Viperidae. Persistent bleeding from fang puncture wounds, venepuncture or injection sites, other new and partially healed wounds, and postpartum, indicates that the blood is incoagulable. Spontaneous systemic haemorrhage is most often detected in the gingival sulci (Plate 4). Epistaxis, haematemesis, cutaneous ecchymoses, haemoptysis, and subconjunctival, retroperitoneal, and intracranial haemorrhages (Fig. 20) are also reported. Patients envenomed by Burmese Russell's vipers may suffer haemorrhagic infarction of the anterior pituitary (Sheehan's syndrome) (Fig. 21). Hypotension and shock are common in patients bitten by North American rattlesnakes (e.g. *C. adamanteus, C. atrox*, and *C. scutulatus*), *Bothrops, Daboia*, and *Vipera* species (e.g. *V. palaestinae* and *V. berus*). The central venous pressure is usually low and the pulse rate rapid, suggesting hypovolaemia resulting from extravasation of fluid into the bitten limb. Patients envenomed by Burmese Russell's vipers and children envenomed by *Vipera berus* show evidence of generally increased vascular permeability. Direct myocardial involvement is suggested by an abnormal ECG or cardiac arrhythmia. Patients envenomed by some species of the genera *Vipera* and *Bothrops* and Australasian elapids may experience early transient and recurrent syncopal attacks associated with features of an autopharmacological or anaphylactic reaction, such as vomiting, sweating, colic, diarrhoea, shock, and angio-oedema. These symptoms may appear as early as 5 min or as late as many hours after the bite. Early collapse after bites by Australian brown snakes (genus *Pseudonaja*) and tiger snakes (genus *Notechis*) has been attributed to coronary and pulmonary thromboembolism. Renal failure is a common mode of death in patients envenomed by Viperidae. Victims of Russell's viper may become oliguric within a few hours of the bite and complain of loin pain suggesting renal ischaemia. Neurotoxicity, resembling that seen in patients bitten by Elapidae, is a feature of envenoming by a few species of Viperidae (e.g. *C. d. terrificus,* berg adder—*Bitis atropos* and other small *Bitis* species, and the Sri Lankan *D. russelii*). There is evidence of generalized rhabdomyolysis (Fig. 22), but progression to respiratory or generalized paralysis is unusual.

Envenoming by European vipers

The common viper or adder (*V. berus*) (Fig. 9), the only venomous snake found in Britain, occurs in England, Wales, Scotland, and northern Europe, extending into the Arctic Circle and through Asia as far east as Sakhalin Island and south to northern Korea. There are four other vipers that are widely distributed in mainland Europe: the nose-horned or sand viper (*V. ammodytes*) in the Balkans, Italy, Austria, and Romania; the asp viper (*V. aspis*) in France (south of Paris), Spain, Germany, Switzerland, and Italy; Lataste's viper (*V. latasti*) in Spain and Portugal, and Orsini's viper (*V. ursinii*) in south-eastern France, central Italy, and Eastern Europe. The Montpellier snake (*Malpolon monspessulanus*) is a large back-fanged colubrid snake whose bite can cause transient mild symptoms.

Clinical features of European viper bite

Pain usually develops quickly at the site of the bite and local swelling is evident within a few minutes, but is sometimes delayed for 30 min or longer. Local blisters containing blood are uncommon. Swelling and bruising may advance to involve the whole limb within 24 h, extend on to the trunk, and in children become generalized. A few cases of intracompartmental syndromes and necrosis have been described. Pain, tenderness, and enlargement of local lymph nodes is sometimes noticeable within hours. Marked lymphangitis and bruising of the affected limb appears within a day or two. Dramatic, early systemic symptoms may appear within 5 min of the bite or be delayed for many hours. They include retching, vomiting, abdominal colic, diarrhoea, incontinence of urine and faeces, sweating, vasoconstriction, tachycardia, shock, and angio-oedema of the face, lips, gums, tongue, throat, as well as epiglottis, urticaria, and bronchospasm. These symptoms may persist for as long as 48 h. Hypotension is the most important sign. It usually develops within 2 h, and may be transient (resolving spontaneously within 2 h), or persistent, recurrent, or progressive, and fatal. ECG changes include flattening or inversion of T waves, ST elevation, second-degree heart block, and cardiac brady- and tachyarrhythmias, atrial fibrillation, and myocardial infarction. Defibrinogenation (incoagulable blood) or milder degrees of coagulopathy and spontaneous bleeding into the gastrointestinal tract, lungs (Fig. 23), or urinary tract are uncommon. Other clinical features include fever, drowsiness, and, rarely, coma and seizures secondary to hypotension or cerebral oedema, respiratory distress/pulmonary oedema (in children), acute renal failure, cardiac arrest, intrauterine death, acute gastric dilatation, and paralytic ileus. Laboratory findings include a neutrophil leucocytosis (more than 20 000/µl in severe cases), thrombocytopenia, initial haemoconcentration and later anaemia resulting from extravasation into the bitten limb, and, rarely, haemolysis, elevation of serum creatine kinase, and metabolic acidosis. Deaths usually occur between 6 and 60 (average 34) h after the bite. Most adder bites cause only trivial symptoms, but patients must be assessed individually. Children may be severely envenomed: in a French series there were three deaths in a group of seven children aged between 2½ and 10 years. The dangers of adder bite should not be underestimated. The antivenom treatment of adder bite is discussed below.

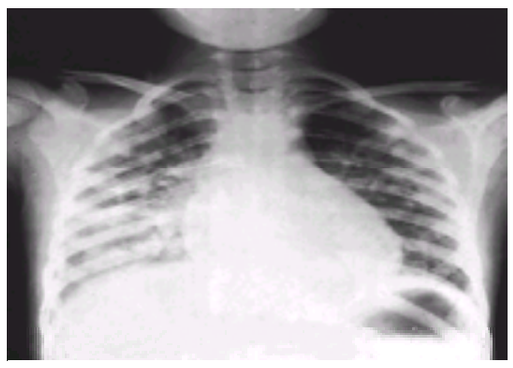

Fig. 23 Chest radiograph of a 9-year-old girl, 3 days after being bitten by *Vipera berus*, showing interstitial pulmonary bleeding. (By courtesy of Dr R. Pugh, Hull, and *The Practitioner*.)

Laboratory investigations

The peripheral neutrophil count is raised to 20 000 cells/µl or more in severely envenomed patients. Initial haemoconcentration, resulting from extravasation of plasma (*Crotalus* species and Burmese *D. russelii*), is followed by anaemia caused by bleeding or, more rarely, haemolysis. Thrombocytopenia is common following bites by pit vipers (e.g. *C. rhodostoma, Crotalus viridis helleri*) and some Viperidae (e.g. *Bitis arietans* and *D. russelii*), but is unusual after bites by *Echis* species. A useful test for venom-induced defibrinogenation is the 20-min whole-blood clotting test. A few millilitres of venous blood is placed in a new, clean, dry, glass test tube, left undisturbed for 20 min, and then tipped once to see if it has clotted or not. Incoagulable blood indicates systemic envenoming (consumption coagulopathy or anticoagulant) and may be diagnostic of a particular species (for example, *Echis* species in the northern third of Africa). Patients with generalized rhabdomyolysis show a steep rise in serum creatine kinase, myoglobin, and potassium levels. Black or brown urine suggests generalized rhabdomyolysis or intravascular haemolysis. Concentrations of serum enzymes, such as creatine kinase and aspartate aminotransferase, are moderately raised in patients with severe local envenoming, probably because of local muscle damage at the site of the bite. High concentrations suggest generalized rhabdomyolysis. Urine should be examined for blood/haemoglobin, myoglobin and protein, and for microscopic haematuria and red cell casts. Electrocardiographic abnormalities such as sinus bradycardia, ST–T changes, various

degrees of atrioventricular block, and hyperkalaemic changes may be seen.

Immunodiagnosis

Specific snake venom antigens have been detected in wound swabs, aspirates or biopsies, serum, urine, cerebrospinal fluid, and other body fluids. Of the various techniques for their detection, radioimmunoassay is probably the most sensitive and specific, but enzyme immunoassay (**EIA**) has been the most widely used. Under ideal conditions, relatively high venom antigen concentrations (wound swabs or aspirates) may be detected quickly enough (15–30 min) to allow the selection of the appropriate monospecific antivenom. A commercial test kit for Australian elapids is produced by CSL, Melbourne. For retrospective diagnosis, including forensic cases, tissue around the fang punctures, wound and blister aspirate, serum, and urine should be stored for EIA immunodiagnosis.

Management of snake bite

First aid

The patient should be reassured and moved to the nearest hospital or dispensary as quickly, as comfortably and passively as possible. The bitten limb should be immobilized with a splint or sling and all unnecessary movement discouraged.

Most traditional first aid methods are potentially harmful and should not be used. Local incisions and suction do not remove venom effectively and may introduce infection, damage tissues, and cause persistent bleeding. Vacuum extractors, potassium permanganate, and ice packs may potentiate local necrosis. Electric shocks may act as counterirritants but are dangerous and have not been proved beneficial. Tourniquets and compression bands are potentially dangerous as they can cause gangrene (Fig. 24), increased fibrinolysis, and bleeding in the occluded limb, peripheral nerve palsies, compartmental ischaemia, and intensification of local signs of envenoming.

Fig. 24 Gangrene of forearm in a Thai patient who applied a tight tourniquet above the elbow for several hours after being bitten by a Malayan pit viper. (Copyright D.A. Warrell.)

The pressure immobilization method developed by the late Struan Sutherland and his colleagues in Australia involves bandaging the entire bitten limb as tightly as for a sprained ankle, using a long crêpe bandage, starting at the toes or fingers, and incorporating a splint (Fig. 25). In animals, this method exerted a pressure of about 55 mmHg and was effective in preventing the systemic uptake of Australian elapid and some other venoms. Anecdotal experience supports the use of the method. Several reported patients have deteriorated after release of the pressure bandage. Prospective clinical studies are needed to assess the risks and benefits of this interesting technique. In the meantime, it is recommended for the first-aid of bites by Australasian elapids, sea snakes, and other elapid snakes whose venoms can have a rapid neurotoxic effect (e.g. kraits, coral snakes, and some cobras). The method is not recommended for bites by snakes whose venoms cause massive local swelling and necrosis as these effects may be accentuated by the bandage, which will increase pressure in fascial compartments, risking ischaemic necrosis.

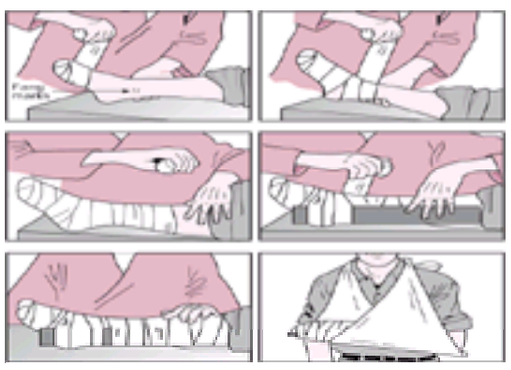

Fig. 25 Sutherland's pressure immobilization method for envenoming by neurotoxic species, such as Australasian elapids. (By courtesy of Australian Venom Research Unit, University of Melbourne.)

Pursuing and killing the snake is not recommended, but if the snake has been killed it should be taken with the patient to hospital, but it must not be handled as even a severed head can inject venom.

Patients being transported to hospital should lie on their left side to prevent aspiration of vomit. Persistent vomiting can be treated with chlorpromazine by intravenous injection (25–50 mg for adults, 1 mg/kg for children). Syncope, shock, angio-oedema, and other autonomic symptoms can be treated with 0.1 per cent adrenaline (epinephrine) by subcutaneous injection (0.5 ml for adults, 0.01 ml/kg for children) and an antihistamine such as chlorphenamine (chlorpheniramine) maleate by intravenous injection (10 mg for adults, 0.2 mg/kg for children). Patients with incoagulable blood will develop haematomas after intramuscular and subcutaneous injections, and so the intravenous route should be used whenever possible. Respiratory distress and cyanosis should be treated by clearing the airway, giving oxygen, and, if necessary, assisted ventilation. If the patient is unconscious and no femoral or carotid pulses can be detected, cardiopulmonary resuscitation must be started immediately.

Hospital treatment

Clinical assessment

In most cases of snake bite there are uncertainties about the species and the quantity and composition of venom injected, which can be resolved only by admitting the patient for at least 24 hours of observation. Local swelling is usually detectable within 15 min of pit viper envenoming and within 2 h of envenoming by most other vipers, but may not develop in patients bitten by some neurotoxic species such as kraits, coral snakes, and sea snakes. Fang marks are sometimes invisible. Tender enlargement of regional lymph nodes draining the bitten area is an early sign of envenoming by Viperidae, some Elapidae, and Australasian elapids. All the tooth sockets should be examined meticulously as this is usually the first site of spontaneous bleeding (Plate 4): other common sites are the nose, conjunctivas, skin, and gastrointestinal tract. Persistent bleeding from venepuncture sites and other wounds implies incoagulable blood. Hypotension and shock are important signs of hypovolaemia or cardiotoxicity, seen particularly in patients bitten by North American rattlesnakes and some Viperinae (e.g. *V. berus, D. russelii, V. palaestinae*). Ptosis is the earliest sign of neurotoxic envenoming (Fig. 15). Respiratory muscle power should be assessed objectively and repeatedly, for example by measuring vital capacity. Trismus and generalized muscle tenderness suggest rhabdomyolysis (sea snakes). If a procoagulant venom is suspected, the coagulability of whole

blood should be checked at the bedside using the 20-min, whole-blood clotting test.

Antivenom treatment

The most important decision is whether or not to give antivenom, the only specific treatment for envenoming. There is now abundant evidence that in patients with severe envenoming the benefits of this treatment far outweigh the risks of antivenom reactions (see below). Antivenom has reduced the mortality of systemic envenoming by *Echis ocellatus* in Nigeria from 20 to 3 per cent and by *C. d. terrificus* in Brazil from 74 to 12 per cent. Antivenoms are effective in reversing hypotension caused by *V. berus* envenoming and coagulopathies caused by *Bothrops* species, *D. russelii, C. rhodostoma, T. albolabris*, and *Oxyuranus scutellatus*. Antivenom, also known as antivenin, antivenene, and antisnakebite serum, is the partially purified immunoglobulin (whole IgG, $F(ab')_2$, or Fab fragments) of horses or sheep which have been immunized with venom.

General indications for antivenom

Antivenom is indicated if there are signs of systemic envenoming such as:

1. haemostatic abnormalities, for example spontaneous systemic bleeding, incoagulable blood, or thrombocytopenia;
2. neurotoxicity;
3. hypotension and shock, abnormal ECG, or other evidence of cardiovascular dysfunction;
4. generalized rhabdomyolysis.

Supporting evidence of severe envenoming is a neutrophil leucocytosis, elevated serum enzymes such as creatine kinase and aminotransferases, haemoconcentration, severe anaemia, myoglobinuria, haemoglobinuria, methaemoglobinuria, hypoxaemia, and acidosis.

In the absence of systemic envenoming, local swelling involving more than half the bitten limb, extensive blistering or bruising, bites on digits, and rapid progression of swelling are indications for antivenom, especially in patients bitten by species whose venoms are known to cause local necrosis (e.g. Viperidae, Asian cobras, and African spitting cobras).

Special indications for antivenom

Some developed countries can afford a wider range of indications.

United States and Canada

After bites by the most dangerous rattlesnakes (*C. atrox, C. adamanteus, C. viridis, C. horridus*, and *C. scutulatus*) antivenom therapy should be given early, even before systemic envenoming has become obvious. Rapid spread of a local swelling is considered an indication for antivenom, as is immediate pain or any other symptom or sign of envenoming after bites by coral snakes (*Micruroides euryxanthus*, *Micrurus fulvius*, and *M. tener*).

Australia

Antivenom should be given to any patient with proved or suspected snake bite if there are tender regional lymph nodes or any other evidence of systemic spread of venom, and in anyone effectively bitten by an identified highly venomous species.

Europe

(Adder—*Vipera berus*—and other European Vipera). Zagreb antivenom, or Protherics ViperaTAb (Table 1), is indicated to prevent morbidity and reduce the length of convalescence in patients with moderately severe envenoming, as well as to save the lives of severely envenomed patients. Indications are:

1. a fall in blood pressure (systolic to <80 mmHg, or by more than 50 mmHg from the normal or admission value) with or without signs of shock;
2. other signs of systemic envenoming (see above) including spontaneous bleeding, coagulopathy, pulmonary oedema or haemorrhage (shown by chest radiograph), ECG abnormalities, and a definite peripheral leucocytosis (more than 15 000/µl) and elevated serum creatine kinase;
3. severe local envenoming—swelling of more than half the bitten limb developing within 48 h of the bite—even in the absence of systemic envenoming;
4. in adults, swelling extending within 4 h beyond the wrist after bites on the hand or beyond the ankle after bites on the foot within 4 h of the bite.

Patients bitten by European Vipera who show any evidence of envenoming should be admitted to hospital for observation for at least 24 h. Antivenom should be given whenever there is evidence of systemic envenoming ((1) or (2) above), even if its appearance is delayed for several days after the bite.

Prediction of antivenom reactions

Skin and conjunctival tests do not predict early (anaphylactic) or late (serum sickness type) antivenom reactions and should not be used.

Contraindications to antivenom

Atopic patients and those who have reacted previously to equine antiserum are at increased risk of developing severe antivenom reactions. In such cases, antivenom should be given only if there is severe envenoming. Reactions may be prevented or ameliorated by pretreatment with subcutaneous adrenaline (epinephrine), antihistamine, and hydrocortisone, or a continuous intravenous infusion of 1:1 000 000 adrenaline while antivenom is being given. However, this prophylaxis is not safe enough to be recommended for routine use. Rapid desensitization is not recommended.

Selection and administration of antivenom

Antivenom should be given only if its stated range of specificity includes the species responsible for the bite. Opaque solutions should be discarded, as precipitation of protein indicates loss of activity and an increased risk of reactions. Expiry dates quoted on ampoules are often very conservative for commercial reasons. Liquid and lyophilized antivenoms stored below 8 °C usually retain most of their activity for 5 years or more. Monospecific (monovalent) antivenom is ideal if the biting species is known. Polyspecific (polyvalent) antivenoms are used in many countries because of the difficulty in identifying the species responsible for bites. Polyspecific antivenoms may be effective but a higher dose is required because they contain less of the specific neutralizing antibody per unit of immunoglobulin than monospecific antivenoms. Antivenoms may exhibit a range of paraspecific neutralizing activity. For example, the South African Institute for Medical Research's 'polyvalent antivenom', which is raised against the venoms of 10 species, has paraspecific activity against a further five species.

It is almost never too late to give antivenom while signs of systemic envenoming persist, but, ideally, it should be given as soon as it is indicated. Antivenom has proved effective up to 2 days after sea snake bites and, in patients still defibrinated, weeks after bites by Viperidae. In contrast, local envenoming is probably not reversible unless antivenom is given within a few hours of the bite. The intravenous route is the most effective. An infusion of antivenom diluted in approximately 5 ml of isotonic fluid/kg body weight is easier to control than an intravenous 'push' injection of undiluted antivenom given at the rate of about 4 ml/min, but there is no difference in the incidence or severity of antivenom reactions in patients treated by these two methods.

Dose of antivenom

Manufacturers' recommendations are based on mouse protection tests and may be very misleading. Few clinical trials have been performed to establish appropriate starting doses, and in most countries antivenom is used empirically. Many hospitals in the rural tropics give a standard dose of 1 to 2 ampoules to very patient who claims to have been bitten, irrespective of clinical severity. This practice squanders scarce, expensive antivenom and exposes non-envenomed patients to the risk of

reactions. Some suggested initial doses are given in Table 1. *Children must be given the same dose as adults.*

Response to antivenom

Often, there is marked symptomatic improvement soon after antivenom has been injected. In shocked patients, the blood pressure may rise and consciousness return (*C. rhodostoma, V. berus, Bitis arietans*). Neurotoxic signs may improve within 30 min (*Acanthophis* spp, *N. kaouthia*), but the response usually take several hours. Spontaneous systemic bleeding usually stops within 15 to 30 min and blood coagulability is restored within 6 h of antivenom treatment, provided a neutralizing dose has been given. More antivenom should be given if severe signs of envenoming persist after 1 to 2 h, or if blood coagulability is not restored within about 6 h. Systemic envenoming may recur hours or days after an initially good response to antivenom. This is explained by the continuing absorption of venom from the injection site after clearance of antivenom from the bloodstream. The apparent serum half-lives of antivenoms in envenomed patients range from 26 to 95 h. Envenomed patients should therefore be assessed daily for at least 3 or 4 days.

Antivenom reactions

Early (anaphylactic) reactions

These develop within 10 to 180 min of starting antivenom in between 3 and 84 per cent of patients. The incidence increases with dose and decreases when more highly refined antivenom is used, and when administration is by intramuscular rather than intravenous injection. The symptoms are itching, urticaria, cough, nausea, vomiting, other autonomic manifestations, fever, and tachycardia. Up to 40 per cent of patients with early reactions develop systemic anaphylaxis: hypotension, bronchospasm, and angio-oedema. Deaths are rare, but individual cases, such as the asthmatic boy who died from anaphylactic shock after receiving Pasteur antivenom in England in 1957, have been widely publicized and have led to an unreasonable rejection of antivenom treatment. Early antivenom reactions are unlikely to be type-I, IgE-mediated hypersensitivity reactions to equine serum protein. They result from complement activation by immune complexes or aggregates of IgG.

Pyrogenic reactions

Pyrogenic reactions result from contamination of the antivenom with endotoxin-like compounds. Fever, rigors, vasodilatation, and a fall in blood pressure develop 1 to 2 h after treatment. In children, febrile convulsions may be precipitated.

Late reactions

Late reactions of serum sickness type may develop between 5 and 24 (mean 7) days after antivenom therapy. The incidence of these reactions and the speed of their development increases with the dose of antivenom. Clinical features include fever, itching, urticaria, arthralgia (sometimes involving the temporomandibular joint), lymphadenopathy, periarticular swellings, mononeuritis multiplex, albuminuria, and, rarely, encephalopathy. This is a classical immune complex disease.

Treatment of antivenom reactions

Adrenaline (epinephrine) is the effective treatment for early reactions; 0.5 to 1.0 ml of 0.1 per cent (1 in 1000, 1 mg/ml) is given by intramuscular injection to adults (children 0.01 ml/kg) at the first signs of a reaction. The dose may be repeated if the reaction is not controlled. Patients with profound hypotension, severe bronchospasm, or laryngeal oedema may be given adrenaline by slow intravenous injection (0.5 mg diluted in 20 ml of isotonic saline over 10–15 min). A histamine anti-H_1 blocker, such as chlorphenamine (chlorpheniramine) maleate (10 mg for adults; 0.2 mg/kg for children) should be given by intravenous injection to combat the effects of histamine release during the reaction. Pyrogenic reactions are treated by cooling the patient and giving antipyretics. Late reactions respond to an oral antihistamine such as chlorphenamine (2 mg every 6 hours for adults; 0.25 mg/kg per day in divided doses for children) or to oral prednisolone (5 mg every 6 hours for 5 to 7 days for adults; 0.7 mg/kg per day in divided doses for children).

Supportive treatment

Neurotoxic envenoming

Bulbar and respiratory paralysis may lead to death from aspiration, airway obstruction, or respiratory failure. A clear airway must be maintained and, if respiratory distress develops, a cuffed endotracheal tube should be inserted or a tracheostomy performed. Provided they are adequately ventilated, patients with neurotoxic envenoming remain fully conscious with intact sensation. Patients have been effectively ventilated manually (by Ambu bag or anaesthetic bag), as in the 1952 poliomyelitis epidemic in Copenhagen, for 30 days and have recovered after 10 weeks of mechanical ventilation. Although artificial ventilation was first suggested for neurotoxic envenoming more than 100 years ago, patients continue to die because they are denied this simple procedure. Anticholinesterases have a variable but potentially useful effect in patients with neurotoxic envenoming, especially when postsynaptic neurotoxins are involved. The 'Tensilon test' should be performed in all cases of severe neurotoxic envenoming, as with suspected myasthenia gravis. Atropine sulphate (0.6 mg for adults; 50 µg/kg for children) or glycopyrronium is given by intravenous injection followed by an intravenous injection of edrophonium chloride (10 mg for adults; 0.25 mg/kg for children). Patients who respond convincingly can be maintained on neostigmine methyl sulphate (50–100 µg/kg) and atropine, every 4 hours by continuous infusion.

Hypotension and shock

If the central venous pressure is low or there is other clinical evidence of hypovolaemia, a plasma expander, preferably fresh whole blood or fresh-frozen plasma, should be infused. If there is evidence of increased capillary permeability (e.g. facial and conjunctival oedema, serous effusions, haemoconcentration, hypoalbuminaemia, etc.) it may be safer in the long term to rely on a selective vasoconstrictor such as dopamine (starting dose 2.5–5 µg/kg per min by intravenous infusion). Delayed hypotension developing about one week after bites by Burmese *D. russelii* may respond to intravenous hydrocortisone.

Oliguria and renal failure

Urine output, serum creatinine, urea, and electrolytes should be measured each day in patients with severe envenoming and in those bitten by species known to cause renal failure (e.g. *D. russelii, C.d. terrificus, Bothrops* spp., sea snakes). If urine output drops below 400 ml in 24 h, urethral and central venous catheters should be inserted. If urine flow fails to increase after cautious rehydration, diuretics should be tried (e.g. furosemide (frusemide)) by slow intravenous injection, 100 mg followed by 200 mg, and then mannitol. Dopamine (2.5 µg/kg per min by intravenous infusion) has proved effective in some patients bitten by Russell's vipers. If these measures are ineffective, the patient should be placed on strict fluid balance. Peritoneal or haemodialysis will usually be required. In Rangoon, the mortality of established renal failure following *D. russelii* envenoming has been reduced to less than 30 per cent by using peritoneal dialysis, usually for only 72 h.

Local infection at the site of the bite

Bites by some species (e.g. *Bothrops* spp., *C. rhodostoma*) are likely to be complicated by local infections caused by bacteria in the snake's venom or on its fangs. This should be prevented with penicillin, chloramphenicol, or erythromycin and a booster dose of tetanus toxoid, especially if the wound has been incised or tampered with in any way. An aminoglycoside such as gentamicin should be given for 48 h if there is evidence of local necrosis.

Management of local envenoming

Bullae are best left intact. The bitten limb should not be elevated as this increases the risk of intracompartmental ischaemia. Once definite signs of necrosis have appeared (blackened anaesthetic area with putrid odour or signs of sloughing), surgical debridement, immediate split-skin grafting, and broad-spectrum antibiotic cover are indicated.

Intracompartmental syndrome and fasciotomy

Increased pressure within tight fascial compartments such as the digital pulp spaces and anterior tibial compartment may cause ischaemia. This complication is most likely after bites by North American rattlesnakes, *Calloselasma rhodostoma*, *Trimeresurus flavoviridis, Bothrops* spp., and *Bitis arietans*. The signs are excessive pain,

weakness of the compartmental muscles and pain when they are passively stretched, hypoaesthesia of skin supplied by nerves running through the compartment, and obvious tenseness of the compartment. Detection of arterial pulses by palpation or Doppler does not exclude intracompartmental ischaemia. Intracompartmental pressures exceeding 45 mmHg carry a high risk of ischaemic necrosis. In these circumstances, fasciotomy may be justified, but it did not prove effective in saving envenomed muscle in experimental animals. Fasciotomy is contraindicated until blood coagulability has been restored. Early adequate antivenom treatment will prevent the development of intracompartmental syndromes in most cases. Necrosis of digits is especially common.

Haemostatic disturbances

Once specific antivenom has been given to neutralize venom procoagulants, restoration of coagulability and platelet function may be accelerated by giving fresh whole blood, fresh-frozen plasma, cryoprecipitates (containing fibrinogen, factor VIII, fibronectin, and some factors V and XIII) or platelet concentrates. Heparin has been used to treat a variety of snake bites, usually with disastrous results. Heparin did not prove beneficial in patients envenomed by *Echis ocellatus*.

Other drugs

Corticosteroids, antifibrinolytic agents (aprotinin–Trasylol and e-amino-caproic acid), antihistamines, trypsin, and a variety of traditional herbal remedies have all been used, but none has proved effective and many are potentially harmful.

Treatment of snake venom ophthalmia

When cobra venom is 'spat' into the eyes, first aid consists of irrigation with generous volumes of water or any other bland liquid which is available. Unless a corneal abrasion can be excluded by fluorescein staining or slit-lamp examination, treatment should be the same as for any corneal injury: a topical antimicrobial such as tetracycline or chloramphenicol should be applied. Instillation of antivenom is not recommended. A 0.1 per cent adrenaline eyedrop preparation relieves the pain.

Interval between bite and death

Exceptionally, patients may die 'within a few minutes' (reputedly after a bite by the king cobra, *Ophiophagus hannah*) or as long as 41 days (*E. carinatus*) after snake bite. However, most deaths occur about 8 h after cobra bites (*N. naja*), 18 h after krait bites (*Bungarus caeruleus*), 16 h after North American rattlesnake bites (*Crotalus* spp.), 3 days after *D. russelii* bites, and 5 days after *Echis* bites.

Prevention of snake bite

To reduce the risk of bites, snakes should never be disturbed, attacked, cornered, or handled, even if they are thought to be a harmless species or appear to be dead. Venomous species should never be kept as pets or as performing animals. In snake-infested areas, boots, socks, and long trousers should be worn for walks in undergrowth or deep sand, and a light should always be carried at night. Collecting firewood, dislodging logs and boulders with bare hands, pushing sticks or digits into burrows, holes, and crevices, climbing rocks and trees covered with dense foliage, and swimming in overgrown lakes and rivers are particularly hazardous activities. Unlit paths and gutters are especially dangerous after heavy rains. To prevent sea-snake bites, fishermen should not touch these animals when they are caught in nets or on lines, swimmers and divers should not aggravate them and should avoid wading in the sea, especially in muddy estuaries, in sand, or near coral reefs. It is futile and ecologically undesirable to attempt to exterminate venomous snakes. Various substances toxic to snakes, such as insecticides and methylbromide, have been used to keep human dwellings free of these animals. However, no effective but harmless snake repellent has been discovered.

Immunization against envenoming

The idea of inducing protective levels of antibodies against lethal venom components in high-risk populations by pre-exposure immunization has been tried, with inconclusive results, in Japan (*T. flavoviridis*) and considered in Burma (*D. russelii*). To be effective, high titres of a neutralizing antibody would have to be present at the time of the bite. The accelerated secondary response stimulated by envenoming would be too late to be useful.

Venomous lizards

Of the lizards, two species—the gila monster (*Heloderma suspectum*) and Mexican beaded lizard (*H. horridum*), up to 60 to 80 cm long—are venomous (Plate 5). They occur in the south-western United States, western Mexico, and Central America as far south as Guatemala. Venom from mandibular glands is conducted along grooved lower teeth. It contains lethal gila and horridum glycoprotein toxins, phospholipase A_2, and several fascinating bioactive peptides: helospectins I and II and helodermin (vasoactive intestinal peptide analogues) and extendins-3 and -4 (glucagon-like peptide-1 analogues). Humans are rarely bitten. The lizard clings on with a bulldog-like grip and may leave radiolucent teeth in the wound. There is immediate severe local pain and regional lymphadenopathy. Systemic symptoms include weakness, dizziness, hypotension, syncope, sweating, rigors, tinnitus, nausea, vomiting, leucocytosis, and ECG changes. There are no reliable reports of fatalities, but a patient envenomed by *H. suspectum* developed refractory hypotension resulting in myocardial infarction and renal failure and associated with coagulopathy. Specific antivenom is not available. Strong analgesia may be required. Hypotension should be treated with plasma expanders and, if persistent, with a pressor agent such as dopamine.

Poisonous amphibians

The moist skin of amphibians such as frogs, toads, newts, and salamanders is an accessory respiratory organ, which is protected from micro-organisms by highly toxic secretions containing amines, peptides, proteins, steroids, and alkaloids. Some compounds are synthesized *de novo*, while others are sequestered from prey such as ants, beetles, and millipedes. The bitter flavour and lethal effects of these secretions and the vivid warning coloration of many species defend them against predators. The skin of poison frogs (Dendrobatidae) of Central and South America secrete lipophilic alkaloids such as batrachotoxins (*Phyllobates* spp.), which activate sodium channels; histrionico toxins (*Dendrobates histrionicus*) (Plate 6), which block nicotinic receptors; pumiliotoxins (*D. pumilio*), which affect sodium channels; and epibatidine (*Epipedobates tricolor*), a powerful analgesic and nicotinic receptor agonist. Two Colombian tribes, the Embará and Noanamá Chocó, use the skin poisons of three species of Phyllobates to coat the tips of their blow-gun darts (Plate 7). Some toads can squirt venom from their parotid glands, this contains bufadienolides which affect membrane Na^+/K^+-ATPase. When licked or put in the mouth by dogs or children or when ingested as Chinese traditional medicines such as *Kyushin*, *Yixin Wan*, or the topical aphrodisiac *Ch'an-Su*, the poisons can cause fatal digoxin-like poisoning. Symptoms include hypersalivation, cyanosis, cardiac arrhythmias, and generalized convulsions. Antidigoxin antibodies ('Digibind') have some therapeutic effect.

The skin of three species of newts, genus *Taricha*, from the western United States, contains tarichatoxins identical to tetrodotoxin, which also occurs in some toads, frogs, fish, crustaceans, and octopuses (see below). Tetrodotoxin can be absorbed through the gastric mucosa, explaining the death of a man who swallowed a 20-cm long Oregon rough-skinned newt (*Taricha granulosa*). He developed paraesthesia of the lips, progressing to more generalized numbness and weakness, and had a cardiopulmonary arrest about 2 h after swallowing the newt.

Poisonous birds

The feathers, skin, and breast muscles of three species of pitohui or thickhead, passerine birds from New Guinea (genus *Pitohui*, Pachycephalidae) contain homobatrachotoxin, a potent steroidal alkaloid that activates sodium channels and was originally isolated from the skin of South American poison-dart frogs (*Phyllobates,* Dendrobatidae—see above). Poisonous pitohuis have an unpleasant peppery odour and their skin has a bitter flavour. Contact with their feathers causes numbness and burning of the tongue, lip or skin wounds, and sneezing. This may be a protective mechanism, and the striking 'warning' coloration of the hooded pitohui (*P. dichrous*) (Plate 8) may be the subject of Müllerian mimicry by less poisonous species. Judging by their reputation in Papua New Guinea, other species, including birds of paradise and the blue-capped Ifrita (*Ifrita kowaldi*), may also prove to have poisonous tissues.

Venomous fish

More than 100 species of fish can inflict dangerous stings on humans. Venom is injected through spines in front of the fins and tail and in the gill covers. The Indo-Pacific region and other tropical waters have the richest venomous fish fauna, but dangerous species such as sharks, chimaeras, and weevers also occur in temperate northern waters and a number of large rivers in South American, West Africa, and Southeast Asia are inhabited by freshwater stingrays (*Potamotrygon*

spp.). The following groups are capable of fatal envenoming: Squaliformes (sharks and dogfish), Rajiformes (stingrays and mantas), Siluroidei (catfish), Trachinidae (weevers), Scorpaenidae (scorpionfish and stonefish), and Uranoscopidae (stargazers and stonelifters). Venom glands are embedded in grooves in the spines or, in the case of stingrays, lie beneath a membrane covering the long barbed precaudal spine.

Incidence and epidemiology

Weeverfish are common around the British coast especially in Cornwall. Hundreds of stings occur in some years, with a peak incidence in August and September. A total of 58 cases were seen at one hospital at Pula on the Adriatic coast over a period of 13 years. It has been estimated that there are 1500 stings by rays and 300 stings by scorpionfish in the United States each year. Stings by venomous freshwater rays (*Potamotrygon hystrix, P. motoro*) are common in the Amazon region of Brazil and especially in Acré. In 4 years, 81 cases of stonefish (*Synanceja* spp.) sting were seen in Pulau Bukom Hospital near Singapore. Ornate, but aggressive and venomous members of the genera *Pterois* and *Dendrochirus* (lion, zebra, tiger, turkey, or red fire fish) (Plate 9), which are popular aquarium pets, often sting their owners on the fingers. Most fish stings are inflicted on the soles of the feet of people wading near the shore or in the vicinity of coral reefs. Venomous fish are effectively camouflaged (*Synanceja* spp.) or lie partly covered by sand. Stingrays lash their tails at the intruding limb and usually impale the ankle (Plate 9). Fatal fish stings are very rarely reported.

Venom composition

The instability of most fish venoms at normal ambient temperatures has made them difficult to study. Stingray and weeverfish venoms contain peptides, enzymes, and a variety of vasoactive compounds such as kinins, 5-hydroxytryptamine, histamine, and catecholamines. Pharmacological effects include local necrosis, direct actions on cardiac skeletal and smooth muscle resulting in ECG changes, hypotension, paralysis, and central nervous system depression.

Clinical features

Immediate sharp, agonizing pain is the dominant symptom. Hot, erythematous swelling extends up the stung limb and may persist with pain for several days and be complicated by necrosis (Plate 10) and secondary infection by marine *Vibrio* spp. (such as *V. vulnificus*) and other unusual bacteria, particularly if the spine remains embedded in the wound. Stingray spines, which are up to 30 cm long, can cause severe lacerating injuries especially to the lower legs, but if the victim inadvertently lies on the ray or falls onto it, the spine may penetrate the thoracic or abdominal cavities with fatal results.

Systemic effects are uncommon after weever stings (Trachinidae), but people stung by rays or Scorpaenidae (scorpion- and stone-fish) may develop nausea, vomiting, signs of autonomic nervous system stimulation; such as diarrhoea, sweating and hypersalivation; cardiac arrhythmias, hypotension, respiratory distress, neurological signs, and generalized convulsions. Patients have died within 1 h of being stung by *Synanceja verrucosa*.

Treatment

Pain is alleviated by immersing the stung limb in water which is uncomfortably hot (but less than 45 °C) yet not scalding. The 50 °C recommended by some authorities will cause a full thickness scald! Temperature can be assessed with the unstung limb. Addition of magnesium sulphate is unnecessary. Injection of a local anaesthetic is less effective even when applied as a ring block in the case of stung digits, but a local nerve block with 0.5 per cent of plain bupivacaine does seem to work. The venomous spine (which may be barbed), fragments of membrane, and other foreign material should be removed as soon as possible. Systemic effects must be treated symptomatically. An adequate airway should be established and cardiopulmonary resuscitation may be needed. Severe hypotension may respond to adrenaline (epinephrine), bradycardia to atropine. The Commonwealth Serum Laboratories (**CSL**) in Australia manufacture an antivenom specific for *Synanceja trachynis, S. verrucosa*, and *S horridus*. This has paraspecific activity against the venoms of the North American scorpionfish (*Scorpaena guttata*) and some other members of the Scorpaenidae. One ampoule (2 ml or 2000 units) is given intravenously for each two puncture marks found at the site of the sting. The dose is increased for patients with severe symptoms. Antibiotic treatment for secondary infections should take into account the range of possible marine pathogens. Ciprofloxacin covers *Vibrio* and *Aeromonas* spp.

Prevention

Fish stings can be prevented by employing a shuffling gait when wading, by avoiding handling living or dead fish, and by keeping clear of fish in the water, especially in the vicinity of tropical reefs. Footwear protects against most species except stingrays.

Poisoning by ingestion of aquatic animals

Acute gastrointestinal symptoms ('food poisoning') after eating seafood are usually caused by bacterial or viral infections such as *Vibrio parahaemolyticus* (crustaceans, especially shrimps), *V. cholerae* (crabs and molluscs), non-O group 1 *V. cholerae* (oysters), *V. vulnificus* (oysters), *Aeromonas hydrophila* (frozen oysters), *Plesiomonas shigelloides* (oysters, mussels, mackerel, cuttlefish), *Shigella* spp. (molluscs), *Campylobacter jejuni* (clams), *Salmonella typhi* (molluscs), hepatitis A virus (molluscs, especially clams, and oysters), Norwalk virus (clams and oysters), and astro- and caliciviruses (cockles and other molluscs). Botulism has been caused by eating smoked fish and canned salmon; and in Japan and elsewhere, fish and molluscs became contaminated with methyl mercury from industrial waste, causing severe neurological damage and fetal abnormalities ('Minamata disease').

Toxins in seafood may also give rise to gastrointestinal neurotoxic and histamine-like symptoms. Two main syndromes are described.

Gastrointestinal and neurotoxic syndromes

Nausea, vomiting, abdominal colic, tenesmus, and watery diarrhoea may precede neurotoxic symptoms of paraesthesia of the lips, buccal cavity, and extremities, distorted temperature perception (so that cold objects impart a burning sensation like dry ice), myalgia, progressive flaccid paralysis, dizziness, ataxia, cardiovascular disturbances, bradycardia, and rashes. Important causes of this syndrome are:

1. *Ciguatera fish poisonings*—Symptoms develop between 1 and 6 h (extreme range, minutes to 30 h) after eating fish such as groupers, snappers, parrot fish, mackerel, moray eels, barracudas, and jacks. These are warm-water shore or reef fish. The global incidence is thought to exceed 50 000 cases per year. Up to 1 per cent of the population may be affected each year (e.g. in Kiribati, Tokelau, and Tuvalu in the Pacific region) with a case fatality of 0.1 per cent. The toxins responsible are polyethers—such as ciguatoxin (activates Na^+ channels), maitotoxin (activates Ca^{2+} channels), and scaritoxin, ultimately derived along the food chain from benthic dinoflagellates such as *Gambierdiscus toxicus*. They are concentrated in the liver, viscera, and gonads, especially of large carnivorous fish. The increasing market for exotic fish from the Caribbean and elsewhere has led to cases of ciguatera in Britain. Gastrointestinal symptoms resolve within a few hours, but paraesthesiae and myalgia may persist for a week or even months. Similar symptoms (chelonitoxication) may follow ingestion of marine turtles in the Indo-Pacific area, but the case fatality is much higher.
2. *Tetrodotoxin poisoning*—Scaleless porcupine, sun, puffer, and toad fish (order: Tetraodonitiformes) may become highly poisonous at certain seasons, such as May to June, the spawning season in Japan. Tetrodotoxin, an aminoperhydroquinazoline, is one of the most potent non-protein toxins known. It produces neurotoxic and cardiotoxic effects by blocking voltage-gated sodium ion channels. It is found: concentrated in the ovaries, viscera, and skin of tetraodontiform fish; in the skin of newts (genus *Taricha*), frogs and toads (genera *Colostethus, Atelopus, Bracycephalus*), and salamanders; in the saliva of octopuses; from the digestive glands of several species of gastropod molluscs; in a starfish, flat worm (*Planorbis* spp.), and Nemertine worms in Japan; and is produced by some bacteria (*Pseudomonas* spp.).
3. Puffer fish ('fugu') is particularly popular in Japan where, despite stringent regulations, there are still cases of tetrodotoxin poisoning, with about four deaths each year. Neurotoxic symptoms develop within 10 to 45 min and death from respiratory paralysis usually occurs between 2 and 6 h after eating the fish. There may be no gastrointestinal symptoms. Erythema, petechiae, blistering, and desquamation may appear.
4. *Paralytic shellfish poisoning*—Bivalve molluscs, such as mussels, clams, oysters, cockles, and scallops (and also xanthid, coconut, and horseshoe crabs) may acquire tetrahydropurine neurotoxins such as saxitoxin from dinoflagellates (*Alexandrium* spp.). These may be sufficiently abundant between latitudes 30 °N and 30 °S during the warmer months of May to October to produce a 'red tide'. The dangerous season is signalled by the deaths of large numbers of fish and sea birds. Symptoms develop within 30 min of ingestion and may progress to fatal respiratory paralysis within 12 h in 8 per cent of cases. Milder gastrointestinal and neurotoxic symptoms (neurotoxic shellfish poisoning) without paralysis can follow the ingestion of molluscs contaminated by brevitoxins from *Gymnodinium breve*. These microalgae can also cause a 'red tide'. In the United Kingdom there have been several outbreaks of neurotoxic red-whelk (*Neptunea antiqua*) poisoning attributable to tetramine.

5. *Amnesic shellfish poisoning*—develops after ingestion of mussels and other molluscs contaminated with domoic acid from diatoms (*Pseudonitzschia* spp.). Gastroenteritis starts within 24 h of exposure and, in severe cases, within 48 h there is headache and coma followed by short-term memory loss.

Histamine-like syndrome (scombrotoxic poisoning)

The red flesh of scrombroid fish (tuna, mackerel, bonito, and skipjack) and of canned non-scrombroid fish, such as sardines and pilchards, may be decomposed by the action of bacteria such as *Proteus morgani* and *Klebsiella pneumoniae*, which decarboxylate muscle histidine into saurine, histamine, cadaverine, and other unidentified toxins: 100 g of spoiled fish may contain almost 1 g of histamine. Histamine absorbed from the gut is normally broken down by *N*-methyl-transferase and diamine oxidase (histaminase), but if the histamine concentration is very high, or the patient is taking a diamine oxidase inhibitor such as isoniazid (as antituberculosis chemotherapy), scombrotoxic poisoning may result. Toxic fish may produce a tingling or smarting sensation in the mouth when eaten. Within minutes or up to a few hours after ingestion, flushing, burning, sweating, urticaria, and pruritis may develop with headache, abdominal colic, nausea, vomiting, diarrhoea, bronchial asthma, giddiness, and hypotension.

Diagnosis and treatment

The differential diagnosis includes bacterial and viral food poisoning and allergic reactions.

No specific treatments or antidotes are available, but gastrointestinal contents should speedily be eliminated by emetics and purges. Activated charcoal adsorbs saxitoxin and other shellfish toxins. Mannitol has been advocated for ciguatera poisoning. Atropine is said to improve gastrointestinal symptoms and sinus bradycardia in patients with gastrointestinal and neurotoxic poisoning. Calcium gluconate may relieve mild neuromuscular symptoms. Oximes and anticholinesterases appear ineffective in ciguatera and tetrodotoxin poisoning, respectively. Patients who develop respiratory paralysis should be intubated and ventilated. The symptoms of scrombrotoxic poisoning can be alleviated with antihistamines and bronchodilators.

Prevention

Ciguatera toxin, tetrodotoxin, scombrotoxins and some other marine toxins are heat-stable so cooking does not prevent poisoning. Some toxins are fairly water-soluble and may be leached out by soaking, so water in which fish are cooked should not be drunk. In tropical areas, the flesh of fish should be separated as soon as possible from the head, skin, intestines, gonads, and other viscera which may contain high concentrations of toxin. All scaleless fish should be regarded as potentially tetrodotoxic and very large fish carry an increased risk of being ciguatera-toxic. Moray eels should never be eaten because of the high risk of unusually rapid and severe ciguatera fish poisoning. Scrombroid poisoning can be prevented by eating fresh fish or by freezing them as soon as possible after they are caught. Shellfish should not be eaten during the dangerous seasons and when there are red tides.

Poisoning by ingesting carp's gallbladder

In parts of the Far East, the raw bile and gallbladder of various species of freshwater carp (e.g. the grass carp *Ctenopharyngodon idellus*, 'plaa yeesok' *Probarbus jullieni*) are believed to have medicinal properties. Patients in China, Taiwan, Hong Kong, Japan, Thailand, and elsewhere have developed acute abdominal pain, vomiting, and watery diarrhoea 2 to 18 h after drinking the raw bile or eating the raw gallbladder of these fish. One patient developed flushing and dizziness. Hepatic and renal damage may develop, progressing to oliguric or non-oliguric acute renal failure (acute tubular necrosis). The hepatonephrotoxin has not been identified, but is heat-stable and may be derived from the carp's diet.

Venomous marine invertebrates

(Cnidarians (coelenterates): jellyfish, cubomedusoids, sea wasps, Portuguese-men-o'-war or bluebottles, hydroids, stinging corals, sea anemones, etc.)

The tentacles of cnidarians are armed with millions of nematocysts (stinging capsules). When triggered by contact or chemicals, stinging hairs are everted at enormous acceleration and force, penetrating the skin. These produce lines of painful irritant weals. Cnidarian venoms contain peptides and other vasoactive substances such as 5-hydroxyhistamine, histamine, prostaglandins, and kinins which cause immediate excruciating pain, inflammation, and urticaria.

Epidemiology

The most dangerous species, the box jellyfish, cubomedusoid, sea wasp, or indringa (*Chironex fleckeri*) of northern Australia, has caused more than 70 deaths since 1883. Most stings occur in December and January. Fatal jellyfish stings in the Indo-Pacific region—from India, north to the Philippines, and east to Bougainville Island—are attributable to *Chiropsalmus quadrumanus* and *C. quadrigatus*. Fatal stings have also been inflicted by the Portuguese man-o'-war (*Physalia* spp.) and the Chinese jellyfish *Stomolophus nomurai*. Many stings in northern Queensland are caused by *Carukia barnesi* and other tiny cubomedusoids (Irukandji stings). Hundreds of thousands of swimmers off the northern Adriatic coast were stung by a plague of *Pelagia noctiluca* during the summers of 1977 to 1979. Stings by the sea anemone, *Anemonia sulcata*, are also reported from the coasts of Slovenia and Croatia.

Clinical features

Nematocyst stings may leave a diagnostic pattern on the skin: *C. fleckeri* produces wide, striated brownish-purple weals (Plate 11), whereas *C. barnesi* causes a transient erythematous macule and the Portuguese man-o'-war (genus *Physalia*) produces chains of oval weals surrounded by erythema. Immediate severe pain is the commonest symptom. Chirodropids (genera *Chironex* and *Chiropsalmus*) cause the most severe systemic symptoms such as respiratory arrest, generalized convulsions, pulmonary oedema, and cardiac arrest within minutes of the accident. Other systemic effects include cough, nausea, vomiting, abdominal colic, diarrhoea, rigors, severe musculoskeletal pains, and profuse sweating. 'Irukandji' syndrome consists of severe musculoskeletal pain, anxiety, trembling, headache, piloerection, sweating, tachycardia, hypertension, and pulmonary oedema starting about 30 min after a sting by *C. barnesi* (and at least seven other species of tiny cubomedusoids) and persisting for hours. *Physalia* species can also cause severe systemic envenoming, including intravascular haemolysis, peripheral gangrene, and renal failure.

Treatment

Patients stung by jellyfish must be removed from the water as soon as possible to prevent drowning. The aim is to prevent a further discharge of nematocysts on fragments of tentacles stuck to the skin. Alcoholic solutions such as methylated spirits and suntan lotion, the traditional remedy, cause massive discharge of nematocysts. Commercial vinegar or a 3 to 10 per cent aqueous acetic acid solution are, however, effective against stings by *Chironex* spp. and other cubozoans, including Irukandji. Baking soda and water (50 per cent (w/v)) is effective for the widely distributed Atlantic genus, *Chrysaora*. Vinegar is not recommended for stings by *Chrysaora*, *Physalia*, or *Stomalophus* spp. Ice packs relieve the intense pain. Pressure immobilization may increase the amount of venom injected and is not recommended. Cardiopulmonary resuscitation has proved life-saving in several Australian patients who became cyanosed, comatose, and pulseless. A specific 'sea wasp' antivenom for *C. fleckeri* is manufactured in Australia. Treatment with verapamil is not recommended.

Prevention

Bathers, especially children, should keep out of the sea at times of the year when dangerous cnidarians are prevalent, especially when warning notices have been put up; or they should bathe in 'stinger-resistant' enclosures, but these do not exclude Irukandji. Wet or 'Lycra' suits, nylon stockings, and other clothing will protect against nematocyst stings.

Echinodermata (starfish and sea urchins)

These animals are protected by hard exoskeletons with numerous long, sharp projecting spines and grapples (globiferous pedicellariae) which can release venom when embedded in the skin. Severe pain and local swelling may result, and sometimes systemic effects such as syncope, numbness, generalized paralysis, aphonia, respiratory distress, cardiac arrhythmias, and even death. Embedded fragments of spines may lead to secondary infection and chronic granulomas or damage to

bones and joints.

Treatment

Hot water (see above) may relieve the pain. Skin penetrated by the spines, usually the soles of the feet, should be softened with 2 per cent salicylic acid ointment or acetone. The spines can then be squeezed out or removed surgically. No antivenoms are available.

Mollusca (cone shells and octopuses)

The 500 species of cone shells (genus *Conus*) are carnivorous marine snails that harpoon their prey (fish, polychaete worms, and other molluscs), implanting a radular tooth charged with venom containing a mixture of small (10–30 amino acid) peptide toxins. These include: conotoxins which block acetylcholine receptors and voltage-sensitive Ca^{2+} and Na^{+} channels; conantokins which are *N*-methyl-D-aspartate receptor antagonists with anticonvulsant activity; and conopressins which target vasopressin receptors. Cone shells are attractive and valuable collectors' items. People who pick them up may be stung. Symptoms of envenoming are nausea, vomiting, paraesthesia and numbness of the lips and site of sting, numbness, dizziness, ptosis, diplopia, dysarthria, dyspnoea, and loss of consciousness. In a series of 35 cases mostly stung by *Conus geographus* reported in Japan (1896–1996), 10 died within 2 to 5 h of the sting (Plate 12).

Several species of small octopus found in the Australian and West Pacific region (blue ringed octopuses—genus *Hapalochlaena*—Plate 13) can inject salivary tetrodotoxin when they bite swimmers with their powerful beaks. These bites are painful and cause local bleeding, swelling, and inflammation. Severe neurotoxic symptoms, and even fatal generalized paralysis, may develop within 15 min of the bite.

Treatment

No antivenoms are available. Cardiopulmonary resuscitation and mechanical ventilation may be required.

Venomous arthropods

(Hymenoptera (bees, wasps, yellowjackets, hornets, and ants))

The commonest and most severe stings from *Hymenoptera* spp. are caused by members of the families Apidae (e.g. honey bees, *Apis mellifera*, *A.. cerania*, bumble bees, etc.), Vespidae (e.g. wasps, genera *Polistes* and *Paravespula*), American yellowjackets and 'hornets' (genera *Vespula* and *Dolichovespula*) and European and Asian true hornets (genus *Vespa*), and Formicidae (e.g. fire ants, genus *Solenopsis*). Allergic reactions to single stings from *Hymenoptera* spp. are common, whereas toxic reactions resulting from many stings are rare, except in the Americas. Venom allergens include phospholipases A, hyaluronidase, acid phosphomonoesterases, and melittin (*A. mellifera*). Non-allergenic compounds include vasoactive amines such as histamine, 5-hydroxytryptamine, catecholamines and kinins, cholinesterase (in the venom of the common European wasp (*Paravespula germanica*), pheromones, and 2-methylpiperidine alkaloids in venoms from *Solenopsis* (fire ant) spp.

Epidemiology

Fewer than 10 people die from hymenopteran sting anaphylaxis in England and Wales each year, 2 or 3 per year in Australia, and in the United States there are between 40 and 50 deaths per year. The incidence of systemic reactions to stings by *Hymenoptera* spp. has been reported as 0.4 to 0.8 per cent in children. In an adult population in the United States, the prevalence of systemic allergic sting reactions was found to be 4 per cent; 20 per cent of this population showed evidence of venom hypersensitivity (skin tests or radioallergosorbent test, **RAST**). In Britain, most patients allergic to bee venom are beekeepers or their relatives. Since the escape of swarms of African honey bees (*A. m. scutellata*) in Brazil, in 1957, this aggressive strain has spread throughout Latin America and north as far as Las Vegas in the United States. About 30 deaths from mass attacks by these bees have been reported each year. Two species of fire ants, *Solenopsis richteri* and *S. invicta*, were imported into the United States from South America in 1918 and have now spread to 13 southern states where an estimated 2.5 million individuals are stung each month. The incidence of systemic allergic reactions is about 4 per 100 000 population per year, and there have been fatalities.

Clinical features

Toxic effects

In non-sensitized individuals, a sting, which, in the case of Vespidae and Apidae, introduces about 50 µg of venom, will rapidly produce a hot, red, painful swelling and weal a few centimetres in diameter, which persists for a few hours. These effects are dangerous only if the airway is obstructed, for example following stings on the tongue. As few as 30 stings can cause fatal systemic envenoming in children, but children and adults have survived more than 1000 stings by *A. mellifera*. In some patients, symptoms have suggested histamine toxicity: vasodilatation, hypotension, vomiting, diarrhoea, throbbing headache, coma, and bronchoconstriction. In Latin America, victims of attacks by *A. m. scutellata* have shown evidence of generalized rhabdomyolysis (grossly elevated serum creatine kinase, aminopeptidases, and myoglobin), intravascular haemolysis, hypercatechola-minaemia (hypertension, pulmonary oedema, myocardial damage), bleeding, hepatic dysfunction, and acute renal failure (Plate 14). In non-sensitized people, stings form *Solenopsis* spp. produces pain, itching, swelling, and erythema around a central weal which last a few hours, and later vesicles or pustules. In an unsensitized patient an estimated 10 000 *S. invicta* stings caused no systemic envenoming.

Allergic effects

Clinical suspicion of dangerous venom hypersensitivity arises when systemic symptoms follow a sting. Patients may die within minutes of the sting. Systemic symptoms include: a tingling scalp; itching of the palms, soles, axillas, and perineum, becoming generalized; flushing; dizziness; syncope; wheezing; abdominal colic (uterine colic in women), diarrhoea, incontinence of urine and faeces; tachycardia and visual disturbances; all developing within a few minutes of the sting. Over the next 15 to 20 min, urticaria, angio-oedema of the lips, gums, and tongue, a generalized redness of the skin with swelling, oedema of the glottis, profound hypotension, and coma may develop. A few patients develop serum sickness a week or more after the sting. Some patients with sting allergy have other evidence of an atopic disposition. Reactions are enhanced by b-blockers.

Diagnosis of anaphylaxis and venom hypersensitivity

Serum concentrations of mast-cell tryptase may be raised for up to 6 h after an anaphylactic attack, distinguishing this diagnosis from panic attacks and other causes of collapse. Type I hypersensitivity is confirmed by detecting venom-specific IgE in the serum using RAST or by prick skin tests. Patients who have suffered a systemic reaction, have a 50 to 60 per cent risk of a reaction to their next sting. Local reactions, even massive ones involving persistent swelling of the whole stung limb, in the absence of systemic symptoms do not predict a systemic reaction when stung again. Children who have generalized urticaria after a sting have only a 10 per cent chance of a systemic reaction when restung. Hypersensitivity to venom may be lost spontaneously, especially by children and young adults. The RAST test can be used for a postmortem diagnosis of Hymenoptera sting anaphylaxis.

Treatment

The barbed stings of Apidae remain embedded at the site of the sting and continue to inject venom, so they should be removed immediately by any means possible. Vespids can withdraw their stings and sting repeatedly. Wasp stings may become infected because these insects feed on rotting meat. Domestic meat tenderizer (papain) diluted roughly 1:5 with tap water is said to produce immediate relief of pain. Ice packs and aspirin are also effective. Systemic but not topical antihistamines can be used for more severe local reactions. Massive local reactions may require aspirin, non-steroidal anti-inflammatory agents, or even corticosteroids. **Systemic anaphylaxis** must be treated with 0.1 per cent (1:1000) adrenaline (epinephrine) (0.5–1 ml for adults; 0.01 mg/kg for children) given by intramuscular injection, or, if the patient is unconscious or pulseless, diluted 1:100 000, by intravenous injection. In rare cases, blood pressure fails to respond even to large doses of adrenaline and plasma expanders. These patients should be given cardiopulmonary resuscitation, selective bronchodilators such as salbutamol, pressor agents such as dopamine, and intravenous histamine H_1 and H_2 blockers such as chlorphenamine (chlor-pheniramine) maleate (10 mg for adults; 0.2 mg/kg for children) and cimetidine. Corticosteroids probably have no effect in acute anaphylaxis but may prevent relapses a few hours later. Patients who know they are hypersensitive should wear an identifying tag (such as provided by Medic-Alert in Britain) as they may be discovered unconscious after being stung. They should be trained to give themselves adrenaline using an 'EpiPen' or similar apparatus. Adrenaline delivered by a pressurized inhaler ('Medihaler-Epi') or squirted down the endotracheal tube

produces transient blood levels insufficient to combat anaphylaxis. Respiratory tract obstruction and shock are the main causes of death.

Severe envenoming from multiple stings by *Hymenoptera* spp. should be treated with adrenaline, intravenous antihistamines (doses as above), and corticosteroids. Intensive care is essential. Intravenous mannitol and bicarbonate may protect the kidneys from the damaging effects of myoglobinuria and haemoglobinaemia ('pigment nephropathy'), as in patients with the crush syndrome. Experimental antivenoms have been produced but are not yet commercially available. Exchange transfusion or plasmapheresis might be considered to remove venom in severe cases. Renal dialysis is often needed.

Prevention

Patients over the age of 25 years who have a history of systemic anaphylaxis following a sting and who have evidence of hypersensitivity (venom-specific IgE detectable in the serum or a positive skin test) should be considered for desensitization with purified venoms. This treatment proved significantly more effective than placebo or the previously used whole body extracts of *Hymenoptera* spp. in preventing anaphylactic reactions to sting challenge. Desensitization usually involves weekly visits to the hospital for at least 8 weeks for the administration of gradually increasing doses of venom. When protection has been demonstrated by the patient's ability to tolerate 100 µg of venom (equivalent to two stings) they are ready for maintenance therapy, usually 100 µg of venom every 4 to 8 weeks. A period of 2 to 5 years of maintenance desensitization is recommended, after which more than 90 per cent of subjects will remain protected against systemic reactions after stopping treatment. Desensitization is complicated by systemic reactions in 5 to 15 per cent of patients and by local reactions in 50 per cent.

Wasps are attracted by sweet things and meat in kitchens, greengrocers, orchards, and vineyards. Vespidae are attracted by brightly coloured floral patterns and perfumes. Hornets are attracted by light. Some species are so aggressive that their nests must be eradicated before their territory can be used for farming.

Venomous lepidoptera

The stinging hairs of some species of adult moths can cause contact dermatitis and urticaria ('lepidopterism'), while caterpillars can produce local or even systemic effects ('erucism'). Venomous lepidoptera are found in all parts of the world, but most cases of lepidopterism are reported from Middle and Southern America. Severe cutaneous urticating eruptions (Plate 15) can be caused by caterpillars of the genus *Megalopyge* (called 'pussmoths' in the southern United States) and by adult female moths of the genus *Hylesia* which have barbed setae ('flechettes') on their abdomens. Epidemics of stings by these moths have been described, especially from coastal areas of Brazil, Peru, Venezuela, and Mexico. Caterpillars of the genus *Lonomia* (*L. obliqua, L. achelous*) can inject through their bristles venom containing a plasminogen activator, plasmin-like enzyme, protease-activating factors V and XIII, and prothrombin, resulting in defibrinogenation, spontaneous bleeding into the skin, urinary tract, and even fatal intracranial haemorrhage (Plate 16). Laboratory findings in envenomed patients are decreased plasma fibrinogen, factor V, factor XIII, and plasminogen concentrations, as well as increased fibrin(ogen) degradation products and fibrinolytic activity but a normal platelet count.

In Pará State, Brazil, rubber tappers are frequently in contact with caterpillars (*Premolis semirufa*) whose stinging hairs can cause a disabling arthritis of the hands ('pararama').

Venomous coleoptera (beetles)

The most famous vesicating beetle is 'Spanish fly'—*Lytta vesicatoria* (Meloidae—blister beetles). Its venom contains cantharidin, which causes blistering when applied to the skin and priapism (hence its reputation as an aphrodisiac) and renal failure when given systemically or absorbed after eating the legs of frogs which have fed on meloid beetles.

'Nairobi eye' and similar blistering conditions in Australia and South-East Asia are caused by species of the genus *Paederus* (Staphylinidae) (Plate 17). A typical skin lesion (dermatitis linearis) consists of erythema, itching, and blistering caused by inadvertently crushing and smearing the beetle. Systemic symptoms such as fever, arthralgia, and vomiting may arise in severe cases. The active principle pederin is the most complex non-proteinaceous insect toxin known. Treatment is palliative. The toxin is easily spread to other sites such as the eye by fingers.

Scorpions (Scorpiones: Buthidae, Scorpionidae)

Species capable of inflicting fatal stings occur in North Africa and the Middle East (genus *Androctonus*, *Buthus*, and *Leiurus*); South Africa (*Parabuthus* spp.); India (*Mesobuthus tamulus*); North, Central and Southern America, Trinidad, and Tobago (genera *Tityus* (Plate 18) and *Centruroides*). Scorpion toxins target Na^+, K^+, Ca^{2+}, and Cl^- channels causing direct effects and the release of neurotransmitters such as acetylcholine and catecholamines.

Epidemiology

There have been no deaths from scorpion sting in the United States since 1968. However, between 1000 and 2000 deaths were reported each year in Mexico, but recently this number has declined dramatically. Case fatality is highest (formerly about 50 per cent) in children less than 4 years old. In Trinidad, stings by *Tityus trinitatis* are an occupational hazard of sugar cane and cocoa plantation workers. In the 1960s, there were 33 deaths in a group of 698 cases. Mortality was 25 per cent in children under 5 years compared to 0.25 per cent in adults. In Brazil, mortality was about 1 per cent in adults and 15 to 25 per cent in children less than 6 years old. In India, many people are stung by the red scorpion (*Mesobuthus tamulus*) with fatalities in adults and children.

Clinical features

Intense local pain is the commonest symptom. There may be slight local oedema and tender enlargement of regional lymph nodes, but stings by *Hemiscorpius lepturus* (Iran, Iraq, Pakistan, and Yemen) cause a local macular lesion which may blister and become necrotic resulting in sloughing of a large area of skin (Plate 19). Systemic symptoms may develop within minutes or be delayed for as much as 24 h. Symptoms vary depending on the species and geographical area. Scorpion venoms stimulate the release of acetylcholine and catecholamines, often resulting in initial cholinergic and later adrenergic symptoms. Early symptoms include vomiting, profuse sweating, piloerection, alternating brady- and tachycardia, abdominal colic, diarrhoea, loss of sphincter control, and priapism. Later, severe life-threatening cardiorespiratory effects may appear: hypertension, shock, tachy- and bradyarrhythmias, ECG changes (Fig. 26), and pulmonary oedema (Fig. 27) with or without evidence of myocardial dysfunction. Severe cardiovascular complications are particularly associated with stings by *Leiurus quinquestriatus, Mesobuthus tamulus*, and *Tityus* species. Stings by the North American *Centruroides sculpturatus* produce neurotoxic effects such as fasciculation, spasms, respiratory paralysis, and convulsions. Victims of the Trinidad black scorpion (*Tityus trinitatis*) develop severe abdominal pain with nausea, vomiting and haematemesis, hyperglycaemia, and biochemical evidence of acute pancreatitis.

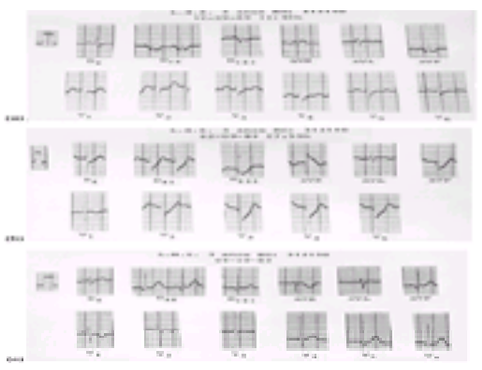

Fig. 26 Electrocardiographic changes caused by envenoming by the Brazilian scorpion (*Tityus serrulatus*). (By courtesy of Dr Carlos Amaral, Belo Horizonte, Brazil.) (a) ECG of 3-year-old girl 2 h after sting, showing sinus tachycardia and mild T-wave and ST-segment changes in the inferior and anterior leads. (b) Same patient 24 h after the sting, showing sinus tachycardia with marked ST down-sloping and ST displacement in the inferior and anterolateral leads. (c) ECG of the same patient 3 days after the sting, showing return to normal sinus rhythm and ST pattern.

Fig. 27 Pulmonary oedema caused by *Tityus serrulatus* envenoming. (By courtesy of Dr Carlos Amaral, Belo Horizonte, Brazil.) (a) Chest radiograph of a 9-year-old girl 24 h after sting, showing alveolar infiltrates in both lungs with air bronchograms. The heart size is increased. (b) Chest radiograph of 7-year-old girl 10 h after sting, showing bilateral pulmonary oedema with enlarged heart.

Treatment

Pain responds temporarily to local infiltration or ring block with local anaesthetic. Local injection of emetine or dehydroemetine is said to relieve the pain but may cause necrosis. Parenteral opiate analgesics, such as pethidine or morphine, may be required, but are said to be dangerous in victims of *C. sculpturatus*.

Antivenom is manufactured in a number of countries. Its use is strongly advocated in Africa and the Americas, but ancillary pharmacological treatment is regarded as being much more important in the Middle East and India. However, if specific antivenom is available it should be administered intravenously as soon as possible in patients with systemic envenoming and in young children stung by dangerous species, even before the development of these symptoms. Patients with cardiovascular symptoms benefit from vasodilator treatment with a-blockers (e.g. prazosin), calcium-channel blockers (e.g. nifedipine), or ACE inhibitors (e.g. captopril). Atropine should not be used except in cases of life-threatening sinus bradycardia. The use of cardiac glycosides and b-blockers is controversial. Anticonvulsants such as phenobarbital (phenobarbitone) are recommended for neurotoxic symptoms.

Prevention

Scorpions can be kept out of houses by including a row of ceramic tiles in the outside wall, making the doorsteps at least 20 cm high, and using residual insecticides, such as 1 per cent lindane or dieldrin powders.

Spiders (Araneae)

All but one family of this enormous order are venomous, but few species have proved dangerous to humans. Spiders bite with a pair of small fangs, the chelicerae, to which the venom glands are connected (Plate 20). There are four medically important genera of venomous spiders: *Loxosceles* cause necrotic araneism and *Latrodectus, Phoneutria*, and *Atrax* cause neurotoxic araneism.

Epidemiology

Loxosceles laeta (Plate 21) is widely distributed and causes many bites in people in Central and Southern America, especially in Chile, where the mortality ranges from 1 to 17 per cent. *L. reclusa*, the brown recluse spider, caused at least 200 bites and six deaths in the United States during the last century. More than 60 cases were reported from Texas between 1959 and 1962. Bites by *L. rufescens* have been reported from the Mediterranean region, North Africa, and Israel. Most bites from *Loxosceles* spp. occur in bedrooms while people are asleep or dressing, and in the United States a number of men were bitten on the genitalia while they sat on outdoor lavatories in which the spiders had spun their webs. *Latrodectus tredecemguttatus* (sometimes referred to, loosely, as 'tarantula') lives in fields in Mediterranean countries and has been responsible for a series of epidemics of bites. In Italy, 946 cases were reported between 1946 and 1951. *L. hasseltii*, the Australian redback spider (Plate 22), causes up to 340 bites each year in Australia and 20 deaths have been reported. The black widow spider (*L. mactans*) was responsible for 63 deaths in the United States between 1950 and 1959. Other species of *Latrodectus* are found in Latin America.

Phoneutria nigriventer (Plate 20 and Plate 23), the banana spider, causes bites and deaths in South American countries. These spiders have been imported to temperate countries on bunches of bananas, causing a few bites and deaths. The funnel web spiders (genus *Atrax*) are restricted to south-eastern Australia and Tasmania. The Sydney funnel web spider (*A. robustus*) occurs only within a 160-mile (256 km) radius of Sydney. The aggressive males of this species caused at least 13 deaths between 1927 and 1980. Members of the related genera *Hadronyche* and *Missulina* may be equally dangerous. In England, mild neurotoxic araneism has been described after bites by *Steatoda nobilis* (Theridiidae) and the woodlouse spider (*Dysdera crocata*).

Necrotic araneism

The bite itself is usually painless and unnoticed. Burning develops over several hours at the site of the bite, with swelling and development of a characteristic macular lesion (Plate 24(a)) which shows areas of red (vasodilatation), white (vasoconstriction), and blue (prenecrotic cyanosis). Eventually the lesion forms a blackened eschar (Plate 24(b) and Plate 24(c)) which sloughs in a few weeks, sometimes leaving a necrotic ulcer. The necrotic area may, rarely, cover an entire limb. Facial lesions may cause much oedema. Some 13 per cent of cases have systemic symptoms such as fever, headaches, scarlatiniform rash, jaundice, methaemoglobinaemia, and haemoglobinuria resulting from intravascular haemolysis. Renal failure may ensue. The average case fatality is about 5 per cent.

Neurotoxic araneism

The bite is very painful but local signs are minimal (*L. mactans*) or moderate (*L. hasselti*). After about 30 min there is painful regional lymphadenopathy, then headache and nausea and vomiting, with local sweating and piloerection ('gooseflesh') (Plate 25) and painful muscle spasms and tremors that may be severe enough to embarrass respiration. Local sweating and piloerection at the site of the bite is very suggestive of neurotoxic araneism. Other features include tachycardia, hypertension, restlessness, irritability, psychosis, priapism, and rhabdomyolysis. The 'facies latrodectismica' is a painful grimace caused by facial spasm and trismus associated with swollen eyelids, congested conjunctivas, flushing, and sweating (*L. tredecemguttatus*). Similar effects are seen in patients bitten by *Phoneutria* and *Atrax* spp.

First-aid treatment

In the case of bites by spiders with rapidly acting and potent venoms, such as *A. robustus* and *Hadronyche* species, firm crêpe bandaging and splinting of the bitten limb may delay venom spread until the patient reaches hospital.

Specific treatment

Antivenoms for a bite from *Latrodectus* spp. are made in Australia, the United States, Russia, Italy, Croatia, South, Africa and South America; for *Atrax* spp. bites in Australia; for *Loxosceles* spp. in Peru, Brazil, and Argentina; and for *Phoneutria* spp. in Brazil. Neurotoxic araneism seems more responsive to antivenom than does the necrotic type.

Supportive treatment

Oral dapsone (100 mg twice daily) is said to reduce the extent of necrotic lesions by inhibiting neutrophil degranulation. Calcium gluconate (10 ml of a 10 per cent solution, given by slow intravenous injection) relieves the pain of muscle spasms caused by the venom of *Latrodectus* spp. rapidly and more effectively than muscle relaxants such as diazepam or methocarbamol. Antihistamines, corticosteroids, a-blockers, and atropine have also been advocated. For necrotic araneism cause by *Loxosceles* spp. surgical debridement, corticosteroids, antihistamines, and hyperbaric oxygen all have their advocates, but there is no basis for recommending their use.

Ticks (Acari)

Taxonomy and epidemiology

Ticks, with mites, form the order Acari of the class *Arachnida*. Adult females of about 34 species of hard tick (family *Ixodidae*) and immature specimens of nine species of soft ticks (family *Argasidae*) have been implicated in human tick paralysis. The tick's saliva contains a neurotoxin which causes presynaptic neuromuscular block and decreased nerve-conduction velocity. The tick embeds itself in the skin with its barbed hypostome introducing the salivary toxin while it engorges with blood.

Although tick paralysis has been reported from all continents, most cases occur in western North America (*Dermacentor andersoni*), eastern United States (*D. variabilis*), and eastern Australia from north Queensland to Victoria (*Ixodes holocyclus*) known as the bush, scrub, paralysis-, or dog tick). In British Columbia there were 305 cases with a 10 per cent mortality between 1900 and 1968. About 120 cases have been reported in the United States, and in New South Wales there were at least 20 deaths between 1900 and 1945.

Clinical features

Ticks are picked up in the countryside or from domestic animals, particularly dogs, in the home. The majority of patients and almost all fatal cases are children. After the tick has been attached for about 5 or 6 days a progressive ascending, lower motor neurone paralysis develops with paraesthesiae. Often a child, who may have been irritable for the previous 24 h, falls on getting out of bed first thing in the morning and is found to be weak or ataxic. Paralysis increases over the next few days: death results from bulbar and respiratory paralysis and aspiration of stomach contents. Vomiting is a feature of the more acute course of *Ixodes holocyclus* envenoming.

This clinical picture is often misinterpreted as poliomyelitis. Other neurological conditions, including Guillain–Barré syndrome, paralytic rabies, Eaton–Lambert syndrome, myasthenia gravis, or botulism, may also be suspected. Diagnosis depends on finding the tick, which is likely to be concealed in a crevice, orifice, or hairy area of the body. The scalp is the commonest place. Fatal tick paralysis has been caused by a tick attached to the tympanic membrane.

Treatment

The tick must be detached without being squeezed. It can be painted with ether, chloroform, paraffin, petrol, or turpentine, or prised out between the partially separated tips of a pair of small, curved forceps. Following removal of the tick there is usually a rapid and complete recovery; but in Australia, patients have died after the tick has been detached. An antivenom, raised in dogs, is available in Australia, and, recently, rabbits have been used to produce an antitoxin against *I. holocyclus* saliva. This is recommended for severely affected or very young patients; 20 to 30 ml are given intravenously.

Centipedes (Chilopoda)

Many species of centipedes can inflict painful bites (Fig. 28), producing swelling, inflammation, and lymphangitis. Systemic effects such as vomiting, headache, cardiac arrhythmias, and convulsions are extremely rare and the risk of mortality was probably greatly exaggerated in the older literature. The most important genus is *Scolopendra* which is distributed throughout tropical countries. Local treatment is the same as for scorpion stings. No antivenom is available.

Fig. 28 Venom 'jaws' (modified limbs) of a Thai centipede (*Scolopendra* species). (Copyright DA Warrell.)

Millipedes (Diplopida)

Most species possess glands in each of their body segments which secrete, and in some cases squirt out, irritant liquids for defensive purposes. These contain hydrogen cyanide and a variety of aldehydes, esters, phenols, and quinonoids. Members of at least eight genera of millipedes have proved injurious to humans. Important genera are *Rhinocricus* (Caribbean), *Spirobolus* (Tanzania), *Spirostreptus* and *Iulus* (Indonesia), and *Polyceroconas* (Papua New Guinea). Children are particularly at risk when they handle or try to eat these large arthropods. When venom is squirted into the eye, intense conjunctivitis results and there may be corneal ulceration and even blindness. Skin lesions initially stain brown or purple, blister after a few days, and then peel. First aid is generous irrigation with water. Eye injuries should be treated as for snake venom ophthalmia (see above).

Leeches (Phylum Annelida, Class Hirudinea)

Leeches are blood-sucking, hermaphroditic, egg-laying annelids which have elongated annulated bodies. They attach themselves to leaves, rocks. or the host by a posterior sucker. To feed, the leech applies its anterior sucker containing the mouth armed with three radially arranged jaws which make a Y-shaped incision. Blood is sucked out by the action of the muscular pharynx. To prevent blood clotting, the saliva contains a histamine-like vasodilator and anticoagulants, such as: hirudin from the medicinal leech (*Hirudo medicinalis*), which inhibits thrombin and factor IXa; hementin from *Haementeria ghilianiı*, which is directly fibrinolytic; and hementerin from *H. depressa* (= *H. lutzı*), a plasminogen activator. Other enzymes include esterases, antitrypsin, antiplasmin, and antielastase. Recombinant hirudin is now produced as a therapeutic anticoagulant. The medicinal leech is still used by plastic surgeons to reduce haematomas under skin grafts; the wound may become infected with *Aeromonas hydrophila* which lives symbiotically in the leech's gut.

Two groups of leeches cause human morbidity and even mortality in tropical countries.

Land leeches

Species of the genera *Haemadipsa* and *Phyrobdella* are 1 to 8 cm long. They infest, often in enormous numbers, the damp, leafy floor and low vegetation of rainforests, choosing game trails and watering places. By standing on the posterior sucker and waving the anterior sucker, they can sense their prey with amazing efficiency. They drop on to the prey or pursue it with a looping or lashing motion. These leeches usually attach themselves to the lower legs or ankles and are adept at penetrating clothing, even long trousers tucked into socks and lace-up boots. The bite is usually painless and infested persons may not realize what has happened until they hear a squelching sound, notice that their feet are warm and wet, and see blood welling over the tops of their boots. Land leeches ingest about 1 ml of blood

in one hour and then drop off, but the wound continues to bleed for some time and forms a fragile clot.

Aquatic leeches

These species may be swallowed by those who drink stagnant water or even mountain stream water, or they may attack bathers, entering the mouth, nostrils, eyes, vulva, vagina, urethra, or anus. The enormous brightly coloured buffalo leech (*Hirudinaria manillensis*) of South-East Asia, is up to 16 cm long and can ingest 1 ml of blood in 10 min. *Limnatis nilotica* occurs around the Mediterranean, Middle East, and North Africa. *Myxobdella africana* occurs in East Africa. *Dinobdella ferox* (5 cm long) is found in Asia. Some aquatic leeches are very slow feeders and may remain attached for days or even weeks.

Clinical features

The main effect is blood loss, but other symptoms include pain caused by the bite, secondary infection, a residual itching, and phobia. Ingested aquatic leeches usually attach to the pharynx but may penetrate the bronchi or oesophagus. *H. manillensis* entering via the anus can reach the rectosigmoid junction of the bowel causing perforation and peritonitis. Patients with a leech in the pharynx often have a feeling of movement at the back of the throat with cough, hoarseness, stridor, breathlessness, epistaxis, haemoptysis, and haematemesis. Fatal upper airway obstruction may result. Bleeding may persist for up to a week after the leech has dropped off. In rural Thailand, vaginal bleeding in girls who have swum in ponds or canals is often attributable to infestation by aquatic leeches. Sexual abuse may be wrongly inferred if this diagnosis is not considered. Transmission of rinderpest and other viruses, leptospirosis, and *Trypanosoma cruzi* has been suggested but not proved. Secondary infection of medicinal leech bites by *Aeromonas hydrophila* has been described.

Treatment

Leeches will detach if a grain of salt, a lighted match or a cigarette, alcohol, turpentine, or vinegar are applied. Local bleeding can be stopped by applying a styptic, such as silver nitrate or a firm dressing. Aquatic leeches that have penetrated the respiratory, upper gastrointestinal, genitourinary tracts, or rectum must be removed by endoscope. Spraying with 30 per cent cocaine, 10 per cent tartaric acid, or dilute (1:10 000) adrenaline (epinephrine) makes the leech detach from the nasopharynx, larynx, trachea, or oesophagus, while irrigation with a concentrated salt solution may be effective in the genitourinary tract and rectum. Leeches should not be pulled off so roughly that the mouth parts are left in the wound as this will lead to a chronic infection. Antimicrobial treatment of secondary bacterial infections (e.g. of *Aeromonas hydrophila* with cefuroxime or a quinolone) may be required.

Prevention

This can be achieved by impregnating clothing, especially the bottoms of trousers and socks, with repellents such as dibutyl phthalate and diethyl toluamide. They may also be applied to the skin and the inside and outside of footwear. If these compounds are not available, invasion of footwear during jungle walks can be prevented, rather messily, by rolling a rope of tobacco in the tops of the socks and keeping the feet well soaked with water. Children should be discouraged from bathing in leech-infested waters and all drinking water should be boiled or filtered.

8.3Poisonous plants and fungi

M. R. Cooper, A. W. Johnson, and H. Persson

There are relatively few plants and fungi that cause serious poisoning, but some have a very wide geographical distribution: in this group are oleanders (*Nerium* and *Thevetia* spp.), monkshood (*Aconitum napellus*), thorn apple (*Datura* spp.), angels' trumpets (*Brugmansia* spp.), *Euphorbia* spp. and the death cap fungus (*Amanita phalloides*).

Most incidents with plants occur in small children and are entirely accidental. Adults may sometimes confuse edible and toxic plants, but are more often poisoned by deliberate ingestion of those with psychoactive properties; ingestion of toxic plants as a means of suicide occurs sporadically in most parts of the world but in Sri Lanka and South India yellow oleander (*Thevetia peruviana*) is a common agent of suicide. In many countries poisoning by fungi is a more prominent medical problem than poisoning by plants, and is mostly the result of misidentification.

The general principles for treatment of poisoning outlined elsewhere (see Chapter 8.1) also apply to plant and fungal poisoning. In most cases only simple measures (applied at home) are necessary, such as rinsing of the mouth and giving peroral fluids for dilution. However, if a highly toxic plant or fungus has been ingested in significant amounts, energetic gut decontamination is required, including gastric emptying and administration of activated charcoal, to which most of the toxins bind well. Symptomatic and supportive care should be given as necessary, and specific antidotes are available for a few types of poisoning.

Plant poisoning

Clinical effects can be used to classify plant poisoning. However, poisoning by some plants causes symptoms of more than one type, and the severity may vary according to the sensitivity of the individual.

Digestive tract irritation

Some plants have very irritant sap: that of cuckoo pint (*Arum maculatum*), dumb cane (*Dieffenbachia* spp.) (Plate 1), elephant's ear (*Philodendron* spp.), and black bryony (*Tamus communis*) contains calcium oxalate, and that of *Euphorbia* spp., mezereon, and spurge laurel (*Daphne* spp.) diterpene esters. These cause immediate soreness, reddening, and even blistering of the lips and mouth, salivation, and dysphagia.

With most plants, however, the first signs of poisoning are nausea, abdominal cramps, and vomiting. In many cases the vomiting may eliminate the poisonous substances and partly prevent the development of further toxic effects; elimination is also promoted by the associated diarrhoea. Toxic agents causing irritation of the stomach and intestines include anthraquinones found in *Aloe* spp. and purging buckthorn (*Rhamnus cathartica*), cytisine in *Laburnum* spp. (Plate 2), lectins in *Jatropha*, protoanemonin in *Anemone* spp. and *Helleborus* spp., saponins in horse chestnut (*Aesculus hippocastanum*) and ivy (*Hedera* spp.), and viscotoxins in mistletoe (*Viscum album*). Unidentified irritants are present in white bryony (*Bryonia dioica*), holly (*Ilex* spp.), *Lantana camara*, privet (*Ligustrum vulgare*), pokeweed (*Phytolacca americana*), and snowberry (*Symphoricarpos alba*). With other plants, some of which are much more toxic than those mentioned so far, the start of gastrointestinal symptoms is delayed for several hours (up to 2 days). The toxins responsible include colchicine in autumn crocus (*Colchicum autumnale*) and glory lily (*Gloriosa superba*), the very highly toxic lectins in jequirity beans (*Abrus precatorius*) (Plate 3), castor beans (*Ricinus communis*) (Plate 4), and false acacia (*Robinia pseudoacacia*), oxalic acid in some members of the Polygonaceae family, solanine in *Solanum* spp. (Plate 5), and unidentified agents, such as that in spindle (*Euonymus europaeus*).

After ingestion of plants containing irritant sap, rational procedures to follow are rinsing of the mouth and dilution by drinking fluids; the addition of activated charcoal may be beneficial. Gastric emptying is rarely indicated, unless large amounts or highly toxic plants have been ingested. Symptomatic care is given as required.

Cardiovascular disturbances

In addition to the well-known effects of the cardiac glycosides of foxglove (*Digitalis purpurea*) (Plate 6), there are various other plants that produce the digitalis-like effects seen in digoxin overdosage (see Chapter 15.5.1): lily of the valley (*Convallaria majalis*), bluebell (*Hyacinthoides non-scripta*), oleander (*Nerium oleander*) (Plate 7), and yellow oleander (*Thevetia peruviana*). Cardiovascular effects are also induced by aconitine in *Aconitum* spp. (Plate 8) and larkspurs (*Delphinium* spp.). Aconitine causes a burning sensation in the mouth and pharynx, gastrointestinal symptoms, paraesthesia, and, in particular, cardiac arrhythmias (mainly ventricular) that may prove fatal. Other examples of cardiovascular toxins are: andromedotoxins (grayanotoxins) in mountain laurel (*Kalmia latifolia*), *Menziesia* spp., *Pieris* spp., and *Rhododendron* spp., phoratoxin in American mistletoes (*Phoradendron* spp.), proveratrines in *Veratrum* spp., taxines in yews (*Taxus* spp.) (Plate 9), and veratrine in death camas (*Zigadenus* spp.). These cardiac glycosides also irritate the digestive tract.

Gastric emptying (avoid ipecacuanha) is performed and activated charcoal administered if the ingested dose and time since ingestion indicate its usefulness. In addition to symptomatic and supportive care, digoxin-specific antibodies (ovine Fab fragments such as 'Digibind' and 'DigiTab') have been used successfully in reversing life-threatening digitalis effects in plant poisoning, notably poisoning by *Thevetia peruviana* (Apocynaceae), a common agent of suicide in South Asia, and anecdotally in poisoning by other Apocynaceae and even toad skin toxins. In experimental animals, fructose-1,6-diphosphate has also proved effective. Ingestion of aconitine alkaloids also requires vigorous gastrointestinal decontamination, careful cardiac monitoring, and treatment of arrhythmias.

Central nervous effects

Some plants contain hallucinogenic compounds, for which they are smoked, chewed, eaten, or infused in water to make teas. Among the plant hallucinogens are tetrahydrocannabinols in cannabis (*Cannabis sativa*), alkaloids in khat (*Catha edulis*) (Plate 10), D-lysergic acid amide in morning glory (*Ipomoea* spp.), mescaline in peyote (*Lophophora williamsii*), myristicin in nutmeg (*Myristica fragrans*), and vincristine and vinblastine in periwinkle (*Vinca* spp.); others contain hyoscine (see atropine-like effects below).

Patients who have taken hallucinogens require reassurance and supportive treatment.

A number of plants contain convulsants, although actual clinical cases mainly involve Umbelliferae, such as cowbane (*Cicuta virosa*) and hemlock water dropwort (*Oenanthe crocata*) that contain cicutoxin and oenanthotoxin respectively. Other convulsants include hypoglycin A in ackee (*Blighia sapida*), coriamyrtin in *Coriaria*

myrtifolia, anthracenones in *Karwinskia humboldtiana*, tetranortriterpenes in chinaberry (*Melia azedarach*), alkaloids in moonseed (*Menispermum canadense*), podophylloresin in May apple (*Podophyllum peltatum*), and strychnine and brucine in nux vomica (*Strychnos nux-vomica*). Cicutoxin, one of the most potent convulsants known, may cause an extremely dramatic syndrome with gastroenteritis, increased secretions, and long-lasting intense episodes of generalized tonic-clonic convulsions, resulting in severe metabolic acidosis and multiple organ failure. Consumption of unripe ackee fruit (*Blighia sapida*) causes epidemic vomiting (Jamaican vomiting sickness) and a toxic hypoglycaemic syndrome which can result in fatal encephalopathy.

Treatment is symptomatic and supportive, aiming at control of convulsions and secondary effects.

Atropine-like effects

The tropane alkaloids atropine, hyoscine (scopolamine), and hyoscyamine present in some plants of the Solanaceae competitively inhibit the muscarinic effects of acetylcholine and block the parasympathetic nervous system. This will cause a classic anticholinergic syndrome. *Datura stramonium* is used as a hallucinogen in parts of Africa (for example in Niger where it is known as 'sobi-lobi') (Plate 18). The symptoms may vary depending on the proportion of the alkaloids in the different plants. Typical is a warm, dry-skinned and dry-mouthed, thirsty, anxious, excited, and hallucinating patient. Facial flushing, tachycardia, and mydriasis are also common. In serious cases, arrhythmias, urinary retention, psychosis, convulsions, coma, and respiratory failure may ensue; fatal outcome has been reported. The plants in this group include angels' trumpets (*Brugmansia* spp.) (Plate 17) and thorn apple (*Datura stramonium*), which are among the most common plants involved in poisoning cases worldwide, deadly nightshade (*Atropa belladonna*) (Plate 16) and henbane (*Hyoscyamus niger*). Unilateral dilatation of the pupil (gardener's mydriasis), usually without systemic effects, may be seen in gardeners who rub their eyes after handling members of the Solanaceae such as angels' trumpets (*Brugmansia* spp.).

Gastrointestinal decontamination is performed, if appropriate, considering ingested dose and time since ingestion. A quiet environment, with reassurance and good symptomatic and supportive care, is basic. In cases where typical central and peripheral anticholinergic effects are present, specific treatment with physostigmine, 1 to 2 mg intravenously in adults (children 0.02 to 0.04 mg/kg), may be useful in reversing hallucinations, delirium, and psychotic behaviour. Physostigmine should be withheld if cardiotoxic agents have been ingested or there is widening of the QRS complexes.

Nicotine-like effects

Nicotine in tobacco plants (*Nicotiana tabacum*) and other alkaloids with similar actions, such as coniine from hemlock (*Conium maculatum*) (Plate 15), used for judicial executions in ancient Athens, first stimulate and then paralyse all autonomic ganglia. Centrally, small doses cause respiratory stimulation, while large doses can lead to convulsions and arrest of respiration. Many other symptoms may occur but they are complex and unpredictable. Nicotine-like effects occur with gelsemine and related alkaloids in yellow jessamine (*Gelsemium sempervirens*), cytisine in *Laburnum* spp., and lobeline in *Lobelia* spp.

Gastrointestinal decontamination by gastric lavage (not ipecacuanha-induced emesis because of rapid onset of symptoms) and administration of activated charcoal are indicated at an early stage. In severe cases, extensive symptomatic and supportive care may be necessary.

Liver damage

Various plants in the Compositae (*Senecio* spp.), Leguminosae (*Crotalaria* spp.), and Boraginaceae (*Heliotropium* and *Symphytum* spp.) (Plate 11) as well as some in other families contain pyrrolizidine alkaloids, which principally affect the liver. Poisoning has occurred from contamination of cereal crops by these plants and their subsequent incorporation into bread, and from their use in herbal medicines and bush teas. These alkaloids can cause acute damage to the liver (veno-occlusive disease), which has occurred mainly in Jamaica, India, and Afghanistan. Symptoms, including nausea, abdominal pain and distension, hepatomegaly, and sometimes fever and vomiting, first appear a few days after ingestion. A chronic cirrhosis of the liver can occur in people ingesting small quantities of pyrrolizidine alkaloids over a long period.

Treatment can only be supportive as, once absorbed, there is no specific method of preventing the toxic effects of these alkaloids.

Kidney damage

This can occur after ingestion of plants rich in oxalates, for example the leaves of rhubarb (*Rheum rhabarbarum*) and docks and sorrels (*Rumex* spp.). Nephrotoxicity may also occur after ingestion of terpene-containing plants, such as *Daphne mezereum* and *Juniperus sabina*.

Fluid replacement is essential and generous hydration advisable to promote renal excretion of oxalates.

Hydrocyanic acid toxicity

Parts of some plants contain relatively high concentrations of cyanogenic glycosides. The most likely sources are the kernels of fruits of *Prunus* species (almonds, apricots, cherries, peaches, etc.) or of loquat (*Eriobotrya japonica*), a large number of apple pips (*Malus* spp.), the berries or leaves of the cherry laurel (*Prunus laurocerasus*), or inadequately prepared cassava (*Manihot esculenta*) (see below). The glycosides will release cyanide only when the kernels or other plant material are being chewed. This takes some time, so the onset of symptoms is not so rapid as after ingestion of inorganic cynanide compounds. In practice, cyanide poisoning from plants (with the exception of cassava) is a rare phenomenon.

When it is suspected that large amounts of cyanogenic glycosides have been ingested, gastrointestinal decontamination is indicated. If typical symptoms ensue, treatment is the same as for hydrocyanic acid poisoning from any other source (see Chapter 8.1).

Skin damage

The most common form of skin damage by plants is a non-allergic dermatitis that results from direct contact with various plants that contain irritants, for example the stinging hairs of the stinging nettle (*Urtica dioica*), the diterpene-containing latex of *Euphorbia* spp., or the calcium oxalate crystals of *Dieffenbachia* spp. and other members of the Araceae family. There are also allergic forms of dermatitis that result from hypersensitivity to plant allergens. The most common and severe forms of allergic contact dermatitis in the United States are caused by poison ivy (*Rhus radicans*) (Plate 12) and western poison oak (*Toxicodendron diversilobum*), and in the United Kingdom by a primula (*Primula obconica*), but such cutaneous hypersensitivity can occur to a very large number of vascular plants.

Contact with the sap of some plants followed by exposure to sunlight (ultraviolet radiation) can give rise to a characteristic skin reaction. Phototoxic psoralens (furanocoumarins) are present in various members of the Umbelliferae, including giant hogweed (*Heracleum mantegazzianum*) (Plate 13), other *Heracleum* spp., and parsnips (*Pastinaca sativa*), and also celery (*Apium graveolens*), especially when infected with the pink rot fungus (*Sclerotinia sclerotiorum*). Other psoralen-containing plants are rue (*Ruta graveolens*) (Plate 14) and the gas plant (*Dictamnus albus*). Typical lesions in dermatitis caused by psoralens are erythema, papules, vesicles, and enormous bullae localized to exposed areas of skin.

Treatment is as for a chemical burn. Psoralens can also induce hyperpigmentation that can last for several months.

Food plant toxicity

The following toxins are present in plants used regularly for food:

1. Lectins. These phytohaemagglutinins are glycoproteins, and beans (Leguminosae) are the main food source. The lectins are not readily digested by pepsin and have a strong affinity for the intestinal mucosa, where they prevent absorption of carbohydrates. Adequate cooking destroys the lectins, but eating raw or incompletely cooked beans can cause diarrhoea, while long-term exposure can lead to retarded growth and may even be fatal.
2. Cyanogens. Cyanogenic glycosides are present in some staple foods, such as cassava, sweet potato, and yam, all of which can be made safe to eat by adequate soaking, drying, or fermentation. Chronic poisoning may cause tropical ataxic neuropathy and spastic paraparesis ('konzo').
3. Alkaloids. Dangerously high quantities of these may develop in some plant foods, for example potato tubers that have sprouted or been stored in the light and

become green. The green colour is chlorophyll and is harmless, but under conditions where greening occurs the glycoalkaloid solanine and its derivatives will also have been produced; these exhibit anticholinesterase activity.

4. Oxalates. These accumulate in some members of the Polygonaceae, notably rhubarb, of which only the red leaf stalks should be eaten, and then only after cooking.
5. Polyphenols. These are a possible cause of upper digestive tract cancers that may develop after eating sorghum, or taking teas or alcoholic drinks containing high concentrations of tannins.

Some specific diseases attributable to plants are: lathyrism, a paralytic disease caused by a neurotoxic amino acid in chick peas (*Lathyrus sativus*); favism that occurs among natives of some Mediterranean and Middle Eastern countries who have a genetic deficiency of glucose-6-phosphate dehydrogenase and cannot digest broad (fava) beans (*Vicia faba*); and Jamaican vomiting sickness that results from eating the unripe fruits of the ackee (*Blighia sapida*). Other foods that cause poisoning are the seeds of *Mucuna pruriens*, flour ground from the cones of cycads (for example *Zamia* spp.) (Plate 19), and young fronds of bracken fern (*Pteridium aquilinum*).

Herbal medicines

It should not be assumed that herbal preparations are safe because they are 'natural', and some may have harmful effects that are not immediately obvious, for example carcinogenicity, hepatotoxicity, or teratogenicity. For example, plants of the genus *Aristolochia* are constituents or contaminants of some Chinese herbal medicines (such as 'Mu Tong' and 'Fang Ji') and can cause genotoxic carcinogenesis and interstitial nephritis. Adulteration of herbal medicines with cheaper ingredients, heavy metals, and orthodox drugs is not uncommon.

Fungal poisoning

Fungal poisoning (mycetismus) is a sporadic problem in many parts of the world. It is usually accidental, occasionally homicidal or suicidal, and may become epidemic when conventional food is scarce in times of war or famine. In 2000, outbreaks of mushroom poisoning involving 212 people with 17 deaths were reported from Voronezh and Volgograd in Russia.

The toxicity of fungi may vary with location, season, and in different years; for some mushroom toxins there may also be a variation in the susceptibility of individuals. Cases of fungal poisoning can be classified into those that develop signs of toxicity within a few hours of ingestion, or after a delay of 10 (occasionally 6) to 24 h or several days.

Symptoms that develop within a few hours

Gastroenteritis

Few of the chemical agents responsible for this type of poisoning have been identified. The fungi in this group include flat-capped psalliota (*Agaricus placomyces* or *A. praeclavesquamosus*), yellow-staining mushroom (*Agaricus xanthodermus*), honey fungus (*Armillaria mellea*), the devil's mushroom (*Boletus satanas*), *Chlorophyllum molybdites* (*Lepiota morgani*), *Entoloma* spp., *Hebeloma* spp., wax caps (*Hygrocybe* spp.), sulphur tuft (*Hypholoma fasciculare*), milk caps (*Lactarius* spp.), shaggy parasol (*Macrolepiota rhacodes*), broad-gilled agaric (*Megacollybia platyphylla*), Jack-o'lantern or copper trumpet (*Omphalotus olearius*), pink coral fungus (*Ramaria formosa*), brittle gills (*Russula* spp.), earthballs (*Scleroderma* spp.), and spotted tricholoma (*Tricholoma pardinum*).

Gastrointestinal symptoms usually start within a few hours and resolve fairly quickly, but are sometimes more intense and result in fluid and electrolyte imbalance.

Treatment is symptomatic and admission to hospital is seldom necessary, but may occasionally be required, especially in children and the elderly.

Cholinergic symptoms

The parasympathomimetic effects of muscarine, which is the toxic ingredient of certain *Inocybe* and *Clitocybe* species, include abdominal pain and diarrhoea, sweating, lacrimation, salivation, myosis, bronchorrhoea, and sometimes bronchospasm, bradycardia, and hypotension. Only trace amounts of muscarine occur in fly agaric (*Amanita muscaria*) (Plate 20) after which the toxin was named.

Treatment is specific and includes 1 to 2 mg of atropine in adults (children 0.02 mg/kg) that effectively antagonizes muscarinic overstimulation. The dose is repeated as required.

Mental confusion

This may result from poisoning by panther cap (*Amanita pantherina*), fly agaric (*Amanita muscaria*), and *Amanita strobiliformis*, whose active ingredients are isoxazoles (ibotenic acid and muscimol) that act as g-amino-butyric acid agonists. Anxiety, euphoria, visual disturbances, erratic behaviour, hallucinations, and gastrointestinal symptoms may occur, and peripheral anticholinergic symptoms are also frequently observed; the occasional appearance of muscarine symptoms in *Amanita muscaria* poisoning is a rare phenomenon.

Treatment is symptomatic and supportive. Diazepam, 5 to 10 mg in adults (children 0.1 to 0.2 mg/kg), repeated as required, can be given for sedation. In severe cases with evident psychotic behaviour, chlorpromazine or haloperidol may be useful.

Hallucinations

These are mainly visual and are the predominant feature in poisoning by psilocybin, a tryptamine derivative. Psilocybin and related substances are found in *Psilocybe* species and several other genera of (usually small) fungi, often collectively called 'magic mushrooms'; among these are some *Conocybe* spp., *Gymnopilus* spp., *Panaeolina foenisecii*, *Panaeolus* spp., *Pluteus* spp., and *Stropharia* spp. These fungi are eaten because of their psychoactive properties. The effects of the toxin are similar to those of LSD (stimulation of central and blockade of peripheral serotonin receptors). Other early symptoms are relaxation, euphoria, depersonalization, and altered sense of time and space. Less pleasurable, but equally typical symptoms, are vertigo, bizarre and terrifying hallucinations, anxiety, agitation, tachycardia, mydriasis, and flushing. Gastrointestinal symptoms, apart from nausea, are uncommon. Occasionally fever and seizures are observed in children. Sometimes frightening flashbacks occur after days or weeks.

Treatment is symptomatic, with reassurance and rest in a quiet environment. In cases of severe anxiety and agitation, diazepam may be given; in addition haloperidol or chlorpromazine is often necessary.

Alcohol-associated effects

When alcohol is taken at the same time as some fungi, notably an ink cap (*Coprinus atramentarius*) but also club foot (*Clitocybe clavipes*), or up to 5 days after they are eaten, a reaction similar to that induced by disulfiram (Antabuse) used for treating alcoholics (see Chapter 26.7.1) is produced. The skin becomes flushed, and sweating, mydriasis, nausea, anxiety, dyspnoea, and hypotension can occur as a result of the accumulation of acetaldehyde, because the toxin (named coprine in *C. atramentarius*) blocks the liver enzyme aldehyde dehydrogenase.

Treatment is symptomatic and supportive.

Symptoms with delayed onset

Severe gastroenteritis

Gastrointestinal symptoms that appear after a long latent period followed by liver damage, and sometimes also by kidney damage, are typical of poisoning by amatoxins, a group of cyclic octapeptides occurring in the death cap (*Amanita phalloides*) (Plate 21), which is by far the most common cause of death from the

ingestion of fungi. Amatoxins also occur in the destroying angel (*Amanita virosa*), the fool's mushroom (*Amanita verna*) and some *Galerina* and *Lepiota* spp. (in particular *Galerina marginata* and *Lepiota cristata*). These toxins inhibit transcription from DNA to mRNA by blocking RNA polymerase II (B). This results in deficient protein synthesis and subsequent cell death. The main target organs are the intestinal mucosa, liver, and kidneys.

Abdominal pain and vomiting, but in particular a severe, watery diarrhoea, start 10 to 24 h (more rarely at 6 h but normally around 12 h) after ingestion. Dehydration and exhaustion will ensue. Sometimes there is a transient recovery, after which the signs and symptoms of liver damage gradually appear from the second day. Hepatic failure may ensue, and this is the cause of death in fatal cases. Impaired kidney function is common initially because of dehydration; kidney dysfunction at a later stage is normally an indication of toxic renal damage and is a poor prognostic sign.

The mainstay of treatment is early admission to hospital, with rapid correction of fluid, electrolyte, and metabolic disturbances, adequate and preferably slightly increased diuresis for the first few days, and multiple oral doses of activated charcoal until 3 days after ingestion. Silibinin (also called silybin or silymarin), the main active constituent of milk thistle (*Silybum marianum*), reduces hepatic amatoxin uptake and, although its value in the clinical setting is controversial, it should be considered in patients who present after significant ingestion, as judged from their history and clinical findings. The dose of silibinin is 5 mg/kg intravenously over 1 h, followed by 20 mg/kg/24 h as a continuous infusion for 3 days after ingestion. Benzylpenicillin in large doses may be an alternative, if silibinin is not available. Haemodialysis or haemoperfusion is not indicated, unless the patient is admitted very early and before the onset of symptoms (very unusual) or in cases where there is pre-existing renal dysfunction. Liver transplantation may be the only therapeutic option.

Gastrointestinal and central nervous effects

The toxin gyromitrin, found in the false morel (*Gyromitra esculenta*), decomposes in the stomach to form hydrazines (in particular monomethylhydrazine). Hydrazines block pyridoxine synthesis, cause glutathione depletion in erythrocytes, and form free oxygen radicals that may bind to macromolecules in the liver. Gastrointestinal symptoms, associated with headache, vertigo, sweating, diplopia, nystagmus, ataxia, cramps, delirium, and sometimes coma, appear 6 to 24 h after ingestion or inhalation of cooking vapour. Severe poisoning may also cause hypoglycaemia, hepatic damage, and haemolysis; renal damage has also been reported.

Apart from symptomatic and supportive care, treatment includes administration of pyridoxine at 25 mg/kg over 30 min to prevent and control neurological symptoms; repeat doses may be required. It is advisable to administer a glucose infusion and to maintain adequate diuresis.

Kidney failure

Poisoning characterized by kidney dysfunction after a latent period of 2 to 4 days, in milder cases even up to 2 weeks, is typical of the group of brownish-orange *Cortinarius* spp. (*C. orellanus*, *C. speciosissimus*, and *C. splendens*) that contain orellanine, a highly nephrotoxic tetrahydroxylated di- *N*-oxidized bipyridine, and some less toxic derivatives such as orelline. During the latent period some patients may have diffuse gastrointestinal symptoms (often a day or more after the mushroom meal), but this is not the rule. This lack of early warning signs makes *Cortinarius* poisoning especially insidious, and patients are almost invariably admitted to hospital when the renal damage is already established and treatment procedures to prevent the toxic effects are no longer relevant. Typically, symptoms appear days after the meal, with fatigue, intense thirst, headache, chills, and abdominal, lumbar, and flank pain. After a transient polyuric phase, oliguria and anuria may follow. Renal function will recover in some cases, whereas in others kidney failure is permanent.

As these patients are normally admitted very late, management possibilities are restricted to monitoring of renal function and symptomatic care, including haemodialysis. In cases of persistent renal failure, kidney transplantation may be an alternative to chronic dialysis. If admitted during the first day, vigorous gut decontamination and haemoperfusion for poison elimination may be considered on theoretical grounds.

Allergic reactions

The roll-rim cap (*Paxillus involutus*) (Plate 22), previously eaten with impunity, may suddenly give rise to an immunohaemolytic anaemia in which decreased haemoglobin levels result in shock and even renal insufficiency. A respiratory allergy, called farmer's lung, results from inhaling spores of the mould *Faenia rectivergula* that is sometimes present on grain or hay. Spores of oyster mushrooms (*Pleurotus ostreatus*) or puffballs (*Lycoperdon* spp.) can also cause respiratory allergies. Skin allergies have been reported with the shiitake mushroom (*Lentinus elodes*).

Ergotism and mycotoxicoses

The ascomycete fungus *Claviceps purpurea* infects (Plate 23) cereal crops, in which its hard, purplish-black fruiting bodies or sclerotia (ergots) develop in the seed heads. Ergots contain several alkaloids that can cause disease when flour made from contaminated grain is eaten. There are two forms of ergotism ('St Anthony's fire'): vasoconstriction, sometimes leading to loss of extremities through gangrene (occurring after small quantities of contaminated food have been eaten over a long period) and a less common, acute form characterized by muscular tremors, convulsions, and hallucinations.

Other potent toxins (mycotoxins) are produced by some moulds (*Acremonium*, *Alternaria*, *Aspergillus*, *Fusarium*, *Penicillium*) that develop on growing crops, particularly if wet and harvested late, but occur mainly in cereal grains, rice, or nuts stored under damp, inadequately ventilated conditions. Intoxication may result from ingestion or inhalation. Aflatoxins (from *Aspergillus* spp.), ochratoxins (from *Aspergillus ochraceus* and *Penicillium verrucosum*), and trichothecenes and zearalenone (from *Fusarium* spp.) have been detected in foods and are suspected of causing immunosuppression, myelosuppression, hepatotoxicity, nephrotoxicity, neurotoxicity, dermatotoxicity, oestrogenicity, mutagenicity, teratogenicity, and carcinogenicity (liver, colon, alveolar cells). Ochratoxin A, which inhibits mitochondrial oxidative phosphorylation in the proximal tubule of the nephron, has been implicated as a possible cofactor in Balkan nephropathy. Specific mycotoxins can be detected at 0.1 ng/ml by radioimmunoassay and enzyme immunoassay.

Sources of information

A directory of poison information centres worldwide is kept by the International Programme on Chemical Safety (IPCS), WHO, Geneva. A computerized, image-based, identification system for poisonous plants and fungi has been developed by the Royal Botanic Gardens, Kew, in collaboration with the Medical Toxicology Unit of Guy's and St Thomas' Hospital Trust, London. The system, called *Poisonous Plants and Fungi in Britain and Ireland* is available on CD-ROM from the Royal Botanic Gardens, Kew. Similar systems are being developed for other countries.

8.4.1 Occupational and environmental health and safety

J. M. Harrington with contributions from K. Gardiner, I. S. Foulds, T. C. Aw, E. L. Baker, and A. Spurgeon

General introduction

J. M. Harrington

Definition and scope

Occupational health is that area of public health concerned with managing the health of working people. Occupational health professionals include physicians, nurses, hygienists (scientists with experience in monitoring and more importantly controlling the exposure of working people to chemical, physical, and biological agents in their place of work), toxicologists, and—increasingly these days—psychologists to the assess the psychosocial aspects of work. Safety engineers are responsible for prevention and investigation of accidents at work (see under Occupational safety).

Occupational health issues can be promoted by these professionals, but for long-term success it is crucial that both managers and the workforce consider it an integral part of their working practices and philosophy. It is in everyone's interest that the workforce is 'happy, healthy, and here'!

History of occupational disease

Stone Age flint knappers were probably exposed to airborne silica dust during their work. However, life expectancy then was probably shorter than the pathogenesis of silicosis. Some industries like mining have always been hazardous. The ancient Egyptians recognized this by restricting such work to slaves and criminals. By the Middle Ages, the plight of the free miner had been recognized by Georgius Agricola (1494–1555) and Paracelsus (1493–1541). Agricola not only described the 'galloping consumption' of Carpathian silver miners but also proposed ways of reducing the dust in mines by improved ventilation.

The first authoritative treatise on occupational disease was written by Ramazzini (1633–1764). His book *De Morbis Artificium* is unsurpassed in its classic descriptions of many occupational diseases ranging from mercurialism in mirror workers to repetitive strain injury in clerical workers. The Industrial Revolution in Britain brought occupational diseases to the attention of Parliament, largely through the work of philanthropists like Robert Owen, Robert Peel, and Lord Shaftesbury. Early legislation to control the worst vicissitudes of factory labour was emasculated by Parliament but the process had begun. The First Act of 1802 (which, interestingly, introduced the concept of limiting the hours of work) was followed by others leading to the 1833 Act which saw the start of His/Her Majesty's Factory Inspectorate (HMFI)—an enforcing authority.

By the early twentieth century the toxic effects of arsenic, mercury, phosphorus, and lead were so common that notification of these diseases became required by law and compensation for ill health was granted. Clearly, working conditions in the Western world have improved greatly since then but the recent revelations about factory life in Eastern Europe as well as the working conditions for many in Third World countries demonstrate an important tenet of occupational health practice: that is, while occupational disease may be preventable, the continued—often necessary—use of hazardous materials and processes ensures that many such diseases cannot be eliminated, only controlled.

Occupational health services

The notion that employers should provide health care for workers is hardly new. During the fourteenth century, the Pope — not an employer in this connection! — decreed that prostitutes should be examined regularly for evidence of sexually transmitted disease. Whether the results were significant epidemiologically is not recorded. The first recognizable occupational health service in England began in the mid eighteenth century when the London (Quaker) Lead Company recognized the adverse effect of mining on workers and provided health and welfare services in northwest England. Since then, occupational health provision has expanded along different lines in different countries.

The International Labour Organization (Convention 161, 1985) urged members 'to develop progressively occupational health services for all workers.... The provision made should be adequate and appropriate to the specific needs of the undertaking.' Services are not universally available and interpretation of the requirements varies greatly between countries and employment sectors. Initially, most services arose from a mixture of philanthropy and self-interest; the theory being that the healthy worker was likely to be more productive. Present-day services range from total health care including primary care and hospital medicine (as in the states of Eastern Europe), to industry-specific systems concerned almost solely with the adverse health effects of a single industrial environment (as with the extractive, offshore, and chemical industries). Services in the United States and much of Europe may include general health promotion and education, but much inequity in health care exists between enterprises within the same country.

Recent increase in the provision of occupational health services has followed the enactment of effective health and safety legislation. The Health and Safety at Work etc. Act (1974) in the United Kingdom is an example. Some countries such as the Nordic countries, The Netherlands, and Australia, require the provision of occupational health services by law. Statutory provision of such services in the United Kingdom and the United States is limited to particular industrial sectors and specific occupational exposures such as ionizing radiation, heavy metals, fibrogenic materials, and carcinogens. In general, major Health and Safety Acts will 'enable' a variety of government departments to create legislation in the form of 'regulations' requiring action from employers in particular occupational and environmental circumstances. The increasing attention paid in the United Kingdom to public health issues has enhanced the chances of improving occupational health services, although, counterintuitively, many of the larger industrial enterprises are divesting themselves of an 'in-house' service.

The European Community, through 'directives', increasingly drives the occupational health and safety agenda in member states requiring them to modify or create

legislation in response.

The latest moves from Brussels have been to encourage the delivery of occupational health to all by 'competent' persons, although the mode of delivery—even the definition of competent—has been left to member states for interpretation.

An ideal 'menu' of such services depends on many variables including the industrial sector, existing legislation, management/employee collaboration, the availability of employment, and compensation for damage. Most importantly, the level of service provided should be based on a thorough risk assessment of the work processes in that organization and a clear and logical procedure of risk management.

To deliver even such a basic service will require multidisciplinary teams including trained physicians, hygienists, and nurses. Few companies have such services and many are too small even to contemplate such provision.

Developments will be tempered primarily by the economic climate, perceptions of what constitutes occupationally mediated disease, and political will. However, an exponential rise in legal action, insurance costs, and compensation will play a significant part in persuading management that competent occupational health services are an absolute requirement of profitable organizations. If this is to encompass the small and medium-sized enterprises then provision must come either from larger employers (such as the National Health Service) or from private providers. It is important to remember that in the United Kingdom, for example, companies employing fewer than 250 people account for 99 per cent of all businesses and 40 per cent of the working population.

Prevention

The prevention of occupational disease depends upon recognition of the condition as occupational, assessment of the level and duration of exposure and hence its possible effects, control of the problem at source, audit of the risk management procedures, and perhaps health surveillance of those exposed using suitable techniques. These procedures are dealt with later in the chapter.

Recognition of diseases as occupational may vary from country to country. The EC has proposed a harmonization of national lists of occupational disease for the purpose of compensation of workers.

Compensation for occupational diseases

In the early years of Western industrialized society, the chances of a worker winning compensation for an occupationally related disease or injury were slim, resting as they did on a successful common law suit against the employer for negligence. Such cases are still notoriously difficult to win. However, by the end of the nineteenth century, many countries in Europe as well as the United States had passed workman's compensation laws of one sort or another. Such schemes were usually restricted to specified diseases or occupations. For example, the 1897 Act in Britain was for accidents only, with six diseases added in the 1906 Act. Today the Industrial Injuries Scheme extends to 67 diseases.

The principles underlying such schemes are that they should be 'no fault', that the disease should be, with reasonable certainty, caused by work, and that the benefit claimed should offset job loss, wage earning deficit, disability, or provide death benefit to the next of kin. While the scheme in Britain has suffered considerable erosion over the last 10 years, similar schemes exist in one form or another in all EC member states with the exception of The Netherlands where compensation for ill health is of a more general nature. Advice on proposed additions to the list of compensatable diseases is made in the member states by government appointed advisory groups. In Britain, this group is the Industrial Injuries Advisory Council which reports to the Secretary of State for Work and Pensions.

New EC recommendations propose that national schemes be made uniform. In addition, the EC wishes to see the introduction of a concept to aid those who can prove they have an occupationally related disease which is not on the standard list—the so-called 'individual proof' system. In Britain such a dual system of specified agents and individual claim opportunities exists only for asthma. No specific agents are listed for dermatitis.

It is important that the clinician is aware of such schemes. If the disease and work exposure seem related, and are listed, the patient should be advised to claim for compensation.

Assessment of the workforce and their environment

K. Gardiner and J. M. Harrington

Introduction

Occupational health comprises recognition, evaluation, and control. Control (including prevention) is the paramount element; there is no point in knowing what may happen or diagnosing what has happened if no remedial action is taken. For too long, society/industry has relied on occupational physicians to identify the failures in control by means of diagnosing occupationally related disease without giving sufficient weight to the need for control and therefore prevention.

As a result of this realization, current health and safety legislation is driven by risk assessment, i.e. those who generate the risk(s) are responsible for undertaking an assessment, the detail of which must be commensurate with the complexity of the situation and the ultimate risk. It follows from this that the quantified risk must be managed, and hence employers must now add risk management to their portfolio of activities.

Before embarking on any evaluation, especially where there is suspicion of occupational aetiology, great care needs to be exercised beforehand to determine what the legislation requires, what the known toxicological/health effects are, previous evidence from similar circumstances/environments, etc. This is the 'recognition' aspect, and highlights the necessity not only to be well informed but also competent (i.e. to be able to interpret and act upon the information appropriately).

Evaluation

One aspect of occupational medicine, distinct from most others, is that commonly one is dealing with groups rather than individual patients. In the main, this acts to complicate the evaluation as interindividual variance is added to the intrinsic intraindividual variance (for example, two people exposed to exactly the same quantity of toluene over the same time period will not excrete the same amount of urinary hippuric acid or excrete it at the same rate). In order to minimize any erroneous decisions and to maximize the usefulness of any information, evaluation of the workforce (and workplace) must be conducted in a systematic manner. This is often achieved by posing a number of simple questions.

The most fundamental of these questions is why? It is essential that the rationale for evaluating an individual or group is clear and justifiable. However, as occupational health professionals exist to eliminate ill health at work their priority must always be to eliminate problems in the workplace immediately rather than to delay while quantifying them. The law is prescriptive for only for a limited number of hazards (ionizing radiation, lead, asbestos).

Where large groups are involved, it may be necessary to evaluate a subset—this is the 'who' question. When there is no other over-riding need for selection (such as those working for extended periods (more than 8 h per day), those working at an elevated metabolic/breathing rate, those already unwell, or those likely to undertake unusual or unscheduled tasks (maintenance)), individuals

should be chosen randomly.

The timing of measurements (i.e. 'when') is often critical. Should health outcome measures be taken before, during, or after the putative exposure or is there some legislative requirement that dictates the timing? For example, urinary mandelic acid (for styrene exposure) is best collected at the end of a working shift whereas urinary trichloroacetic acid (for trichloroethylene exposure) is best measured at the end of the working week, this being determined, in part, by the differing half-lives of the substances concerned.

Usually, the issue of what to assess is self-evident, but, as with all other aspects of this systematic approach, answers to the questions are interlinked, certainly with the 'why' question. For example, is biological monitoring or biological effect monitoring required? The former is the detection of a chemical or its metabolite in a biological sample as a measure of exposure. The latter is measurement of a change in some biochemical or physiological variable to indicate the effect of the contaminant on the body.

Choice of an appropriate technique for making these measurements should be based where possible on sensitivity and specificity.

The technique should be both suitable and sufficient for its purpose. For example, in the diagnosis of occupational asthma suitable techniques include peak flow meters, simple spirometry (time–volume curves), and whole-body plethysmography, but the simplest of these may be adequate.

Remedial action

The law is clear: the employer must adapt the workplace to be a safe environment for the employees. The employees should not have to adapt themselves to the stresses and strains of their work. Despite this philosophy, it is common for the chain of control to start with ineffective pre-employment medicals whose aim is only to avoid exposing people to contaminants likely to exacerbate allergies or other diseases.

Control is often viewed as a physical alteration of the workplace (engineering) or alteration of the behaviour of the workforce (administrative). It is preferable to have designed the workplace appropriately in the first place. Unfortunately, most control is required remedially, after an unacceptable level of risk has been identified as a result of a formal risk assessment. Remedial action may involve:

- elimination—removal of the process;
- contaminant substitution—replacemnt of the contaminant with one carrying a lower risk;
- process modification (temperature, agitation, enclosure, etc.);
- substance modification (wavelength, form, size, etc.);
- isolation/segregation (time, distance, shielding);
- local extract ventilation;
- minimization of the duration and frequency of exposure;
- education and training and the use of personal protective equipment.

Occupational dermatology

I. S. Foulds

An occupational dermatosis is a pathological condition of the skin for which occupational exposure can be shown to be a major contributory factor. Legal definitions vary between countries. In the United Kingdom the majority are defined by Prescribed Disease D5 of the Department of Health and Social Security as 'non-infective dermatitis of external origin (including chrome ulceration of the skin but excluding dermatitis due to ionizing particles or electromagnetic radiation other than radiant heat)'. However, this definition may exclude newly described dermatoses, and in the case of occupationally acquired hypomelanosis a new category (Prescribed Disease C25) was necessary.

Incidence

The true incidence of occupational dermatoses is difficult to obtain, as in some countries occupational accidents and illnesses are not differentiated, and others fail to separate dermatitis from other skin diseases. Few statistics are derived from short absences from work or disease without disability, and most information is based on compensation paid.

Dermatitis, mostly due to irritant contact factors, accounts for 95 per cent of all occupational dermatoses. In the United Kingdom a million working days a year may be lost from such conditions. The diagnosis and management is discussed elsewhere (see Chapter 23.1).

Some managers and even some doctors believe that people with dermatitis are out to obtain whatever they can in the way of compensation. However, in times of high unemployment, many people are reluctant to seek help in case they are labelled as suffering from industrial dermatitis and are then transferred to less skilled work with the loss of bonuses or even their jobs. Once labelled in this way, they are unlikely to find alternative employment.

Many employers believe that they do not have a problem with dermatitis, but careful inspection of employees' skin shows that the condition may be present in up to a third of the workforce. Considerable time is lost due to dermatitis and suffering due to discomfort, depression, and social ostracism is impossible to quantify.

Employees' and employers' attitudes to dermatitis

As with many skin diseases there are many myths attached to dermatitis. The 'leper approach' still exists. Many people believe that dermatitis is infectious and can be passed on by towels and touching; this results in the affected individual becoming socially isolated. Under no circumstances should dermatitis ever be regarded as infectious. It can only be acquired by wear and tear occurring to the skin or by the development of an allergy to a substance that has been in contact with the skin. Affected individuals therefore should not have unnecessary restrictions placed on them.

When someone develops severe occupational dermatitis this is often apparent to their colleagues who, after discussion, may think that their own skin problems are also occupationally related. However, since skin diseases are common, individual problems may be falsely attributed to a work-related cause. With outbreaks of apparent dermatitis, great care is needed in handling the situation to identify the causes and differentiate those with occupationally related problems from those with other skin diseases. It may be necessary to ask for the help of a dermatologist with specialist knowledge if the confidence of the workforce is to be maintained.

Barrier creams

No cream provides a barrier to penetration of substances into the skin. In fact, in some situations they may actually enhance penetration. Although there are numerous formulations available, they can be divided into those suitable for dry or for wet work.

The main benefit they offer is from their bases such as lanolin which may help to improve the hydration (suppleness) of the skin, with the result that, when cleansers are used, less degreasing of the skin occurs. In theory, this may help to reduce irritant contact dermatitis from repeated hand washing. There is no evidence that barrier creams protect against sensitizers, and occasionally sensitization may occur to some of the constituents of the cream. The use of a barrier cream may give an employee a false sense of security and lead to increased skin abuse.

Skin cleaning

When substances remain on the skin after the working day, the risk of irritation or sensitization is increased. The most efficient skin cleaners, however, are often the most irritant of substances due to their solvent or detergent content. If cleaners are too mild for the task, workers will often use degreasing agents in the manufacturing process, for example solvents or paraffins, to obtain adequate cleaning. Although these substances will 'clean' they are potentially very irritant with repeated use. It is often not appropriate to provide one type for different jobs. Agents should be chosen that clean adequately in a short period of time without having too strong a degreasing effect.

After-work creams

There are many such creams, essentially moisturizers, which have the benefit of increasing the hydration of the skin following cleaning at the end of the day. They are of particular benefit in occupations where excessive drying of the skin may occur. Their use should be encouraged where hot air driers are used as these tend to dry the skin unduly.

Skin protection

In industrial situations the hands and forearms are most at risk. The use of proper gloves (along with gauntlets or arm bands to prevent powders entering under the cuff) coupled with a high standard of hygiene, can minimize contact and provide adequate protection. Where moving machinery is present, wearing gloves may pose a potential danger. Even when gloves are used, they may be taken off to undertake tasks requiring manual dexterity, resulting in contaminated hands being placed back inside the gloves.

A wide range of materials have been used to manufacture gloves including cotton, leather, nylon, glass fibre, acrylonitrile, rubber, neoprene, butyl rubber, viton, polyurethane, PVC, PVA, and Teflon. These confer individual benefits in specific occupational applications.

Non-dermatitic occupational dermatoses

These form a minority of occupational dermatoses and awareness of their existence is important for those involved in managing skin patients. The more important are briefly mentioned below:

1. Psoriasis (see Chapter 23.1) may erupt at sites of injury or as a response to friction in manual workers. When this occurs on the hands, it may be confused with dermatitis although vesicles (blisters) are not found in psoriatic skin.
2. Infections include anthrax (albeit rare in the United Kingdom), human papilloma virus warts, orf (a poxvirus), and fungal infections such as tinea pedis and cattle ringworm (*Trichophyton mentagrophytes*).
3. Chronic paronychia due to candida occurs in those exposed to wet work.
4. Acne may be caused by a variety of chemicals including oils, coal tar chlorphenols, and petroleum products. Chloracne is a particularly refractory form of acne caused by halogenated aromatic chemicals, which may also cause systemic toxicity. Mild cases may be difficult to differentiate from conventional acne but multiple comedones (blackheads) are found over the malar regions. Industrial accidents can result in exposure and subsequent symptoms: for example in 1976 an explosion in a chemical plant near Seveso, Italy resulted in the exposure of the local population to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin which caused severe systemic and cutaneous symptoms.

5. Vitiligo may be occupationally acquired. Several substituted phenols including *p*-tertiary-butyl phenol and monobenzyl ether of hydroquinone may cause hypomelanosis indistinguishable from vitiligo.
6. Scleroderma may be caused by exposure to vinyl chloride, and has been reported with trichlorethylene and organic solvents. Scleroderma-like lesions have also been reported in people exposed to epoxy resin fumes, and silicosis associated with scleroderma has been reported in miners.
7. A variety of chemicals may cause alteration of skin pigment; for example mercury and silver, which causes argyria.
8. Occupationally induced itching may occur in atopic individuals who exhibit dermographism due to histamine release from mast cells caused by fibres typically around 3 µm in size which can penetrate the skin. This occurs with exposure to glass fibres, ceramic fibres, and fibreglass.

Occupational cancer (see also Chapter 6.1)

J. M. Harrington

Background

Georgius Agricola's account in 1555 of the illnesses of Carpathian silver miners includes evidence of a rapidly progressive and fatal lung disorder. The fact that these mines are now known to contain uranium ore suggests that exposure to radon gas may well have been high enough to cause lung cancer in the miners. Nevertheless, it is Percival Pott's description in 1775 of an excess risk of scrotal cancer in postpubertal chimney sweeps that first raised the possibility of chemicals—particularly polynuclear aromatic hydrocarbons (PAH)—causing cancer. Confirmatory evidence from animal experiments did not arrive until 1915 and the first carcinogenic hydrocarbon was identified by Kennaway in 1924 as 1,2,5,6-dibenzanthracene.

While the polynuclear aromatic hydrocarbons were generating interest as skin carcinogens, clinical observations of dyestuff workers were suggesting a link between bladder cancer and aromatic amines. In 1895, Rehn described three cases in a group of 45 workers in Germany involved in the preparation of fuchsin. Further reports followed from other countries and the classic studies of Case and his colleagues in the 1950s showed that 2-naphthylamine and benzidine were human carcinogens in manufacturing and user industries. 2-napthylamine was a contaminant of the antioxidant used in tyre manufacture. Rehn discovered that an organ distant from the point of first contact could bear the main force of the carcinogenic effect if its exposure was most prolonged and most intense.

In the same year that Rehn made his discovery, Röntgen discovered X-rays and 3 years later, the Curies isolated radium. Unfortunately, knowledge of the carcinogenic properties of ionizing radiation came from the skin and bone marrow cancers suffered by these early pioneers with confirmatory animal data following soon after. The bone sarcomas noted in laboratory animals were followed by human evidence in the 1930s among the painters of luminous dials who used radium-235 and mesothorium. The inventor of the luminous paint, Dr von Sochocky, died of aplastic anaemia in 1928. Again in the 1930s, case reports were appearing of lung cancer (an unusual tumour in those days) in workers exposed to asbestos fibre. In asbestosis cases the incidence was reported as 18 per cent and reports of pleural mesothelioma followed a decade or so later.

Thus, within a century of Rehn's discovery, chemical carcinogenesis had become a well-recognized phenomenon with much of the evidence coming from occupational studies.

Diagnosis

Clinical acumen remains of paramount importance. It is clinicians who have played the major role in discovering new causes of cancer with confirmatory evidence coming from laboratory studies and epidemiological investigations (see Fig. 1).

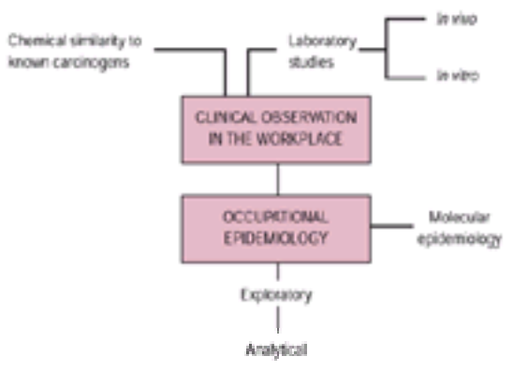

Fig. 1 The scientific basis for establishing occupational causality.

Such information is collated and interpreted by various national and international agencies. The most reliable source is the monograph series of the International Agency for Research on Cancer (**IARC**) based in Lyon. To date they have published over 70 such monographs with several updating supplements. When a patient is diagnosed as having cancer, it is important that the clinician should review the occupational history to consider an occupational cause. If this seems probable, enquiries should be made to see if state compensation is available for that cancer and that workplace exposure.

Attribution of cancer to occupational causes

The most widely accepted estimates of the proportion of all cancers attributable to occupational exposures is 4 per cent with a range of 2 to 8 per cent for a developed country like the United States. For the 20 per cent or so of the population in which occupationally related cancers are almost exclusively concentrated (manual workers aged 20 or over, in mining, agriculture, and industry broadly defined), perhaps as much as one lung or bladder cancer in every five may be attributed to workplace exposure.

In addition, it is necessary to consider other exposures which may interact with workplace exposures. These are particularly relevant when considering the relative effectiveness of removing or reducing exposure to one or more jointly acting agents. Few good studies have been completed on interaction, but there is good evidence for the multiplicative effects of cigarette smoking and asbestos exposure in the genesis of lung cancer. Besides asbestos, interactions have been demonstrated to be at least additive for tobacco consumption and exposure to arsenic and nickel compounds as well as ionizing radiation.

Table 1 and Table 2 show some important examples of occupational exposures causing cancer.

Polynuclear aromatic hydrocarbons

Polynuclear aromatic hydrocarbons are a large and complex group of compounds mainly generated during the incomplete combustion of carbonaceous products, of which coal and oil result in the most important occupational exposures. Cigarette smoke contains a number of these compounds and so it is often difficult to distinguish lifestyle from occupational factors. The site of action of these compounds is mainly the lung, skin, and bladder. The industries most prominently linked to such exposures are coke ovens, gas production, steel industries, aluminium refineries, iron and steel foundries as well as workers exposed to exhaust fumes from soot, pitch, tar, and petroleum products.

Aromatic amines

Aromatic amines are a group of chemically similar compounds which have particular importance as dyestuffs or antioxidants or as intermediates in dye production. Some are known human bladder carcinogens, a larger number are known animal carcinogens but for which human data are limited or lacking. The more potent carcinogens are now banned.

Metals and metalloids

The most important carcinogenic metals are compounds of arsenic, chromium, and nickel. Arsenic and its compounds cause lung and skin cancer, and these risks occur in the extraction of metalliferous ores (which are frequently contaminated by arsenic compounds) and in the now limited use of arsenic in pesticides and other industrial usages. Hexavalent chromium compounds used in the pigment and plating industries have been shown to cause lung cancer. Lung and nasal cancer are associated with the refining of nickel and the most likely causative agents are the oxidic and sulphidic nickel compounds. Other metals for which there is evidence of carcinogenicity include beryllium and cadmium.

Other organic compounds

Benzene is widely used in industry both as the base compound and as an important building block in the organic chemical industry. It causes leukaemia and aplastic anaemia. Vinyl chloride monomer, which is the starting point for synthesis of polyvinyl chloride, causes angiosarcoma of the liver. The most potent lung carcinogens are apparently the chloromethyl ethers which are used in ion exchange resins. Other suspect organics include acrylonitrile, acrylamide, butadiene, diethyl sulphate, epichlorhydrin, ethylene dibromide, formaldehyde, styrene oxide, tetrachloroethylene, and trichlorothylene.

Industrial processes

Some processes listed in Table 1 are linked to specific exposures, such as polynuclear aromatic hydrocarbons in aluminium production and radon in underground mining. For others such as boot and shoe manufacture, furniture making, and painting, the specific relevant exposures have not been identified.

Musculoskeletal disorders

T. C. Aw

Musculoskeletal disorders rank alongside stress as a major cause of workplace ill health. As musculoskeletal disorders are common in the general population, their suspected relationship to specific occupations or activities can often be difficult to confirm. A combination of occupational, psychological, personal, social, and home factors may be involved. The epidemic of repetitive strain injury in

Australia during the 1980s highlighted the complex interaction of symptoms, group perceptions, and employment.

Repetitive strain injury

This term was coined to describe pain and discomfort in the wrist and forearm associated with the performance of repeated tasks, mainly at work. Other terms used synonymously are cumulative trauma disorder, occupational overuse syndrome, and work-related upper limb disorder, with some terms restricting the definition to conditions in upper limbs caused by work. Unfortunately, there is no widely accepted case definition, and several disorders such as carpal tunnel syndrome, de Quervain's disease, epicondylitis, and tenosynovitis are often included in the entity. Clusters of cases have been recognized in occupational groups such as typists, telephonists, computer keyboard operators, musicians, cleaners, hairdressers, butchers, and assembly line workers. While the wrist and forearm are the anatomical regions most frequently affected, the symptoms are often very diffuse and the shoulder and neck may also be involved. Risk factors common to many cases are:

1. repeated movements at certain joints, often through the full range of movements, for example flexion and extension at the wrists;
2. constrained postures, sometimes at the extremes of the range of movements, and often against pressure or force.

Low back pain

This is possibly the commonest musculoskeletal condition experienced by people at work. Poor lifting and manual handling techniques and sitting for prolonged periods in the course of work activities (for example professional drivers) are contributory factors. Nurses, porters, and brick-layers are groups with a high prevalence of low back pain. The total cost of sickness absence, early retirement, and treatment for low back pain in many countries is considerable.

Occupations associated with musculoskeletal disorders

Several occupations are associated with a high risk of sustaining an occupationally related musculoskeletal injury. These include fractures and joint damage in construction workers, miners, and deep sea fishermen, avascular bone necrosis from decompression sickness in tunnellers and divers, acro-osteolysis in workers exposed to vinyl chloride monomer, and septic bone and joint lesions from brucellosis in meat process workers. The joints of coal-face workers, farmers, and professional dancers are subjected to frequent heavy impact loading leading to a high incidence of degenerative changes of the hip and knee.

Clinical investigations and management

Several investigations such as erythrocyte sedimentation rate, C-reactive protein, rheumatoid factor, and imaging may help to exclude an underlying medical condition.

The management of a case of occupational musculoskeletal disorder requires alleviation of symptoms and the consideration of modifications to the system of work or the layout of the workstation. Non-steroidal anti-inflammatory medication and physiotherapy can reduce pain, discomfort, and limitation of function. Localized areas of inflammation will respond to local injections of corticosteroids. Physical therapy procedures and occasionally surgery may be considered. There should be an evaluation of ergonomic factors in the design of equipment at the individual's workplace. This requires attention to the adequacy of the workstation, ease of access of the worker to tools, components, and other equipment, and the suitability of the general work environment—its lighting, temperature, humidity, and noise. Training in proper methods of lifting and manual handling is essential.

Musculoskeletal disorders affecting occupation

Patients with known arthritic disease, such as rheumatoid arthritis and systemic lupus erythematosis, need to be assessed for the effect that the condition may have on the performance of their work duties. The fluctuating nature of most forms of chronic arthritis makes precise predictions difficult. Physical disability can improve despite persistence of the disease. This is due both to the beneficial effects of treatment and to the patient's adaptation to the consequences of the disease.

Cardiovascular system

J. M. Harrington

Cardiovascular disease is the major cause of mortality and morbidity in industrialized countries (see Section 15). The association between personal risk factors and cardiovascular disease is well known, but less attention has been paid to occupational and environmental influences.

There is good evidence from the classical studies of London bus drivers and conductors that sedentary workers have a higher risk of ischaemic heart disease than those who are more active. There is some evidence linking job stress and heart disease. The Whitehall II studies suggest that control over one's job is an important factor in determining subsequent risk of myocardial infarction.

Exposure to chemicals such as carbon disulphide, chlorinated organic solvents, nitroglyecrine, and vinylchloride monomer may contribute to cardiovascular disease. The cardiovascular effects of exposure to heavy metals are largely secondary to their nephrotoxic effects. Toxic industrial gases produce their effect secondary to anoxia. Among physical agents, vibration is known to cause peripheral vascular disease and acute high exposure to noise is known to raise blood pressure. Workers on rotating shifts have an increased risk of ischaemic heart disease.

Genitourinary system

J. M. Harrington

The kidney plays a crucial role in the excretory and detoxification mechanisms of the body. Perhaps the most effective detoxification manoeuvre of the liver is to increase the polarity or acidity of the absorbed substance. This, in turn, increases the water solubility of the chemical and hence its renal excretion. The kidney, therefore, bears the brunt of many exposures to toxic chemicals. Some toxic substances do reach the kidney unchanged but most are metabolized to some extent or other. Some, such as cadmium, become sequestered in the renal cortex while others, such as the aromatic amines, are present in the bladder long enough and at a high enough concentration to induce malignant change in the transitional cell epithelium.

Sudden, severe exposures to some chemicals can cause acute nephropathy. Such compounds may damage the kidney directly due to their instrinsic nephrotoxicity or may induce secondary damage due to prerenal effects, such as the haemolysis following arsine exposure. Hypovolaemic shock can follow acute fluid loss or extreme heat, while post-traumatic renal failure can follow crush injuries or high-voltage electric shock, both of which cause muscle necrosis. Chronic lower-dose exposure leading to nephropathy is more commonly associated with metals or organic solvents.

The metals most commonly implicated in renal disease are mercury, cadmium, lead, and, perhaps, uranium (see Chapter 8.1). Mercury exposure resulting in acute tubular necrosis or the nephrotic syndrome is most unusual these days. Under present-day workplace exposures, the effects of inhaled mercury vapour or absorption of mercury salts are more likely to cause mild proteinuria and limited tubular dysfunction. Biological monitoring of mercury-exposed workers has had to become more sophisticated. Sensitive tests of urinary enzymes, such as *N*-acetyl-b-D-glucosamidase, are necessary to detect those subtle effects. Similarly, modern industrial exposures to cadmium rarely result in the proximal or distal tubular dysfunction or renal cortical damage that was more prevalent in the past. However, cadmium is only slowly leached from the renal cortex and remains a potentially serious long-term cumulative poison. The environmental cadmium contamination which caused widespread tubular dysfunction with hypercalciuria and osteomalacia in multiparous postmenopausal Japanese women (Itai-Itai disease) has not been described in the West. Lead nephropathy is also a rarity nowadays, but was not uncommon in the early part of this century. Lead is capable of causing damage to all parts of the nephron. More subtle tests of renal enzymes are now needed to assess the effects of lead exposure on the kidney. Soluble uranium compounds such as uranium hexafluoride have been shown to be potent nephrotoxins after acute accidental exposure but this problem is virtually unknown in a well-controlled modern facility.

Chlorinated aliphatic solvents such as carbon tetrachloride and chloroform can cause the hepatorenal syndrome. The renal damage is largely an effect on the proximal tubular epithelium which can lead to tubular necrosis and acute oliguric renal failure. The weight of evidence from case–control studies of workers exposed to solvent suggests an excess risk of glomerulonephritis. The mechanism is unclear, but a link with Goodpasture's syndrome suggests possible autoimmune damage to the glomerular basement membrane.

Although the prostate possesses the curious ability to concentrate (and excrete) heavy metals, little evidence exists of occupationally related prostatic disease. Earlier reports of a link between cadmium exposure and prostatic cancer have not been confirmed. Cancers of the urinary tract associated with occupational exposure to aromatic amines and polynuclear aromatic hydrocarbons were described earlier.

Gastrointestinal tract

T. C. Aw

The gastrointestinal tract acts as a semipermeable membrane through which ingested pollutants are absorbed. There are defence mechanisms that limit the damage to the gastrointestinal tract from such pollutants, and minimize their absorption. The mucous lining of the gut and diarrhoea and vomiting form part of these defence mechanisms. Hence, systemic absorption via the gastrointestinal tract plays a relatively minor role in causing occupational disease.

Acute gastroenteritis may follow the ingestion of chemicals such as soluble salts of heavy metals.

The liver is frequently at risk from occupational exposures, as it is the target organ for detoxification and metabolism of absorbed compounds. A wide variety of infectious and chemical agents cause different types of hepatocellular injury which may eventually lead to cirrhosis and liver failure (Table 3).

The haemopoietic system

T. C. Aw

The metal most frequently associated with bone marrow damage is inorganic lead. Lead causes anaemia by inhibiting the enzymes involved in haem synthesis and also by haemolysis. Determination of blood lead levels is used in the monitoring of lead-exposed workers. A diagnosis of lead poisoning is supported by symptoms of malaise, colic, and constipation, signs of anaemia and peripheral motor neuropathy (rare, usually only in severe cases), and laboratory evidence of basophilic stippling of erythrocytes, elevated blood lead, low haemoglobin, raised free erythrocyte protoporphyrin, and raised urinary †-aminolaevulinic acid. Indications of excessive lead absorption should lead to removal of the affected worker from further occupational exposure, with full investigation into the circumstances of exposure to lead at work and possibly elsewhere.

Massive intravascular haemolysis is caused by acute exposure to arsine, phosphine, and stibine. These are gases encountered in the smelting and refining of metals, galvanizing processes, and in

certain soldering procedures. They are formed from the reaction between nascent hydrogen and arsenic, phosphorus, and antimony respectively.

Occupational exposure to ionizing radiation can occur following the industrial use of radioactive sources to test the integrity of welds, in the health-care industry, and in nuclear power stations (see Chapter 8.5.9).

Benzene is encountered in the petroleum industry, and is used as a starter chemical for the production of other aromatic organic compounds. Its effects on the haemopoietic system include early platelet deficiency, mild haemolysis, and pancytopenia. Major effects are aplastic anaemia and lymphoid and myeloid leukaemia.

Methaemoglobinaemia can result from exposure to occupational and environmental agents such as nitrates, and nitro and amino derivatives of aromatic compounds. Specific examples are aniline, aminobenzene, nitrobenzene, and nitrates in the soil.

Infections

T. C. Aw

Certain industries are associated with an increased risk of occupational infections, and the health-care industry is possibly the best example of this. Working in tropical environments also exposes workers to the risk of tropical diseases. Occupational and environmental infections involve a range of organisms from viruses, rickettsiae, bacteria, and fungi to larger organisms such as parasites and insects. Occupations involved include farming, forestry, and sewage work.

In the health-care industry, blood-borne infections such as hepatitis B and human immunodeficiency virus (**HIV**) pose practical problems for the safety of staff during contact with infected patients, and the safety of patients during contact with infected staff. Worldwide, several dozen cases of HIV have been documented to have occurred in health-care workers following contact with infected blood or body fluids from patients. These have involved needlestick injuries, mainly from contaminated hollow-bore needles, or substantial blood contamination of damaged skin. Only two cases of HIV transmission from health-care workers to patients have been noted. One involved a dentist and the other an orthopaedic surgeon. With hepatitis B, the incidence of outbreaks from doctor to patient and vice versa is much more common. Until recently, transmission of hepatitis B from doctor to patient was thought to involve only those who were e-antigen positive carriers. There have been several cases to date involving surface-antigen positive but e-antigen negative carriers. This has led to a review of occupational procedures that may pose a risk to patients from such carriers. Protection of health-care staff from hepatitis B infection involves the intramuscular administration of yeast-derived genetically engineered vaccines (plasma-derived vaccines were previously used) to staff at risk. The vaccine does not protect against other hepatitis infections (hepatitis C, D, and G) which are similar to hepatitis B in their transmission and sequelae . Other occupational infections affecting staff in microbiological laboratories and other health-care workers include tuberculosis, salmonellosis, syphilis, and malaria.

The reproductive system

T. C. Aw

Occupational and environmental exposures may affect female and male reproductive systems and influence different stages in the outcome of pregnancy. Children can be affected by parental exposure to physical and chemical hazards.

The male reproductive system

Exposure to the pesticides 1,2-dibromo-3-chloropropane (**DBCP**) and chlordecone (Kepone), are among the best documented cases. Liquid DBCP was used as a nematocide for crops. Chlordecone was used as an insecticide. Gynaecomastia has been reported in male workers following prolonged contact with oestrogenic agents such as diethylstilbestrol, and in those involved in the preparation of oral contraceptive products.

Effects on the male reproductive system may also occur following exposure to heat (potentially a problem in workplaces such as foundries), microwave and ionizing radiation, cytotoxic drugs, animal growth promoters, fumigants such as ethylene dibromide, and heavy metals, for example lead, manganese, and mercury compounds.

The female reproductive system

Effects on the female reproductive system range from alterations in the menstrual cycle—both the amount of menstrual flow as well as the regularity of cycles—spontaneous abortions, and infertility. Rubella can be a problem for female health-care workers and those working in microbiological laboratories, especially if adequate procedures are not in place for occupational health vetting and immunization of this occupational group. Concerns about an increase in spontaneous abortions amongst female anaesthetists exposed to anaesthetic gases were investigated, and recent reviews of the findings suggest that the evidence is weak. Nevertheless, occupational exposure standards were set in the United Kingdom in 1996 for limiting workplace exposure to nitrous oxide, halothane, enflurane, and isoflurane. Similar concerns about working with visual display units (such as computer monitors) and spontaneous abortions led to several large-scale epidemiological studies. These studies indicated that the association could well have occurred by chance, given that spontaneous abortions are relatively common events and that there has been a rapid increase in use of visual display unitss in recent years.

Other occupational and environmental exposures that can affect the female reproductive system are ionizing radiation, cytotoxic drugs, lead, and ethylene oxide.

Other environmental effects

Environmental contamination with 'endocrine-disruptors' such as plasticizers has been thought to be responsible for an alteration to the sex ratio of fish populations. Pollution from similar organic compounds has been suggested to be contributing to the decline in mean sperm counts for male populations in several parts of Europe. These observations have led to proposals for testing chemicals for endocrine disrupting properties.

Neurological disorders

E. L. Baker

Neurological disorders caused by exposure to chemicals

Central nervous system effects

Exposure to chemicals, primarily encountered by workers in manufacturing, construction, and agricultural jobs, can cause transient and persistent effects on the central nervous system (Table 4). Transient central nervous system dysfunction is most commonly caused by exposure to volatile organic solvents, to organophosphate insecticides, or to carbon monoxide. In each instance, these substances, acting through different mechanisms, may cause central nervous system dysfunction ranging from acute intoxication manifested by light-headedness and dizziness to loss of consciousness and even death. Persistent central nervous system sequelae may occur following one exposure episode if exposure levels are high and the time of exposure is prolonged.

Persistent central nervous system dysfunction, manifesting as neurobehavioural performance deficits, has been reported following chronic exposure to moderate concentrations of various agents encountered in the workplace and occasionally in the environment. This syndrome, chronic toxic encephalopathy, consisting primarily of memory impairment, impaired psychomotor function, and mood disorders, has been seen following chronic exposure to lead, styrene, and certain organic solvents. In more severe cases the deficits persist, but do not progress, following cessation of exposure. If behavioural symptoms are present without evidence of abnormal neurobehavioural test performances (i.e. organic affective syndrome) reversal of these manifestations usually occurs following cessation of exposure.

Peripheral nervous system effects

Exposure to certain agents (Table 5) may cause either motor or sensorimotor polyneuropathy. Rarely, exposure to lead at high levels for long periods may cause upper extremity motor neuropathy, consisting of wrist extension weakness or wrist drop. Certain substances (for example acrylamide, hexacarbon solvents, and certain organophosphorus compounds) may act as axonal toxins causing a mixed sensorimotor polyneuropathy manifesting as symmetrical, distal sensory loss. Upon removal from exposure, the symptoms usually recede over a period of months with modest or no residual damage.

Other nervous system effects

A variety of other neurological effects have been reported following exposure to toxic agents in the environment (Table 6). In most cases, symptoms recede once exposure has ceased.

Neurological disorders caused by physical factors

Repetitive trauma disorders

See under Musculoskeletal disorders and Section 18.

Entrapment neuropathies

In certain occupations, sustained postures such as working overhead may cause muscular hypertrophy or other changes resulting in entrapment of nerve roots or individual nerves. Such conditions are diagnosed by obtaining a careful work history and are managed by modification of the work environment.

Vibration-induced neuropathy (see also Section 24)

Certain jobs involving the use of vibrating hand tools or pneumatic drills may be responsible for the occurrence of peripheral neuropathy. These disorders may originate from a combination of physical trauma to the nerve itself as well as damage to blood vessels which supply the nerves.

The role of psychology in occupational health

A. Spurgeon

There is growing recognition of the importance of psychological factors in a range of occupational health concerns. The following represents the main areas where psychology is now considered to have a significant contributory role.

Occupational stress

Reports of work-related stress have increased dramatically in recent years. A number of factors in the working environment have been identified as potential psychosocial hazards. These are usually categorized as in Table 7.

Prolonged exposure to one or more of these conditions may result in a range of symptoms of psychological distress such as feelings of anxiety, irritable or aggressive behaviour, lack of concentration, lack of confidence and an inability to make decisions, sleep disturbance, and fatigue. There may also be associated physical symptoms such as frequent headaches and nausea. Occupational stress is often identified as a result of the individual's inappropriate (maladaptive) coping strategies such as frequent short-term absences, alcohol and other substance abuse, poor time-keeping, and by uncharacteristically poor work performance. Effective management of occupational stress usually requires an integrated approach which includes attention to both the workplace and the individual and consists of intervention at three levels:

1. Primary intervention focuses on the identification of particular sources of stress in the working environment and the institution of measures to eliminate or reduce these.
2. Secondary intervention focuses on improving the coping skills of employees by the use of specific forms of stress management training (for example relaxation, conflict management, assertiveness, time management) and health promotional activities. These are particularly appropriate where workplace stressors are intrinsic to the particular occupation and therefore non-removable, for example the potential for aggressive confrontation with members of the public.
3. Tertiary intervention is concerned with counselling and rehabilitation of psychologically distressed individuals. The source of stress may often be multifactorial, and not therefore solely work-related, but it has an impact upon work performance and may be exacerbated by the demands of work

Neurobehavioural effects (see Sections 24 and 26)

The response to hazard exposure

A growing number of occupational health complaints are characterized by a lack of a firm diagnosis or clear occupational causation. These include, in particular, complaints which consist of a range of non-specific symptoms, typically headache, fatigue, nausea, depressed mood, cognitive confusion, and sometimes eye and nasal irritation. They are reported in diverse situations such as in air-conditioned offices (sick-building syndrome), proximity to low-frequency electromagnetic fields and perceived exposure to very low (often undetectable) levels of chemicals. In addition the prevalence of musculoskeletal complaints in many workplaces has been shown to be related to the presence of psychosocial hazards. At an individual level the reporting of such complaints, the decision to be absent from work, and the subsequent response to treatment and the duration of absence from work also appear to be strongly related to psychological factors. An important element is the structure of health beliefs and attitudes which the individual brings to the situation. This influences their response to real or perceived exposure to hazards by determining their selection of which information to attend to and their subsequent interpretation of that information. Specific examples of syndromes with these features which occur in both an occupational and wider community setting may be multiple chemical sensitivity and chronic fatigue syndrome. Current approaches to effective management of these and other similar conditions favour a 'biopsychosocial' approach which rejects the artificial distinction between a physically and a psychologically based complaint and treats both physical and psychological symptoms simultaneously.

Risk perception

Individual response to exposure to hazards is one aspect of the wider subject of risk perception. Public and individual perceptions of risk are invariably at odds with quantitative risk assessment based on real data. Risk perception and associated safety behaviour are known to depend on a range of attitudinal factors, notably whether exposure to the hazard is perceived to be voluntary or involuntary, whether the consequences are perceived to be short or long term, who is perceived to be responsible or to benefit, the perceived importance or vulnerability of those at risk, and the level of concern generated by the media and the activity of pressure groups. Modern approaches to risk assessment accept that subjective and objective evaluations of risk should both be taken into account when defining the tolerability of any risk to individuals or groups, either in the workplace or in the wider environment. In addition, communication about risk is unlikely to be effective if it does not take account of the existing attitudes and beliefs of the audience and the reasoning behind these. The application of this to the development of a positive safety culture is discussed elsewhere.

8.4. Occupational safety 2

Richard T. Booth

Introduction

Accidents at work occur under a variety of circumstances. A few serious accidents involve fires and explosions in chemical process plants, and transportation disasters. But the vast majority of accidents involve everyday events such as contact with moving machinery, falls, cuts from handling materials, slipping on or striking against objects, and injuries from hand tools. Road accidents at work are the main cause of occupational fatalities. Despite the diversity of accidents, it is now agreed that the causes of all these accidents and principles of safety management are common to all, and to the control of health hazards at work.

The regulation of occupational safety in the United Kingdom evolved along two largely independent pathways. The first was the development of legislative controls of safety, gradually embracing an increasing range of hazards and of industries and employers. The second pathway was the development of safety management.

The distinctive feature of industry- and hazard-based safety legislation from 1844 was that the regulators identified the hazards, implicitly assessed the risks (largely as a reaction to events), and prescribed 'blanket' rule-based control standards. Safety was driven by legislation, and a knowledge of the law was the foundation of workplace controls, as described in 1972 by the Robens' Report for the Committee on Safety and Health at Work.

In contrast, safety management began (in Great Britain at least) after World War I, promoted by the British Industrial Safety First Movement, later the Royal Society for the Prevention of Accidents. Industrial accident prevention was seen as being achieved by committees, workers' participation, the employment of safety officers, joint accident investigations, and the promotion of a positive safety culture.

Limitations of this approach were the tendency to distance safety management from operational management generally, the adoption of a reactive approach to prevention, seeing accident causation in very simple terms, and a predilection for panaceas, such as 'accident proneness'.

The first determined attempt to amalgamate these two pathways or 'traditions' of safety within a framework of law was proposed by the Robens' Report. The Committee recognized that much safety law was outdated, too detailed, prescriptive, and legalistic. Robens proposed the wholesale repeal of the then existing law and its replacement with 'goal-setting' legislation. The Robens' philosophy was partly realized by the Health and Safety at Work, etc. Act of 1974, but arguably only fully implemented in the early 1990s as a result the European Union (**EU**) Framework and other directives (heavily influenced in most cases by experience in Great Britain), together with the government's deregulation initiatives. Whereas traditional law drove the safety system, the contemporary doctrine is that the law should underpin good, and promote best, practice. To a large extent, the Health and Safety Commission and the Health and Safety Executive (**HSC**, **HSE**) together became not just the custodian of the law, but also the custodian of good practice (as evidenced by standards) and the prime mover of the safety system. The duty of employers was no longer slavishly to adhere to a set of statutory rules, but to develop their own safety organization and arrangements that could be shown to follow good practice, which employers' and employees' organizations had been involved in framing.

The last 30 years have therefore seen the recognition of safety as an integral part of company management. Risk assessment is accepted as the essential basis for prevention.

The size of the problem

During 1998 to 1999, 188 employees were killed at work in Great Britain. In addition, 65 self- employed people and 369 members of the public (including trespassers and suicides on the railways) received fatal injuries at work. The numbers of non-fatal accidents are less certain. Accidents at work in Great Britain should be reported to the relevant enforcing authority under the terms of the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations 1995 (**RIDDOR**). However, the Department of Employment in its in 1992 Labour Force Survey suggested that only about 30 per cent of reportable accidents to employees were reported. Reporting levels vary sharply in different employment sectors; from 80 per cent in the energy sector to 17 per cent in agriculture. Only about 5 per cent of reportable accidents to the self-employed are reported.

In 1991, the HSE argued, from the evidence of reported accidents, that accident rates in Great Britain were lower than in other industrialized countries. But the findings of the Labour Force Survey suggest that the lower accident rates in Great Britain may be partly a consequence of serious under-reporting and also a result of differences in reporting criteria. Notably, the published Great Britain data do not include fatal and serious injury from occupational road accidents. These data are included in reports from many EU countries. Some further reservations about accident data as a measure of safety performance are mentioned later.

Table 1 shows the frequency, causes, and results of different kinds of accident. Accidents leading to fatal injuries can be markedly different from those leading to major injuries. Falls on the level cause most major injuries, but few fatalities. Falls from heights and injuries from moving/falling objects contribute substantially to both severity categories.

Table 2 shows the kinds of injuries associated with fatal and serious non-fatal accidents. Fractures (15 per cent), concussion and internal injuries (14 per cent), and injuries of more than one type (26 per cent) were the injuries most often associated with fatality. Nearly three-quarters of all major injuries are attributable to fractures. The nature of injury was unknown in 9.3 per cent of cases, presumably because these details were not given on the standard pro-forma but were included in supplementary documents that did not find their way into the statistics.

The evolution of safety management

Accident prevention requires the creation, and maintenance, of a safe working environment, and the promotion of safe behaviour—the avoidance of error—by those doing hazardous work. However, safety management has emphasized the prevention of repetitions of accidents that have already occurred, using information derived from detailed accident investigations. Accidents meriting investigation usually involve a casualty, and it is not surprising that the behaviour of those injured may dominate the minds of the investigators. Reactive prevention tends to be easier than proactive prevention. Assessing risks and devising preventive plans without the help of accident data is difficult: it involves weighing the probabilities of a wide range of unwanted outcomes, and preparing an integrated control plan to cope with all the detected hazards.

Key features of the traditional approach were the search for a primary accident cause, and the debate about whether the primary cause was an unsafe act or an

unsafe condition.

Most practical accident prevention involved the preparation of a safety rule designed to prevent a recurrence of the unsafe act, or a physical safeguard to obviate the unsafe condition existing immediately before the accident.

The causation debate, with its political overtones and desire to apportion blame, often missed three crucial inter-related, issues:

- The concept of a single primary cause for an accident is a bizarre simplification of a complex multicausal process. The term 'unsafe act' embraces a wide range of unintentional errors and intentionally risky behaviour 'violations'.
- The distinction between the contribution of unsafe conditions and unsafe acts in causation has masked the more important distinction between the relative contribution of conditions and behaviour in prevention, and the need for prevention plans to promote both safe conditions and safe behaviour.
- The argument has focused almost exclusively on the errors made by those people involved in the accidents, not the managers and engineers whose errors (remote in time and place from the accident) may have created a physical environment conducive to the risk of serious accidents.

The safety management approach proved inadequate to cope with major hazards created by rapidly developing technology. Preventive measures may be rendered obsolete by each technical advance. Rules and safeguards devised in the aftermath of accidents may later be perceived as overzealous and may conflict with the needs of both employers and employees to get the job done. Both parties may tacitly conspire to evade the safety rules or to defeat the physical safeguards. Measures taken to prevent one specific accident may conflict with the measures adopted to prevent a different accident, and with production-oriented rules. Rule books and legislation drawn may become incomprehensible and contradictory. At least two company rules may exist for any situation: the rule to get the job done in time, and a more demanding rule that may be invoked when things go wrong.

Proactive safety management

Accident investigations and prevention programmes must address the distinctive elements of the accident causation process described below.

H4>Multicausality

Few accidents are associated with a single cause. Rather, they happen as a result of a chance concatenation of many distinct causative factors, each one necessary but not sufficient to cause a final breakdown. The coverage of prevention plans should therefore seek to permeate all aspects of the organization's activities. Accident investigators should continue to seek out causative factors even when 'a familiar, abnormal event is found which is therefore accepted as explanation, and a cure is known'.

Active and latent failures

Active failures are errors that have an immediate adverse effect, while latent failures lie dormant in an organization becoming evident only when combined with local triggers. The triggers are the active failures: unsafe acts, and unsafe conditions such as mechanical failure.

Skill-, rule-, and knowledge-based errors, and violations

The standard framework for classifying error is the skill—rule—knowledge-based model.

Skill-based errors involve 'slips' or 'lapses' in highly practised and routine tasks. Knowledge-based errors are failures to create an adequate new rule to cope with a situation. Violations, or risk taking, are another category of error. Someone deliberately does something contrary to a rule, such as an approved operating procedure.

Hazard identification, risk assessment, and preventive action

These are the essential foundation of safety management—the avoidance of latent failures and of safe personal behaviour in the face of danger—the avoidance of active failures.

To create and maintain a safe working environment, and to work safely in a dangerous environment, people must have the knowledge and skills and must know the rules, and be motivated, to:

1. identify hazards;
2. assess accurately the priority and importance of the hazards (risk assessment);
3. recognize and accept personal responsibility for dealing with the hazards in an appropriate way;
4. have appropriate knowledge about what should be done (including specified rules);
5. have the skills to carry out the appropriate necessary sequence of preventive actions, including monitoring the adequacy of the actions, and taking further corrective action.

The organization should be aware of circumstances where managers, supervisors, and other personnel may:

- underestimate the magnitude of risks;
- overestimate their ability to assess and control risks;
- have an impaired ability to cope with risks.

The aims of safety management

The aim of safety management is not limited to hazard identification, control, and monitoring. Employers must plan for safety. Decisions have to be made about priorities for resource allocation, training needs, the appropriate risk-assessment methods to be adopted, the need to assess human reliability, and the choice of tolerable-risk criteria. Safety criteria should underpin every decision made by the enterprise and must be considered as an integral part of day-to-day decision-making. The employer must establish an organization and communications systems that helps to integrate safety within the management process, and which ensures that everyone is fully informed about safety issues, and ideally has had an opportunity to discuss them.

Key functions of safety management

1. *Policy and planning*: relies on the determination of safety goals, objectives, and priorities, and a programme of work designed to achieve the objectives, which is subject to measurement and review.
2. *Organization and communication*: involves establishing clear lines of responsibility and two-way communications at all levels.
3. *Hazard management*: depends on ensuring that hazards are identified, risks assessed, and control measures determined, implemented, and subject to measurement and review.
4. *Monitoring and review*: requires the establishment of whether the above steps are in place, in use, and work in practice.

The four key elements of safety management are underpinned by the requirements of the Management of Health and Safety at Work Regulations 1999.

Safety management and safety culture

These procedures and systems are necessary elements of an effective safety programme, but are not the whole story. There is a danger that an organization's safety policies, plans, and monitoring arrangements, although appearing well considered and comprehensive, may create an aura of respectability which disguises sullen

scepticism or false perceptions among influential people at management and shop-floor levels.

The concept of safety culture

The Health and Safety Commission has defined safety culture as follows:

> The safety culture of an organization is the product of individual and group values, attitudes, competencies, and patterns of behaviour that determine the commitment to, and the style and proficiency of, an organization's health and safety programmes.
>
> Organizations with a positive safety culture are characterized by communications founded on mutual trust, by shared perceptions of the importance of safety, and by confidence in the efficacy of preventive measures.

The Confederation of British Industry has reported the results of a survey of 'how companies manage health and safety'. The idea of the culture of an organization was incorporated in the report's title 'Developing a safety culture'. The dominant themes to emerge were:

1. the crucial importance of leadership and the commitment of the chief executive;
2. the executive safety role of line management;
3. involvement of all employees;
4. openness of communication; and
5. demonstration of care and concern for all those affected by the business.

The Health and Safety at Work Act requires all companies employing five or more people to prepare a health and safety policy. A written corporate statement on the safety policy and organization is a crucial element in the promotion and maintenance of a positive safety culture within the organization, and of high standards of safety awareness in the minds of both management and workforce.

The policy should embody a positive approach to the management of safety. It must be more than a one-off event written to fulfil the letter of the Act; its objective should be to establish the corporate attitude to safety and the necessary organization through which the safety objectives can be assured. This must be subject to regular, systematic review.

Monitoring safety performance

Many companies measure safety performance merely by counting the number of accidents, a belated and potentially misleading statistic. In many organizations there are not enough accidents to determine whether differences between sites or over time are due to real differences, or to chance. Company and national accident statistics are influenced by variations in the time that individuals choose to take off for a given injury severity.

The design of a health and safety monitoring system for an enterprise must address two crucial issues:

1. There is no single unambiguous measure of safety performance that is resistant to abuse. Accident data must be combined with other measures.
2. Monitoring should be designed to both check and promote compliance.

Performance measures should be designed to permeate every activity within the organization. A battery of distinctive tests should be incorporated into the safety programme, so that the limitations of one are balanced by the strengths of another.

Safety auditing

Proprietary safety auditing systems are often used to measure safety performance, and to identify aspects of safety management requiring improvement. Audits typically comprise a checklist with about 400 questions and a scoring system. These audits allow companies to compare their safety management procedures against objective criteria, but some companies may try to improve their audit score in ways that do not lead to real improvements in safety.

Safety training

In the past, too much training was of poor quality and of doubtful effectiveness, but training is an essential part of the company's safety arrangements. The Institution of Occupational Safety and Health have published a safety training policy that emphasizes the need for:

1. explicit training in organizations to promote and maintain a positive safety culture;
2. training of senior managers to be competent in strategic safety management;
3. training of managers and workers to be competent in hazard identification, risk assessment, and control;
4. training of trainers to be competent in safety training;
5. in-company evaluation of training effectiveness.

8.5.1 Environmental extremes—heat

M. A. Stroud

Thermoregulation in the heat

Most of human evolution took place in Africa and hence all races are heat tolerant. Indeed, we try to maintain a near tropical microclimate against our skin, by using clothing to reduce heat loss to our surroundings. Our thermal balance is regulated by the hypothalamus which integrates information from skin temperature sensors with core temperature data from receptors in the walls of large blood vessels and in the brain. Rising temperatures trigger both behavioural and physiological responses.

Behavioural changes include reducing physical activity, altering clothing, and seeking shade or cool shelter. Cold drinks are also helpful. Although these responses seem simplistic, decisions may not be straightforward. If physical activity is low and water is in short supply, it is better to increase clothing cover and protect yourself from high radiant heat inputs. If activity must be continued and water is freely available, minimal clothing to permit maximal sweat evaporation is preferable. Immediate physiological responses involve vasodilatation of skin and subcutaneous blood vessels to enhance surface heat loss from radiation, conduction, and convection. The vasodilatation is triggered by a sympathetic cholinergic reflex in response to skin warming with additional direct effects of heat on arteriolar tone. In a resting individual, skin vasodilatation can maintain thermal equilibrium in environmental temperatures up to 32°C, but with higher temperatures or heat production from activity, core temperatures will rise. This will trigger sweating to promote evaporative cooling.

Heat acclimatization

Repeated heat exposure can increase our capacity to lose heat by about 20-fold. This is partly due to greater skin blood flow from increases in circulating volume and improved vasodilatory responses, but changes in sweating responses are more important. In the non-acclimatized, sweating is triggered by a rise in core temperature of about 1°C and maximum rates are limited to about 0.5 l/h. Following acclimatization, a 0.5°C core rise will trigger the response and rates may exceed 2.0 l/h. Acclimatization also leads to aldosterone-mediated reductions in sodium loss in both sweat and urine. The acclimatized individual therefore requires no sodium supplementation and giving supplements can delay the acclimatative process. Avoiding them altogether, however, does risk salt depletion in non-acclimatized persons during prolonged heat stress. Acclimatization develops swiftly and around 90 per cent of maximum heat tolerance is present after 7 to 10 days on which core temperature has risen by more than 1°C for more than 1 h. Physical exertion combined with heat makes changes even more rapid. After returning to cool environments, adaptation is lost in 20 to 40 days.

Susceptibility to heat-related illness

Although we are generally heat tolerant, heat-related illness is relatively common and a number of factors increase vulnerability. Above an environmental temperature of about 35°C, we tend to gain heat from our surroundings and this, along with metabolic heat production, can only be lost via evaporation of sweat. High humidity, hot environments are therefore the greatest threat. Acclimatization status has a marked influence on heat-related risks with the unacclimatized prone to hyperthermia and salt depletion. The fully acclimatized are vulnerable to dehydration from high sweat rates. Dehydration in itself limits sweating capacity and skin blood flow and hence increases risks. It can occur easily since thirst is a poor trigger for adequate drinking. Sweat rates can also exceed gut capacity for water absorption.

Prolonged physical activity can cause heat illness under quite modest environmental conditions. This is particularly common when individuals are obliged to wear insulative or non-vapour-permeable clothing. Military heat casualties are sometimes due to these factors but there have also been fatalities in soldiers who have been heat susceptible for no obvious cause. Such genetic or constitutional vulnerability should be suspected whenever a heat-related problem occurs following relatively modest heat stress. These individuals should be strongly advised to avoid similar circumstances in future. Obesity and poor physical fitness are further risk factors in the heat, as is diabetic autonomic dysfunction. The elderly are generally heat sensitive and, in addition, are prone to problems from the increased circulatory demands of vasodilatation. Drugs can also induce heat illness (see below).

Heat exhaustion

Most casualties in hot environments suffer from heat exhaustion. There is usually a history of prolonged heat stress followed by nausea, weakness, headache, thirst, and sometimes collapse. Patients appear dehydrated with a tachycardia and low blood pressure. If hyperthermic, the casualty should be complaining of feeling hot and should appear flushed and sweaty. The absence of these symptoms and signs, especially with a very high core temperature, suggests heat stroke. Heat exhaustion is ascribable to sodium and/or water depletion but discriminating between the predominant loss can be difficult. Sodium depletion tends to be greater if the casualty was poorly acclimatized and hence sweated relatively more sodium than water. Conversely, water depletion is more common in acclimatized individuals. Muscle cramps or whole body dehydration without marked changes in haematocrit or serum proteins are suggestive of excessive sodium loss, but serum sodium tends to be normal in such cases unless enthusiastic fluid replacement without salt has led to hyponatraemia. This sometimes occurs in runners following marathons in hot environments. In predominantly water-depleted heat exhaustion, haematocrit, serum proteins, and serum sodium tend to be high. Renal impairment occurs in either form of heat exhaustion and the treatment of both types often requires 5 to 10 l of oral or intravenous fluids in the first 24 h. Sodium supplementation is given as appropriate but if unsure about sodium status it is usually safer to provide some than to precipitate acute hyponatraemia.

Heat stroke

Mild heat stroke has occurred when a hot environment or high activity levels have led to pyrexia with cerebral disturbance. Core temperature is usually 38 to 41°C. The condition frequently follows heat exhaustion but temperature rise may have occurred rapidly with no time for salt or water depletion. Sufferers have headaches and may be either drowsy or irritable. They often hyperventilate. The great danger is progression to more severe heat stroke, in which core temperature reaches levels that cause irreversible denaturing of proteins. This usually occurs at above 41.5°C. Damage is widespread and particularly effects brain, liver, kidney, and muscle. Furthermore, the hypothalamic thermoregulatory centre may fail, switching off vasodilatation and sweating, and switching on cold defences inappropriately. Patients may therefore claim to feel cold and on examination may be shivering with a dry, vasoconstricted skin. A disastrous vicious cycle of increasing temperatures can then ensue.

Treatment for all heat stroke requires early recognition and rapid cooling. Tepid water and fan-assisted evaporation may be more effective than cold water immersion which can limit heat loss through intense peripheral vasoconstriction. Intraperitoneal fluids, paralysis, and ventilation may be needed and, in extremis, cooling by cardiac by-pass should be considered. Hyperkalaemia, hypocalcaemia, acidosis, rhabdomyolysis, disseminated intravascular coagulation, and hepatic or renal failure are all common complications. Ventricular fibrillation is a frequent terminal event. Even if apparently resuscitated and cooled successfully, a 12 to 24-h 'lucid interval' may precede major deterioration. Permanent neurological damage is common.

Drug-induced heat illness

Many drugs can cause mild degrees of pyrexia by inducing local or systemic inflammation or hypersensitivity. Some also increase susceptibility to environmental heat by inhibiting central thermoregulation (e.g. barbiturates and phenothiazines) or reducing sweating capacity (e.g. anticholinergics). Salicylate overdose can generate heat stroke by increasing metabolic heat production while impairing hypothalamic regulation. There are two types of heat-related drug reaction, however, which are

particularly dangerous.

Malignant hyperpyrexia

This is usually a dominantly inherited condition although different gene defects may effect families. Administration of a variety of anaesthetic agents, including halothane and suxamethonium, leads to rapid, massive heat production from generalized increases in skeletal muscle tone. Contraction is triggered at the muscle cell membrane and hence neuromuscular blocking agents are ineffective. Intravenous dantrolene, an inhibitor of muscle calcium flux, is helpful and can be used along with ventilation and cooling/supportive measures. Fatalities are common and it is therefore important to avoid risks whenever possible. In patients with a relevant personal or family history, in whom an anaesthetic is unavoidable, oral dantrolene should be given prior to the use of low-risk agents.

Neuroleptic malignant syndrome

This condition has similarities to malignant hyperpyrexia but is induced by idiosyncratic reactions to normal doses of antidopaminergic drugs including phenothiazines and butyrophenones. The onset is less rapid than malignant hyperpyrexia, occurring over a few days. The increased muscle tone is also induced presynaptically and hence neuromuscular blocking agents help. Some recreational drugs such as ecstasy may induce this type of response, although most cases of ecstasy-induced hyperthermia are probably cases of heat stroke induced by enthusiastic dancing with limited fluid intake in hot, humid environments.

8.5.2Environmental extremes—cold

M. A. Stroud

It has only been 10 000 to 15 000 years since ancestral humans dwelt exclusively in warm or hot climates. Humans are therefore poorly cold adapted and hypothermia occurs quite frequently even in temperate regions. With water immersion it may occur in the tropics. In truly cold areas, there is also the risk of non-freezing cold injury and frostbite. Nevertheless, behavioural changes allow us to operate safely in the coldest environments.

Thermoregulation in the cold

Core temperatures in the cold are usually maintained by adjustments in clothing and physical activity. The latter can increase heat production from a resting 100 watts to 1 to 2 kilowatts. This is very effective. While it takes highly specialized, multilayered clothing to keep warm while inactive in an environment of +5°C, clothing insulation equivalent to normal office dress (1 clo) will maintain core temperature at –20°C when working moderately hard.

Our limited physiological cold protection is under hypothalamic control. Falling surface and, to a lesser extent, core temperatures lead to decreased blood flow in the skin due to increased sympathetic adrenergic tone and direct cooling effects of cold on skin arterioles. This minimize surface heat loss. Unfortunately, vasoconstriction also leads to severe cooling of the hands and feet with problems of temporary skin numbness and muscle weakness, and risks of more permanent peripheral cold injury. It is often this peripheral cooling that limits our capacity to work in the cold.

Falling skin temperatures will also lead to higher resting muscle tone and shivering, especially when declining core temperature releases hypothalamic inhibition of shivering. These mechanisms can only increase resting heat production to around 500 watts and, unlike newborn infants and some other mammals, adult humans cannot add significant non-shivering heat production to this figure.

Effects of falling core temperature

Falling core temperature leads to progressive decline in function. At 34 to 36°C, hypothermic individuals are conscious of feeling cold and try to move around, add clothing, or seek shelter. Simultaneously, physiological defences are activated. With further falls, mental and physical problems increase with some individuals becoming withdrawn while others exhibit aggression or disinhibition. Once core temperatures reach 33 to 34°C, victims often stagger and become confused or drowsy. It is also around this point that 'paradoxical undressing' may occur. This phenomenon is well described and appears to be due to hypothalamic dysfunction with alteration of set-point temperature. Victims therefore think that they are hot and appropriate behavioural and physiological responses disappear. At core temperatures varying between 26°C and 32°C, coma will ensue and between 17 to 26°C cardiac output becomes inadequate to sustain life for prolonged periods. The risk of ventricular fibrillation is also high. Nevertheless, successful resuscitations of victims with core temperatures below 15°C have been reported.

Causes of hypothermia

A number of factors increase hypothermic risk. Wetting of skin or clothing extracts enormous amounts of heat and reduces insulation of garments. Complete immersion is particularly hazardous and globally, more than 100 000 people per year die of cold shock or inexorable hypothermia in the water. This far exceeds deaths from drowning without cold. Winds also increase environmental cooling and a still air temperature of +5°C equates to –50°C if wind speed is 40 km/h. Coupled with rain, these effects often contribute to hypothermic accidents amongst hill walkers and mountaineers, although in these cases fatigue may contribute. Prolonged exertion depletes muscle glycogen which reduces heat production capacity from both exercise and shivering. A low blood glucose also impairs hypothalamic temperature control.

Small, thin individuals cool easily due to increased surface-to-volume ratios. They also have reduced subcutaneous insulation and low heat producing mass. A fat individual can maintain core temperature at rest, even if mean skin temperature is 12°C, whereas a thin individual struggles to maintain thermal equilibrium with a skin temperature of 25°C. Sometimes, however, rapid cooling can have benefits. A small child in cold water may cool so rapidly that vagally triggered bradycardia and lowered brain metabolic demands may permit successful resuscitation after very prolonged immersion.

The elderly may also be small and thin and are at risk of so-called 'urban hypothermia'. Poverty, illness, immobility, malnutrition, and a less sensitive regulatory system may contribute but, in many cases, hypothermia on admission to hospital is secondary to other pathology, for example a stroke may have led to prolonged immobility in a cool environment. Drugs that impair consciousness or induce vasodilatation are risk factors, and alcohol is particularly hazardous. Alcoholics with no fixed abode and tendency for hypoglycaemia are frequent urban cold casualties.

Hypothermic illness

General management of the hypothermic casualty is similar to that for any comatose or semicomatose individual. Abnormalities in blood gases, pH, electrolytes, and glucose are common, and pancreatitis or rhabdomyolysis are recognized complications. Accurate measurement of core temperature is surprisingly difficult and axillary, tympanic, and oral temperatures can all be misleading. A low reading rectal thermometer is best. Hypothermia has one, very specific risk. Pronouncement of death is fraught with difficulty since profound bradycardia, minimal stroke volume, and marked respiratory depression occur. The old adage that you are 'never dead unless warm and dead' must be taken seriously.

A variety of rewarming methods are available. Warm blankets and hot drinks will suffice in many cases but, although used widely, metallized 'space blankets' are of no proven benefit. Warmed intravenous fluids are helpful and, in extreme cases, peritoneal warmed fluids or cardiac bypass can be used. Specialized equipment providing heated, humidified air also permits core rewarming. Hot baths are effective but difficult to utilize safely since a paradoxical fall in core temperature can occur as blood flow is rapidly restored to cold limbs. In general, if cooling was prolonged in onset or duration, rewarming must be undertaken with extreme caution. In critical cases, where rapid rewarming is needed, full resuscitation facilities must be available, although safe defibrillation in the presence of water is impossible.

Careful monitoring during rewarming is vital. Blood volumes are often low due to early cold-induced diuresis followed by the inability of hypothermic kidneys to retain salt and water. In immersion casualties, hydrostatic effects on the limbs may have promoted additional fluid loss and, if possible, these individuals must be kept recumbent throughout rescue and rewarming to minimize risks from extreme postural hypotension. Warming cell membranes are extremely unstable and uncontrollable fluxes in potassium and other electrolytes may occur although care must be taken in interpreting biochemical results from cold peripheral blood sampling.

Non-freezing cold injury

Local temperatures of less than12°C prevent normal membrane pumping and paralyse nerve and muscle conduction. If such cooling is prolonged, permanent damage may ensue. Immersion in cold water is particularly likely to cause this type of damage and soldiers in military campaigns are frequent victims of 'trench foot'.
Long-term damage is likely whenever an anaesthetic, paralysed, cold region becomes hot, red, painful, and swollen after rewarming, although this change may take several days. Degeneration of nerve and muscle can then follow leading to prolonged anaesthesia, muscle contractures, or inappropriate peripheral vascular control with intolerance to local heat or cold. There may be slow improvement over months or years.

Frostbite

Human tissues freeze at around –2°C. Ice forms outside cells but the remaining extracellular fluid becomes hyperosmolar and hence severe intracellular dehydration occurs. This denatures proteins. Vascular endothelial cells are particularly vulnerable and following rewarming small blood vessels may leak plasma and then become blocked by red cell sludge and clot. Additional ischaemic necrosis is then superimposed on the frost damage.

Frozen tissues appear hard and white and are anaesthetic. Rewarming leads to pain and swelling often accompanied by blistering. Deep freezing results in irreversible necrosis but appearances can be misleading and early amputation of digits should be avoided. If still frozen, rewarming is best achieved rapidly by using immersion in water at 40 to 42°C, although any thawing should be avoided if refreezing is likely. Once thawed, treatment is similar to that used for burns with prevention of infection paramount. Generous analgesia is required.

8.5.3 Drowning

Peter J. Fenner

Introduction

Drowning is an important cause of accidental death and neurological damage, particularly in children, and is usually preventable. Drowning is listed in the Global Burden of Disease Study as the fourth most common injury worldwide (behind road-traffic accidents, self-inflicted injuries, and violence but ahead of war deaths), and is the twentieth most common cause of death worldwide, with numbers estimated at 504 000 each year.

Drowning is defined as death from suffocation by submersion in a liquid, usually freshwater or seawater. Near-drowning is survival, at least temporarily, from suffocation by submersion.

Mortality and morbidity

Acute hypoxia is the cause of the haemodynamic effects and death. Neurological morbidity in survivors of near-drowning includes difficulty with learning, memory, attention, and planning and cerebral palsy. A major study of childhood immersions has shown that approximately 68 per cent of survivors have no neurological defect, 29 per cent have some deficit, and 3 per cent will live in a permanent vegetative state. Economic costs to the community are immense.

Epidemiology

Bathtub and bucket drownings may involve infants and toddlers under the age of 12 months. Ten per cent of fatal bucket or tub immersions are the result of child abuse. Drowning rates in young children worldwide, many of whom are unsupervised, have decreased little despite preventive strategies such as fencing swimming pools. However, despite the lack of preventive strategies aimed at older children, drowing rates in older children have declined dramatically in the last decade. Ocean drownings are less common than freshwater drownings. Fewer children swim unsupervised in the ocean, and the preventive and rescue efforts of lifesaving and lifeguard associations guarding the beaches have proved effective, especially in Australia and the United States. Reasons for variations in rates of drowning include climate, the availability of beaches, lakes, and other natural and artificial water sources, employment of lifeguards at water parks, use of different kinds of vessels suitable for recreation (kayaks, personal watercraft, etc.), provision and use of lifejackets, and popularity of hobbies, pastimes, and professions associated with a risk of drowning (for example fishing). Recently a study provided proof of the principle that an unexplained drowning or near drowning may have a genetic basis.

Ethnicity

White American children aged 1 to 4 years have twice the drowning rate of African-American children of a similar age, these occurring mainly in residential swimming pools. Conversely, among children and young people aged 5 to 19 years, the rate of drowning in African-Americans is greater than for white Americans. In Australia deaths from drowning in Aboriginal children are more frequent than in whites.

Alcohol

Alcohol affects vision, balance, and movement and is a risk factor in drowning for both adolescent and adult swimmers, as well as for boat operators and passengers, who may fall overboard while intoxicated. Some 25 to 50 per cent of adult drowning victims may have had some exposure to alcohol at the time of rescue, resuscitation, or death.

Pathophysiology

Early animal studies in unanaesthetized dogs suggested that spontaneous respiratory efforts continue for around 60 s after immersion. Complete cardiac arrest supervenes after 4.5 min (mean 262 s). Aspiration is usual in drowning and near-drowning. It has been suggested that approximately 10 to 15 per cent of drowning victims do not aspirate water ('dry' drowning, possibly occurring from laryngeal spasm). However, further studies of these data by Modell suggest the conclusion may be without foundation and the effect may be due to cardiac standstill or other causes of sudden death; careful postmortem examination is required.

The haemodynamic effects following inspiration of liquid are the same irrespective of whether hypotonic, isotonic, or hypertonic solutions are involved, and are similar to anoxic controls. Both groups show a rapid fall in cardiac output, an increase in pulmonary capillary wedge pressure, central venous pressure, and pulmonary vascular resistance. Reduction in the dynamic compliance of the lungs is similar following inspiration of all types of solutions. However, aspiration of large volumes of hypertonic seawater draws fluid by osmosis from the circulation into the lung, resulting in fluid-filled, non-ventilated but perfused alveoli, incapable of normal gas exchange. Aspiration of large amounts of hypotonic fresh water may cause sufficient absorption of fluid into the circulation from the alveoli to cause both acute hypervolaemia and haemolysis, although within an hour redistribution of fluid and pulmonary oedema occurs, causing a decreased circulating blood volume. Although Modell suggested that 85 per cent of human drowning victims aspirate only 22 ml/kg of water or less, Conn estimated that water equivalent to about 10 per cent of body weight may be absorbed from the lungs during freshwater drowning.

The brain has a limited ability to maintain ATP anaerobically when cerebral blood flow is reduced. Without cerebral blood flow, the brain suffers irreparable damage within 4 to 6 min. There is some potential, however, for the restoration of activity for up to 60 min of total anoxia in hypothermia. Death or severe neurological impairment occurs after sumbersion of more than 5 to 10 min. Bystanders' estimates of sumbersion time are usually inaccurate.

Hypothermia

Submersion (not immersion) in ice-water with associated hypothermia is an important cause of near-drowning. Continuous aspiration of cold water results in rapid reduction in the core temperature while the circulation is intact. Such victims may survive, protected by hypothermia, with little or no neurological deficit after long submersion with extreme anoxia. In water at 16 °C with maximum submersion for 10 min or less, a good outcome could often be predicted.

Intact neurological survival occurred in a 6-year-old boy with a rectal temperature of 16.4 °C. after submersion for 65 min when the blood was rewarmed over 96 min in steps of 3 °C. In adults, success is less common. A notable exception was a 31-year-old man with a core temperature of 23 °C who had been asystolic for 80 min

and was warmed by cardiopulmonary bypass and recovered. In warm-water drownings, Frates was unable to show any statistically significant correlation between duration of submersion and survival.

Causes of drowning

Drowning occurs in many different situations including accidental immersion of people with poor or no swimming ability, with head and neck injuries, following cardiac and neurological emergencies (including epilepsy), as a result of impaired ability (including the effects of alcohol and drugs), metabolic disease (including hypoglycaemia), and even child abuse and murder. In countries with large coastlines or bathing beaches, drowning is common and is often caused by swimmers being caught in rip currents (large volumes of water returning back out to sea after onshore wave action): there is no such entity as the frequently suggested 'undertow'. Swimmers in difficulty may be able to shout for help but, contrary to public opinion, those drowning do not. Most drowning victims adopt a characteristic vertical position in the water—legs hang vertically, head tilted back for quick exhalation and inhalation before bobbing under water, with no time nor sufficient breath to call for help. After only 20 to 60 s, victims may submerge permanently.

Clinical features

Prognostic indicators

Success or failure of the resuscitation of the near-drowned depends on the promptness and adequacy of emergency resuscitation and subsequent respiratory intensive care. Up to 25 per cent of drowning victims presenting to the emergency department will die and a further 6 per cent have neurological sequelae.

Those with a normal chest radiograph on admission survive. PaO_2 may not relate to radiographic appearances. Although the cause and pathophysiological changes of pulmonary insufficiency vary depending on the type and volume of fluid aspirated, serum electrolytic and haemoglobin concentrations (or haematocrit) are unhelpful in predicting survival.

Cardiovascular status

This is a better guide to outcome than the neurological status. Mortality is high in victims with circulatory arrest on admission but victims with sinus rhythm, reactive pupils, and neurological responsiveness at the scene of immersion have good outcomes. Victims who are asystolic on arrival at hospital and remain comatose for more than 3 h have a poor outcome unless they are hypothermic. Rapid hypothermia from sudden submersion in cold water (see Chapter 8.5.2) carries a relatively good prognosis, compared with hypothermia after prolonged submersion and cardiac arrest.

Neurological status

Victims who are alert when medical help arrives have a survival rate approaching 100 per cent, whereas the prognosis in those who are comatose with fixed dilated pupils is poor. Victims with blunted consciousness have a survival rate of 87 per cent with no neurological defects, 2 per cent with minor defects, and 11 per cent die. Approximately 40 to 50 per cent of victims who are comatose on arrival have incapacitating brain damage. Those with no spontaneous limb movements and abnormal brainstem function 24 h after the accident have a poor neurological outcome.

A modified Glasgow coma score is helpful in evaluating neurological injury. A score of 5 or less predicts a mortality risk of over 80 per cent. Pupil reactions at the time of arrival differentiate survivors from fatalities but could not differentiate between those with minor or incapacitating neurological deficits. Fixed dilated pupils or total flaccidity are associated with a high mortality. Victims with any motor activity, even posturing or seizures in the immediate postresuscitation period, had a higher incidence of intact survival, but posturing movements persisting or recurring after 12 to 24 h, indicate a high probability of severe brain damage.

An abnormal computed tomography scan in the initial 36 h following an immersion incident is associated with a dismal prognosis. Magnetic resonance imaging with qualitative and quantitative magnetic resonance spectroscopy data may allow a more accurate prognosis.

The gravity of the early clinical state, the estimated duration of cardiorespiratory arrest, the severity of the hypothermia, seizures, and paroxysmal motion activity do not determine the severity of near-drowning encephalopathy. Early EEG patterns with moderate background activity, sleep patterns, response to auditory and painful stimulations, and numerous beta rhythms suggest a good outcome whereas bad outcomes are suggested by high-voltage, rhythmic delta waves, biphasic sharp waves, monotonous EEG, 'burst-suppression' pattern, and the absence of beta rhythms. Children without spontaneous movements and normal brainstem function 24 h after near-drowning suffer severe neurological deficits or death.

Treatment

The near-drowning victim must be treated immediately for ventilatory insufficiency, hypoxia, and the resulting acidosis. A successful outcome depends on early effective resuscitation at the scene and on competent intensive life support. Australian surf lifesaving teaching has shown that respiratory resuscitation in deep water can be effective.

Immediate

Lying the victim on his or her side for assessment of the airway and breathing will assist drainage of any excess water from the lungs. On-site cardiopulmonary resuscitation is necessary, with all victims having supplemental oxygen as soon as possible, preferably at the scene using positive airway pressure (bag, valve, mask). An oropharyngeal airway or endotracheal tube should be inserted in comatose victims if suitably qualified personnel are present. Pulse oximetry is helpful. Vomiting and regurgitation are a significant risk during early resuscitation. Respiratory and cardiopulmonary arrest may occur after an apparently successful rescue, mandating close, uninterrupted monitoring and the early administration of oxygen to all immersion victims.

On hospital arrival

On arrival at the hospital, after initial establishment of a clear airway and cardiocirculatory support, arterial blood gas tensions and pH should be measured. The pH of the blood will indicate whether a metabolic acidosis remains secondary to a significant period of hypoxia.

Mechanical ventilation may be necessary with positive end-expiratory pressure or continuous positive airway pressure. A central venous catheter, or pulmonary artery catheter in selected cases, helps to assess the effective circulating blood volume to guide fluid therapy.

In both freshwater and seawater aspiration, large volumes of intravenous colloid are usually needed while circulating blood volume and cardiac output are estimated. Failure of response to intravascular replacement with 20 ml/kg of colloid is an indication for starting inotropes. Steroid and prophylactic antibiotic therapy do not appear to increase the chance of survival.

Inpatient treatment

Extracorporeal membrane oxygenation has been used successfully for the treatment of adult respiratory distress syndrome secondary to near-drowning, although this addresses only the pulmonary not the cerebral injury. Patients with severe hypoxaemia may also have irreversible cerebral ischaemia.

If adult respiratory distress syndrome occurs, it is usually within 6 h of admission. There is evidence that alveolar epithelial barrier function is well preserved even after aspiration of large quantities of hypertonic salt water. Surfactant has been used with some success in refractory respiratory failure in near-drowning, but it is expensive.

The risk of secondary pneumonia is high, especially when mechanical ventilation has been used. Although prophylactic antibiotics are not recommended broad-spectrum antibiotics may be required. Mild reversible renal impairment (serum creatinine <0.30 mmol/l (3.4 mg/dl)) is usual but severe acute renal failure (ARF)

requiring dialysis can occur. It is recommended that any patient who presents after near-drowning or immersion should be assessed for potential ARF by serial estimations of serum creatinine, particularly when there is an increase in the initial serum creatinine, marked metabolic acidosis, an abnormal urinalysis, or marked lymphocytosis.

Prevention of drowning

Swimming pools and natural bodies of water present the greatest risk to young children. Preventive measures include public educational campaigns in the media, education and supervision by the parents, training in cardiopulmonary resuscitation, and better safety standards and safety devices, including pool fencing. The number of pool drownings in Brisbane (Australia) decreased after legislation made pool fencing compulsory. Strategies for the prevention of drowning should also consider hazards in rural areas.

The swimming and safety skills of young children may be improved by training. Education of the public is essential—in Australia only 17 per cent of surf rescues and resuscitations occurred within patrolled areas (up to 95 per cent successful resuscitation), while 55 per cent were saved and resuscitated outside patrolled areas (62 per cent successful); resuscitation success rates fell with increasing distance from patrolled areas. Some 5 per cent of all non-boating drownings in Australia were overseas tourists; 89 per cent of these were drowned in the ocean.

Eighty-nine per cent of children aged 35 to 59 months and 6 per cent of those younger than 3 years of age are sometimes bathed without adult supervision. An adult should supervise infants aged under 3 and all epileptic children in the bath.

Deaths from drowning in accidents involving boating and personalized water craft can be prevented by using lifejackets (personal flotation devices), but as many as 50 per cent of boaters do not use them. Efforts to increase their use should target adolescents, adults, and boating enthusiasts, especially those using motor boats. Specific measures tailored to prevent drowning associated with vessels capsizing and sinking in Alaska's commercial fishing industry have been successful.

More men than women drown in most age groups, probably reflecting an overestimation of their abilities, and more alcohol consumption. Middle-aged men dominate the group who die of cardiac events (mostly on the surface). Those who die of breath-holding hypoxia tend to be young males. Hyperventilation to increase breath-hold time is a dangerous practice that should be discouraged. Drownings are rare at supervised water parks, probably because of the large number of lifeguards on duty.

8.5.4 Diseases of high terrestrial altitudes

D. Rennie

High altitude terrain and populations

Until the late nineteenth century, mountains were viewed by Europeans as dangerous, mysterious, hostile, and remote. Yet there is evidence that mountainous regions have, for many thousands of years, been the home of large and elaborate civilizations such as that of the Incas, which in the fifteenth century included Ecuador to the north and much of northern Chile and Argentina some 5000 km to the south, an empire of at least 12 million people. The Altiplano or high plateau of the Andes is still home to millions of descendants of these Incas, many of whom have never been below altitudes around 4000 m above sea level.

Temperature tends to determine the fauna and flora. Since, other things being equal, temperature falls with increasing altitude, the high altitude climate tends to be an arctic one. The snow line and tree line become lower with increasing distance from the equator and to live, work, hunt, and cultivate at altitudes above 3000 m is possible only within about 40° of the equator. This includes the Andes of Ecuador, Bolivia, Peru, and northern Chile, the Rocky Mountains in the United States, the high lands of east Africa, the Caucasus, the Pamirs, and the Himalayas, but does not include, for example, the European Alps.

The fall in temperature of some 1°C for every 150 m rise in altitude, irrespective of latitude, and the high winds increase the danger of cold injury. The low humidity contributes greatly to fluid loss and dehydration, as does the increased solar radiation, which may be very much exaggerated by reflection from the snow. These factors are, however, common to most arctic environments and are discussed elsewhere.

The fact that so many people of diverse races have been born and have lived at such altitudes, and the fact that, excluding Antarctica, about 2.5 per cent of the land lies above 3000 m, gives high altitude physiology and medicine an economic, political, and cultural relevance. As modern transport brings the highest mountains within range of the meanest purse, tourists, hikers, mountaineers, and downhill and cross-country skiers, as well as mining engineers, geologists, and surveyors, are flocking up into the hills. Every day in July and August about 3600 people visit the summit of Pike's Peak in Colorado (4300 m) and there is now even a 42-km marathon race up and down that mountain. In 1950, three expert Western climbers first reached the base of the ice fall below Mount Everest's Western Cwm, at 5300 m. Twenty-five years later, in a mere 4 weeks, well over 500 inexpert tourists did so.

The vast majority of mankind lives below 1000 m altitude and, though there is an exponential rise in the numbers of lowlanders going to high altitude, they cannot assume that the ascent can be made with impunity.

Hypoxia

Though the proportion of oxygen in the air (20.93 per cent) is the same at every altitude, the atmospheric pressure decreases with increasing altitude. The total atmospheric pressure at sea level (barometric pressure, PB varies but is usually around 760 torr (mmHg) (101 kPa) and that due to oxygen (the partial pressure of oxygen) is 20.93 per cent of this, that is 159 torr (21.2 kPa). In the lung, the air is rapidly saturated with water vapour at body temperature. At any altitude this is 47 torr (6.25 kPa) at 37°C. The actual combined pressures of gas taken into the lungs is therefore PB– 47 torr and the inspired oxygen tension ($P\mathrm{IO}_2$) is 20.93 per cent of this: 0.2093 × (PB–47). At sea level this is 0.2093 × (760–47) = 149 torr (19.8 kPa). At about 5500 m the atmospheric pressure is about half that at sea level and at the summit of Everest (8848 m) the atmospheric pressure is about 250 torr (33 kPa; one-third that at sea level) and the partial pressure of oxygen is 0.2093 × 250 = 52.3 torr (7 kPa). The partial pressure of water, however, reduces the $P\mathrm{IO}_2$ from 52.5 torr to 0.2093 × (250–47) = 42.5 torr (5.7 kPa). It is clear that the fraction of total inspired gas pressure due to water vapour, which at sea level is 6 per cent, increases with altitude. At the summit of Everest it will be nearly 19 per cent and at 19 200 m (63 000 feet), the total pressure of inspired gases would be a fatal 47 torr—fatal because all of it would be water vapour. Conversely, the proportion of inspired gas due to oxygen, which is 19.6 per cent at sea level, is reduced to 17 per cent at the summit of Everest.

Following a plane's sudden decompression or a rapid balloon ascent, for example, a resting man, just up from sea level, would lose consciousness in a matter of minutes at altitudes between 6400 and 7300 m ($P\mathrm{AO}_2$ = 24–15 torr; 3.2–2 kPa) and in seconds above 7300 m ($P\mathrm{AO}_2$ below 15 torr; 2 kPa), yet during 1 year (1978–9) a total of 14 men, on the three highest peaks in the world (Everest, K2, and Kanchenjunga) were not only fully conscious at rest more than 1000 m higher than this but were able to climb over difficult terrain in bad weather to their respective summits (8848 m, 8611 m, and 8598 m) all without the benefit of supplemental oxygen.

Acclimatization

The difference between the ineffectual newcomer on arrival at high altitudes and the resident is the sum of a myriad of physiological adjustments called 'acclimatization'. This seems to depend solely upon the length of exposure and the age when first exposed and has little to do with genetic factors. The time of greatest adjustment is in the hours and days after arrival at a higher altitude, but changes may continue for years.

The alterations in response to hypoxia affect every tissue. They may be summarized as a series of adjustments which boost oxygen supply to the mitochondria by keeping the partial pressure of oxygen in the tissue capillaries as high as possible, by decreasing the distance oxygen has to diffuse in the tissues, and by increasing the concentrations of respiratory enzymes. A few of the principal steps involved may be summarized as follows.

Ventilation

When $P\mathrm{AO}_2$ has fallen to 55 to 60 torr (7.3–7.9 kPa) at an altitude of about 2000 to 3000 m, the peripheral chemoreceptors are stimulated by hypoxia and ventilation is increased. This initial reaction is amplified over the next 3 or 4 days so that $P\mathrm{AO}_2$ levels which are only very slightly lower than normal (as one would find at, say, 1000 m altitude) now begin to stimulate ventilation. After a few weeks of sojourn, however, ventilation slowly decreases and this process continues for years, though ventilation is always higher in sojourners than in people who were born and have lived all their lives at altitude. With exercise, ventilation increases more at high altitude than at sea level and more in sojourners than in natives.

Driving respiration by hypoxia implies, from the point of view of carbon dioxide (CO_2), 'hyperventilation', since CO_2 is blown off and a respiratory alkalosis develops. The $P\mathrm{CO}_2$ falls in a linear manner with altitude, and the alkalosis is only partly compensated by a rise in urinary excretion of bicarbonate. The effect of the increased ventilation is rapidly to increase the alveolar oxygen pressure by reducing the oxygen gradient between ambient and alveolar air and by reducing $P\mathrm{ACO}_2$.

Pulmonary diffusion

Though no increase in pulmonary diffusing capacity occurs in sojourners at high altitude, natives have increased pulmonary diffusing capacity with a lowered alveolar–arterial oxygen gradient, associated with an increased capillary surface for diffusion. This is due to an opening up of pulmonary capillaries, and to polycythaemia which decreases the distance necessary for gaseous diffusion. In the newcomer to high altitude, exercise is accompanied by a marked fall in arterial oxygen saturation, in contrast to the unchanged values on exercise at sea level, and this may be partly due to a limitation in diffusion.

Circulation

Though there is an abrupt increase in cardiac output on ascent to high altitude, there follows a progressive decrease in stroke volume and maximal cardiac output is reduced at all levels of exercise including maximal exercise. There is no evidence for insufficient myocardial oxygenation and there is argument about whether or not the myocardium is actually depressed by the hypoxia. There is an immediate alteration in the distribution of blood flow. For example coronary and cutaneous flow both fall, cerebral and retinal flow increase, renal flow temporarily decreases, and then, with acclimatization, returns to normal.

The oxygen-carrying ability of the blood is considerably increased by the massive increase in red cell production, in total red cell mass, and, more importantly, in tissue capillarity. It is somewhat offset by the higher haematocrit which increases the blood viscosity and decreases the rate of flow. The shift in the oxy–haemoglobin dissociation curve to the right, which occurs on ascent and is due to an increase in red cell 2,3-diphosphoglycerate, favours unloading of oxygen to the tissues, but this particular adjustment is offset by the shift to the left caused by alkalosis.

Tissue adaptations

Apart from the very major role of increased tissue capillarity which reduces the average capillary–mitochondrial distance and so dramatically reduces the distance for diffusion, increased myoglobin facilitates oxygen diffusion and there is an increase both in mitochondrial density and in many enzymes of the respiratory pathway (e.g. in cytochrome oxidase).

Oxygen uptake

Though the oxygen uptake at rest is not diminished even at very high altitudes, above an altitude of 1500 m the maximal oxygen uptake, $\dot{V}O_{2max}$, falls about 10 per cent for each gain in altitude of 1000 m between 1500 and 6700 m and though it is improved by administration of pure oxygen, it does not return to normal until several days after descent. The cause of this drop in $\dot{V}O_{2max}$ has been debated. If, at any one altitude, the work load is increased, $\dot{V}O_2$ may reach a maximum but ventilation, already increased at high altitude, is still able to increase further and so does not seem to be the factor limiting $\dot{V}O_{2max}$.

At altitude, as opposed to at sea level, arterial oxygen saturation falls with increasing exertion, but at moderate altitudes rises again near maximal exertion. There is probably no increase in alveolar–arterial oxygen gradient and, because of the rise in haemoglobin, the amount of oxygen carried is kept up. Diffusion may be a little limited but diffusion and the blood's oxygen carrying capacity are probably not factors limiting $\dot{V}O_{2max}$. After a few days at high altitude, however, maximal heart rate and, particularly, maximal cardiac stroke volume are reduced, the cause being unclear, and so the inability of the heart to go on increasing cardiac output seems to be the reason for the fact that $\dot{V}O_{2max}$ declines progressively with increases in altitude.

Extreme altitudes

At extreme values, where every increment in height results in a precipitous fall in $\dot{V}O_{2max}$, the oxygen cost of the work of ventilation rises considerably and it assumes an even greater proportion of total oxygen cost when $\dot{V}O_{2max}$ is reduced to really low levels. Moreover, the maximal ventilation itself is reduced at such altitudes and, in addition, there is a diffusion defect within the lungs which becomes very marked on exercise. This, together with the steady decline in maximal cardiac output, causes maximal oxygen uptake to fall very precipitously at 8848 m where PB is around 250 torr almost to resting or basal levels of oxygen uptake, a figure of about 5 m/kg per min. The state of a climber at 8000 m who is comfortable resting in his tent but whose $\dot{V}O_{2max}$ is reached when he puts on his boots, for example, is perilous.

Alveolar gas samples taken on the summit of Everest (8848 m; barometric pressure 253 torr, 33.4 kPa) show an inspired PO_2 = 43 torr (5.68 kPa), and alveolar PO_2 = 35 torr (4.62 kPa). Estimated arterial gas values are: PO_2 = 28 torr (3.7 kPa); PCO_2 = 7.5 (0.99 kPa); pH = greater than 7.7; oxygen saturation = 70 per cent. A number of reports have suggested mild, possibly permanent, defects in cognition in climbers who have ascended to extreme high altitudes.

Illness due to altitude

Acute mountain sickness

For centuries it has been known that when lowland dwellers climb mountains some of them become ill. The illness, usually called acute mountain sickness, generally begins after a few hours, and is characterized by non-specific symptoms such as headache and vomiting. In the vast majority of people it is transient and trivial but in a few becomes progressive, severe, and may be fatal. It is to some extent relieved by breathing oxygen and it is cured by descent to sea level. Its cause is unknown.

Acute mountain sickness may be more than a temporary annoyance. It is of concern because it is probably a manifestation of mild, transitory cerebral oedema, and in a small proportion of cases this oedema may worsen and become clinically overt (high altitude cerebral oedema). Acute mountain sickness is also associated with, and made much worse by, the increased hypoxia consequent upon high altitude pulmonary oedema.

Symptoms and signs

Symptoms come on between 8 and 96 h after ascent and include, after an initial euphoria, lethargy, headache, fitful sleep with arousals, an increasingly severe headache, often occipital, nausea, vomiting, dizziness, and loss of balance. The sufferer lies groaning in his sleeping bag, refusing food, and dozing. After a day or two of rest, the symptoms disappear and are soon forgotten, yet they may recur on further ascent to a greater altitude.

The signs are few: an irritable, depressed, but usually fit person, often, because he is starved, smelling of ketones and vomit, and holding his aching head. The most useful diagnostic sign is ataxia. Occasionally the patient, especially if vomiting and taking diuretics, may be too dehydrated and hypotensive to stand up. At this stage crackles may be heard in more than a quarter of people examined.

In a few, the symptoms rapidly worsen with the onset of pulmonary oedema. Soon the breathlessness, even at rest, is extreme and may be accompanied by a dry cough. The patient, anxious and sometimes incoherent, becomes progressively more dyspnoeic and sometimes orthopnoeic. He is very cyanosed, with a mild pyrexia (38.3°C), a pronounced tachycardia, and sometimes mild hypotension. There are no signs of cardiac failure, but loud crackles can easily be heard all over the chest and frothy sputum, sometimes tinged with blood, wells out of the mouth and nose.

Pulmonary oedema, if very severe, decreases oxygenation and so tends to be accompanied by high altitude cerebral oedema but each syndrome may occur independently as features of acute mountain sickness. In cerebral oedema without pulmonary manifestations, the patient, having had progressively worsening symptoms of acute mountain sickness for several days, becomes incoherent, hallucinated, and too ataxic and drowsy to stand up or look after himself. He may be unable to get out of his tent, or he may do so and then fall into a snow drift and lie there. Soon he is stuporose and snoring stertorously. His sleeping bag may be wet with urine and in a few hours he is in deepening coma. There are rarely any localizing signs; mild bilateral papilloedema is characteristic.

Predisposing factors

Males and females are equally likely to develop the acute mountain sickness syndrome, and the incidence is inversely related to age. There is no good evidence that the incidence of acute mountain sickness relates to prior physical fitness as expressed by, say, maximal oxygen consumption, and much anecdotal evidence from

many experienced observers is that there is no such relationship. We now know, however, that statistically-speaking, the higher the vital capacity, the less the chance of acute mountain sickness and there is increasing evidence that susceptibility to acute mountain sickness is correlated with a poor ventilatory response to hypoxia, measured at sea level. Many other physiological functions have been measured at sea level but none usefully predict whether any one individual will develop acute mountain sickness. Factors related statistically to the occurrence of acute mountain sickness are severe exertion, pre-existing respiratory infection, starting an ascent at a higher altitude; previous acute mountain sickness, especially pulmonary oedema; and having a low vital capacity and a poor ventilatory response to hypoxia. Healthy, high-altitude dwellers seem to be at unusually high risk of pulmonary oedema after brief descent to lower altitudes followed by reascent.

Pathophysiology

On ascent to high altitudes, a great many factors affect cerebral oxygenation: an increase in the rate and depth of breathing; a fall in plasma volume and increase in haemoglobin; an increase in cerebral blood flow due to hypoxic cerebral vasodilatation (to some extent off set by hypocapnic cerebral vasoconstriction); and increases in brain oxygen extraction. The net result is that cerebral oxygen delivery and metabolism are both normal at the sort of altitudes most climbers are likely to experience. But this is not to say that all brain function is normal. There is now good evidence, for example, that at levels of hypoxia frequently met by climbers the synthesis of neurotransmitters such as serotonin is diminished, and this may explain the changes in mood and reversible defects in cognition that have been reported.

Patients with acute mountain sickness, whether this is due to failed or exaggerated physiological adjustments to hypoxia, tend to have ventilation that is inappropriately low for the altitude. They thus have lower blood oxygen and higher PCO_2 levels. Pulmonary oedema causes a vicious cycle of deepening hypoxia.

People with acute mountain sickness also have an antidiuresis and retain fluid. The skull is a rigid box, so small increases in volume lead to large increases in pressure, and recent work suggests that those people who have relatively large ratios of cerebrospinal fluid to brain volume may be able to displace the cerebrospinal fluid more easily and so be protected. There is movement of fluid into the cells, and considerable hypoxic cerebral vasodilatation. As Hackett has argued, neither is sufficient to cause high altitude cerebral oedema. The finding, using MRI, of oedema of the white matter in cerebral oedema of high altitude lends support to the concept that in acute mountain sickness there is vasogenic cerebral oedema. This is an oedema due to movement of fluid and proteins from inside the blood vessels across the blood–brain barrier, perhaps due to a failure of vascular autoregulation and transmittal of increased pressures to the capillaries. This fits with the observation that steroids, which are useful in high altitude cerebral oedema and in prevention of acute mountain sickness, are effective only in the vasogenic sort of cerebral oedema. Hypoxia stimulates the formation of inducible nitric oxide synthase (iNOS) which increases the permeability of the blood–brain barrier, and iNOS may be the cause of the oedema where cerebral capillary pressure is already raised. Autopsies in people who have died from cerebral oedema have shown, besides oedema, numerous tiny haemorrhages from the capillaries.

Moderate acute mountain sickness is associated with oedema of the brain, but exposure to high altitude causes increased brain volume (increased brain water, or blood volume, or both) in men whether they have acute mountain sickness or not. The reason why some individuals are susceptible to developing symptoms is not known, but there is increasing interest in the idea that susceptibility might depend on the ability of an individual's craniospinal anatomy to accommodate volume increases. Since the mean volume needed to raise intracranial pressure 10-fold is 26 ml for an adult, small individual differences in compliance on the part of the intraspinal space might explain differences in susceptibility. Evidence that mild acute mountain sickness is due to cerebral oedema is as yet lacking, though this is likely.

It is known that on ascent to high altitude there is a shift in blood from the systemic 'capacitance vessels' (veins) to the pulmonary circuit. Exercise and cold increase this shift, while phentolamine, an a-adrenergic blocker, decreases pulmonary vascular resistance and improves gas exchange in high altitude pulmonary oedema. In addition, there is a greater than normal hypoxic pulmonary arterial vasoconstriction with a rise in pulmonary artery pressure. Nifedipine, which reduces pulmonary arterial pressure, has been shown to be effective in both the prevention and treatment of high altitude pulmonary oedema. Neither of these processes causes the pulmonary oedema but both contribute to it. Cardiac function is not impaired. Pulmonary wedge pressures, reflecting average pulmonary venous pressures, are normal, as are atrial pressures.

The oedema fluid of people suffering from high altitude pulmonary oedema has been shown, using bronchopulmonary lavage, to be high in protein content, which is characteristic of a breakdown in vascular permeability, and not like that of 'high-pressure' cardiogenic pulmonary oedema. Recent work, however, suggests a more complex picture. Albumin escape rates into the alveolae may not be sufficiently increased in high altitude pulmonary oedema, and the increased alveolar protein might be due to water reabsorption from the alveolae. The oedema fluid also contains large numbers of cells, the vast majority of them macrophages as well as markers of chemotactic activity and inflammation. Various mediators of inflammation, such as E-selectin, are raised early in high altitude pulmonary oedema. This accords with the observation that upper respiratory infections seem to predispose to high altitude pulmonary oedema, but recent studies suggest that the high permeability leak is non-inflammatory.

Cases of high altitude pulmonary oedema after minimal exertion at modest altitudes, in people with congenital absence of the right pulmonary artery, suggest that pulmonary hypertension and shearing forces due to a massively increased circulation (in these cases through one lung) might together contribute to high altitude pulmonary oedema. It seems that in high altitude pulmonary oedema some lung capillary beds are closed off, whether by hypoxic vasoconstriction or by capillary wall oedema and thrombosis. The ventilation/perfusion mismatch increases hypoxia and there is diversion of the whole circulation through the remaining, widely patent capillaries, which are damaged both by the increased pressure and the shear stress of the large flow. As a consequence, they leak in a patchy fashion, causing the typical patchy appearance on radiographs of high altitude pulmonary oedema. Nitric oxide improves high altitude pulmonary oedema by reducing this ventilation/perfusion mismatch.

Incidence

Lacking rigorous, large-scale studies, we can say that acute mountain sickness has been reported below 1550 m, is uncommon below 3000 m, and that the higher the altitude, the faster the ascent, and the greater the exertion the higher the incidence (from fewer than 10 per cent to 60 per cent), and the worse the illness.

Most large studies suggest that some symptoms, for example a bad headache that is not relieved by 600 mg of aspirin, occur in over half of lowlanders going to above 4000 m and that over 10 per cent of climbers have more than one severe symptom at that altitude. High altitude pulmonary oedema occurs in about 5 per cent of people at that altitude, but symptomless crackles in the lung in almost a quarter. Cerebral oedema, which takes a few days to develop, is less common, occurring in perhaps 0.5 to 2 per cent.

Diagnosis

The differential diagnosis is small. For mild acute mountain sickness the non-specific symptoms mean that hypothermia, exhaustion, and dehydration should be considered. The effects of alcohol and marijuana may duplicate those of acute mountain sickness. For pulmonary and cerebral oedema, only infectious diseases (pneumonia or meningoencephalitis) are likely possibilities, though carbon monoxide poisoning due to poorly ventilated tents occurs. Periodic breathing with apnoeic phases is normal at high altitude and not by itself a cause for alarm, though it may be very marked in cerebral oedema. Fever is moderate in high altitude pulmonary oedema, which is accompanied by extreme tachycardia and cyanosis, without purulent sputum. In cerebral oedema there is no meningism and little if any pyrexia, nor evidence of ear infection or of localizing signs. There is a striking absence of any signs of cardiac decompensation (cardiac enlargement, raised neck veins). Giving oxygen—which is expensive, often not available, and has to be given in 4 to 5 l/min amounts—frequently produces equivocal results as everyone at high altitude, with almost any illness or none at all, feels temporarily better on oxygen.

All illnesses improve on descent, but the very dramatic recovery on descent in acute mountain sickness, and particularly in pulmonary and cerebral oedema, is so striking as to be diagnostic in itself. Numerous cases have been described of people unconscious and worsening at 4000 m who were fully conscious at 3000 m.

The physician who sees the patient on descent is, however, usually obliged to perform a battery of tests on the patient who, except in the case of very prolonged cerebral oedema, is recovering fast. The chest radiograph will show scattered fluffy patches of oedema; the electrocardiogram shows simple right ventricular hypertrophy and 'strain', and the cerebrospinal fluid will be normal.

Prophylaxis

Acute mountain sickness and its complications are the consequence of ascent that for any one individual is too high or too fast and are therefore easily and completely preventable by going up slowly. Everyone going to high altitudes has the responsibility to set a schedule for themselves that includes frequent rests, and

that allows them to descend at will. Acute mountain sickness affects the capacity to reason, so everyone must also take responsibility for their fellows, realizing that pulmonary or cerebral oedema can be rapidly fatal and that it is often simple to walk a sufferer down 1000 m, whereas a few hours delay can endanger the patient's life and that of scores of rescuers. Even now, communications are frequently faulty, planes and helicopters may not exist or may crash, or be unable to get near. Energetic propaganda advising slow ascent and rest days and nights has been shown to lower the incidence of acute mountain sickness.

Since insensible water loss is increased due to the increased exertion, the extra ventilation and the dry air, every effort must be made to avoid dehydration, by drinking enough to urinate clear, dilute urine. The climber should also eat plenty, especially carbohydrates. There is evidence that sleeping tablets, which further lower the already lowered oxygen saturation during sleep should be avoided.

Acetazolamide, 5 mg/kg per day, reduces the incidence and severity of acute mountain sickness when taken before and during ascent. It probably works by decreasing cerebrospinal fluid formation and, more importantly, stimulating nocturnal respiration by causing an intracellular acidosis in the respiratory centre so that periodic episodes of apnoea, which are very common at altitude, are abolished and blood oxygen saturation is never allowed to fall. Its principal side-effect is tingling in the hands, feet, and around the mouth.

Dexamethasone, (2 mg every 6 h or 4 mg every 12 h) a glucocorticoid effective in the management of cerebral oedema, has been shown to prevent acute mountain sickness, while reducing the retinal arterial dilation that follows exposure to hypoxia.

Treatment

Rest, aspirin for headache, and a descent of 500 m or so for a couple of nights usually suffice, though ataxia may require the patient be assisted down further. Acetazolamide (250 mg, 8-hourly), started 12h before ascent, increases oxygenation during sleep and relieves symptoms. Dexamethasone (4 mg 6-hourly) is highly effective. Diuretics are logical, given the water retention. The presence of pulmonary oedema or coma necessitates urgent removal down at least 1000 m, and careful observation. In addition to descent, oxygen, should be administered (if necessary through an endotracheal tube at a rate of 5–6 l/min). Immediate descent by even a small amount may save the lives of such critically ill patients, and reliance on air evacuation is dangerous.

In pulmonary oedema, sit the patient up if this makes him comfortable and give frusemide (20–40 mg orally) and morphine (15 mg intravenously). Both these drugs divert blood from the pulmonary to the systemic circuit. Frusemide causes a diuresis and morphine decreases anxiety and respiration rate.

The calcium blocker, nifedipine, prevents high altitude pulmonary oedema in susceptible subjects, improves oxygenation, and reduces the excessive rise in pulmonary artery pressure in pulmonary oedema. It works by improving the matching of perfusion to ventilation, by lessening the formation of oedema fluid, and by decreasing the inflammatory response. Its side-effects (hypotension and tachycardia) suggest that its use should be limited to established oedema. Further studies may confirm that inhaled nitric oxide is useful.

A portable, light-weight hyperbaric bag, made of impermeable nylon, has been developed. The victim lies inside while the air pressure is increased using a foot pump, by 104 torr. For example at 4200 m, where ambient barometric pressure is 449 torr, the pressure in the bag, 553 torr, would be equivalent to an altitude of 2544 m. This is therefore equivalent to taking the patient down 1656 m. Controlled clinical trials have shown the bag to be effective in acute mountain sickness and mild pulmonary oedema, and expeditions should consider taking such bags with them, though descent is still the best, quickest, and usually the safest therapy.

In cerebral oedema, intravenous dexamethasone in large doses (e.g. 8 mg) should be given to reduce the oedema. A cuffed endotracheal tube should be passed, the lungs kept inflated and the bladder kept empty with a Foley catheter (all these devices should form part of the kit of a responsible physician travelling at high altitudes).

Prognosis

This depends not merely on the altitude and terrain but on the speed with which early signs are noticed by the patient's colleagues and their determination and skill in evacuating him to lower altitudes immediately. Once pulmonary oedema and to the rarer but more dangerous cerebral oedema have developed, the patient probably has about a one-third chance of dying. If he lives, full recovery is the rule.

Retinal haemorrhage of high altitude

On ascent, there a considerable increase in cerebral and retinal blood flow. Ophthalmoscopy around 5000 to 6000 m has shown a 20 to 25 per cent increase in diameter of both arteries and veins, and striking increase in the tortuosity of these vessels (Fig. 1). Suffusion of the optic disc with blood due to capillary dilatation may delude the examiner into diagnosing papilloedema.

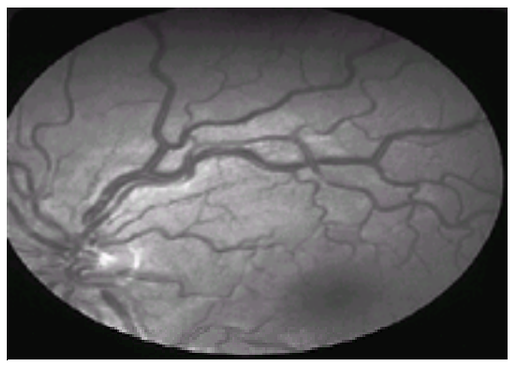

Fig. 1 The left optic fundus of a 26-year-old male climber photographed at 5900 m altitude. Both the veins and arteries are dilated and tortuous and there is hyperaemia of the optic disc as well as mild papilloedema. The climber had severe headache, nausea, and vomiting.

Studies have shown that one-third to one-half of symptomless climbers descending from between 7000 and 8000 m down to 5000 m altitude develop flame-shaped retinal haemorrhages (Fig. 2). The haemorrhages are usually near the optic disc, may be of any size, and are usually unnoticed and resolve on descent, unless they are at the fovea, where they may leave a permanent blind spot.

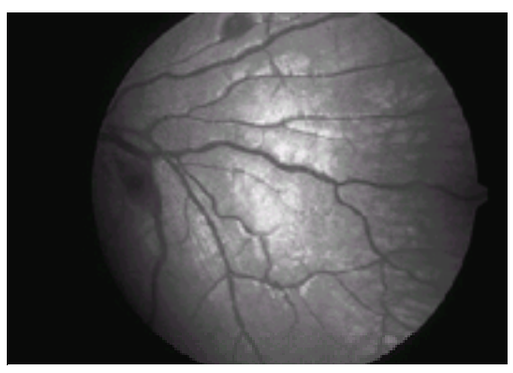

Fig. 2 The left optic fundus of a fit and symptomless 28-year-old male climber photographed at 5900 m altitude. The vessels are dilated, as in Fig. 1, but are less

tortuous. Retinal haemorrhages are shown.

They may be caused by transmission of high thoracic pressures developed during straining or prolonged coughing, and transmitted through a vasculature dilated because of hypoxia. It is probable that the finding of retinal haemorrhages in someone at high altitude is not by itself a reason to counsel descent.

Peripheral oedema

Swelling of hands, face, and ankles may occur in climbers on ascent to high altitude, just as on long-continued hiking at sea-level, and rarely there may be gross anasarca. The oedema is more common in women than in men though no association with menses has been found. It is associated with acute mountain sickness and pulmonary oedema but may occur by itself, and it is relieved by the diuresis that accompanies descent.

Other illnesses of high altitudes

People frequently ask their physicians whether their hearts will be all right at high altitude. The physiological facts are that the normal heart is not limited by heights up to the top of Everest. Unhappily, the doctor has no tests that are sensitive or specific enough to give an accurate prediction, unless the patient has symptoms. The doctor has to remind the prospective trekker that he or she is going on an adventure, and getting away from, among other things, good emergency medical treatment. The physician should be very hesitant to forbid any activity which may have great meaning to the patient, in the absence of actual, as opposed to theoretical, evidence that it is harmful.

On theoretical grounds, people with diseases which limit ventilation, diffusion of oxygen, circulation, and tissue adaptation, will fare badly at high altitudes. Often, however, there is little evidence and doctors should be cautious about the constraints they place on a patient's activities and frank about our ignorance.

Chronic mountain sickness (Monge's disease)

This is a clinical syndrome affecting a few very long-term residents at altitudes, and equivalent to the alveolar hypoventilation syndrome seen at sea level. It is to be distinguished from the persistent failure of a newcomer to adjust to the altitude which results in weeks or even months of acute mountain sickness. It usually occurs in men between the ages of 20 and 50, and the symptoms are of headache, dizziness, depression, irritability, and, most strikingly, drowsiness and even episodes of coma. The signs are those of polycythaemia that is excessive for the altitude (in the high 70s) and cyanosis with suffused, congested conjunctiva, ear lobes, cheeks, and lips, as well as clubbed finger nails. Signs of congestive heart failure may be present. Poor ventilation is reflected by a low oxygen saturation and arterial $P\mathrm{CO}_2$. The right heart may be enlarged on chest radiograph and there is evidence of right ventricular hypertrophy on ECG, itself a reflection of marked pulmonary hypertension. All the symptoms, signs, and physiological abnormalities are cured by descent to sea level, and sufferers should move there permanently.

Myocardial infarction

All idigenous populations studied at high altitudes have, compared with people in the West, low rates of coronary disease, perhaps because they exercise more, eat less (especially less salt), have lower serum lipids and have less hypertension. In the United States, the decline in mortality from arteriosclerotic disease with increasing altitude may be due to migration down to lower altitudes of people liable to coronary disease.

The physician at sea level is often asked by people whether it is safe for them to go up to 3000 or 4000 m altitude to ski or to climb. Logic dictates that as the myocardium has no oxygen reserves, as myocardial oxygen extraction even at sea level leaves no room for improvement, and as coronary flow is decreased, people who have poor coronary circulation will be at great risk when they ascend from sea level and start hard exercise. There are, however, no credible studies, with useful denominators, to guide the physician. A prudent physician might tell the patient not to ascend until he is fit to take exercise at sea level, but unless the patient has had a previous myocardial infarction, we have no evidence that an electrocardiogram, with or without exertion or breathing low oxygen mixtures simultaneously, has any predictive value at all, and the patients' previous history of fitness and of illness is likely to be far more useful.

Pulmonary emboli

Deep vein thrombosis tends to occur in climbers at very high altitudes partly because the erythropoietic stimulus never shuts off above an altitude of about 5500 m so that the blood is very viscous and partly because of dehydration and enforced inactivity due to storms. Pulmonary emboli, sometimes fatal, occur. Evacuation to lower altitudes and the administration of aspirin as an anticoagulant should be tried.

Sickle-cell anaemia

Since cells containing HbS sickle, when hypoxic, become sticky and rigid, it is not surprising that homozygous cases of HbS (sickle-cell anaemia) are at great danger from high altitude. In Denver, at 1609 m, people who are heterozygotes (sickle-cell trait) apparently lead normal lives, but cases of splenic infarction in people with sickle-cell trait have been described in men at between 3500 and 4500 m. One should be cautious in advising anyone with sickle-cell trait to exercise at altitudes above about 2000 m.

8.5.5 Aerospace medicine

D. M. Denison and M. Bagshaw

Introduction

Aviation medicine concerns the welfare of humans in flight through the Earth's atmosphere, an oxygen-rich gas that shields the ground below from solar radiation above. Held to the Earth by gravity, compressed under its own weight, the atmosphere is denser close to the ground than further away. Long waves of infrared light penetrate it easily but heat the ground below. Hot ground reradiates some of this heat at shorter wavelengths which are absorbed by carbon dioxide and water vapour, making the air close to the ground much warmer than that higher up. Short waves of ultraviolet sunlight, absorbed by oxygen molecules early in their journey, create a belt of warm ozone at high altitudes. Some rays intercepted in the same region generate secondary rays that extend lower down. Very few reach the ground. At sea level the atmosphere exerts a pressure of about 760 mmHg (101 kPa); it is variably moist, has a temperature that ranges from –60 °C to +60 °C, and moves at wind speeds from 0 to 160 km/h. With increasing altitude, the temperature, pressure, and water content of the atmosphere fall and wind speeds increase. Some of these features are summarized in Fig. 1. On ascent conditions generally become more severe and more uniform, so turbulence decreases. Most flights through the atmosphere last for a day or less, but some balloon flights persist for longer. The main medical problems of flight through the atmosphere are hypoxia, confining people to small spaces, exposing them to high accelerations, and getting them back to the ground safely should something go wrong.

Fig. 1 Some physical features of the Earth's atmosphere, showing the variations in barometric pressure, air temperature, and ozone concentration with altitude. (NB: There is an international aviation safety convention that all altitudes are given in feet.) The shaded diagram on the left illustrates how the Earth's atmosphere is compressed under its own weight. The atmosphere absorbs much solar radiation.

Space medicine concerns the welfare of humans in flight through vacuums remote from the Earth, the protection of its atmosphere, and the pull of its gravity. Here the problems are those of very prolonged flight times, preserving the pressure and composition of a self-contained gaseous environment, much greater radiation hazards, coping with weightlessness, and engineering the safety of extravehicular excursions that may last several hours.

Atmospheric pressure

Total gas pressure falls with altitude in a regular, almost exponential way, halving every 18 000 ft (5500 m), as in Fig. 2. The oxygen content of the atmosphere (20.93 per cent) is constant to very high altitudes, so the same curve can be used to obtain the ambient oxygen pressure by rescaling the ordinate (also shown in Fig. 2). The oxygen pressure of physiological importance is that which exists in ambient air when it is warmed and wetted on entering the bronchial tree. This process necessarily raises water vapour pressure to about 47 mm Hg, regardless of the total gas pressure outside. The oxygen pressure in moist inspired gas (PIO_2) fully saturated with water vapour at 37 °C is given by the relationship:

$$PIO_2 = FIO_2 (PB - 47)$$

where FIO_2, the fractional concentration of oxygen in the inspirate, is 0.2093 when air is inspired.

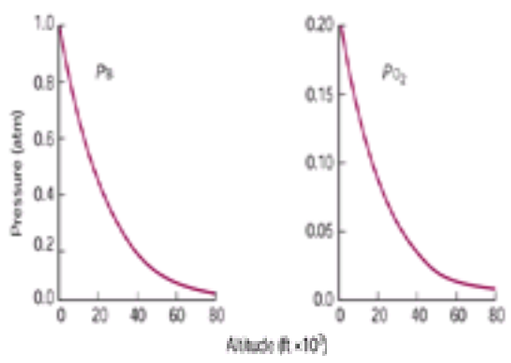

Fig. 2 The variations of barometric pressure (PB) and ambient oxygen pressure (PO_2) with altitude.

Atmospheric temperature

Atmospheric temperature drops more or less linearly with altitude, at about 2 °C/1000 ft (300 m), to the tropopause (40 000 ft (12 200 m)), is stable at –56 °C up to about 80 000 ft (24 400 m)and then rises to almost body temperature at about 150 000 ft (46 000 m), but by then air density is so low that its temperature is unimportant (cf. the dense cold air below).

Atmospheric ozone

Atmospheric ozone is formed by irradiation of diatomic oxygen molecules which dissociate into atoms. At very high altitudes the ultraviolet irradiation is so intense that all oxygen exists in the monatomic form. Lower down, some of the monatomic oxygen produced higher up combines with oxygen molecules to form the triatomic gas O_3 (ozone), at concentrations from 1 to 10 parts per million (**ppm**). The ozonosphere normally exists between 40 000 and 140 000 ft (12 200 and 42 700 m), i.e. from one-fifth to one-thirtieth of an atmosphere. Below 40 000 ft (12 200 m) the irradiation is normally too weak for significant amounts of ozone to form. Concentrations of 1 ppm at sea-level cause lung irritation. Ten times that concentration can cause fatal lung oedema. Although the ozonosphere is at much lower pressure, the ventilation systems of aircraft flying at very high altitudes can take in the ozone and compress it to partial pressures at which pulmonary irritation is a credible hazard.

Mechanical aspects

Propeller-driven aircraft need sufficient air to bite on but not enough to slow them down. They fly best at altitudes below 30 000 ft (9150 m), but if cruising above 10 000 ft (3000 m) they need pressurization to prevent cabin altitudes rising above about 8000 ft (2440 m). They use control surfaces and the resistance of the atmosphere to force changes in direction and ambient air to ventilate the pressurized cabins. Aircraft cabins are usually pressurized and ventilated with sufficient air from outside to dilute the carbon dioxide excreted by the occupants' lungs to an ambient partial pressure of 3 mmHg (0.4 kPa) or less. Many studies have shown that exposure to carbon dioxide at such levels increases lung ventilation slightly and appropriately, but has no other ill effects. Submariners have accepted for many years, with good evidence, a carbon dioxide partial pressure of 7 mmHg (0.9 kPa) as a safe upper limit for continuous exposure of healthy adults for 3 months. Because the ventilating air is dry, humidity in the cabin is low. This dries out the mouth and nose, which is marginally uncomfortable but has no other ill effects. Total water loss from this cause per person over a 10 h flight would be about 100 g.

Jet aircraft propel themselves by throwing a stream of hot gas behind them, but they need atmospheric oxygen to ignite the fuel that does this. They fly best at altitudes above 30 000 ft (9150 m) but below 65 000 ft (19 800 m). Generally, they use control surfaces and the resistance of the atmosphere to change direction and use ambient air to ventilate their pressurized cabins. However, some aircraft, such as 'jump jets', can also manoeuvre by changing their direction of thrust.

Rockets take an oxygen supply with them, and fly best in a vacuum. Space flights are commonly of long duration. There is no atmosphere for control surfaces to work against, or to be compressed to ventilate. Thus all navigation has to be achieved by directional motors and the pressure and composition of cabin atmospheres has to be maintained by on-board systems.

The atmosphere permits vehicles to travel through it at very high speeds. Usually these are achieved and lost so gradually that the changes of pace pass unnoticed, but so-called 'agile' aircraft can make continuous high-speed turns, sustained for a minute or more. The accelerations that such turns produce are proportional to the square of the vehicle's speed and inversely proportional to the radius of its turning circle (as shown in Fig. 3). Because the aircraft turns by applying its broad wing surface to the air, these accelerations are almost perpendicular to that surface and roughly parallel to the long axes of the people within. Most often, aircraft make 'head to the middle' turns, and blood and loosely tethered organs like the liver and heart fall towards the feet (positive '*g*' or $+G_z$ accelerations). Healthy unprotected adults, sitting erect in 'head to the middle' turns will 'black out' at about +3 *G*. Protective devices that raise intrathoracic pressure and apply counterpressure to the abdomen and legs during 'head to the middle' turns can maintain consciousness up to about +10 *G*. When aircraft make 'head-out' turns, (negative '*g*' or $–G_z$ accelerations), mobile organs and blood are forced towards the head, eventually leading to 'red-out'.

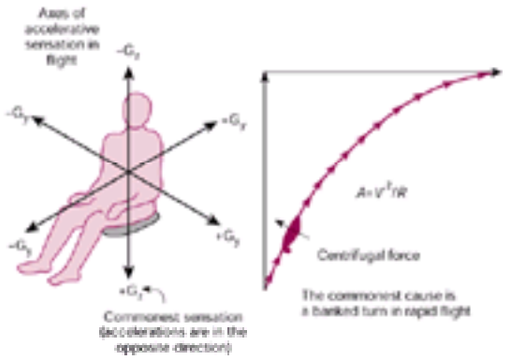

Fig. 3 The axes of acceleration in flight are labelled according to the sensations experienced by the aviator. Thus, when the pilot is accelerated upwards (+ G_z) the body fluids and tissues sare felt to sink towards the feet.

In brief, the important features of the atmosphere are that its temperature and pressure fall and radiation intensities rise with altitude. In addition there is a poisonous belt of ozone at high altitude. The atmosphere also permits vehicles to travel at high speeds and make sustained severe accelerations. The biochemical and mechanical hazards posed by these stresses are extremely challenging but on the whole they only affect professional aircrew. The main biochemical risk, shared by many patients at sea-level and all who fly, is hypoxia.

Biochemical hazards

Hypoxia

Oxygen has a dual role in most animal cells, as it is life-giving and extremely poisonous at the same time. In air, or dissolved in simple solution, it is benign and only ionized with difficulty. However, once an electron is successfully attached to an oxygen molecule it becomes a highly corrosive superoxide ion, forming a cascade of other very destructive oxygen radicals. This is an essential feature of oxygen toxicity, which is discussed in Chapter 8.5.6. Superoxide dismutase and various peroxidases have evolved to protect most cells from the effects of spontaneous formation of oxygen radicals by quenching the ions as rapidly as they appear.

More recently in evolution, other enzymes developed which harness this property of oxygen molecules in a controlled way. There are three sorts: oxidases, oxygenases, and hydroxylases. Quantitatively, cytochrome a_3 oxidase is the most important because, using oxygen as the ultimate electron sink, it allows many metabolic processes to proceed and at the same time unlocks and traps most of the energy the body needs (oxidative phosphorylation). However, several other oxidases that release this energy are unable to trap it. They are used to denature various unwanted products of metabolism.

Oxygenases introduce an oxygen molecule into organic molecules creating new compounds. Although these enzymes, of which there are many, only consume a small fraction of the body's total oxygen requirement, they are particularly important because they are responsible for production and dismemberment of many critical compounds such as the amine transmitters of the brain.

Hydroxylases insert one atom of oxygen and another of hydrogen into organic molecules. They too are responsible for many critical metabolic processes and for the denaturation of many drugs in the liver, kidney, and elsewhere.

These enzymes handle virtually all the oxygen uptake measured at the lips but differ in their affinity for oxygen, described by the Michaelis constant (for oxygen). This

constant (K_{mO2}) is that partial pressure of oxygen which, when all other factors are equal, just allows an oxygen-consuming reaction to proceed at half its maximum velocity. The major oxidase (cytochrome a_3), which is the cocatalyst of oxidative phosphorylation, has a very high oxygen affinity and thus a very low K_{mO2}, of 1 mmHg or less. That means this particular type of oxygen consumption, representing 80 to 90 per cent of the whole, can proceed full tilt down to very low levels of oxygen supply indeed. By contrast (Fig. 4), the other enzymes, which are quantitatively less important but qualitatively critical, have Michaelis constants for oxygen that vary from 5 to 250 mmHg. A fall in oxygen supply will influence these processes long before oxidative phosphorylation is affected and at times when overall oxygen consumption is diminished little if at all.

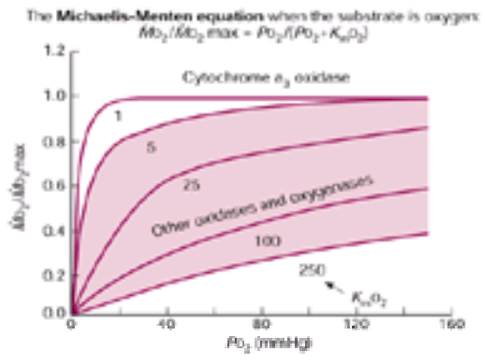

Fig. 4 Curves of oxygen uptake (O_2) as a fraction of the theoretical maximum (O_2max) against the partial pressure of oxygen (PO_2) for a family of oxygen-handling enzymes with Michaelis constants for oxygen (K_{mO2}) from 1 to 250 mmHg.

Although Fig. 2 describes how ambient oxygen pressure is related to altitude, it does not convey the measure of oxygen supply critical to humans, namely the pressure of oxygen to be found in the lungs. That pressure is determined by two equations (Fig. 5). The alveolar ventilation equation states that alveolar CO_2 pressure ($PACO_2$) depends only on CO_2 excretion (CO_2) and alveolar ventilation (Va), so:

$$PACO_2 = k(CO_2/V\text{a}).$$

The alveolar air equation states that since at any one time there is a fixed trading ratio between oxygen uptake and CO_2 excretion ($R = CO_2/O_2$), alveolar oxygen pressure (PAO_2) can be calculated from the moist inspired oxygen pressure (PIO_2*) and alveolar PCO_2, so:

$$PAO_2 = PIO_2^* - (PACO_2/R).$$

Progressive hypoxia leads to a mild hyperventilation (i.e. a rise in Va and fall in $PACO_2$). Knowing this it is possible to sketch a graph of alveolar oxygen pressure against altitude as in Fig. 6(a).

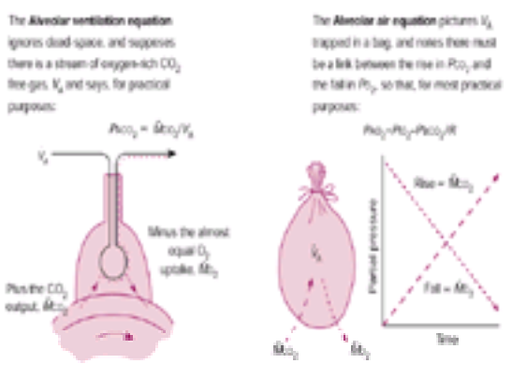

Fig. 5 Graphical representations of the alveolar ventilation and alveolar air equations.

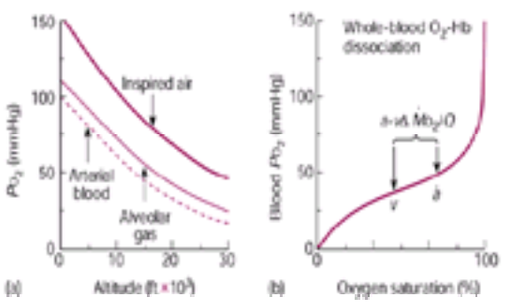

Fig. 6 (a) Variations in moist inspired, alveolar, and arterial oxygen pressure (PO_2) with altitude in normal men. (b) The conventional oxygen–haemoglobin dissociation curve of whole blood plotted to the same pressure scale as the left-hand graph, so that arterial O_2 content can be read directly (at the same horizontal level as the PO_2 curve. It also emphasizes that the arteriovenous oxygen content difference (a–v‡) is proportional to the ratio of oxygen uptake (MO_2) to local blood flow (Q).

When arterialized blood leaves a healthy lung it has an oxygen pressure some 10 mmHg less than that in the alveoli, due to uneven matching of ventilation to perfusion, some anatomical shunting, and an almost nominal obstacle to diffusion. In resting people, the alveolar–arterial oxygen gradient does not change much with altitude, although the relative importance of the factors contributing to it alter considerably; so subtracting a further 10 to 15 mmHg describes the relation between arterial oxygen pressure and altitude (also shown in Fig. 6).

The most important change is the loss of the head of pressure driving oxygen from the alveoli to blood, as the fall in alveolar PO_2 is much greater than that in mixed venous PO_2 (because of the shape of the oxygen dissociation curve). As a result the alveolar–venous gradient for oxygen diffusion is smaller and equilibration slower than at ground level.

People ascending to altitude in a matter of minutes, rather than over several days, make two adaptive responses to hypoxia: an increase in blood flow and the modest hyperventilation mentioned previously. These limit but do not abolish the effects of lack of oxygen. The consequences (Fig. 7) include loss of night vision, impairment of the ability to learn complex and then simple tasks, a deterioration in the performance of already learnt skills, a progressive loss of muscular power (aerobic capacity), and eventually loss of consciousness, convulsions, and death.

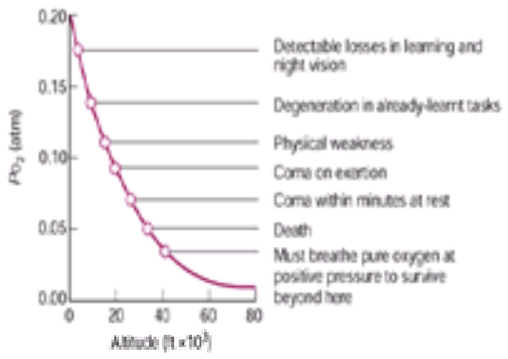

Fig. 7 A summary of the functional consequences of altitude hypoxia.

As Fig. 7 shows, people abruptly exposed to altitudes of 10 000 ft (3000 m) and above are mentally unreliable and physically weak. This altitude is taken as the ceiling above which it is mandatory to provide aviators with oxygen. To be safe, the ceiling that is actually used is almost always 8000 ft (2440 m), at which barometric pressure is 565 mmHg, arterial oxygen pressure is around 55 mmHg (i.e. sitting just at the top of the sloping part of the oxyhaemoglobin dissociation curve), and venous oxygen pressures have only fallen by 1 to 2 mmHg. It is the maximum cabin altitude that is generally permitted in civilian passenger aircraft. There is some evidence that, even at this altitude, people tire more quickly and learn more slowly than at ground level. Some aircraft have a lower maximum cabin altitude, but this requires a stronger and thus heavier cabin to contain the higher pressure, or engines producing a higher mass flow (such as the Concorde supersonic transport aircraft) which makes the aircraft less economical to run.

Two physiological features of altitude hypoxia are especially important in aviation. The first is a total lack of awareness that the mind is breaking down. This means that an affected individual cannot be relied upon to take corrective action, however well trained. It follows that protective equipment has to be designed to sense the hypoxia and come into operation automatically. The second feature, known as the time of useful consciousness, describes how rapidly consciousness is lost and thus dictates how quickly this equipment must respond.

The time of useful consciousness is the interval after the onset of hypoxia during which an aviator can be relied upon to act sensibly. This is a difficult characteristic to test, as sophisticated abilities need to be sampled in an adequate and time-consuming way at moments when the level of consciousness may be changing rapidly. Many studies have confirmed the general relation between this time interval and the altitude of sudden exposure, which is shown in Fig. 8(a). The time of useful consciousness diminishes from about 4 min at 25 000 ft (7620 m) to a minimum of roughly 15 s, which is reached at 35 000 (10 700 m) to 40 000 ft (12 200 m). This asymptote represents the sum of the 7 s or so required for blood to travel from the lungs to the brain and the equal time needed for the brain to consume the oxygen that is already dissolved in its substance.

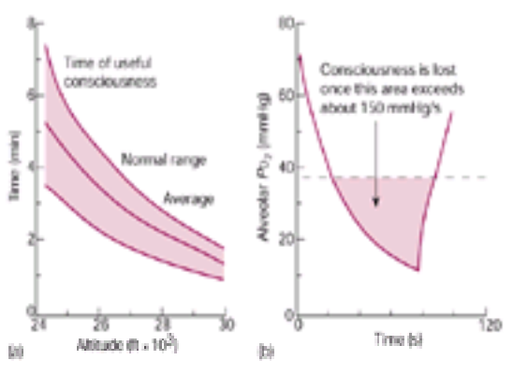

Fig. 8 (a) Variations in the time of useful consciousness with altitude. (b) One way of expressing the dose of hypoxia needed to bring about the loss of consciousness.

Some recent studies have defined the dose of hypoxia that can be suffered before useful consciousness is lost. In trained and healthy men breathing normally (i.e. with an alveolar PCO_2 of 35 to 40 mmHg), it is equivalent on a curve of alveolar PO_2 against time, to an area of 150 mmHg s, where PO_2 is less than 38 mmHg (Fig. 8(b)). However, this is sensitive to many other factors, of which the most important are the degree of hyperventilation and the acceleration that the person is exposed to at the time. Hyperventilation causes cerebral vasoconstriction, and a 'positive *g*' opposes the upward flow of blood to the brain (see below). Sometimes deterioration in consciousness is quickened by vasovagal syncope, but more often the heart is beating quite rapidly as consciousness is lost. Exertion also quickens loss of consciousness, as mentioned previously, because it forces blood to rush through the lungs, leaving insufficient time for oxygen equilibration.

The minimum cabin pressure of 565 mmHg (75.1 kPA) (8000 ft (2440 m)) in commercial passenger aircraft, is sufficiently low to bring a normal person's arterial PO_2 along the plateau of the oxyhaemoglobin dissociation curve until it is sitting just at the top of the steep part (Fig. 6). Because their blood is still fully saturated with oxygen they will not be cyanosed at this altitude. At ground level, many people with chest diseases have arterial oxygen pressures that are as low as 55 to 60 mmHg (or even lower, in which case they become cyanosed). As they ascend to 8000 ft (2440 m) their arterial PO_2 will fall further. If their hypoxaemia at ground level is due to a mismatch of ventilation to perfusion, as is usually the case, the drop in arterial PO_2 will not be as extensive as in normal people (about 40 mmHg), but if it is due to diffusion defect associated with desaturation on exertion, as in some fibrotic conditions, it may be greater. However, in either event, it can be reversed completely by the administration of oxygen, because 30 per cent oxygen at 8000 ft (2440 m) is equivalent to breathing air at ground level. The medical services of all the major airlines can provide a personal oxygen supply for any passenger if they are given notice beforehand. (It is worth checking the altitudes of the patient's destination and of any stopping point *en route* at the same time.)

Oxygen equipment and pressure cabins

Aircraft that fly below 10 000 ft (3000 m) do not need any oxygen equipment at all. Most of those that fly higher have reinforced cabins capable of holding a higher pressure inside them than out. These are of two sorts, the high-differential type, seen in passenger and transport aircraft generally, and the low-differential variety found in military high-performance aircraft. The former, holding a high transmural pressure, usually prevent pressure falling below 565 mmHg (8000 ft (2440 m)). They provide an environment in which oxygen equipment is not needed routinely and the occupants breathe cabin air. However, it is always possible that the pressure-cabin system can fail, allowing the pressure within to fall to the level of that outside. This fall can be limited by descent to a lower altitude, but it is not always practical to put the aircraft into a very steep dive, for reasons of structure or air traffic control. Similarly, it is not always practical to descend below 10 000 ft (3000 m) because, in mid-Atlantic for example, there may not be sufficient fuel for the vehicle to reach the nearest land through the dense air at the lower altitudes. For these reasons, if there is a cabin-pressure failure, an emergency oxygen supply is available for passengers and crew.

A high-differential cabin limits the vehicle's range and manoeuvrability. It also increases the risk of catastrophic damage if the fuselage is punctured. So, military high-performance aircraft are fitted with low-differential cabins. These usually prevent cabin pressure falling below 280 mmHg (37.2 kPA) (equivalent to a pressure altitude of 25 000 ft (7620 m)). That is the level at which decompression sickness becomes a serious hazard (see below). In such aircraft, oxygen equipment is needed routinely.

Sometimes military air crew have to escape in flight. The faster the aircraft is travelling the more difficult this is to do. All modern fighters are equipped with ejection seats to launch the crew into the air stream and get them clear of the tail. Usually, the ejected crew free-fall in their seats until below 10 000 ft (3000 m). This gets them through the cold hypoxic upper air as quickly as possible. A small seat- or suit-mounted emergency oxygen supply sees them safely through this stage. Then

their parachutes deploy automatically as they are released from their seats to get them safely to ground.

Mechanical effects of pressure change

In civilian passenger and transport aircraft the climb to cruise altitude takes about 30 min and involves a fall of about 200 mmHg (26.6 kPA) in cabin pressure (to the equivalent of 8000 ft (2440 m)). Descent to the ground takes much the same time. Body fluids and tissues generally are virtually incompressible and do not alter shape to any important extent when such pressures changes are applied. The same is true of cavities such as the lungs, gut, middle ear, and facial sinuses that contain air, provided that they can vent easily. Gas-containing spaces that cannot vent easily behave differently.

The thoracoabdominal wall can develop transmural pressures of +100 mmHg or so briefly, but is normally flaccid and has a transmural pressure of a few millimetres of mercury. Gas within will usually be at a pressure very close to that outside, and must follow Boyle's law. Ascent from ground level (760 mmHg) to 8000 ft (2440 m) (565 mmHg) will expand a given volume of trapped gas in a completely pliable container by about 35 per cent, which is equivalent to a radial increase of 10 per cent if it were in a sphere or 18 per cent in a cylinder of fixed length. In the abdomen this may cause slightly uncomfortable gut distension in healthy people but it is not an important problem.

The time constant of emptying of a lung that is kept full by continued decompression is less than 1 s in healthy people (peak expiratory flow is normally 1.5 lungfuls/s). Evidence from very rapid decompressions in fighter aircraft shows that healthy people at functional residual capacity can tolerate decompressions of about 200 mm Hg, from about 280 mm Hg to 80 to 120 mm Hg, which are complete in as little as 0.1 s. Even very diseased lungs can vent themselves over a minute or so. In consequence, the risk of lung rupture in normal flight is extremely rare (Fig. 9).

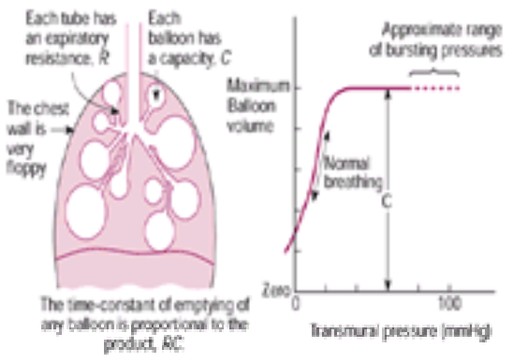

Fig. 9 A graphical summary of the factors determining lung rupture.

The cavity of the middle ear poses a separate problem since it vents easily but sometimes fails to fill because the lower part of the Eustachian tube behaves as a non-return valve, especially when it is inflamed. As a result, the cavity equilibrates quite easily on ascent but does not refill on descent, and the ear-drum bows inwards, causing pain that can be severe.

Altitude-induced decompression sickness

If ambient pressure falls quickly to less than half its original value, the gas dissolved in blood and tissue fluids may come out of solution precipitously, forming bubbles and obstructing flow in small blood vessels. The time symptoms take to develop varies widely between individuals and shortens markedly as the altitude of exposure rises. A guide to these times and variability is given in Fig. 10. Symptoms usually resolve quickly after a descent of a few thousand feet and rarely persist after descent to ground level, on oxygen. Should they persist, treatment should be along the lines detailed in Chapter 8.5.6. The risk continues to be significant in some military flights but, with the exception of passengers who have been scuba-diving very recently, it is not a hazard in commercial flights (see below).

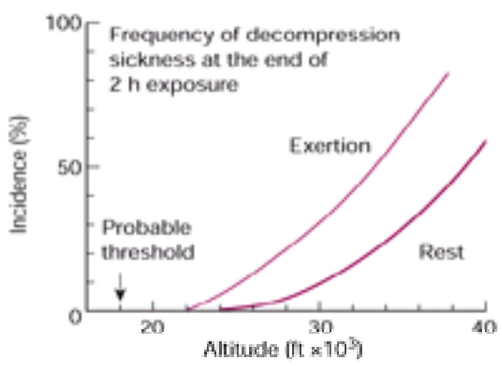

Fig. 10 The incidence of decompression sickness (percentage) at the end of 2 h of exposure to various altitudes in men at rest, or exerting themselves.

Medical problems

Most doctors at times have to consider whether their patients are fit to fly as passengers. No aircraft flight is without risk. These risks include mechanical failure of the aircraft, adverse weather conditions, pilot error, and medical incapacitation of aircrew. Commercial flying, however, is very safe. Worldwide, the accident rate is 1 in 2 million flying hours with some countries achieving 1 in 5 million flying hours. Medical conditions causing temporary or incomplete incapacitation of passengers are not uncommon in flight. The stress of modern of travel should not be underestimated. Passengers on international flights are required to check in at least 2 h before departure, airports often have very long walkways and it may be difficult to obtain help. Many passengers are elderly with heavy luggage, and flight legs may often take 12 h or more.

No significant mental or physical ill effects in healthy people can be attributed to the pressure or composition of cabin atmospheres in normal commercial passenger flight. Flights generate other concerns, namely those of jet-lag, ear and sinus problems, deep vein thrombosis, cross-infections, the safe transport of passengers who are unwell, and the medical fitness of aircrew.

Jet-lag or circadian dysrhythmia

When people are transported across two time zones or more, bodily rhythms, especially sleep/wake cycles, are disturbed and take several days to readjust, at the rate of 1 day per time zone crossed. As a result people feel sleepy when they need to be awake and vice versa. These effects are compounded by interrupted sleep and physical inactivity on prolonged flights. The combined effects may increase people's vulnerability to infections but at present there is no good evidence that this is so. What is clear is that jet-lag affects the ability to think straight for a while and may well interfere with the ability to drive. A number of studies are in progress.

Ear and sinus problems

As the pressure in the cabin changes, gases trapped in the body expand and contract. This can lead to a little abdominal discomfort on ascent and relief on descent, but matters little in healthy passengers. However, air trapped in the nasal sinuses and the cavity of the middle ear can cause pain, commonly more marked on

descent than ascent. Swallowing, jaw-wriggling, and nose-blowing manoeuvres usually sort things out, but passengers who know they have active ear or sinus problems should take decongestants with them and, if the problems are more than trivial, seek medical advice beforehand.

Cross-infection

Transmissible respiratory infections, such as tuberculosis, can be passed to fellow passengers in flight via person to person droplet spread The major obstacle to study is that passengers disperse widely and rapidly soon after landing and may not associate or report infections subsequent to flight. The risk of cross-infection in aircraft is reduced by passing recirculated cabin air through high-efficiency particulate filters which have an efficiency in excess of 96 per cent.

Deep vein thrombosis

There is a evidence that people obliged to sit in cramped positions for a long time, whether in underground bomb shelters, cars, trains, planes, or at home, may be more to liable to develop deep vein thrombosis. Ironically, this was first recognized explicitly during the airborne bombardment of London in 1940. The condition is notoriously difficult to diagnose. Again, because passengers disperse far and wide and may not link thromboembolic phenomena with recent journeys, the evidence relating the condition to flight is unsatisfactory. The mild hypoxia of commercial flight produces complex changes in clotting mechanisms. The topic is highly controversial. Good epidemiological studies are required. Passengers who have recently given birth or suffered abdominal or pelvic surgery, or are taking hormonal medication, are at increased risk and should take medical advice before travelling. The advice is usually simple: 'walk around as much as you can during the flight'.

Passengers who are unwell

Although the reduced total and oxygen pressures of the cabin atmosphere have little effect on healthy people, they can adversely affect passengers who are already unwell. Those at risk are people with definite heart or lung disease or recent chest or abdominal surgery. Almost all can be transported safely provided that the carrier knows beforehand. Usually the provision of 2 to 4 litres of oxygen per minute is sufficient for those with heart and lung problems. Passengers in late pregnancy or with a recent pneumothorax or very recent surgery need particular care.

Amongst the apparently well, those with recent fractures should note that air trapped beneath their plaster casts may expand so new casts should be split before travel. Patients who have recently undergone clinical procedures that introduce gas into the body (for example arthroscopies, air encephalograms, pulmonary needle biopsies) should not fly until it is known that the gas has been resorbed. Passengers should not scuba-dive in the 12 h before flight because otherwise they may suffer decompression illness *en route*. This should be increased to 24 h if the dive depth exceeded 30 ft (9 m). If an apparently fit passenger develops progressive limb pain in flight, oxygen should be given immediately and the passenger advised to stay at ground level for at least 12 h at the next landing point.

Methods of safe transport are well understood. The essence of the problem is passenger education. Passengers should be given accurate and easily understood information about the very slight risks of flying and about when they should seek medical advice or inform the carrier before flying. A number of carriers provide helpful information on their web sites (for example: http://www.britishairways.com/heath).

Medical fitness of aircrew

Commercial aircrew are responsible for very expensive vehicles and for many lives. In battle, military aircrew may be responsible for much more expensive vehicles and weapons and for very many more lives. Because of this and the great costs of training, military forces and airlines demand the highest physical and psychological standards of aircrew. The medical criteria set for entry to training are usually higher than those for aircrew who are already trained and experienced. Commercial and private aircrew need a current certificate that they are 'fit to fly', which can only be provided by authorized medical examiners. In Europe medical standards for commercial aircrew are imposed by the Joint Aviation Authorities in line with the standards set by the International Civil Aviation Authority.

Summary

Aerospace medicine is a subject that is largely understood. The major peer-review journal in the field is *Aviation, Space and Environmental Medicine*, published by the Aerospace Medical Association. 'Fitness to fly' certificates for commercial and military aircrew can only be provided by authorized medical examiners. Further epidemiological studies are needed on deep vein thrombosis, the effects of jet-lag, and the transmission of respiratory infections resulting from commercial flights. For the care of individual patients, airline medical services are a valuable source of advice and will provide in-flight supplies of oxygen if needed. Specialist organizations can supply medical and nursing support for patients who are too ill to travel alone. Surprisingly few patients are truly too unfit to fly.

8.5.6 Diving medicine

D. M. Denison and T. J. R. Francis

Introduction

Divers are exposed to many hazards. Frequently it is too late or impractical to give specific help once trouble occurs, so diving medicine is largely concerned with prevention. It depends upon a thorough understanding of the jobs that divers do and the risks that they run completing them. Almost every diving accident is due to a failure of education or equipment design.

Leaving a typical shore (Fig. 1), the sea bed falls with a slope of about 1 in 50 until it is 200 to 300 m deep. This shallow stretch is the continental shelf. The bed then angles more steeply (roughly 1 in 15), as the continental slope, to descend to vast flat expanses of soft mud, the abyssal plains, at depths of 3 to 6 km, interrupted by occasional mountains and chasms. The deepest point is just over 11 km below the surface. Water is almost incompressible. Ambient pressure rises linearly with depth by 1 atmosphere for every 10 m descent. Diving is confined largely to the continental shelves, i.e. to pressures of 1 to 30 atmospheres.

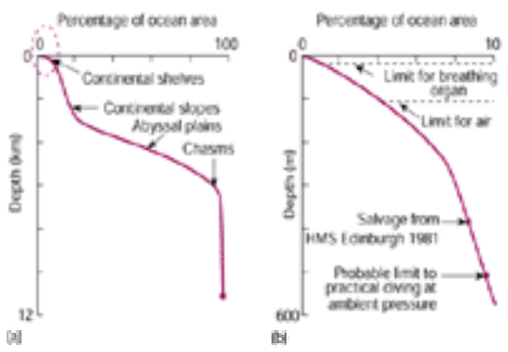

Fig. 1 (a) A cumulative depth versus area plot of the oceans. (b) A similar plot of the top 600 m, including the continental shelves.

Currents, arising from differences in water temperature and salinity, course across the abyssal plains and well up the continental slopes as mineral-rich streams to supply vegetable life in sunlit upper zones. Animals that feed on these plants or each other are concentrated so that 80 per cent of the biomass lies in the top 200 m, mainly close to the shore. Together, these sites form an area equal to that of Africa, infinitely more fertile and, as yet, virtually unfarmed.

Limitations to diving

At the surface, tidal currents are accelerated or slowed down by features of the shore but often exceed the speed at which people can swim (Fig. 2(a)). It may only be practical to dive in slack water, i.e. for an hour or two each day. Waves are often sufficiently high to prevent divers being launched or recovered safely (Fig. 2(b)). Tidal currents tunnelled along marine canyons, and springs of fresh water or falls of cold ocean water can carry divers in unexpected directions without them being aware.

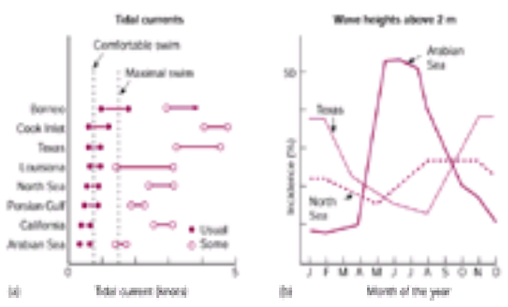

Fig. 2 (a) A plot of the usual and the not uncommonly seen tidal currents in eight diving sites around the world. (b) A plot of the percentage incidence of waves exceeding a height of 2 m at different times of the year in three of the diving sites.

Dawn arrives late and dusk comes early to the sea. Light that is not reflected at the surface is absorbed and scattered, halving its intensity with every 1 or 2 m of descent. It is effectively 'night' below 80 m. Most sports diving takes place in clear shallow waters at placid times of the year. Professional diving, for example harbour work, hull inspections and repairs, pipeline surveys, oil-rig work, and wreck salvage, occurs throughout the year, alongside or beneath large obstructions, in turbid waters where finding the task, let alone completing it, may be very demanding. Artificial illumination is often ineffective because of backscattering.

Underwater, binaural localization of sound is poor. Noises are transmitted almost five times as fast and many times more efficiently through water than air. Loss of air conduction raises auditory thresholds by 30 to 60 dB. Neoprene foam hoods that keep the head warm raise thresholds by a further 30 dB or so. Superior transmission of sound also increases susceptibility to blast injury.

All of the oceans except for the surface waters of tropical seas are too cold for individuals to remain in for long without insulation (Fig. 3). In air, people maintain body temperature at 37 °C with minimal effort when the air temperature is 18 to 24 °C, the zone of thermal neutrality. In water, this zone is high and narrow (35.0 to 35.5 °C). Loss of tactile discrimination and manual dexterity are major problems when working in cold water.

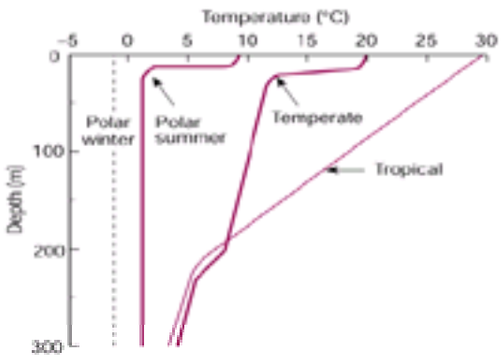

Fig. 3 Variations in sea temperature with site and depth. Note that water temperatures of less than 20 °C are too cold for unclothed individuals to stay in for very long.

Problems of simple immersion

On immersion blood is displaced upwards from the abdomen and legs, some 500 ml entering the chest, distending the large veins and the right atrium. Local stretch receptors signal an excess circulating volume and promote diuresis. On emmersion the displaced blood drops down from the chest revealing hypovolaemia.

Effort in water is lost in moving, making most tasks more tiring and less efficient than on land (Fig. 4). The maximum sustained thrust that swimmers can develop is about 5 kg, which is just enough for propulsion at 1 to 2 knots. On full inspiration an adult swimmer is about 2.5 kg positively buoyant and needs half of their maximum swim power to descend. A swimmer breathing out to residual volume will be about 2.5 kg negatively buoyant and will need half of their maximum swim power to ascend. The swimmer's almost weightless body can be displaced with ease. The body can be poised at will but body weight can no longer be used to apply leverage or torque, or to stay in place when a current is running.

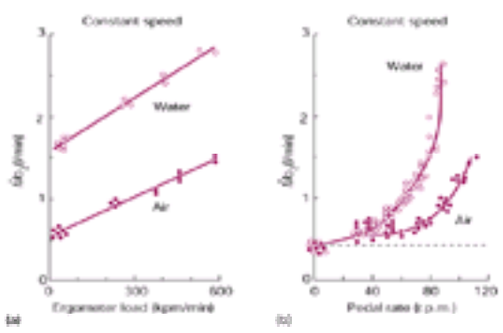

Fig. 4 A comparison of oxygen consumption (O_2) when pedalling a cycle ergometer in air and under water, (a) at a constant speed (60 rev/min) and (b) at a constant light load. Note the high cost of moving the limbs through water. Most people's aerobic capacity is about 2.5 litres O_2/min.

Considerations before diving—fitness to dive

Divers have a physically demanding job and often work in sites remote from medical aid. They must be strong and free of any active or latent condition that could erupt while they are away. Military and commercial divers must have annual medical examinations for 'fitness to dive', and sports divers are urged strongly to do likewise. The medical checks have three aims: to determine whether candidates are fit to swim in swift currents and rough waters at remote sites, to discover whether they are fit enough to rescue a fellow diver in trouble, and to find out if they have any specific problems that would make them a liability to themselves or others under water.

Divers are expected to be bodily fit and mentally stable and free of conditions such as epilepsy and ill-controlled diabetes or asthma. They should not be addicted to alcohol or any other drug and they should not have a history, or other evidence, of obstructive lung disease, ruptured eardrums, or aural surgery. Divers who are generally fit to dive should not be allowed to do so when they have chest, upper airway, or ear infections, or if they become obese. They should not dive while taking any medication that could impair their ability to think clearly or orientate themselves in space correctly.

Three unresolved issues in 'fitness to dive' assessments cause concern: the role of lung function tests, the significance of a probe-patent foramen ovale, and how to deal with a history of asthma.

The role of lung function tests

If a candidate runs several kilometres a day, is a good swimmer, was always good at games at school, and has no history of recent respiratory disease it is very likely that they will be fit enough to dive. The forced expired volume in 1 s (**FEV1**), which should be more than 75 per cent predicted, if multiplied by 35, measures the most air that the subject can process in 1 min. The forced vital capacity (**FVC**), which is a guide to the volume of useable lung, should also be more than 75 per cent predicted because there is good evidence that subjects with a low FVC and, by inference, lungs that are too small for their bodies, are more liable to lung rupture on rapid ascents. The FEV1/FVC ratio is not especially helpful. The expiratory flow rate that matters in diving is the peak expiratory flow (**PEF**)/FVC ratio which is a reasonable measure of the time constant of emptying when the lung is full. The peak expiratory flow rate should be at least one and a half predicted FVC per second.

Patent foramina ovale

On most ascents many bubbles can be detected in systemic venous blood. The bubbles are normally trapped unnoticed in pulmonary capillaries. One in four healthy people has a slightly patent foramen ovale that may allow bubbles to pass into the left heart causing cerebrospinal or coronary gas embolism. Four out of five of the victims of cerebrospinal gas embolism in diving have patent foramina, but it is unclear whether that is cause or effect. Systemic venous bubbles are common but arterial gas embolisms are rare. Bubbles have complicated inflammatory interactions with vessel walls, and any significant load arriving in the lung could trigger pulmonary vasoconstriction, raising right heart pressures and opening a previously 'closed' foramen. Present evidence does not justify excluding one-quarter of the population from diving, as gas embolism is rare.

A history of asthma

It has been the custom to bar candidates with a history of asthma from diving, because of the fear that they were more likely to rupture their lungs on fast ascents. However, childhood asthma often disappears and very many people with current mild asthma are known to have completed very many dives without ill effect. It seems there is a case for relaxing this requirement slightly, but three questions prevail: is the candidate fit enough to cope with a diving emergency, liable to

exercise-induced asthma, or likely to bronchoconstrict on the inhalation of salt water? Perhaps the most reasonable view at present is to allow a candidate with very mild asthma to dive, provided that they can demonstrate a stable and essentially normal spirometry over a 2-month period, that they do not have exercise-induced asthma, and that they do not constrict abnormally to a saline aerosol challenge.

Problems of descent

On leaving the surface, gas in the chest, abdomen, and clothing is subject to Boyle's law. Vertical movements may quickly become uncontrolled because of the positive feedback between depth and buoyancy. The deeper divers go, the denser they become and the more rapidly they fall. The higher they rise, the less dense they become and the faster they ascend. The chest wall can only maintain a pressure difference equivalent to 1 or 2 m of water, so the gas within the respiratory tract (lungs, upper airways, sinuses, the middle ear, and the Eustachian tubes) is virtually at the same pressure as the surrounding sea. The lung of a person breath-hold diving to 30 m (4 atmospheres absolute) is compressed from total lung capacity to residual volume, so they will need half of their aerobic capacity to ascend. Gas in clothing exaggerates these changes, leaving little margin for controlling unexpected ascent or descent.

Descent may lead to several mechanical problems that become obvious early in a dive (suit/facemask squeeze, lung squeeze, sinus squeeze, middle-ear squeeze, inner-ear squeeze, reversed ear syndrome, alternobaric vertigo, and caloric vertigo). These occur commonly, even on breath-hold dives.

The squeezes

On descent, rising ambient pressure may force the diver's face into the air-filled mask, uless the mask is vented, leading to facial oedema and subconjunctival haemmorhages. These will resolve spontaneously and need no treatment. Similarly a dry suit, particularly if poorly tailored, can pinch the skin resulting in linear wheals that are commonly distributed around the neck, axillae, and groins. Again, these require no active intervention but should not be confused with the cutaneous signs of decompression illness. Occasionally suit squeeze can be severe enough to limit a diver's movements in a deep-water emergency. Increasing ambient pressure compresses the lung according to Boyle's law but more blood is drawn into the chest to replace the vanishing lung so lung sqeeze is only serious at great depths in breath-hold dives. When gas in obstructed sinuses is compressed, sinus walls become oedematous and may bleed. The blood or clot is usually expelled by trapped gas expanding on ascent.

When gas trapped in the middle ear contracts it draws the ear drum inwards and the round and oval windows of the inner ear outwards. Difficulty in clearing the ears is the commonest problem in diving. Attempts to clear them by over-vigorous Valsalva manoeuvres have the opposite effects. If one ear clears much before the other disorientation may occur due to uneven stimulation (alternobaric vertigo). If the external auditory canals are unequally blocked at the start of a dive, cool water will enter one canal before the other leading to caloric vertigo. Drum ruptures in any of these conditions normally heal spontaneously. Diving should not be permitted until the drums have healed. Persistent ruptures require surgery.

Problems at the bottom of a dive

For more sustained dives, gas must be delivered to the diver at the same pressure as the surrounding water. It can be sent via an umbilical pipe from the surface, in which case it can flush through the helmet or face mask continuously—which is wasteful of gas but easily engineered—or it can supply a regulating valve that provides gas on demand only. Alternatively, the diver can take self-contained underwater breathing apparatus (scuba). This feeds a demand regulator and rarely lasts for more than 1 h. Professional divers often use a combination of all three systems, i.e. a surface-demand supply for routine use, with a helmet-flushing capability for occasional comfort or emergency use, and a small, back-mounted gas supply ready in case the surface supply fails. Sustained dives can cause biochemical problems (nitrogen narcosis, oxygen toxicity, and the high-pressure nervous syndrome). These influence the choice of the breathing mixture to be used.

Nitrogen narcosis

Air can be breathed safely down to depths of 50 m, although tests of sophisticated cerebral function show that there is already some impairment at 20 m. Below 50 m, mental deterioration becomes obvious, manifested by actions such as divers offering their mouthpiece to neighbouring fish. This occurs as further nitrogen dissolves in some parts of nerve membranes, making them thicker. Replacing the nitrogen with smaller helium molecules allows divers to go deeper. Changes in function develop within minutes and are rapidly reversible, because they depend purely on passive chemical solution. If divers breathe an oxygen–helium mix rather than air they can descend to the lowermost parts of the continental shelves (730 m) without narcosis. Nitrogen narcosis is a wholly preventable hazard of diving, which can be completely reversed within minutes by ascent and needs no treatment.

Oxygen toxicity

Oxygen becomes toxic to the lungs when alveolar oxygen pressure exceeds half an atmosphere, and it becomes toxic to the nervous system when the alveolar, and so arterial, oxygen pressure exceeds 2 atmospheres. Effects are due to complex chemical interactions, rather than physical solution, and so take time to develop and reverse. Oxygen damages the lung by irritating its endothelial and epithelial surfaces. The time taken for symptoms to appear depends upon the dose. It varies from several hours at half an atmosphere PO_2 to a few hours at 2 atmospheres. Above that pressure, the neurological sequelae overshadow the pulmonary damage that still occurs (Fig. 5).

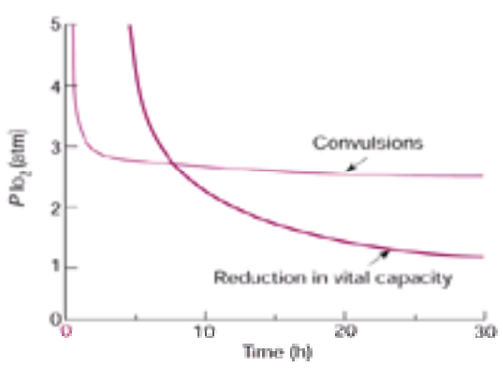

Fig. 5 Commonly observed pulmonary and central nervous O_2 toxicity versus time curves related to inspired PO_2 (PO_2) (constructed from the data of many workers).

High-pressure nervous syndrome

At great depths, people breathing oxygen–helium mixtures show neurological disturbances due to direct compression of nerve tissues, making parts of the membranes thinner. Nerve impulses travel more easily and convulsions result. Thickening the tissues with some nitrogen prevents this and allows divers to go deeper.

Problems of ascent

Return to the surface poses three hazards: expansion of gases trapped in sinuses, lung rupture, and decompression sickness.

Expansion of gas in sinuses

If gases trapped in sinuses cannot escape on ascent they will press on the walls and eventually burst them. Rupture of the ethmoid sinus is rare but feared because of the risk of cerebral infection.

Lung rupture

In a sustained dive the lungs contain enough gas to burst them on ascent unless they are adequately vented. The full lung has a bursting pressure of about 75 mmHg (1 m of seawater) and time constants of emptying that are close to 0.3 s. Divers are taught to exhale continuously whenever they ascend, and to ascend no faster than the bubbles they exhale. In such ascents the lungs have time to empty sufficiently and the risk of rupture is low.

Lung rupture often occurs in divers breath-holding on ascent or ascending too fast. Central tears lead to mediastinal emphysema. Peripheral tears cause pneumothorax. Gas may also enter the circulation as air emboli. Escaped gas expands as the ascent continues, making matters worse. The victim may lose consciousness immediately but otherwise notes dyspnoea, cough, or haemoptysis a few minutes later. Voice change and discomfort in the throat or behind the sternum may also be noticed. There may be surgical emphysema of the neck and upper chest, increased cardiac dullness or crepitus, and/or evidence of a pneumothorax. If air embolism has occurred there will be additional neurological signs. Uncomplicated pneumomediastinums, superficial emphysema, or non-tension pneumothorax are treated by oxygen alone. They should not be positive-pressure ventilated. Tension pneumothorax needs an immediate chest drain. Patients with neurological signs should be recompressed as soon as possible.

Decompression sickness occurs because during any dive extra inert gas, usually nitrogen or helium, goes into passive solution in tissues. On ascent this gas can come out of solution in an uncontrolled way, forming bubbles in the circulation and within tissues. As the ascent continues, these bubbles increase in size and number, blocking blood vessels and distorting or rupturing cells. On redescent the bubbles contract and are eventually resorbed. If the first or the subsequent ascent is slow enough, few if any bubbles are formed, the extra gas diffuses into the bloodstream and out of the lungs easily, and the diver reaches the surface unharmed.

A vast amount of experimental work has been done to determine the safe limits to 'no-stop' diving (Fig. 6) and the depth–time profiles that have to be followed on returning to the surface after any longer dive. Knowledge of safe practice is tabulated in a series of lengthy decompression schedules, which can be obtained from diving clubs or the helplines given below. After very long dives the ascent is very slow and can take several days.

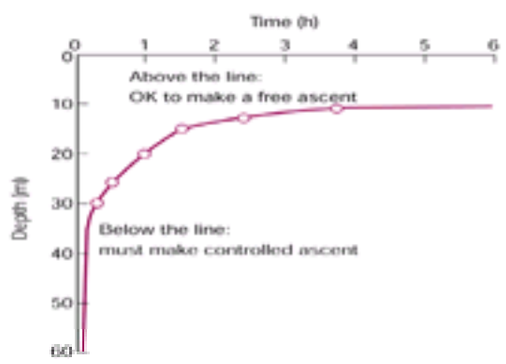

Fig. 6 The 'no-stop' diving curve that determines whether a dive has been shallow and brief enough for the diver to make a free ascent to the surface.

About 1 per cent of dives conducted to recommended schedules, and many badly conducted dives, lead to decompression sickness. The most common presentation in military and commercial diving is limb pain, commonly of the shoulders or elbows in divers and of the knees and hips in tunnel workers. Pain may present a few minutes after a dive or as much as 24 h after the diver has left the water, often as a dull and poorly localized ache of gradual onset. It is not usually made worse by movement of the joint, although weight bearing may make knee pain worse. Physical signs of inflammation are uncommon. Left untreated, the pain will regress and disappear over 2 or 3 days. Recompression commonly improves the pain quickly.

Although sports divers also experience limb pain, neurological symptoms are more prevalent. Sensory disturbance is common, with numbness and paraesthesiae being frequent manifestations, often patchily distributed with no clear dermatomal or peripheral nerve distribution. A particularly fulminant form commences with girdle pain accompanied by loss of sensation and power in the lower limbs. Involvement of the brain is common and may be subtle. Denial is a frequent feature. Any of the higher functions can be involved, including loss of short-term memory, altered affect, visual disturbance, and loss of consciousness. Involvement of the inner ear can present in an identical manner to inner ear squeeze.

Divers who display any manifestation of decompression illness within 24 h of a dive should be managed as if they have the condition. This involves instigating first aid measures and obtaining an informed opinion. The two mainstays of the first aid management are the provision of oxygen (as close to 100 per cent as possible) and rehydration. Within the United Kingdom, informed opinions can be obtained from the British Hyperbaric Association or the Institute of Naval Medicine via their 24-h helplines (0831 151523 and 02392 768026 respectively).

All but trivial cases of decompression illness should be recompressed as soon as possible. It is an effective treatment. The object is to reduce the size of existing bubbles and prevent the formation of new ones, before irreversible infarction and oedema occur.

Problems after the dive

Most ascents are associated with the appearance of many bubbles in systemic venous streams, but these do not usually cause symptoms and so such dives are considered to be 'safe'. Decompression tables that have been established experimentally define the boundaries beyond which more than 2 or 3 per cent of divers will experience symptoms of decompression illness. Such dives are 'unsafe'. There is no doubt that the neurological or other sequelae to unsafe dives may fail to resolve completely, but these are regarded as the consequences of unsafe practices. More recently, diving physicians have been asking whether 'safe' dives lead to insidious, cumulative damage. Although the damage is slight or subclinical, there is definite evidence now that they do. Autopsies on asymptomatic divers with no history of acute decompression illness have revealed that their brains and spinal cords contain considerably more microinfarcts than those of non-diving controls. More importantly, radiographs of the long bones of divers and caisson workers show increasing numbers of aseptic infarcts in a sizeable minority (up to 11 per cent). The incidence is higher in those with a history of overt decompression illness but also occurs in those without. Infarcts can occur after a single decompression, but their incidence rises with age, depth, and diving intensity. Those in the shafts of bone are asymptomatic, but those at juxta-articular surfaces can be severely disabling (dysbaric osteonecrosis). They are more common in caisson workers than divers, but are even seen in professional breath-hold divers, such as the Ama of Japan, in whom the dissolved gas burden must be light. The aetiology is unknown, but gas embolism is the favoured explanation.

Commercial diving, especially saturation diving, causes the lung's total and vital capacities to expand, its FEV1:FVC ratio to fall, and its pulmonary capillary blood volume, as judged by carbon monoxide transfer, to fall. The effects are slight but definite and may be cumulative. The expansions in lung volumes are attributed to the training effects of breathing compressed gases for long times. The fall in the FEV1:FVC ratio is mainly due to the rise in FVC but there are hints of additional small-airway damage. The fall in pulmonary capillary blood volume appears to be due to transient episodes of hyperoxia during saturation diving procedures, but may also be associated with the influx of bubbles from systemic veins on 'safe' decompressions.

It is also known that commercial divers develop a mild degree of high-tone deafness, currently attributed to the noise of gas flows within their helmets.

Codes of safe diving practice given in the Health and Safety Executive's Diving Operations at Work Regulations 1998 and the Compressed Air Regulations 1996 have been accepted nationally and internationally.

Conclusion

Diving is a sometimes very vigorous activity that demands a high degree of mental and physical fitness. It exposes people to several physical and chemical challenges that are reasonably well understood. Because it takes place remote from medical help, there is a strong emphasis on prevention of illness by following

safe practices. The practices have been developed empirically on the non-appearance of symptoms in brief trains of dives. There are now indications that these practices may not be quite as safe as first thought, but the cumulative effects are generally slight.

8.5.7 Lightning and electrical injuries

Chris Andrews

Introduction

Lightning is a powerful force; it provides spectacular displays and has evoked an extensive mythology. The comparatively recent discovery and distribution of electricity have had an equally profound effect, and provide truth to the adage that 'electricity is a good servant and a bad master'.

Epidemiology

Lightning injury

The accepted case fatality of lightning shock is around 30 per cent. Estimated mortality is around 0.3 per million population in the United States each year, compared with 1.5 per million in Singapore, 0.3 per million in Australia, and fewer than 0.1 per million in the United Kingdom.

In the early part of the twentieth century, most individuals struck were outdoor workers (67 per cent) and outdoor recreationalists (28 per cent). The present corresponding figures are 45 per cent and 50 per cent, which may be explained by changes in social and work habits. Indoor strikes (for example by current conducted through communication or power apparatus) continue to account for about 5 per cent of these accidents.

Males are more often injured than females (1.67 males to 0.33 females); the age group most at risk are those aged 20–29 years. Risky situations include sheltering under trees, on open water, on tractors and in open fields, and playing golf. Regional differences correlate well with storm activity and population density in that area.

Electrical injury

Industrial and domestic situations are the two main areas in which electrical injury occurs.

Electrocution ranks fifth in the causes of workplace death, accounting for the death of 10 000 workers each year in the United Sates, with a further 10 million being injured. Most of the victims work for utility companies, followed by mining and construction workers. Contact with power lines causes 53 per cent of fatal shocks, and contact with power tools account for a further 22 per cent. The most dangerous times of day seem to be between 10 a.m. and 3 p.m. on Mondays, Tuesdays, and Thursdays. Most of the victims are trade and labouring staff; sales, clerical, and professional categories are at least risk. Metal ladders and antennas are particularly dangerous and can be hoisted easily into overhead power lines. Codes of safe practice are written accordingly.

In domestic situations, contact with overhead lines is again important. Faulty repair of equipment and faulty apparatus, wiring, and especially power and extension cords account for large numbers of deaths and injuries. Children are at particular risk. Death from domestic electric shock has shown a marked decrease with the introduction of residual current devices (known as RCDs). These detect a large proportion of potentially dangerous situations—they sense if current is diverted from the supply main to earth and interrupt it in a matter of milliseconds.

Mechanisms of injury

Lightning injury

Lightning injury may be sustained in four separate ways. First, a person may be struck directly. Secondly, a nearby object, such as a tree or a building, may be struck, and someone in direct contact with it may receive a shock. Thirdly, without direct contact an arc may 'jump' to a nearby person from the struck object, thereby generating a 'side flash'. Finally, as current disperses away from the base of a strike to ground, an individual may divert current flowing in the ground to themselves. This is termed shock due to increase in earth potential. Recently a fifth mechanism has been proposed — the transient flow of current due to corona and streamer formation.

Both cardiac and respiratory function cease instantaneously under lightning strike, the cardiac arrest being asystolic. Cardiac function restarts under local pacemaker control, but respiratory function does not recommence and secondary hypoxic cardiac arrest supervenes.

The major cranial orifices are portals of entry for lightning current, and from there pathways to the brainstem are short. Respiratory function is thought to be affected there, and thence conduction through the cerebrospinal fluid and then blood to the myocardium.

The QT prolongation resulting from lightning injury may predispose to episodic arrythmias. There is no evidence to that lightning inhibits body metabolism. Resuscitation is as urgent as with any other injury.

Electrical injury

With electric shock it is important to assess the points of entry and exit and the pathway of current through the body. Once the pathway has been determined, a locus for expected injury can be established and the flow of current can be estimated from the applied voltage divided by the impedance of the proposed pathway. Most impedance is in the skin barriers, and the impedance demonstrated is non-linear. There is an initial (contact) impedance which decreases as current flow continues. Impedance also varies with time since application, contact surface area, and frequency.

For currents with a frequency of 15 to 100 Hz, externally applied from hand to hand or hand to foot, relevant parameters include 0.5 mA as the threshold of perception and 10 mA for 'let go' current. A 50 per cent chance of fibrillation exists at 2000 mA conducted for 10 ms, or at the other extreme 100 mA conducted for 10 s. Direct internal application of less than 200 µA to the heart muscle may induce fibrillation.

Joule heating may account for tissue damage in the path of the current. It may be calculated from the power dissipation in the tissue—the square of the tissue current times its impedance, the former often being hard to estimate. The complex phenomenon of electroporation, where cell membranes are breached by the electrical

induction of unstable pores in the membrane, may alternatively lead to cell death.

Presentation of the injured person

Lightning injury

A witnessed strike offers the best chance of resuscitation. The victim is not dangerous to touch, and does not constitute a risk to the rescuer. Immediate cardiopulmonary resuscitation is paramount. It has been stated that:

> Any person found with linear burns and clothing exploded off should be treated as the victim of a lightning strike. Feathering burns are pathognomic of lightning injury and occur in no other type of injury. ...Another complex diagnostic of lightning injury includes linear or punctate burns, tympanic membrane rupture, confusion, and outdoor location...
>
> Cooper *et al*. (2000)

In assessing a lightning victim, the following features must be sought.

Cardiovascular and pulmonary consequences

Asystolic arrest is the main cardiac event in lightning injury. ECG signs may take many forms, with ischaemic and infarct forms. They almost invariably resolve completely over time. Alterations in QT interval and arrythmias of many kinds are seen. ECG changes may not occur until late in the course, and so are a poor diagnostic tool. Respiratory arrest is common. A person not suffering cardiopulmonary arrest is highly unlikely to die from lightning strike ($p < 0.0001$).

Neurological consequences

Direct neural injury may occur both centrally and peripherally. All forms of intracranial bleeding have been reported. Direct cerebral damage particularly affects the basal ganglia, cerebellum, and brainstem. Dural tears, scalp haematomata, and fractures are also seen. Seizures occur as a result of anoxia and injury.

Peripheral nerve injury, including autonomic injury, can give prolonged and long-lasting disability which often develops late. Other late features include spinal cord atrophic paralysis, cerebellar ataxia, inco-ordination, paraesthesiae, and aphasiae. Ongoing complex regional pain syndromes may be seen.

Keraunoparalysis and burns

Over 70 per cent of victims demonstrate keraunoparalysis. This is a syndrome of cold, pulseless, mottled, and asensory extremities. The syndrome resembles a compartment syndrome and occurs in the line of passage of the strike current. It resolves spontaneously within 24 h with no sequelae, and requires no surgical intervention.

Burns are of minor consequence in lightning injury, and again require little intervention. Entry and exit burns may be full thickness though small. Arborescent (feathering) burns resemble fern-like patterns on the skin. Their aetiology is unknown, but they fade within 24 h. Linear burns are due to the passage of hot plasma tongues over the skin. Eschar is simply allowed to separate without further treatment. Flash may be seen, like sunburn or welder's flash, from the profound radiation of the strike. Sheet burns resulting from efflux of hot plasma may be a variant of linear burning, since both seem to follow moisture and sweat lines. There may be contact burns from heated metal such as buckles and coins.

Eye, ear, and explosive injuries

The explosive force of the lightning insult blasts clothing apart, and may cause percussive injury to the lungs and abdominal viscera. Tympanic membranes are usually ruptured, perhaps from the explosive force of the strike. Percussive eye injury, particularly retinal, has been reported. Cataracts may develop much later.

Other injuries

Renal and haematological damage have occasionally been reported. In pregnant women the fetus is unlikely to survive. Menstrual and sexual difficulties have been reported.

Electrical injury

In contrast to lightning injury, victims may suffer prolonged attachment to the source of electrical current, making them dangerous to touch. Before resuscitation they must be removed from the current source, and this usually means interrupting the current flow at the supply point.

Burns are far more serious, and may merit intense surgical treatment. The likelihood of internal burning (remembering the possibility of electroporation) may require further surgical intervention. Cardiac and respiratory burns may also exist.

Cardiovascular consequences

Fibrillation is the most common cardiac abnormality following electrical injury. Cardiopulmonary resuscitation is urgently required. Electricity suppliers have standard first aid/resuscitation procedures. Cardiac dysfunction may persist for long periods, and ECG signs may not resolve.

Neurological and muscular consequences

Neural injury may be categorized into early and late syndromes, at cerebral, cord, and peripheral level.

Early tetanic muscular contraction locks the victim onto the electrical conductors. This tetany may compromise respiratory function. Neurological injury may be hard to distinguish from hypoxic and vasospastic injury. Similarly, neural injury is often hard to separate from ischaemic injury due to vessel spasm. Early and late generalized convulsions may occur. Pareses and paraesthesiae may develop, both early and late.

In the long term complex regional pain syndromes and other chronic pain syndromes must be considered.

Burns

Burns are often severe in electrical injury and merit much treatment effort. Arc and flame burns and contact burns from current entry and exit are seen. For example, tetanic gripping of the electrical conductor causes grasp burns to the hand.

Severe internal thermal or electroporation damage may occur. The management is largely surgical. Joints, ligaments, and tendons may be severely damaged by the heat generated, and osteonecrosis may be seen.

Other aspects

Widespread muscle damage generates myoglobin that must be cleared by the kidney with a severe risk of renal damage. Other metabolic and biochemical disturbances secondary to hypoxia may develop. Massive hyperkalaemia has implications for the use of depolarizing muscle relaxants.

Eye damage includes retinal damage, with punctation and detachment, and thermal damage to other media. During follow-up the possibility of ocular pareses and cataracts must be recognized.

After shock during pregnancy the prognosis for the fetus is poor. Non-focal injury is more likely in survivors.

Psychological consequences of electrical and lightning injuries

Although electrical and lightning injuries are fundamentally different in nature and management, their psychological sequelae are similar. Sequelae may be disabling. To a large extent psychological consequences of persisting pain and dysfunction cannot be separated from organic psychological consequences.

Emotional sequelae include depression, often with organic features. It is hard to separate this from the emotional reaction to injury and continuing disability. Aggression, anxiety, and phobic features are common. Marital disharmony commonly follows social withdrawal, disinterest, and a fatigue state. Loss of interest in sex and in relationships, together with a feeling of fault or guilt, may be associated. Sleep disturbance is common.

There is loss of short-term memory with impaired concentration, higher mental functions, and loss of identity and ability.

Treatment of the injuries

First, urgent and life-saving treatment must be administered. Secondly, there must be surveillance for delayed sequelae, and thirdly long-term monitoring for morbidity, including cataract formation and psychological problems.

Lightning injury

First the casualty is resuscitated and evacuated. Cardiopulmonary resuscitation is continued until medical emergency help is obtained. Ventilation and cardiac support may be required.

ECG monitoring must be used to detect subtle effects like QT prolongation. Associated trauma is treated.

In the long term, patients are observed for development of pain syndromes. Ocular and auditory function are monitored. Sensitivity to the psychological sequelae is required, and preventive interviewing may be useful.

Carbemazepine, gabapentin, clonazepam, flecainide, and mexilitine are useful to control neurally derived pain and resulting weakness. An antidepressant (see below) is a useful adjunct to this.

Electrical injury

Urgent life support is indicated. Ventilatory and inotropic support and correction of arrhythmias may be required.

For burns, progressive debridement and/or amputation may be needed. Renal damage should be prevented.

Associated trauma is treated. Ocular and auditory function are monitored and psychological disturbances are reviewed. In the long term surveillance is similar to lightning injury.

Psychological elements

In all cases the management of the psychological syndrome is paramount and may be the greatest determinant of long-term functional capability. Awareness of the impact of the injury on employment and relationships and social networks is fundamental. Cognitive and computer aids are being developed.

An antidepressant such as a selective serotonin reuptake inhibitor, possibly citalopram, paroxetine, venlafaxine, or a tricyclic such as clomipramine, may be useful.

Early and continuing neuropsychological assessment is desirable.

Controversy

The place of polaxamers in discovering the extent of electroporation and in delineating debridement levels is of great interest.

The mechanisms of the psychological disability remain to be elucidated. Victims are frequently 'written off' as malingering or simply depressed, when a more extensive syndrome exists. The useful duration of monitoring of otherwise asymptomatic people has not been determined.

8.5.8 Podoconiosis

S. M. Evans, J. J. Powell, and R. P. H. Thompson

Introduction

Podoconiosis (from the Greek *podos* 'of the foot' and *konia* 'dust'), named and characterized by the late Dr Ernest W. Price, is a non-filarial form of elephantiasis affecting the feet and legs of barefoot agrarian communities. It is endemic in parts of Africa, Central and South America, northwest India, and Indonesia. The disease is an obstructive lymphopathy, caused by the penetration of fine particles of silica and aluminosilicates into the tissues of the foot.

Aetiology

Areas of high prevalence are typified by a reddish brown volcanic soil that has a high clay content and is extremely slippery after rain. A large proportion of the soil comprises particles of less than 2 µm in diameter, in which the aluminosilicate kaolinite predominates. Other environmental features of areas in which podoconiosis occurs include high altitude (1250 to 2500 m), average daytime temperatures of 20 °C, and a high hot-seasonal rainfall in excess of 1000 mm annually. In these conditions, weathering of the volcanic alkali basalt rock favours formation of a fertile clay soil, which attracts subsistence farming and a largely barefooted population. In adjacent, tropical, non-endemic, lowland areas, more complete chemical degradation of the parent rock reduces soil fertility and also the biological activity of the soil particles.

The greater exposure of men to soil particles during farming is probably responsible for their higher incidence of podoconiosis compared with that of women. In areas of high prevalence, for example in highland areas of East Africa, up to 70 adults in every 1000 are affected. There appears to be a familial tendency to develop the disease, and this may reflect an inherited inability of the immune system to process and detoxify ultrafine particles. The socio-economic consequences of belonging to such a family, in terms of marriage opportunity and employment, are considerable.

Microparticles

Using polarized light microscopy, birefringent particles are frequently seen in lymph node macrophages, but in tissue sections from the foot electron microscopy is needed. Price's X-ray microanalytical studies of the tissues of the foot and femoral nodes in areas with podoconiosis demonstrated the presence of ultrafine particles, consisting mainly of silicon and aluminium with smaller amounts of titanium and iron. Particles were found both within macrophage phagolysosomes (Fig. 1) and free within the tissue, and their elemental compositions matched those of the fine particles of the local soil. Morphological analysis identified kaolinite (an aluminosilicate), amorphous silica, titanium and iron oxides, with some quartz, exactly as in the local soil. Such mineral particles are also found in many areas of the world without podoconiosis so the exact reason for their pathogenicity can only be hypothesized. However, fine particles have been shown to be important aetiological agents in a number of human diseases, in particular chronic inflammatory lung conditions such as silicosis and asbestosis, and asthma.

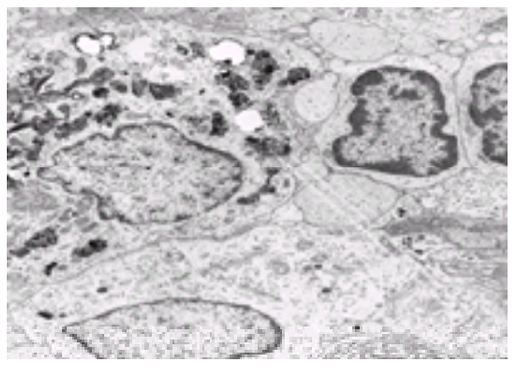

Fig. 1 Electron micrograph of a femoral lymph node of an elephantiasic person. Note the two macrophages on the left, the upper of which contains a number of clumps of microparticles. X-ray analysis showed that most of these were silica with varying amounts of aluminium, iron, and titanium (×7200).

In podoconiosis, the small size of the particles is likely to play an important role in dictating toxicity. Evidence for this comes from data showing that a significantly higher proportion of the soil in endemic areas consists of particles less than 5 µm in diameter than in neighbouring non-endemic areas. Indeed, particles released after digestion of diseased femoral lymph nodes were found to range in size from 0.3 to 6.0 µm. Transcutaneous entry of macromolecules and micron-sized particles is well recognized, but it may be facilitated in podoconiosis by the presence of larger, abrasive crystals of quartz in the silt fraction of the soil.

The volcanic origin of the rock is clearly important. Using thermoluminescence, specific defects in the crystal lattice, which are fixed in the rock as the hot volcanic lava undergoes rapid cooling, have been identified in microparticles from affected areas. Furthermore, newly fractured mineral crystals exhibit much higher reactivity than those that have been weathered. The microtopography of particle surfaces has been analysed by thermostimulated exoelectronic emission, which also identified a characteristic peak in soil fractions from endemic areas.

Another factor is persistence, since the particles are not easily dissolved or degraded in the tissues. In experiments with cultured murine macrophages, soil particles from endemic areas were toxic at a lower concentration than the corresponding soil fraction from non-endemic areas. Thus, the particles have a direct toxicity to immunocytes but this could be modified by interactions with other ions (such as iron) or biomolecules.

Once internalized, toxic mineral microparticles exert a range of effects, from mild irritation to extensive fibrosis and obstructive lymphopathy.

Pathology

The earliest histological feature of podoconiosis is seen in the dermis where collections of lymphocytes accumulate around channels of the superficial lymphatic plexus, sweat ducts, and sweat glands. A chronic inflammatory infiltrate is evident in the adventitia of the deeper lymphatic vessels, with subendothelial oedema gradually replaced by fibrosis. Similarly, lymph node capsules are thickened by fibrosis and the interfollicular sinuses become dilated and packed with lymphocytes. Macrophages are evident in the cortex of the node and frequently contain aggregations of particles, which often exhibit birefringence. With increasing severity of disease, fibrosis becomes more advanced, especially at the corticomedullary boundary.

Clinical appearances

The clinical manifestations of podoconiosis depend upon the degree to which fibrosis occurs in the dermis. Two main types are described, although most cases show

features of both types, between the two extremes.

In the soft or 'water-bag' type, there is little dermal fibrosis and minimal hyperkeratotic change. The skin is smooth and can be grasped between the fingers. Lymphoedema is marked and extends gradually from the dorsum of the foot to involve the whole lower leg. The swollen limb pits on pressure (Fig. 2(a)).

Fig. 2 Clinical types of elephantiasis. (a) The soft or 'water-bag' type. Swelling is readily reduced by compression or elevation. The skin is soft and can be pinched off the bones. (b) The hard or 'leathery' type. The skin is rough and fixed to deeper tissues. Nodulation is seen on the toes and dorsum of the foot.

By contrast, the hard or 'leathery' type is characterized by extensive dermal fibrosis, which may be more than 3 cm thick. The skin is fixed to deeper tissues, does not pit, and hyperkeratosis and hyperpigmentation are marked. In front of the ankle and behind the toes, there may be many folds of firm, rough skin, which are easily traumatized, and multiple nodules often develop (Fig. 2(b)).

A subgroup of the hard or 'leathery' type is the 'slipper' type, in which hyperkeratosis is distributed around the back of the heel, the borders of the sole, over the toes and on to the dorsum of the foot. Lymphatic obstruction is confined to the deep lymphatics of the plantar region so that the dermal fibrotic reaction occurs in the distribution of a slipper.

Natural history

Podoconiosis usually starts between the ages of 10 and 20 and progresses at a variable rate over months or years. The first symptoms are a burning sensation of the soles of the feet and itching of the lower legs, usually intermittent and unilateral at first, especially in bed at night or after exertion. Uncovering or raising the leg usually alleviates symptoms, but alcohol consumption, exercise, or menstruation may exacerbate them. The first swelling is usually evident just proximal to the first toe cleft, and spreads after a time to involve the rest of the dorsum of the foot, and later the whole lower leg. The chronic progression of the disease is marked by intensification of the burning discomfort and itching, and it may be punctuated by acute episodes of lymphangitis. Infected ulcers and cellulitis may complicate the clinical picture. Both legs are always involved, although there may be considerable asymmetry. Once established, the femoral lymph nodes are often enlarged and tender but they rarely suppurate.

Management

Price has emphasized the importance of obtaining the co-operation and understanding of patients in order to maximize the benefits of intervention.

The mineral load in the tissues cannot be reduced once it has been absorbed. Therefore, the main strategy is aimed at prevention. Provision of footwear is the most obvious protection, and it is highly effective, but matting to cover the bare ground of residential huts is also used. Occasionally, it is possible to arrange a change of employment or residence.

Anti-inflammatory analgesics, such as aspirin, are effective for burning discomfort. Reduction of oedema will improve itching, more easily accomplished in the early phases of the disease and in the soft or 'water-bag' type. Elevation of the foot of the bed and elasticated stockings may be sufficient initially, but a programme of treatment using compressive methods (compressive bandaging or intermittent compression machines) is needed in more advanced cases.

Finally, a variety of traditional drugs in tropical Africa, derived from plants, has been used in podoconiosis with the aim of reducing fibrosis and progression of the disease. Some of these contain benzopyrones, coumarin, and toxerutin, which may have antifibrogenic properties, but none has yet been convincing in the long-term control of limb swelling in this unpleasant and disfiguring disease.

8.5.9 Radiation

J. R. Harrison

There are two types of radiation: ionizing and non-ionizing. The former includes radiation from naturally occurring sources, such as radon gas or cosmic rays, and man-made sources, such as X-rays. The latter includes radiation from natural ultraviolet light and radiowaves and man-made emissions from radio transmitters and mobile phones. In all cases the electromagnetic radiation may cause biological damage by the deposition of energy in the body. They have the capacity to produce early acute effects and some have the ability to produce late effects, such as cancer. High doses can cause early death.

Ionizing radiation

Physicians are likely to become involved with radiation issues if people are over-exposed. For example, the theft of a caesium-137 radiotherapy source in Goiânia, Brazil led to 50 people being over-exposed, resulting in four deaths. In that incident large areas of land and property were contaminated. In the accident at the Chernobyl nuclear power plant 28 members of the workforce died of radiation-related injuries. The release of radioactivity also led to widespread contamination of houses, land, and foodstuffs. Experience shows that in these situations both individual and public health concerns dominate the agenda and place a burden on health professionals.

In the early twentieth century, due to a lack of knowledge about the harmful biological effects of ionizing radiation, many radiologists received high doses to their hands (often calibrating their machines by an erythema dose). Subsequently many died of radiation-induced cancers.

Atoms, radioactivity, and radiation

Some isotopes of elements are unstable and undergo radioactive decay. The time necessary to reach a stable form depends on the element and ranges from a few fractions of a second to several thousand years. The unit for radioactivity is the becquerel (Bq): 1 Bq equals one atomic disintegration per second. The average amount of natural potassium-40 (^{40}K) in every kilogram of the average person is 60 Bq. This means that about 15 million ^{40}K atoms disintegrate inside a person each hour.

Electromagnetic radiation (X-rays and gamma rays) or subatomic particles such as alpha and beta particles and neutrons can all interact with matter and tissues and cells. The different types of radiation penetrate matter, the extent of the penetration being determined by the size, charge, and energy of the particle/wave. Alpha particles are stopped by a thin piece of paper or the dead layer of the skin, while beta particles can penetrate the hand but will be stopped by a thin sheet of aluminium. X- and gamma rays penetrate the body and an aluminium sheet but are stopped by lead. Neutrons penetrate most materials but may be stopped by thick polythene or concrete (hydrogenous materials). These overall properties of radiation affect the degree of cellular damage following exposure and the methods needed for protection.

Ionizing radiation has sufficient energy to break chemical bonds and ionize atoms and molecules, producing ion pairs. These ions are charged and are capable of causing further ionization and energy deposition leading to physicochemical changes in cellular constituents. Some of these changes may be of no biological consequence and others may be repaired, but there is a finite probability that damage may cause cell death or irreparable damage to vital cell constituents such as the DNA.

Dose quantities

The absorbed dose is a measure of the mean energy absorbed by unit mass of tissue, and the absorbed dose in gray (Gy) is equal to the deposition of one joule (J) of energy in one kilogram (kg) of tissue. Overall, the greater the dose, the greater the likelihood of a biological effect being seen.

Various radiation and tissue weighting factors are used to convert the absorbed dose in gray to an effective dose in sievert (Sv). This system allows external and internal exposures to be combined into one dose—on the basis of equality of risk. Once a radionuclide is incorporated it will continue to expose surrounding tissues until it finally decays or is excreted.

Submultiples of the gray and sievert are commonly used, such as the milligray (mGy) and millisievert (mSv), which is one-thousandth of a sievert. For example, the world average individual dose received due to exposure to natural background radiation is about 2 mSv per year compared with the occupational dose limit of 20 mSv per year.

Acute radiation sickness

An acute exposure (measured in seconds, minutes, or hours) causes cell damage, the severity of which depends on the tissue type, or even death. It is characterized by a sudden sensation of anorexia or nausea and is soon followed by vomiting and sometimes diarrhoea. In the sensitive mucosal stem cells of the gastrointestinal tract, in particular in the stomach and small intestine, 5-hydroxytryptamine (**5-HT$_3$**) is released into the bloodstream which stimulates the nausea/vomiting centres in the brain and other 5-HT$_3$ receptors. There is a concomitant increase in bowel motility, which may be caused by bile salts acting on the damaged mucosa. The total spectrum of effects is dependent upon the dose but may be anorexia, nausea and vomiting, and diarrhoea. Radiation sickness extends beyond the early symptoms, as damage to other tissues, such as the bone marrow, causes lowering of blood cell counts leaving the body vulnerable to infection. High radiation doses can also lead to permanent sterility, serious damage to other organs, and to death (with or without medical treatment).

Many other symptoms may arise which depend on the dose, the dose rate, and the area of the body affected. These might include loss of hair, skin burns, or haemorrhages in the short term and increased incidence of cancer in the long term. These symptoms may vary due to individual susceptibility and because in most uncontrolled situations the nature of the exposure is non-uniform. In radiotherapy, where exposures are controlled and fractionated to enable normal sensitive tissues to recover between treatments, nausea and/or vomiting usually only occur where there is a high-dose total-body irradiation, for example in the ablation of bone marrow for subsequent bone marrow transplantation. It is normal to give antiemetics such as ondansetron (a 5-HT$_3$ antagonist) to reduce such side-effects.

At doses greater than 1 Gy significant reductions in blood cell counts follow depletion of the bone marrow, and can lead to reduced resistance to infections, haemorrhages, and anaemia. If there is significant direct exposure or surface contamination with radioactive materials skin burns may occur leading to further fluid loss and the danger of infection. The acute symptoms are sometimes grouped together and called the acute radiation syndrome. Combined injuries have a worse prognosis, and this is important in medical management. Without medical treatment an acute dose of approximately 4 Gy is likely to lead to death within 60 days in 50 per cent of those exposed. Doses in excess of 10 Gy are likely to result in earlier death, even with treatment. Similar doses over longer periods (days, weeks) may

cause a variety of symptoms, but death is unlikely as the cells and tissues have time to repair the damage.

The following figures are given as guidelines for adults: anorexia may be seen in 5 per cent of those at 0.4 Gy and 95 per cent at 3 Gy, nausea in 5 per cent at 0.5 Gy and 95 per cent at 4.5 Gy, vomiting in 5 per cent at 0.6 Gy and 100 per cent at 7 Gy, and diarrhoea in 5 per cent at 1 Gy and over 20 per cent at 8 Gy. If the time from exposure to onset of any of the above symptoms is less than 1 h the dose is likely to be more than 3 Gy, if more than 3 h the dose is likely to be more than 1 Gy, and if they last for more than 24 h the dose is likely to be more than 6 Gy. These general spectra can be helpful to physicians as an aid to medical triage before more refined estimates can be made.

Clinical treatment of radiation injuries

General

Experience from many radiation accidents has shown that the heterogeneous nature of the exposures tends to confound both the clinical and pathological picture so that estimating the scale of the radiation damage and exposure is difficult. The early treatment of conventional injuries is the main factor that determines survival in patients who have been accidentally irradiated.

Casualties on admission can be classified into four treatment categories: mild, moderate, severe, and lethal. Stating specific dose ranges for these categories is not possible, primarily because of the difficulty in converting an exposure to a meaningful tissue dose; however, equivalent whole-body dose ranges would be less than 2 Gy, 2 to 5 Gy, 5 to 10 Gy, and more than 10 Gy respectively. The most reliable prognostic guides for treatment in the early stage are the change in levels of blood cells, which relates to dose, and cytogenetics, which will give a good estimate of dose.

The degree of radiation-induced marrow aplasia (reversible or irreversible) may not be known for days because of the uncontrolled nature of the exposure and the likelihood that it was non-uniform and heterogeneous. However, assessment of the dose, while important, is secondary to the treatment.

Reliable triage and good clinical care based on comprehensive biological data will ensure the best chance of recovery provided that some critical stem cells survive the radiation exposure. There is a need for biological monitoring, such as absolute lymphocyte counts and cytogenetics, to assess the effective dose and the probability of survival.

Sepsis

The suppression of bone marrow activity will reduce the resistance to bacterial and viral infections. For febrile neutropenic casualties, blood, urine, and faecal samples for cultures need to be taken on admission. Patients must be started on broad-spectrum antimicrobials and these should be given until the patient is afebrile. Experience has shown that fungal lung infections can be the cause of late deaths when all the other radiation effects have been stabilized. Early use of antifungal agents and gammaglobulin for viral infections is essential.

Marrow aplasia

Following a suspected high radiation exposure, initial patient assessment should be based on dosimetric testing (biological, physical), daily full blood counts, viral titres (for cytomegalovirus and HIV for example), HLA subtyping for possible bone marrow transplantation, and the administration of haematopoietic growth factors (colony stimulating factors such as granulocyte or granulocyte/macrophage colony stimulating factors). Particular care is needed if the patient has other injuries, such as pulmonary infections, burns, or smoke inhalation.

Subsequent supportive therapy might include platelet transfusions, particularly if surgery is indicated for other injuries. Other treatments might include the use of thrombopoietic drugs. However, bone marrow transplants should only be given if an autologous donor is available.

Gastrointestinal

Vomiting should be controlled by use of effective antiemetics such as ondansetron. This relaxes the gut and reduces mechanical damage to the lining of the small intestine. Antiemetics also help to reduce fluid loss. Diarrhoea should be treated with fluids and electrolytes and efforts should be made to improve host defences by elemental diets, vitamins, and glutamine parenterally or intravenously.

Cutaneous

Remove all clothing as soon as possible, bathe very gently in lukewarm baths, use acetic acid or ion exchangers if surface contamination is thought to be soluble caesium, and only remove contamination mechanically from the soles of the feet or the palms of the hands.

Later treatments might include the use of topical creams, systemic acitretin, and gamma interferon. These have been found to be helpful in treating the chronic skin damage seen in the Chernobyl firefighters.

Combined injury

Radiation injury is not immediately life threatening; initial care should address the associated conventional injuries, for example thermal burns and wounds. After stabilization, radio-isotope decontamination should be performed before emergency surgery, definitive care, and treatment of radiation injuries. Collection of biological samples during the resuscitation stages will supplement the initial data collected during triage. Ideally, definitive care should immediately follow resuscitation.

Management of soft tissue wounds requires alternative ways to close wounds, for example biological wound coverings and skin grafts. Surgical correction of life-threatening and other major injuries should be carried out as soon as possible (within 36 to 48 h); elective procedures should be postponed until late in the convalescent period (45 to 60 days) following haematopoietic recovery. Treatment of thermal burns should include early excision of potentially septic tissue and closure of the wounds, preferably by skin grafting.

Counselling

Overexposure to ionizing radiations increases the risk of subsequent radiation-induced cancers. So it is important that over-exposed patients are counselled on the radiation risks in comparison with other risks in life. Experience from the Chernobyl accident has shown that many people have unwarranted fears from their radiation exposures due to poor communications and a lack of trust.

Non-ionizing radiation

Ultraviolet radiation

The main organs affected by ultraviolet radiation are the skin and the eye. There is evidence that ultraviolet radiation can also induce changes in the immune system but the significance of this to humans is not yet clear. The most serious health effects are the cutaneous malignancies.

The skin

Short-term effects

Short-term skin effects are sunburn, principally consisting of erythema and oedema, both of which may be very severe. In some people this sunburn is followed by increased production of melanin (a suntan). A suntan is not an indication of good health and only offers minimal protection against further exposure. It is a sign that

damaged skin is attempting to protect itself from further harm.

Long-term effects

The most serious long-term effect is the induction of cancer. The non-melanoma skin cancers are mainly basal cell carcinomas and squamous cell carcinomas. They are relatively common in white populations, although they are rarely fatal. The overall incidence is difficult to assess because of under-reporting. Malignant melanoma is the main cause of death from skin cancer, particularly in young people, although its incidence is lower than that of non-melanoma skin cancers. The risk of developing malignant melanoma has increased substantially in white populations for several decades, and the annual incidence in the United Kingdom is now approaching 10 new cases per 100 000. Chronic exposure to solar radiation causes photoageing of the skin, which is characterized by a leathery, wrinkled appearance and loss of elasticity. A small quantity of ultraviolet radiation is beneficial in terms of vitamin D synthesis in the skin.

The eye

Responses of the human eye to acute exposure to ultraviolet radiation include photokeratitis and photoconjunctivitis. Repeated exposure is also a major factor in the causation of non-malignant clinical lesions of the cornea and conjunctiva such as climatic droplet keratopathy, pterygium, and, probably, pinguecula. Epidemiological data on cataract formation in highly exposed people suggest that cumulative exposure to ultraviolet radiation is a principal causative factor in the development of, at least, cortical cataracts, although the extent to which this is an important risk factor for cataracts in the general population is unclear.

Immune responses

Biological studies have shown that exposure to ultraviolet radiation can suppress the normal antigen-specific immune response to some skin tumours and to various skin pathogens, although immunity acquired from prior infection is not affected. The significance for human health of ultraviolet radiation-induced immune suppression is not clearly established at present.

Radiofrequency electromagnetic waves

The possible hazards to humans of exposure to high-intensity radiofrequency electromagnetic waves are more controversial, but individuals chronically exposed to such radiation at high intensity have been reported as developing such conditions as anaemia, alopecia, or psychological disorders. In animal studies, changes in the high spontaneous rate of cancer in particular strains have been reported. The widespread use of radiofrequency microwaves (in mobile phones and ovens for home and restaurant cookery) has made their safety a more important question. With the exception of the danger from induction heating, with consequent damage due to thermal burns, there is no evidence that there is significant risk of danger to the general public from the use of such appliances. The National Radiological Protection Board has given advice that acceptable exposures should not result in a rise in body temperature of more than 0.5 °C as shown by skin and rectal temperature. Local tissue temperatures should not exceed 38 °C for the head, 39 °C for the trunk, or 40 °C for the limbs.

Magnetic fields

With the increasing use of magnetic resonance imaging interest has developed in the possible hazards to humans of exposure to strong and varying magnetic fields. Once again, the biological evidence is largely anecdotal and in part contradictory, and mainly involves transient psychological changes. The National Radiological Protection Board has recommended that for static magnetic fields the individual being imaged should not be exposed to a field greater than 2.5 tesla (T) to the whole or a substantial portion of the body. There is no evidence so far to suggest that the embryo is sensitive to magnetic fields and radiofrequency at the intensities encountered in clinical magnetic resonance imaging, but it is felt to be prudent to exclude pregnant women during the first trimester.

Summary

The man-made use of ionizing radiation in medicine and industry and for nuclear power has shown that high doses are lethal and early (deterministic) effects are visible and can be shorten life. Latent (stochastic) effects, particularly cancers, are well documented and risk estimates based on the study of occupationally and medically exposed cohorts are reasonably robust. Legislative dose limits will prevent deterministic effects and reduce the risk of stochastic effects to an acceptable level, although all doses should be kept as low as reasonably practicable. Information on the possible health effects of radiofrequencies and electromagnetic fields is less robust. However, the degree of risk acceptable to the public and workforce is likely to change.

8.5.10 Noise

R. McCaig and T. C. Aw

Introduction

Noise is one of the most prevalent hazards in the workplace, particularly where there is a large manufacturing sector. In developed countries exposure to noise remains a significant occupational health problem with well-established sources of exposure in engineering, printing, textiles, and other production processes being supplemented by those in entertainment and broadcasting, and, more recently, by the growth of telephone customer service centres, where workers are potentially exposed to noise from head sets. Although it has been known for over a century that excessive exposure to noise results in hearing loss, it is only within the last 20 to 30 years that comprehensive hearing conservation programmes have been adopted in industry. Noise-induced hearing loss, which is entirely preventable, remains a common occupational injury.

The vibration of objects in air propagates acoustic energy which impinges on the tympanic membrane. The subjective effect of this energy may be pleasant, as in speech or music, yet it retains the potential to be harmful at sufficient intensities. The term 'noise' generally refers to loud or harsh sound of any kind. The ear is sensitive to a very wide range of pressure change and, to accommodate this, a logarithmic scale is required. A reference pressure of 0.000 02 pascal (Pa), the threshold of hearing, is used and a rating in decibels is obtained from the formula:

$$\text{sound pressure} = 20 \log_{10} \text{measured pressurereference pressure decibel (dB).}$$

Thus a sound pressure of 0.2 Pa is equivalent to 80 dB, and one of 2.0 Pa to 100 dB.

A sound pressure level of 60 dB may be found in an office environment and levels between 90 dB and 100 dB in factories. Simple instruments are available to measure sound levels. However, the full characterization of a noise source requires more complex analysis, including the frequency spectrum. Most noise sources operate continuously but some produce intermittent peaks of exposure (impulse noise) arising from sources such as drop forging or the detonation of explosives. Separate criteria for the risk of damage apply to these two types of exposure.

In a normal young adult the ear is sensitive to a range of frequencies from about 20 Hz up to 20 kHz. The ear and brain together are not equally sensitive to all frequencies of sound, being markedly less sensitive at frequencies below 500 Hz and above 4 kHz. The more sensitive frequencies which lie in between 500 Hz and 4 kHz are those required for the perception of speech. Sound level meters contain filtering circuits which allow them to mimic the response of the human ear to sound. Different weightings are available, related to the subjective loudness of sounds. The one most commonly used is the A scale, reported as dB(A).

The effects of noise

Exposure to noise results in both physiological and pathological changes. An early response to acute noise exposure is an increase in blood pressure. More prolonged exposure to a sufficient intensity of noise causes a temporary shift in the threshold of hearing (temporary threshold shift). This may be experienced as a transient dullness of hearing and can be measured objectively. If exposure to noise is prolonged over months and years, a permanent threshold shift can result. Along with a reduction in the sensitivity of hearing, the person also experiences difficulty in differentiating similar sounds, particularly those of the consonants which are heard over a frequency range of 700 Hz to 4 kHz. With severe hearing loss there may be loudness recruitment; when sound intensity is increased beyond the now elevated threshold of hearing, a rapid and uncomfortable increase is experienced in the sound perceived. Noise-induced hearing loss may also be accompanied by tinnitus.

Excessive noise exposure causes damage to the outer hair cells of the cochlea, with breakage and disruption of the pattern of cilia on these cells which operate as local electromechanical amplifiers within the cochlea. When stimulated by oscillations of the basilar membrane at the appropriate frequency these cells contract and, by means of the cilia, pull down the overlying tectorial membrane. In doing so the inner end of the tectorial membrane is brought more closely into contact with the cilia of the inner hair cells, increasing their stimulation and that of the nerve fibres leaving the cells. Thus the outer hair cells assist frequency selectivity and amplification within the cochlea. Noise damage physically disrupts this amplification mechanism.

The 'non-auditory' effects attributed to noise include changes in both performance and health. Exposure to unwanted background noise, in particular speech, can disturb the performance of mental tasks. However, it has not been clearly established that environmental noise, for example around airports, results in an increase in psychiatric morbidity within the surrounding community. There is better evidence that environmental noise from road traffic is associated with an increase in cardiovascular morbidity but such an association has not been established in occupational settings.

Hearing loss

Permanent hearing loss is first detected as a reduction in hearing thresholds at the higher frequencies on the audiogram. Typically, this begins at 4 kHz and, with time, affects the adjacent frequencies creating a 'notch' pattern in the audiogram, described as the 4 kHz dip (Fig. 1). This sensitivity arises from the structure and configuration of the outer ear and the cochlea. With continuing exposure this hearing loss will extend to the lower frequencies and the thresholds will worsen (Fig. 2). Much of the damage is incurred during the initial years of exposure. Younger people may not be aware of hearing loss. It is in early middle age when the difference in hearing thresholds between those exposed to noise and the non-exposed becomes more obvious. Thereafter this difference is reduced, as presbyacusis (the reduction in hearing threshold with age) affects both groups.

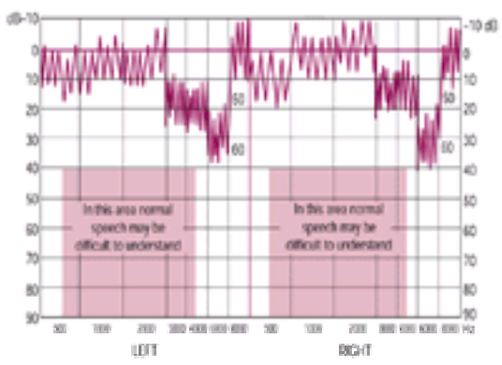

Fig. 1 Hearing loss after continuing noise exposure. Initially the lower frequencies are largely unaffected and there is recovery in the higher frequencies, appearing as a characteristic notching of the audiogram.

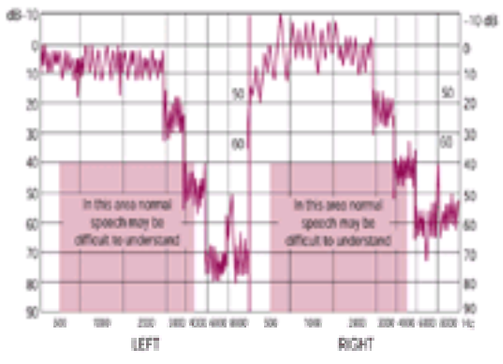

Fig. 2 With continuing noise exposure the extent of loss increases and extends into the lower frequencies.

The management of workers regularly exposed to noise should centre on the reduction of noise at source. A programme of screening audiometry should be introduced where daily personal exposure to noise (a time-weighted measure) is of the order of 85 to 90 dB(A), and in conformity with relevant national legislation and guidance. The technical requirements for industrial hearing conservation audiometry are specified in ISO 6189. Measures are normally taken to avoid temporary threshold shifts at the time of testing, with examinations repeated every 2 to 3 years.

Where abnormalities are detected, it is important to establish the history of occupational and leisure noise exposure, the use of hearing protection, exposure to ototoxic drugs and chemicals, and relevant past diseases and injuries, and tinnitus. Otoscopic examination, bone conduction audiometry, tympanometry to determine middle ear function, and evoked response audiometry may have a role in clinical assessment. Referral for a specialist opinion is relevant where pathology other than noise-induced hearing loss is suspected (such as the rare acoustic neuroma) and where it is thought that a hearing aid or tinnitus masker may be of help to the individual. In some countries noise-induced hearing loss results in the payment of compensation to workers and, where appropriate, individuals should be advised of their eligibility. Redress may also be available through the civil courts.

Hearing conservation

All workers exposed to noise should be included in a hearing conservation programme. This will include measures to control noise at source, the marking of remaining noisy areas, the use of hearing protectors, and the training of workers. In many countries this is required by national legislation. Where this is not the case, published damage risk criteria, for example ISO 1999, can be used to determine risk and the need for intervention. Control at source can be achieved, for example, by redesigning parts and machinery or by providing soundproof enclosures. This is always preferable to reliance on the use of hearing protectors, which must be fitted correctly and used continuously during the period of exposure to noise. This can be difficult to achieve in practice, particularly in the absence of good supervision. Hearing loss found on the audiogram can, however, be persuasive evidence to the worker of the need for improved hearing protection. Health professionals have a role in education in support of hearing conservation.

8.5.11 Vibration

Tar-Ching Aw and R. McCaig

Definition

Vibration is 'the mechanical oscillation of a surface around its reference point'. Workplace exposure to vibration results in local effects, mainly on the hands when the vibration is transmitted to the upper limbs, and as general systemic effects (mainly low back pain) when vibration is transmitted to the whole body. The clinical syndrome in the former has been termed 'vibration white finger' or 'hand–arm vibration syndrome'.

Exposure

Occupational exposure to whole-body vibration occurs in drivers of tractors, forklift trucks, mobile cranes, buses, lorries, and in helicopter pilots. The nature of the surface over which the vehicle is driven may be as important as the characteristics of the vehicle. Hand–arm vibration exposure occurs in factory workers involved in fettling, chipping, grinding, riveting, swaging, and using handheld pneumatic hammers, drills, chisels, and polishing and rotary tools. It also affects forestry, agricultural, and woodworkers using chain saws, miners drilling rock surfaces, and construction and road workers using drills and compactors. It has been estimated that around 3 per cent of the working population are occupationally exposed to sources of vibration.

Clinical effects

Whole-body vibration

Exposure to whole-body vibration causes physiological changes to the cardiovascular, respiratory, and musculoskeletal system. Clinical effects attributed to whole-body vibration include headache, motion sickness, sleep and visual disturbances, and urinary and abdominal complaints. The only effect with reasonable evidence of association with whole-body vibration is low back pain. In drivers, low back pain may occur as a result of vibration, poor posture within the vehicle cab, and/or other work duties such as loading and lifting.

Hand–arm transmitted vibration

This causes secondary Raynaud's phenomenon which manifests as frequent prominent episodic pallor of the digits, usually on exposure to cold. Patients frequently describe digital pallor in the morning, or following an outdoor activity such as fishing or gardening, especially in cold weather. The vascular changes may be accompanied by neurological and musculoskeletal effects which contribute to the disability experienced. Vascular and sensorineural effects may appear and progress independently. The latent period between initial exposure and development of symptoms is usually 5 to 10 years, although periods as short as 6 months or as long as 20 years have been noted depending on the intensity and duration of exposure. The sequence of colour change in the affected digits include pallor, a bluish hue due to cyanosis, and redness with spontaneous reversal of the vascular spasm.

Neurological effects include paraesthesia, reduced temperature perception, loss of manual dexterity, and pain. Severe tingling and discomfort often follow rapid warming of the hands. Loss of proprioception causing the inability to distinguish and hold small objects such as coins or to button up clothes contributes to physical and social disability. Musculoskeletal effects are not as well established, but muscle weakness, exostoses and cysts in the carpal bones, carpal tunnel syndrome, osteoarthritis, and Dupuytren's contracture have been associated with exposure to vibration.

Diagnosis

For a diagnosis of hand–arm vibration syndrome, the following criteria should be met:

a. there must be evidence of sufficient exposure to vibration;
b. episodic pallor of the digits and/or sensorineural effects should be confirmed;
c. other causes of Raynaud's phenomenon or sensory changes must be considered.

The presence of associated musculoskeletal features would add support to the diagnosis. Physical examination may show callosities on the hands, loss of sensation in the affected digits, and muscle weakness, although there may be no obvious abnormalities, especially in the early stages of the disease.
